The patient undergoing neurosurgery is at risk for infection related to the neurosurgical procedure (brain exposure, bone exposure, wound hematomas) and the presence of intravenous and arterial lines for fluid administration and monitoring. Risk for infection is increased in patients who undergo lengthy intracranial operations and those with external ventricular drains in place longer than 48 to 72 hours.

The incision site is monitored for redness, tenderness, bulging, separation, or foul odor. The dressing is often stained with blood in the immediate postoperative period. It is important to reinforce the dressing with sterile pads so that contamination and infection are avoided. (Blood is an excellent culture medium for bacteria.) If the dressing is heavily stained or displaced, this should be reported immediately. (A drain is sometimes placed in the craniotomy incision to facilitate drainage.)

After suboccipital surgical procedures, CSF may leak through the incision. This complication is dangerous because of the possibility of meningitis. Any sudden discharge of fluid from a cranial incision is reported at once because a massive leak requires direct surgical repair. Attention should be paid to the patient who complains of a salty taste, because this can be due to CSF trickling down the throat. The patient is advised to avoid coughing, sneezing, or nose blowing, which may cause CSF leakage by creating pressure on the operative site.

Aseptic technique is used when handling dressings, drainage systems, and intravenous and arterial lines. The patient is monitored carefully for signs and symptoms of infection, and cultures are obtained from the patient with suspected infection. Appropriate antibiotics are administered as prescribed.

Other causes of infection in the patient undergoing intracranial surgery are similar to those in other postoperative patients: pneumonia and urinary tract infections.

### Monitoring for Seizure Activity

Seizures and epilepsy may be complications after any intracranial neurosurgical procedure. Preventing seizures is essential to avoid further cerebral edema. Administering the prescribed antiseizure medication before and immediately after surgery may prevent the development of seizures in subsequent months and years. **Status**

**epilepticus** (prolonged seizures without recovery of consciousness in the intervals between seizures) may occur after craniotomy and also may be related to the development of complications (hematoma, ischemia). The management of status epilepticus is described later in this chapter.

### Monitoring and Managing Later Complications

Other complications may occur during the first 2 weeks or later and may threaten the patient's recovery. The most important of these are thromboembolic complications (deep vein thrombosis, pulmonary embolism), pulmonary and urinary tract infection, and pressure ulcers (Warbel, Lewicki & Lupica, 1999). Most of these complications may be avoided with frequent changes of position, adequate suctioning of secretions, assessment for pulmonary complications, observation for urinary complications, and skin care.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

The recovery at home of a neurosurgical patient depends on the extent of the surgical procedure and its success. The patient's strengths as well as limitations are explained to the family, along with their part in promoting recovery. Because administration of antiseizure medication is a priority, the patient and family are encouraged to use a check-off system to ensure that the medication is taken as prescribed.

Usually no dietary restrictions are required unless another health problem requiring a special diet exists. Although taking a shower or tub bath is permitted, the scalp should be kept dry until all the sutures have been removed. A clean scarf or cap may be worn until a wig or hairpiece is purchased. If skull bone has been removed, the neurosurgeon may suggest a protective helmet. After a craniotomy, the patient may require rehabilitation, depending on the postoperative level of function. The patient may require physical therapy for residual weakness and mobility issues. Occupational therapy is consulted to assist with self-care issues. If the patient is aphasic, speech therapy may be necessary.

### Continuing Care

Barring complications, patients are discharged from the hospital as soon as possible. Patients with severe motor deficits require extensive physical therapy and rehabilitation. Those with postoperative cognitive and speech impairments require psychological evaluation, speech therapy, and rehabilitation. The nurse works collaboratively with the physician and other health care professionals during hospitalization and home care to achieve as complete a rehabilitation as possible.

When tumor, injury, or disease makes the prognosis poor, care is directed toward making the patient as comfortable as possible. With return of the tumor or cerebral compression, the patient becomes less alert and aware. Other possible consequences include paralysis, blindness, and seizures. The home care nurse, hospice nurse, and social worker work with the family to plan for additional home health care or hospice services or placement of the patient in an extended-care facility. (See also the section on cerebral metastases in Chap. 65.) The patient and family are encouraged to discuss end-of-life preferences for care; the patient's end-of-life preferences must be respected (see Chap. 17).

The nurse involved in home and continuing care of patients following cranial surgery needs to remind patients and family

## NURSING RESEARCH PROFILE 61-1

### Suitability of Printed Patient Education Materials

Murphy, P. W., Chesson, A., Berman, S. A., Arnold, C., & Gallowat, G. (2001). Neurology patient education materials: do our educational aids fit our patients' needs? *Journal of Neuroscience Nursing*, 33(2), 99–112.

#### Purpose

Nurses often rely on printed patient education materials to supplement patient teaching. The purpose of the study was to assess the suitability of neurology patient education brochures and related information available on the Internet to determine their appropriateness for patients with low literacy skills.

#### Study Sample and Design

In this descriptive, cross-sectional study, the reading levels of patients and patient education materials were assessed. The Rapid Estimate of Adult Literacy in Medicine tool was used to evaluate a convenience sample of 520 neurology patients. Forty-three patient education materials—35 brochures produced by national organizations and 8 electronic documents from various Internet sources—were assessed using the Fog Index and the Suitability Assessment of Materials Scale. The mean age of patients was 46 years; 40% were African American and 59% Caucasian; 44% were female; the average educational level was 12th grade, with a mean reading level of 7th to 8th grade.

#### Findings

Patient education materials were classified as not suitable, adequate, or superior for use. Organizations with materials at the suitable level include those of the Epilepsy Foundation of America, the National Multiple Sclerosis Society, and the American Heart Association. The National Stroke Association, the American Academy of Neurology, the American Sleep Medicine, and the Muscular Dystrophy Association had brochures in the adequate range. Overall, only 14% of the materials were considered to have superior suitability, whereas 58% were adequate; 28% were determined not suitable. Of the materials available from the Internet, 88% were not suitable. The authors concluded that readily available neurology patient education aids are not matched to the patient population or to the average reading levels of patients.

#### Nursing Implications

Nurses should keep in mind that the brochures evaluated in this study represent primarily those available at national meetings and a small sample of those available on the Internet. The study reinforces that there is a need to consider the reading level of the patient when distributing printed material. The last grade attended in school may not reflect reading ability. Nurses should consider modifying existing materials or developing new materials with attention to instructional graphics, simpler words, patient interaction, and cultural sensitivity.

members of the need for health promotion and recommended health screening.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Achieves optimal cerebral tissue perfusion
  - a. Opens eyes on request; uses recognizable words, progressing to normal speech
  - b. Obeys commands with appropriate motor responses

2. Attains thermoregulation and normal body temperature
  - a. Registers normal body temperature
3. Has normal gas exchange
  - a. Has arterial blood gas values within normal ranges
  - b. Breathes easily; lung sounds clear without adventitious sounds
  - c. Takes deep breaths and changes position as directed
4. Copes with sensory deprivation
5. Demonstrates improving self-concept
  - a. Pays attention to grooming
  - b. Visits and interacts with others
6. Absence of complications
  - a. Exhibits ICP within normal range
  - b. Has minimal bleeding at surgical site; surgical incision is healing without evidence of infection
  - c. Shows fluid balance and electrolyte levels within desired ranges
  - d. Exhibits no evidence of seizures

An overview of care of the patient undergoing intracranial surgery is presented in Chart 61-2.

## TRANSPHENOIDAL SURGERY

Tumors within the sella turcica and small adenomas of the pituitary can be removed through a transsphenoidal approach: an incision is made beneath the upper lip and entry is then gained successively into the nasal cavity, sphenoidal sinus, and sella turcica (see Table 61-3). Although an otorhinolaryngologist may make the initial opening, the neurosurgeon completes the opening into the sphenoidal sinus and exposes the floor of the sella. Microsurgical techniques provide improved illumination, magnification, and visualization so that nearby vital structures can be avoided.

The transsphenoidal approach offers direct access to the sella with minimal risk of trauma and hemorrhage (Greenberg, 2001). It avoids many of the risks of craniotomy, and the postoperative discomfort is similar to that of other transnasal surgical procedures. It may also be used for pituitary ablation (removal) in patients with disseminated breast or prostatic cancer.

## Complications

Manipulation of the posterior pituitary gland during surgery may produce transient diabetes insipidus of several days' duration (Greenberg, 2001). It is treated with vasopressin but occasionally persists. Other complications include CSF leakage, visual disturbances, postoperative meningitis, and SIADH.

## Preoperative Evaluation

The preoperative workup includes a series of endocrine tests, rhinologic evaluation (to assess the status of the sinuses and nasal cavity), and neuroradiologic studies. Funduscopic examination and visual field determinations are performed, because the most serious effect of pituitary tumor is localized pressure on the optic nerve or chiasm. In addition, the nasopharyngeal secretions are cultured because a sinus infection is a contraindication to an intracranial procedure through this approach. Corticosteroids may be administered before and after surgery (because the surgery involves removal of the pituitary, the source of adrenocorticotrophic hormone [ACTH] is removed). Antibiotics may or may not be administered prophylactically (Greenberg, 2001).

Deep breathing is taught before surgery. The patient is instructed that following the surgery he or she will need to avoid vigorous coughing, blowing the nose, sucking through a straw, or sneezing, because these actions may cause a CSF leak (Greenberg, 2001; Hickey, 2003).

## Postoperative Management

Because the procedure disrupts the oral and nasal mucous membranes, management focuses on preventing infection and promoting healing. Medications include antimicrobial agents (which are continued until the nasal packing inserted at the time of surgery is removed), corticosteroids, analgesic agents for discomfort, and agents for the control of diabetes insipidus when necessary (Greenberg, 2001).

## Nursing Management

Vital signs are measured to monitor hemodynamic, cardiac, and ventilatory status (Eisenberg & Redick, 1998). Because of the anatomic proximity of the pituitary gland to the optic chiasm, visual acuity is assessed at regular intervals. One method is to ask the patient to count the number of fingers held up by the nurse. Evidence of decreasing visual acuity suggests an expanding hematoma.

The head of the bed is raised to decrease pressure on the sella turcica and to promote normal drainage. The patient is cautioned against blowing the nose or engaging in any activity that raises ICP, such as bending over or straining during urination or defecation.

Intake and output are measured as a guide to fluid and electrolyte replacement. The urine specific gravity is measured after each voiding (Greenberg, 2001). Daily weight is monitored. Fluids are generally given when nausea ceases, and the patient then progresses to a regular diet.

The nasal packing inserted during surgery is checked frequently for blood or CSF drainage. The major discomfort is related to the nasal packing and to mouth dryness and thirst from mouth-breathing. Oral care is provided every 4 hours or more frequently. Usually, the teeth are not brushed until the incision above the teeth has healed. The use of warm saline mouth rinses and a cool mist vaporizer is helpful. Petrolatum is soothing when applied to the lips. A room humidifier assists in keeping the mucous membranes moist. The packing is removed in 3 to 4 days, and only then can the area around the nares be cleaned with the prescribed solution to remove crusted blood and moisten the mucous membranes (Hickey, 2003).

Home care considerations include advising the patient to use a room humidifier to keep the mucous membranes moist and to soothe irritation. The head of the bed is elevated for at least 2 weeks after surgery.

## Seizure Disorders

### SEIZURES

Seizures are episodes of abnormal motor, sensory, autonomic, or psychic activity (or a combination of these) resulting from sudden excessive discharge from cerebral neurons (Greenberg, 2001; Hickey, 2003). A part or all of the brain may be involved. The international classification of seizures differentiates between two main types: partial seizures that begin in one part of the brain, and generalized seizures that involve electrical discharges in the whole brain (Chart 61-3). Most seizures are sudden and transient.

Chart  
61-3

## International Classification of Seizures

**Partial Seizures (seizures beginning locally)***Simple partial seizures (with elementary symptoms, generally without impairment of consciousness)*

- With motor symptoms
- With special sensory or somatosensory symptoms
- With autonomic symptoms
- Compound forms

*Complex partial seizures (with complex symptoms, generally with impairment of consciousness)*

- With impairment of consciousness only
- With cognitive symptoms
- With affective symptoms
- With psychosensory symptoms
- With psychomotor symptoms (automatisms)
- Compound forms

*Partial seizures secondarily generalized***Generalized Seizures (convulsive or nonconvulsive, bilaterally symmetric, without local onset)**

Tonic-clonic seizures

Tonic seizures

Clonic seizures

Absence seizures

Atonic seizures

Myoclonic seizures (bilaterally massive epileptic)

The underlying cause is an electrical disturbance (dysrhythmia) in the nerve cells in one section of the brain, causing them to emit abnormal, recurring, uncontrolled electrical discharges. The characteristic seizure is a manifestation of this excessive neuronal discharge. There may be associated loss of consciousness, excess movement or loss of muscle tone or movement, and disturbances of behavior, mood, sensation, and perception.

The specific causes of seizures are varied and can be categorized as idiopathic (genetic, developmental defects) and acquired. Among the causes of acquired seizures are hypoxemia of any cause, including vascular insufficiency, fever (childhood), head injury, hypertension, central nervous system infections, metabolic and toxic conditions (eg, renal failure, hyponatremia, hypocalcemia, hypoglycemia, pesticides), brain tumor, drug and alcohol withdrawal, and allergies (Schumacher, Pruitt & Phillips, 2000). Cerebrovascular disease is the leading cause of seizures in the elderly (Berges, Moulin, Berger et al., 2000).

**Nursing Management During a Seizure**

A major responsibility of the nurse is to observe and record the sequence of symptoms. The nature of the seizure usually indicates the type of treatment that is required (Wulf, 2000). Before and during a seizure, the following are assessed and documented:

- The circumstances before the seizure (visual, auditory, or olfactory stimuli, tactile stimuli, emotional or psychological disturbances, sleep, hyperventilation)
- The occurrence of an aura (visual, auditory, or olfactory)
- The first thing the patient does in a seizure—where the movements or the stiffness starts, conjugate gaze position, and the position of the head at the beginning of the seizure. This information gives clues to the location of the seizure origin in the brain. (In recording, it is important to state whether the beginning of the seizure was observed.)

- The type of movements in the part of the body involved
- The areas of the body involved (turn back bedding to expose patient)
- The size of both pupils. Are the eyes open? Did the eyes or head turn to one side?
- The presence or absence of automatisms (involuntary motor activity, such as lip smacking or repeated swallowing)
- Incontinence of urine or stool
- Duration of each phase of the seizure
- Unconsciousness, if present, and its duration
- Any obvious paralysis or weakness of arms or legs after the seizure
- Inability to speak after the seizure
- Movements at the end of the seizure
- Whether or not the patient sleeps afterward
- Cognitive status (confused or not confused) after the seizure

In addition to providing data about the seizure, nursing care is directed at preventing injury and supporting the patient. This includes supporting the patient not only physically but also psychologically. Consequences such as distress, embarrassment, fatigue, and depression can be devastating to the patient (Buelow, 2001). Steps to prevent or minimize injury to the patient are presented in Chart 61-4.

**Nursing Management After a Seizure**

After a patient has a seizure, the nurse's role is to document the events leading to and occurring during the seizure and to prevent complications (eg, aspiration, injury). The patient is at risk for hypoxia, vomiting, and pulmonary aspiration. To prevent complications, the patient is placed in the side-lying position to facilitate drainage of oral secretions and is suctioned, if needed, to maintain a patent airway and prevent aspiration, as described in Chart 61-4. Seizure precautions are maintained, including having available fully functioning suction equipment with a suction catheter and oral airway. The bed is placed in a low position with side rails up and padded if necessary to prevent patient injury. The patient may be drowsy and may wish to sleep after the seizure; he or she may not remember events leading up to the seizure and for a short time thereafter.

**THE EPILEPSIES**

**Epilepsy** is a group of syndromes characterized by recurring seizures. Epileptic syndromes are classified by specific patterns of clinical features, including age of onset, family history, and seizure type (Schachter, 2001). Types of epilepsies are differentiated by how the seizure activity manifests (see Chart 61-3), the most common syndromes being those with generalized seizures and those with partial-onset seizures. Epilepsy can be primary (idiopathic) or secondary, when the cause is known and the epilepsy is a symptom of another underlying condition such as a brain tumor (Schachter, 2001).

An estimated 2 to 4 million people in the United States have epilepsy (1 in 100 adults is affected), and onset occurs before the age of 20 years in greater than 75% of patients (Schachter, 2001). The improved treatment of cerebrovascular disorders, head injuries, brain tumors, meningitis, and encephalitis has increased the number of patients at risk for seizures following recovery from these conditions (Berges et al., 2000). Also, advances in EEG have aided in the diagnosis of epilepsy. The general public has

Chart  
61-4

## Guidelines for Seizure Care

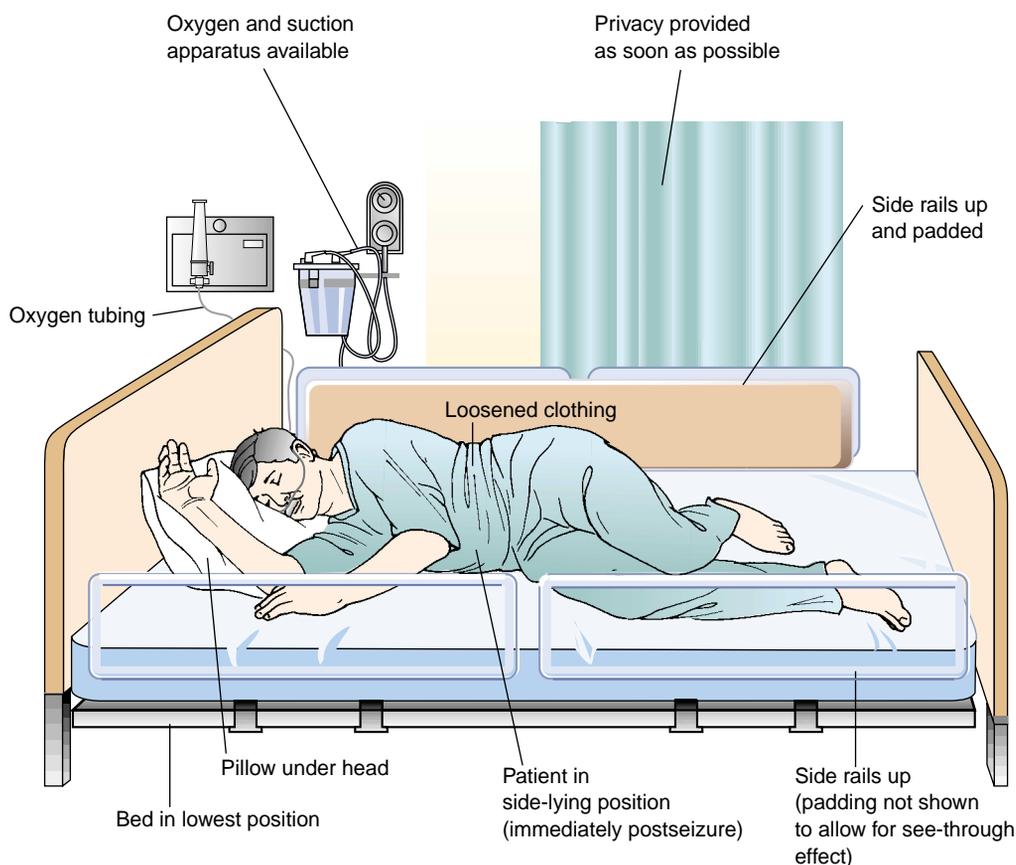

## Nursing Care During a Seizure

- Provide privacy and protect the patient from curious on-lookers. (The patient who has an *aura* [warning of an impending seizure] may have time to seek a safe, private place.)
- Ease the patient to the floor, if possible.
- Protect the head with a pad to prevent injury (from striking a hard surface).
- Loosen constrictive clothing.
- Push aside any furniture that may injure the patient during the seizure.
- If the patient is in bed, remove pillows and raise side rails.
- If an aura precedes the seizure, insert an oral airway to reduce the possibility of the tongue or cheek being bitten.
- *Do not attempt to pry open jaws that are clenched in a spasm to insert anything.* Broken teeth and injury to the lips and tongue may result from such an action.
- No attempt should be made to restrain the patient during the seizure because muscular contractions are strong and restraint can produce injury.

- If possible, place the patient on one side with head flexed forward, which allows the tongue to fall forward and facilitates drainage of saliva and mucus. If suction is available, use it if necessary to clear secretions.

## Nursing Care After the Seizure

- Keep the patient on one side to prevent aspiration. Make sure the airway is patent.
- There is usually a period of confusion after a grand mal seizure.
- A short apneic period may occur during or immediately after a generalized seizure.
- The patient, on awakening, should be reoriented to the environment.
- If the patient becomes agitated after a seizure (postictal), use calm persuasion and gentle restraint.

been educated about epilepsy, which has reduced the stigma associated with it; as a result, more people are willing to acknowledge the diagnosis.

Although there is evidence that susceptibility to some types of epilepsy may be inherited, the cause of seizures in many people is unknown. Epilepsy can follow birth trauma, asphyxia neonato-

rum, head injuries, some infectious diseases (bacterial, viral, parasitic), toxicity (carbon monoxide and lead poisoning), circulatory problems, fever, metabolic and nutritional disorders, and drug or alcohol intoxication (Schachter, 2001). It is also associated with brain tumors, abscesses, and congenital malformations. In most cases of epilepsy, the cause is unknown (idiopathic).

## Pathophysiology

Messages from the body are carried by the neurons (nerve cells) of the brain by means of discharges of electrochemical energy that sweep along them. These impulses occur in bursts whenever a nerve cell has a task to perform. Sometimes, these cells or groups of cells continue firing after a task is finished. During the period of unwanted discharges, parts of the body controlled by the errant cells may perform erratically. Resultant dysfunction ranges from mild to incapacitating and often causes unconsciousness (Greenberg, 2001; Hickey, 2003). When these uncontrolled, abnormal discharges occur repeatedly, a person is said to have an epileptic syndrome (Schachter, 2001).

Epilepsy is not associated with intellectual level. People with epilepsy without other brain or nervous system disabilities fall within the same intelligence ranges as the overall population. Epilepsy is not synonymous with mental retardation or illness. Many who are developmentally disabled because of serious neurologic damage, however, have epilepsy as well.

## Clinical Manifestations

Depending on the location of the discharging neurons, seizures may range from a simple staring episode to prolonged convulsive movements with loss of consciousness. Seizures have been classified according to the area of the brain involved and have been identified as partial, generalized, and unclassified (Greenberg, 2001; Hickey, 2003). Partial seizures are focal in origin and affect only part of the brain. Generalized seizures are nonspecific in origin and affect the entire brain simultaneously. Unclassified seizures are so termed because of incomplete data.

The initial pattern of the seizures indicates the region of the brain in which the seizure originates (see Chart 61-2). In simple partial seizures, only a finger or hand may shake, or the mouth may jerk uncontrollably. The person may talk unintelligibly, may be dizzy, and may experience unusual or unpleasant sights, sounds, odors, or tastes, but without loss of consciousness (Greenberg, 2001; Hickey, 2003).

In complex partial seizures, the person either remains motionless or moves automatically but inappropriately for time and place, or may experience excessive emotions of fear, anger, elation, or irritability. Whatever the manifestations, the person does not remember the episode when it is over.

Generalized seizures, previously referred to as grand mal seizures, involve both hemispheres of the brain, causing both sides of the body to react (Greenberg, 2001; Hickey, 2003). There may be intense rigidity of the entire body followed by alternating muscle relaxation and contraction (generalized tonic-clonic contraction). The simultaneous contractions of the diaphragm and chest muscles may produce a characteristic epileptic cry. The tongue is often chewed, and the patient is incontinent of urine and stool. After 1 or 2 minutes, the convulsive movements begin to subside; the patient relaxes and lies in deep coma, breathing noisily. The respirations at this point are chiefly abdominal. In the postictal state (after the seizure), the patient is often confused and hard to arouse and may sleep for hours. Many patients complain of headache, sore muscles, fatigue, and depression (Buelow, 2001).

## Assessment and Diagnostic Findings

The diagnostic assessment is aimed at determining the type of seizures, their frequency and severity, and the factors that precipitate them (Schachter, 2001). A developmental history is

taken, including events of pregnancy and childbirth, to seek evidence of preexisting injury. The patient is also questioned about illnesses or head injuries that may have affected the brain. In addition to physical and neurologic evaluations, diagnostic examinations include biochemical, hematologic, and serologic studies. MRI is used to detect lesions in the brain, focal abnormalities, cerebrovascular abnormalities, and cerebral degenerative changes (Schachter, 2001).

The electroencephalogram (EEG) furnishes diagnostic evidence in a substantial proportion of patients with epilepsy and aids in classifying the type of seizure (Schachter, 2001). Abnormalities in the EEG usually continue between seizures or, if not apparent, may be elicited by hyperventilation or during sleep. Microelectrodes can be inserted deep in the brain to probe the action of single brain cells. Some people with seizures have normal EEGs, whereas others who have never had seizures have abnormal EEGs. Telemetry and computerized equipment are used to monitor electrical brain activity while patients pursue their normal activities and to store the readings on computer tapes for analysis. Video recording of seizures taken simultaneously with EEG telemetry is useful in determining the type of seizure as well as its duration and magnitude. This type of intensive monitoring is changing the treatment of severe epilepsy.

Single photon emission computed tomography (SPECT) is an additional tool sometimes used in the diagnostic workup. It is useful for identifying the epileptogenic zone so that the area in the brain giving rise to seizures can be removed surgically (Huntington, 1999).

## Women With Epilepsy

More than 1 million American women have epilepsy, and they face particular needs associated with the syndrome (Schachter, Krishnamurthy & Cantrell, 2000). Women with epilepsy often note an increase in seizure frequency during menses; this has been linked to the increase in sex hormones that alter the excitability of neurons in the cerebral cortex. Women of childbearing age require special care and guidance before, during, and after pregnancy. Many women note a change in the pattern of seizure activity during pregnancy. Fetal malformation has been linked to the use of multiple antiseizure medications (Karch, 2002). The effectiveness of contraceptives is decreased by antiseizure medications. Therefore, patients should be encouraged to discuss family planning with their primary health care provider and to obtain preconception counseling if they are considering childbearing (Liporace, 1997).

Because of bone loss associated with the long-term use of antiseizure medications, patients receiving antiseizure agents should be assessed for low bone mass and osteoporosis. They should be instructed about other strategies to reduce their risks for osteoporosis.

## Gerontologic Considerations

Elderly people have a high incidence of new-onset epilepsy (Schachter, 2001). Increased incidence is associated with stroke, head injury, dementia, infection, alcoholism, and aging. Treatment depends on the underlying cause. Because many elderly people have chronic health problems, they may be taking other medications that can interact with medications prescribed for seizure control. In addition, the absorption, distribution, metabolism, and excretion of medications are altered in the elderly as a result of age-related changes in renal and liver function. There-

fore, the elderly must be monitored closely for adverse and toxic effects of antiseizure medications and for osteoporosis. The cost of antiseizure medications can lead to poor adherence to the prescribed regimen in elderly patients on fixed incomes.

## Prevention

Society-wide efforts are the key to the prevention of epilepsy. The risk for congenital fetal anomaly is two to three times higher in mothers with epilepsy. The effects of maternal seizures, antiseizure medications, and genetic predisposition are all mechanisms that contribute to possible malformation. Because the unborn infants of mothers who take certain antiseizure medications for epilepsy are at risk, these women need careful monitoring, including blood studies to detect the level of antiseizure medications taken throughout pregnancy (Karch, 2002). High-risk mothers (teenagers, women with histories of difficult deliveries, drug use, patients with diabetes or hypertension) should be identified and monitored closely during pregnancy because damage to the fetus during pregnancy and delivery may increase the risk for epilepsy. All of these issues need further study (Schachter, Krishnamurthy & Cantrell, 2000).

Head injury is one of the main causes of epilepsy that can be prevented. Through highway safety programs and occupational safety precautions, lives can be saved and epilepsy due to head injury prevented; these programs are discussed in Chapter 63.

## Medical Management

The management of epilepsy is individualized to meet the needs of each patient and not just to manage and prevent seizures. Management differs from patient to patient because some forms of epilepsy arise from brain damage and others are due to altered brain chemistry.

### PHARMACOLOGIC THERAPY

Many medications are available to control seizures, although the mechanisms of their actions are still unknown (Karch, 2002). The objective is to achieve seizure control with minimal side effects. Medication therapy controls rather than cures seizures. Medications are selected on the basis of the type of seizure being treated and the effectiveness and safety of the medications (Shafer, 1999a, 1999b; Winkelman, 1999). If properly prescribed and taken, medications control seizures in 50% to 60% of patients with recurring seizures and provide partial control in another 15% to 35%. The condition is not improved by any available medication in 20% and 35% of patients with generalized and partial epilepsy, respectively (Devinsky, 1999).

Treatment is usually started with a single medication. The starting dose and the rate at which the dosage is increased depend on the occurrence of side effects. The medication levels in the blood are monitored because the rate of drug absorption varies among patients. Changing to another medication may be necessary if seizure control is not achieved or if toxicity makes it impossible to increase the dosage. The medication may need to be adjusted because of concurrent illness, weight changes, or increases in stress. Sudden withdrawal of these medications can cause seizures to occur with greater frequency or can precipitate the development of status epilepticus (Greenberg, 2001).

Side effects of antiseizure agents may be divided into three groups: (1) idiosyncratic or allergic disorders, which present primarily as skin reactions; (2) acute toxicity, which may occur when

the medication is initially prescribed; or (3) chronic toxicity, which occurs late in the course of therapy.

The manifestations of drug toxicity are variable, and any organ system may be involved. Gingival hyperplasia (swollen and tender gums) can be associated with long-term use of phenytoin (Dilantin), for example (Karch, 2002). Periodic physical and dental examinations and laboratory tests are performed for patients receiving medications known to have hematopoietic, genitourinary, or hepatic effects. Table 61-4 lists the medications in current use.

**NURSING ALERT** Nurses must take care when administering lamotrigine (Lamictal), an antiseizure medication. The drug packaging was recently changed in an attempt to reduce medication errors as this medication has been confused with terbinafine (Lamisil), labetalol hydrochloride (Trandate), lamivudine (Epivir), maprotiline (Ludiomil), as well as the combination diphenoxylate and atropine (Lomotil). Any patient given an incorrect medication may suffer adverse effects, and patients with epilepsy are at risk for status epilepticus from having their medication regimen interrupted (Vernarec, 2001).

### SURGICAL MANAGEMENT

Surgery is indicated for patients whose epilepsy results from intracranial tumors, abscess, cysts, or vascular anomalies. Some patients have intractable seizure disorders that do not respond to medication. There may be a focal atrophic process secondary to trauma, inflammation, stroke, or anoxia. If the seizures originate in a reasonably well-circumscribed area of the brain that can be excised without producing significant neurologic deficits, the removal of the area generating the seizures may produce long-term control and improvement (Wiebe, Blume, Girvin et al., 2001).

This type of neurosurgery has been aided by several advances, including microsurgical techniques, depth EEGs, improved illumination and hemostasis, and the introduction of neurolept-analgesic agents (droperidol and fentanyl). These techniques, combined with use of local anesthetic agents, enable the neurosurgeon to perform surgery on an alert and cooperative patient. Using special testing devices, electrocortical mapping, and the patient's response to stimulation, the boundaries of the epileptogenic focus are determined (Huntington, 1999). Any abnormal epileptogenic focus (ie, abnormal area of the brain) is then removed (Wiebe et al., 2001).

As an adjunct to medication and surgery in adolescents and adults with partial seizures, a generator may be implanted under the clavicle. The device is connected to the vagus nerve in the cervical area, where it delivers electrical signals to the brain to control and reduce seizure activity (Kennedy & Schallert, 2001). An external programming system is used by the physician to change stimulator settings. Patients can turn the stimulator on and off with a magnet.

## NURSING PROCESS: THE PATIENT WITH EPILEPSY

### Assessment

The nurse elicits information about the seizure history. The patient is asked about the factors or events that may precipitate the seizures. Alcohol intake is documented. The nurse determines if the patient has an aura (a premonitory or warning sensation) before an epileptic seizure, which may indicate the origin of the seizure (eg, seeing a flashing light may indicate the seizure originated in the occipital lobe). Observation and assessment during

Table 61-4 • Major Antiseizure Medication

MEDICATION	DOSE-RELATED SIDE EFFECTS	TOXIC EFFECTS
carbamazepine (Tegretol)	Dizziness, drowsiness, unsteadiness, nausea and vomiting, diplopia, mild leukopenia	Severe skin rash, blood dyscrasias, hepatitis
clonazepam (Klonopin)	Drowsiness, behavior changes, headache, hirsutism, alopecia, palpitations	Hepatotoxicity, thrombocytopenia, bone marrow failure, ataxia
ethosuximide (Zarontin)	Nausea and vomiting, headache, gastric distress	Skin rash, blood dyscrasias, hepatitis, lupus erythematosus
felbamate (Felbatol)	Cognitive impairments, insomnia, nausea, headache, fatigue	Aplastic anemia, hepatotoxicity
gabapentin (Neurotonin)	Dizziness, drowsiness, somnolence, fatigue, ataxia, weight gain, nausea	Leukopenia, hepatotoxicity
lamotrigine (Lamictal)	Drowsiness, tremor, nausea, ataxia, dizziness, headache, weight gain	Severe rash (Stevens-Johnson syndrome)
levetiracetam (Keppra)	Somnolence, dizziness, fatigue	Unknown
oxcarbazepine (Trileptal)	Dizziness, somnolence, double vision, fatigue, nausea, vomiting, loss of coordination, abnormal vision, abdominal pain, tremor, abnormal gait	Hepatotoxicity
phenobarbital (Luminal)	Sedation, irritability, diplopia, ataxia	Skin rash, anemia
phenytoin (Dilantin)	Visual problems, hirsutism, gingival hyperplasia, dysrhythmias, dysarthria, nystagmus	Severe skin reaction, peripheral neuropathy, ataxia, drowsiness, blood dyscrasias
primidone (Mysoline)	Lethargy, irritability, diplopia, ataxia, impotence	Skin rash
tiagabine (Gabitril)	Dizziness, fatigue, nervousness, tremor, difficulty concentrating, dysarthria, weak or buckling knees, abdominal pain	Unknown
topiramate (Topamax)	Fatigue, somnolence, confusion, ataxia, anorexia, depression, weight loss	Nephrolithiasis
valproate (Depakote, Depakene)	Nausea and vomiting, weight gain, hair loss, tremor, menstrual irregularities	Hepatotoxicity, skin rash, blood dyscrasias, nephritis
zonisamide (Zonegran, Excegran)	Somnolence, dizziness, anorexia, headache, nausea, agitation, rash	Leukopenia, hepatotoxicity

and after a seizure assist in identifying the type of seizure and its management.

The effects of epilepsy on the patient's lifestyle are assessed (Buelow, 2001). What limitations are imposed by the seizure disorder? Does the patient have a recreational program? Social contacts? Is the patient working, and is it a positive or stressful experience? What coping mechanisms are used?

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Risk for injury related to seizure activity
- Fear related to the possibility of seizures
- Ineffective individual coping related to stresses imposed by epilepsy
- Deficient knowledge related to epilepsy and its control

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

The major potential complication of patients with epilepsy is as follows:

- Status epilepticus

## Planning and Goals

The major goals for the patient may include prevention of injury, control of seizures, achievement of a satisfactory psychosocial adjustment, acquisition of knowledge and understanding about the condition, and absence of complications.

## Nursing Interventions

### PREVENTING INJURY

Injury prevention for the patient with seizures is a priority. If at risk for injury (depending on the seizure type), the patient should be placed on the floor and any obstructive items should be removed. The patient should never be forced into a position, nor should anyone attempt to insert anything into the patient's mouth once a seizure has begun. Patients on seizure precautions should have pads applied to side rails while in bed.

### REDUCING FEAR OF SEIZURES

Fear that a seizure may occur unexpectedly can be reduced by the patient's adherence to the prescribed treatment regimen. Cooperation of the patient and family and their trust in the prescribed regimen are essential for control of seizures (Schachter, 2001). It should be emphasized that the prescribed antiseizure medication must be taken on a continuing basis without fear of drug dependence or addiction. Periodic monitoring is necessary to ensure the adequacy of the treatment regimen and to prevent side effects.

In an effort to control seizures, factors that may precipitate them are identified: emotional disturbances, new environmental stressors, onset of menstruation in female patients, or fever (Greenberg, 2001). The patient is encouraged to follow a regular and moderate routine in lifestyle, diet (avoiding excessive stimulants), exercise, and rest (sleep deprivation may lower the seizure threshold). Moderate activity is therapeutic, but excessive exercise should be avoided.

Photic stimulation (bright flickering lights, television viewing) may precipitate seizures; wearing dark glasses or covering one eye may be preventive. Tension states (anxiety, frustration) induce

## NURSING RESEARCH PROFILE 61-2

### Nursing Observation and Documentation of Seizures

Wulf, J. A. (2000). Evaluation of seizure observation and documentation. *Journal of Neuroscience Nursing*, 32(1), 27–36.

#### Purpose

The observation and documentation of seizure activity are challenging yet essential aspects of nursing assessment. Despite their importance, there is a wide variability in nursing observation and documentation skills. The purpose of this study was to evaluate how demographic characteristics and knowledge levels of staff affected seizure documentation skills.

#### Study Sample and Design

This descriptive study included 58 participants: 38 RNs, 17 certified nursing assistants, and 3 licensed practical nurses or recreational therapists employed at a hospital with an epilepsy center. All participants had received mandatory seizure observation training within the 2 years preceding the study. Participants observed and documented the same six videotaped seizure events in a randomly ordered sequence over 4 to 6 weeks. Participants used an event record form with observational guidelines similar to those used in the clinical setting. Two raters evaluated and scored the seizure event records, rating each record for detail and quality.

#### Findings

Seizure event ratings did not vary significantly according to observer characteristics of educational level, employment position, years of employment, or clinical experience with epilepsy. Certified nursing assistants with clinical experience with epilepsy had significantly higher mean seizure rating scores (indicating higher quality and detail) compared to nursing assistants without experience ( $p < 0.01$ ). There were no differences in RNs with and without experience. A master score sheet was developed for each seizure event, and seizures with excess motor activity as an attribute had the highest scores, indicating that a greater number of details about the seizure were observed compared to the master score sheet. Participants missed some details of the seizure events and also documented details not present on the videotapes, such as seizure classification. Opportunities to review videotapes or actual seizures periodically improved observation and documentation skills.

#### Nursing Implications

The findings of this study suggest that use of a videotape of seizures and a scoring tool is useful for initial training and certification and may assist in periodic retraining of all personnel responsible for seizure observation to maintain quality of observation and documentation. Nurses involved in teaching these skills should keep in mind that observation instruction should emphasize not only predominant seizure features such as motor movements but also less frequently made observations such as responsiveness that may assist in seizure classification. Nurses observing and documenting seizure activity should be cautioned not to include items such as seizure classification that are not direct observations and may be incorrect.

seizures in some patients. Classes in stress management may be of value. Because seizures are known to occur with alcohol intake, alcoholic beverages should be avoided.

### IMPROVING COPING MECHANISMS

It has been noted that the social, psychological, and behavioral problems frequently accompanying epilepsy can be more of a handicap than the actual seizures. Epilepsy may be accompanied by feelings of stigmatization, alienation, depression, and uncer-

tainty. The patient must cope with the constant fear of a seizure and its consequences (Buelow, 2001). Children with epilepsy may be ostracized and excluded from school and peer activities. These problems are compounded during adolescence and add to the challenges of dating, not being able to drive, and feeling different. Adults face these problems in addition to the burden of finding employment, concerns about relationships and childbearing, insurance problems, and legal barriers. Alcohol abuse may complicate matters. Family reactions may vary from outright rejection of the person with epilepsy to overprotection. As a result, many people with epilepsy have psychological and behavioral problems.

Counseling assists the individual and family to understand the condition and the limitations imposed by it. Social and recreational opportunities are necessary for good mental health. Nurses can improve the quality of life for patients with epilepsy by educating them and their families about symptoms and their management (Rice, 2000).

### PROVIDING PATIENT AND FAMILY EDUCATION

Of all the care contributed by the nurse to the person with epilepsy, perhaps the most valuable facets are education and efforts to modify the attitudes of the patient and family toward the disorder. The person who experiences seizures may consider every seizure a potential source of humiliation and shame. This may result in anxiety, depression, hostility, and secrecy on the part of the patient and family. Ongoing education and encouragement should be given to patients to enable them to overcome these feelings. The patient with epilepsy should carry an emergency medical identification card or wear a medical information bracelet. The patient and family need to be educated about medications as well as care during a seizure.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Status epilepticus, the major complication, is described below. Another complication is the toxicity of medications. The patient and family are instructed about side effects and are given specific guidelines to assess and report signs and symptoms indicating medication overdose. Many antiseizure medications require careful monitoring for therapeutic levels. Patients should plan to have serum drug levels drawn at regular intervals. There are also many known drug interactions with antiseizure medications. A complete pharmacologic profile should be reviewed with the patient to avoid interactions either potentiating or inhibiting the effectiveness of the medications.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

Thorough oral hygiene after each meal, gum massage, daily flossing, and regular dental care are essential to prevent or control gingival hyperplasia in patients receiving phenytoin (Dilantin). The patient is also instructed to inform all health care providers of the medication being taken because of the possibility of drug interactions. An individualized comprehensive teaching plan is needed to assist the patient and family to adjust to this chronic disorder (Shafer, 1999). Written patient education materials must be appropriate for the patient's reading level (Murphy, Chesson, Berman et al., 2001). See Chart 61-5 for home care instruction points.

#### Continuing Care

Because epilepsy is a long-term disorder, the use of costly medications may create a significant financial burden. The Epilepsy Foundation of America offers a mail-order program to provide

Chart 61-5

## Home Care Checklist • The Patient With Epilepsy

At the completion of the home instruction, the patient and caregiver will be able to:

	Patient	Caregiver
• Take medications daily as prescribed to keep the drug level constant to prevent seizures. The patient should never discontinue medications, even when there is no seizure activity.	✓	
• Keep a medication and seizure chart, noting when medications are taken and any seizure activity.	✓	✓
• Notify the patient's physician if patient cannot take medications due to illness.	✓	✓
• Have antiseizure serum levels checked regularly. When testing is prescribed, the patient should report to the laboratory for blood sampling before taking morning medication.	✓	
• Avoid activities that require alertness and coordination (driving, operating machinery) until after the effects of the medication have been evaluated.	✓	
• Report signs of toxicity so dosage can be adjusted. Common signs include drowsiness, lethargy, dizziness, difficulty walking, hyperactivity, confusion, inappropriate sleep, and visual disturbances.	✓	✓
• Avoid over-the-counter medications unless approved by the patient's physician.	✓	
• Carry a medical alert bracelet or identification card specifying the name of the patient's antiseizure medication and physician.	✓	
• Avoid seizure triggers, such as alcoholic beverages, electrical shocks, stress, caffeine, constipation, fever, hyperventilation, hypoglycemia.	✓	
• Take showers rather than tub baths to avoid drowning if seizure occurs; never swim alone.	✓	
• Exercise in moderation in a temperature-controlled environment to avoid excessive heat.	✓	
• Develop regular sleep patterns to minimize fatigue and insomnia.	✓	✓
• Use the Epilepsy Foundation of America's special services, including help in obtaining medications, vocational rehabilitation, and coping with epilepsy.	✓	✓

medications at minimal cost and access to life insurance. This organization serves as a referral source for special services for people with epilepsy.

For many, overcoming employment problems is a challenge. State vocational rehabilitation agencies can provide information about job training. The Epilepsy Foundation of America has a training and placement service. If seizures are not well controlled, information about sheltered workshops or home employment programs may also be obtained. Federal and state agencies and federal legislation may be of assistance to people with epilepsy who experience job discrimination. As a result of the Americans With Disabilities Act, the number of employers who knowingly hire people with epilepsy may be increasing, but barriers to employment still exist (Buelow, 2001).

People who have uncontrollable seizures accompanied by psychological and social difficulties can be referred to comprehensive epilepsy centers where continuous audio-video and EEG monitoring, specialized treatment, and rehabilitation services are available (Schachter, 2001). Patients and their families need to be reminded of the importance of following the prescribed treatment regimen and keeping follow-up appointments. In addition, they are reminded of the importance of participating in health promotion activities and recommended health screenings to promote a healthy lifestyle. Genetic and preconception counseling is advised.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Sustains no injury during seizure activity
  - a. Complies with treatment regimen and identifies the hazards of stopping the medication
  - b. Patient and family can identify appropriate care during seizure

2. Exhibits decreased fear
3. Displays effective individual coping
4. Exhibits knowledge and understanding of epilepsy
  - a. Identifies the side effects of medications
  - b. Avoids factors or situations that may precipitate seizures (flickering lights, hyperventilation, alcohol)
  - c. Follows a healthy lifestyle by getting adequate sleep and eating meals at regular times to avoid hypoglycemia
5. Absence of complications

## STATUS EPILEPTICUS

Status epilepticus (acute prolonged seizure activity) is a series of generalized seizures that occur without full recovery of consciousness between attacks (Greenberg, 2001). The term has been broadened to include continuous clinical or electrical seizures lasting at least 30 minutes, even without impairment of consciousness. It is considered a medical emergency. Status epilepticus produces cumulative effects. Vigorous muscular contractions impose a heavy metabolic demand and can interfere with respirations. There is some respiratory arrest at the height of each seizure that produces venous congestion and hypoxia of the brain. Repeated episodes of cerebral anoxia and edema may lead to irreversible and fatal brain damage. Factors that precipitate status epilepticus include withdrawal of antiseizure medication, fever, and concurrent infection.

## Medical Management

The goals of treatment are to stop the seizures as quickly as possible, to ensure adequate cerebral oxygenation, and to maintain the patient in a seizure-free state. An airway and adequate oxygenation are established. If the patient remains unconscious and unresponsive, a cuffed endotracheal tube is inserted. Intravenous diazepam (Valium), lorazepam (Ativan), or fosphenytoin (Cere-

byx) is given slowly in an attempt to halt seizures immediately. Other medications (phenytoin, phenobarbital) are given later to maintain a seizure-free state.

An intravenous line is established, and blood samples are obtained to monitor serum electrolytes, glucose, and phenytoin levels (Greenberg, 2001). EEG monitoring may be useful in determining the nature of the seizure activity. Vital signs and neurologic signs are monitored on a continuing basis. An intravenous infusion of dextrose is given if the seizure is due to hypoglycemia. If initial treatment is unsuccessful, general anesthesia with a short-acting barbiturate may be used. The serum concentration of the antiseizure medication is measured because a low level suggests that the patient was not taking the medication or that the dosage was too low. Cardiac involvement or respiratory depression may be life-threatening. There is also the potential for postictal cerebral edema.

## Nursing Management

The nurse initiates ongoing assessment and monitoring of respiratory and cardiac function because of the risk for delayed depression of respiration and blood pressure secondary to administration of antiseizure medications and sedatives to halt the seizures. Nursing assessment also includes monitoring and documenting the seizure activity and the patient's responsiveness.

The patient is turned to a side-lying position if possible to assist in draining pharyngeal secretions. Suction equipment must be available because of the risk for aspiration. The intravenous line is closely monitored because it may become dislodged during seizures.

A person who has received long-term antiseizure therapy has a significant risk for fractures resulting from bone disease (osteoporosis, osteomalacia, and hyperparathyroidism), a side effect of therapy. Thus, during seizures, the patient should be protected from injury using seizure precautions and monitored closely. No effort should be made to restrain movements. The patient having seizures can inadvertently injure nearby people, so nurses should protect themselves. Other nursing interventions for the person having seizures are presented in Chart 61-4.

## Headache

Headache, or cephalgia, is one of the most common of all human physical complaints. Headache is actually a symptom rather than a disease entity; it may indicate organic disease (neurologic or other disease), a stress response, vasodilation (migraine), skeletal muscle tension (tension headache), or a combination of factors. A **primary headache** is one for which no organic cause can be identified. These types of headache include migraine, tension-type, and cluster headaches (Lin, 2001). Cranial arteritis is another common cause of headache. A classification of headaches was issued by the Headache Classification Committee of the International Headache Society in 1988; an abbreviated list is shown in Chart 61-6.

**Migraine** is a symptom complex characterized by periodic and recurrent attacks of severe headache. The cause of migraine has not been clearly demonstrated, but it is primarily a vascular disturbance that occurs more commonly in women and has a strong familial tendency. The typical time of onset is puberty, and the incidence is highest in adults 20 to 35 years of age. There are seven subtypes of migraine, including migraine with and without aura. Most patients have migraine without an aura.

*Tension headaches* tend to be more chronic than severe and are probably the most common type of headache. *Cluster headaches* are a severe form of vascular headache. They are seen five times more frequently in men than women (Greenberg, 2001).

Inflammation of the cranial arteries is characterized by a severe headache localized in the region of the temporal arteries. The inflammation may be generalized (in which cranial arteritis is part of a vascular disease) or focal (in which only the cranial arteries are involved). *Cranial arteritis* is a cause of headache in the older population, reaching its greatest incidence in those older than 70 years of age.

A **secondary headache** is a symptom associated with an organic cause, such as a brain tumor or an aneurysm. Most headaches do not indicate serious disease, although persistent headaches require further investigation. Serious disorders related to headache include brain tumors, subarachnoid hemorrhage, stroke, severe hypertension, meningitis, and head injuries.

## Assessment and Diagnostic Evaluation

The diagnostic evaluation includes a detailed history, a physical assessment of the head and neck, and a complete neurologic examination. Headaches may manifest differently within an individual over the course of a lifetime, and the same type of headache may present differently from patient to patient. The health history focuses on assessing the headache itself, with emphasis on the factors that precipitate or provoke it. Patients are asked to describe headaches in their own words.

Because headache is often the presenting symptom of various physiologic and psychological disturbances, a general health history is an essential component of the patient database. Headache may be a symptom of endocrine, hematologic, gastrointestinal, infectious, renal, cardiovascular, or psychiatric disease. Therefore, questions addressed in the health history should cover major medical and surgical illness as well as a body systems review.

The medication history can provide insight into the patient's overall health status. Antihypertensive agents, diuretic medications, anti-inflammatory agents, and monoamine oxidase inhibitors are a few of the categories of medications that can provoke headaches. Although sometimes exaggerated in importance, emotional factors can play a role in precipitating headaches. Stress is thought to be a major initiating factor in migraine headaches; therefore, sleep patterns, level of stress, recreational interests,

appetite, emotional problems, and family stressors are relevant (Cunningham, 2000). There is a strong familial tendency for headache disorders, and a positive family history may help in making a diagnosis.

A direct relationship may exist between exposure to toxic substances and headache. Careful questioning may uncover chemicals to which a worker has been exposed. Under the Right to Know law, employees have access to the material safety data sheets (commonly referred to as MSDSs) for all the substances with which they come in contact in the workplace. The occupational history also includes assessment of the workplace as a possible source of stress and a possible ergonomic basis for muscle strain and headache.

A complete description of the headache itself is crucial. The age at onset of headache; the headache's frequency, location, and duration; the type of pain; factors that relieve and precipitate the event; and associated symptoms are reviewed. The data obtained should include the patient's own words about the headache in response to the following questions:

- What is the location? Is it unilateral or bilateral? Does it radiate?
- What is the quality—dull, aching, steady, boring, burning, intermittent, continuous, paroxysmal?
- How many headaches occur during a given time?
- What are the precipitating factors, if any (environmental, such as sunlight and weather change; foods; exertion; other)?
- What makes the headache worse (coughing, straining)?
- What time (day or night) does it occur?
- Are there any associated symptoms, such as facial pain, lacrimation (excessive tearing), or scotomas (blind spots in the field of vision)?
- What usually relieves the headache (aspirin, NSAIDs, ergot preparation, food, heat, rest, neck massage)?
- Does nausea, vomiting, weakness, or numbness in the extremities accompany the headache?
- Does the headache interfere with daily activities?
- Do you have any allergies?
- Do you have insomnia, poor appetite, loss of energy?
- Is there a family history of headache?
- What is the relationship of the headache to lifestyle or physical or emotional stress?
- What medications are you taking?

Diagnostic testing is often not helpful in the investigation of headache as there are often few objective findings. In patients who demonstrate abnormalities on the neurologic examination, CT, cerebral angiography, or MRI may be used to detect underlying causes, such as tumor or aneurysm. Electromyography (EMG) may reveal a sustained contraction of the neck, scalp, or facial muscles. Laboratory tests may include complete blood count, erythrocyte sedimentation rate, electrolytes, glucose, creatinine, and thyroid hormone levels.

## Pathophysiology

The cerebral signs and symptoms of *migraine* result from dysfunction of the brain stem pathways that normally modulate sensory input (Goadsby, Lipton & Ferrari, 2002). Abnormal metabolism of serotonin, a vasoactive neurotransmitter found in platelets and cells of the brain, plays a major role. The headache is preceded by a rise in plasma serotonin, which dilates the cerebral vessels, but migraines are more than just vascular headaches. The

exact mechanism of pain in migraine is not completely understood but is thought to be related to the cranial blood vessels, the innervation of the vessels, and the reflex connections in the brain stem.

Migraines can be triggered by menstrual cycles, bright lights, stress, depression, sleep deprivation, fatigue, overuse of certain medications, and certain foods containing tyramine, monosodium glutamate, nitrites, or milk products. Foods in these categories include aged cheese and many processed foods. Use of oral contraceptives may be associated with increased frequency and severity of attacks in some women.

Emotional or physical stress may cause contraction of the muscles in the neck and scalp, resulting in tension headache. The pathophysiology of cluster headache is not fully understood. One theory is that it is due to dilation of orbital and nearby extracranial arteries. Cranial arteritis is thought to represent an immune vasculitis in which immune complexes are deposited within the walls of affected blood vessels, producing vascular injury and inflammation. A biopsy may be performed on the involved artery to make the diagnosis.

## Clinical Manifestations

### MIGRAINE

The migraine with aura can be divided into four phases: prodrome, aura, the headache, and recovery (headache termination and postdrome).

**Prodrome.** The prodrome phase is experienced by 60% of patients with symptoms that occur hours to days before a migraine headache. Symptoms include depression, irritability, feeling cold, food cravings, anorexia, change in activity level, increased urination, diarrhea, or constipation. Patients usually experience the same prodrome with each migraine headache.

**Aura Phase.** Aura occurs in up to 31% of patients who have migraines (Goadsby et al., 2002). The aura usually lasts less than an hour and may provide enough time for the patient to take the prescribed medication to avert a full-blown attack (described in a later section). This period is characterized by focal neurologic symptoms. Visual disturbances (ie, light flashes and bright spots) are common and may be hemianopic (affecting only half of the visual field). Other symptoms that may follow include numbness and tingling of the lips, face, or hands; mild confusion; slight weakness of an extremity; drowsiness; and dizziness.

This period of aura corresponds to the painless vasoconstriction that is the initial physiologic change characteristic of classic migraine. Cerebral blood flow studies performed during migraine headaches demonstrate that during all phases of the attack, cerebral blood flow is reduced throughout the brain, with subsequent loss of autoregulation and impaired CO<sub>2</sub> responsiveness.

**Headache Phase.** As vasodilation and a decline in serotonin levels occur, a throbbing headache (unilateral in 60% of patients) intensifies over several hours. This headache is severe and incapacitating and is often associated with photophobia, nausea, and vomiting. Its duration varies, ranging from 4 to 72 hours (Goadsby et al., 2002).

**Recovery Phase.** In the recovery phase (termination and postdrome), the pain gradually subsides. Muscle contraction in the neck and scalp is common, with associated muscle ache and localized tenderness, exhaustion, and mood changes. Any physical exertion exacerbates the headache pain. During this postheadache phase, patients may sleep for extended periods.

### OTHER HEADACHE TYPES

The tension headache is characterized by a steady, constant feeling of pressure that usually begins in the forehead, temple, or back of the neck. It is often bandlike or may be described as “a weight on top of my head.”

Cluster headaches are unilateral and come in clusters of one to eight daily, with excruciating pain localized to the eye and orbit and radiating to the facial and temporal regions. The pain is accompanied by watering of the eye and nasal congestion. Each attack lasts 30 to 90 minutes and may have a crescendo–decrescendo pattern (Greenberg, 2001). The headache is often described as penetrating and steady.

Cranial arteritis often begins with general manifestations, such as fatigue, malaise, weight loss, and fever. Clinical manifestations associated with inflammation (heat, redness, swelling, tenderness, or pain over the involved artery) usually are present. Sometimes a tender, swollen, or nodular temporal artery is visible. Visual problems are caused by ischemia of the involved structures.

### Prevention

Prevention begins by having the patient avoid specific triggers that are known to initiate the headache syndrome. Preventive medical management of migraine involves the daily use of one or more agents that are thought to block the physiologic events leading to an attack. Medication therapy should be considered for migraine if attacks occur 3 to 4 days per month (Goadsby et al., 2002). Treatment regimens vary greatly, as do patient responses; thus, close monitoring is indicated.

There are several proven or widely used medications for the prevention of migraine. Two beta-blocking agents, propranolol (Inderal) and metoprolol (Lopressor), inhibit the action of beta-receptors—cells in the heart and brain that control the dilation of blood vessels. This is thought to be a major reason for their antimigraine action. Other medications that are prescribed for migraine prevention include amitriptyline hydrochloride (Elavil), divalproex (Valproate), flunarizine, and several serotonin antagonists (Goadsby et al., 2002).

Calcium antagonists (verapamil HCl) are widely used but may require several weeks at a therapeutic dosage before improvement is noted. Calcium-channel blockers are not as effective as beta-blockers for prevention but may be more appropriate for some patients, such as those with bradycardia, diabetes mellitus, or asthma (Goadsby et al., 2002).

Alcohol, nitrites, vasodilators, and histamines may precipitate cluster headaches. Eliminating these factors helps in preventing the headaches (Silberstein & Rosenberg, 2000). Prophylactic medication therapy may include beta-blockers, ergotamine tartrate (occasionally), lithium, naproxen (Naprosyn), and methysergide (Sansert); such therapy is effective in 20% to 40% of cases (Greenberg, 2001).

### Medical Management

Therapy for migraine headache is divided into abortive (symptomatic) and preventive approaches. The abortive approach, best employed in patients who suffer less frequent attacks, is aimed at relieving or limiting a headache at the onset or while it is in progress. The preventive approach is used in patients who experience more frequent attacks at regular or predictable intervals and may have medical conditions that preclude the use of abortive therapies (Evans & Lipton, 2001).

The triptans, serotonin receptor agonists, are the most specific antimigraine agents available. These agents cause vasoconstriction,

reduce inflammation, and may reduce pain transmission. The five triptans in routine clinical use include sumatriptan (Imitrex), naratriptan (Amerge), rizatriptan (Maxalt), zolmitriptan (Zomig), and almotriptan (Goadsby et al., 2002). Numerous serotonin receptor agonists are under study.

Ergotamine preparations (taken orally, sublingually, subcutaneously, intramuscularly, by rectum, or by inhalation) may be effective in aborting the headache if taken early in the migraine process. They are low in cost. Ergotamine tartrate acts on smooth muscle, causing prolonged constriction of the cranial blood vessels. Each patient's dosage is based on individual needs. Side effects include aching muscles, paresthesias (numbness and tingling), nausea, and vomiting. Cafergot, a combination of ergotamine and caffeine, can arrest or reduce the severity of the headache if taken at the first sign of an attack (Karch, 2002).

Perhaps the most widely used triptan is sumatriptan succinate (Imitrex); it is available in oral, intranasal, and subcutaneous preparations and is effective for the treatment of acute migraine and cluster headaches in adults (McAlhany, 2001). The subcutaneous form usually relieves symptoms within an hour and is available in an auto-injector for immediate patient use, although it is expensive in this form. Sumatriptan has been found to be effective in relieving moderate to severe migraines in a large number of adult patients. Sumatriptan may cause chest pain and is contraindicated in patients with ischemic heart disease (Goadsby et al., 2002). Careful administration and dosing instructions to patients are important to prevent adverse reactions such as increased blood pressure, drowsiness, muscle pain, sweating, and anxiety. There are possible interactions when taken in conjunction with St. John's wort (Karch, 2002).

Many of the triptan medications are available in a variety of formulations, such as nasal sprays, inhalers, suppositories, or injections; however, 80% of patients prefer the oral formulations (Goadsby et al., 2002). None of these medications should be taken concurrently with medications containing ergotamine due to the potential for a prolonged vasoactive reaction (Karch, 2002).

The medical management of an acute attack of cluster headaches may include 100% oxygen by face mask for 15 minutes, ergotamine tartrate, sumatriptan, steroids, or a percutaneous sphenopalatine ganglion blockade (Greenberg, 2001).

The medical management of cranial arteritis consists of early administration of a corticosteroid to prevent the possibility of loss of vision due to vascular occlusion or rupture of the involved artery (Greenberg, 2001). The patient is instructed not to stop the medication abruptly because this can lead to relapse. Analgesic agents are prescribed for comfort.

### Nursing Management

When migraine or the other types of headaches described above have been diagnosed, the goals of nursing management are to enhance pain relief. It is reasonable to try nonpharmacologic interventions first, but the use of pharmacologic agents should not be delayed. The goal is to treat the acute event of the headache and to prevent recurrent episodes. Prevention involves patient education regarding precipitating factors, possible lifestyle or habit changes that may be helpful, and pharmacologic measures.

### RELIEVING PAIN

Individualized treatment depends on the type of headache and differs for migraine, cluster headaches, cranial arteritis, and tension headache (Greenberg, 2001; Silberstein & Rosenberg, 2000). Nursing care is directed toward treatment of the acute episode. A migraine or a cluster headache in the early phase requires

Chart 61-7

## Home Care Checklist • The Patient With Migraine Headaches

At the completion of the home instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Define migraine headaches and describe characteristics and manifestations.	✓	✓
• Identify triggers of migraine headaches and how to avoid such triggers as: Foods that contain tyramine, such as chocolate, cheese, coffee, dairy products Dietary habits that result in long periods between meals Menstruation and ovulation (causes hormone fluctuation) Alcohol (causes vasodilation of blood vessels) Fatigue and fluctuations in sleep patterns	✓	✓
• State importance of keeping and how to develop a headache diary.	✓	✓
• State stress management and lifestyle changes to minimize the frequency of headaches.	✓	✓
• State pharmacologic management: acute therapy and prophylaxis, to include medication regimen and side effects.	✓	✓
• Identify comfort measures during headache attacks, such as resting in a quiet and dark environment, applying cold compresses to the painful area, and elevating the head.	✓	✓
• Identify resources for education and support, such as the National Headache Foundation.	✓	✓

abortive medication therapy instituted as soon as possible. Some headaches may be prevented if the appropriate medications are taken before the onset of pain. Nursing care during a fully developed attack includes comfort measures such as a quiet, dark environment and elevation of the head of the bed to 30 degrees. In addition, symptomatic treatment such as antiemetics may be indicated (Goadsby et al., 2002).

Symptomatic pain relief for tension headache may be obtained by application of local heat or massage. Additional strategies may include the use of analgesic agents, antidepressant medications, and muscle relaxants.

### HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** Headaches, especially migraines, are more likely to occur when the patient is ill, overly tired, or stressed. Nonpharmacologic therapies are important and include patient education about the type of headache, its mechanism (if known), and appropriate changes in lifestyle to avoid triggers. Regular sleep, meals, exercise, avoidance of peaks and troughs of relaxation, and avoidance of dietary triggers may be helpful in avoiding headaches (Goadsby et al., 2002; Rice, 2000).

The patient with tension headaches needs teaching and reassurance that the headache is not due to a brain tumor. This is a common unspoken fear. Stress reduction techniques, such as biofeedback, exercise programs, and meditation, are examples of nonpharmacologic therapies that may prove helpful. Patients and their families need to be reminded of the importance of following the prescribed treatment regimen for headache and keeping follow-up appointments. In addition, they are reminded of the importance of participating in health promotion activities and recommended health screenings to promote a healthy lifestyle. See Chart 61-7 for a home care checklist for the patient with migraine headaches.

**Continuing Care.** The National Headache Foundation (see Resources at end of the chapter) provides a list of clinics in the United States and the names of physicians who specialize in headache and who are members of the American Association for the Study of Headache.

### Critical Thinking Exercises

1. Your patient has signs of increased ICP, including disorientation and right-sided weakness. Describe the medical management you would anticipate to control the ICP and the nursing measures that are indicated. How would you determine if your interventions were effective in alleviating the increased ICP? What are signs and symptoms of further deterioration in neurologic status? Explain the physiologic cause of each sign and symptom.
2. Compare and contrast the possible characteristics, causes, prognoses, and nursing interventions for a) the patient who is unconscious, b) the patient in a persistent vegetative state, and c) the patient in coma.
3. A patient is admitted to your unit after undergoing transsphenoidal surgery for a brain tumor. Describe the major complications to assess for, along with the signs and symptoms of each. Describe the nursing measures that are indicated postoperatively. What patient and family teaching is important for the patient and family? How would you modify your teaching and discharge planning if the patient understands little English? If the patient lives alone?
4. You are caring for an 18-year-old patient admitted to the hospital to evaluate the recent onset of seizures and an episode of status epilepticus. He is angry about his situation and states that he has no intention of taking medications or giving up his driver's license. Describe your approach to caring for him. How would your approach differ if the patient is a 28-year-old woman who is 6 months pregnant?

# ● Management of Patients With Cerebrovascular Disorders

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Describe the incidence and social impact of cerebrovascular disorders.
2. Identify the risk factors for cerebrovascular disorders and related measures for prevention.
3. Compare the various types of cerebrovascular disorders: their causes, clinical manifestations, and medical management.
4. Relate the principles of nursing management to the care of a patient in the acute stage of an ischemic stroke.
5. Use the nursing process as a framework for care of a patient recovering from an ischemic stroke.
6. Use the nursing process as a framework for care of a patient with a cerebral aneurysm.
7. Identify essential elements for family teaching and preparation for home care of the stroke patient.

“Cerebrovascular disorders” is an umbrella term that refers to any functional abnormality of the central nervous system (CNS) that occurs when the normal blood supply to the brain is disrupted. Stroke is the primary cerebrovascular disorder in the United States and in the world. Although preventive efforts have brought about a steady decline in incidence over the last several years, stroke is still the third leading cause of death. Approximately 500,000 people experience a new stroke, 100,000 experience a recurrent stroke, and approximately 160,000 die of a stroke each year. With over 4 million survivors (2.2 million men and 2.3 million women), stroke is the leading cause of serious, long-term disability in the United States (American Heart Association, 2000).

Strokes can be divided into two major categories: ischemic (85%), in which vascular occlusion and significant hypoperfusion occur, and hemorrhagic (15%), in which there is extravasation of blood into the brain (American Heart Association, 2000). Although there are some similarities between the two broad types of stroke, overall the etiology, pathophysiology, medical management, surgical management, and nursing care differ. Table 62-1 reviews the major types of ischemic and hemorrhagic strokes.

## Ischemic Stroke

Approximately 400,000 people have an ischemic stroke in the United States each year (Hock, 1999). An ischemic stroke, cerebrovascular accident (CVA), or what is now being termed “brain attack” is a sudden loss of function resulting from disruption of the blood supply to a part of the brain. This event is usually the result of long-standing cerebrovascular disease. The term “brain attack” is being used to suggest to health care practitioners and the public that a stroke is an urgent health care issue similar to a heart attack. This change in terms also reflects a similar management strategy in both diseases. Early treatment results in fewer symptoms and less loss of function. Only 8% of ischemic strokes result in death within 30 days (American Heart Association, 2000).

The net lifetime stroke-related costs in patients over the age of 65 with a first ischemic stroke are estimated at \$62,000 (\$45,000 direct costs plus \$17,000 indirect costs). The cost for younger patients (those less than 65 years) is even greater, at \$198,000 per year (\$65,000 direct costs plus \$133,000 indirect costs). The approximate annual cost in the United States for ischemic stroke care is over \$71.8 billion (Matchar & Samsa, 2000).

Table 62-1 • Major Types of Stroke and Their Causes

CLASSIFICATION	CAUSES
Ischemic	Large artery thrombosis Small penetrating artery thrombosis Cardiogenic embolic Cryptogenic (no known cause) Other
Hemorrhagic	Intracerebral hemorrhage Subarachnoid hemorrhage Cerebral aneurysm Arteriovenous malformation

Ischemic strokes are subdivided into five different types according to their cause: large artery thrombosis (20%), small penetrating artery thrombosis (25%), cardiogenic embolic stroke (20%), cryptogenic (30%) and other (5%) (see Table 62-1).

Large artery thrombotic strokes are due to atherosclerotic plaques in the large blood vessels of the brain. Thrombus formation and occlusion at the site of the atherosclerosis result in ischemia and **infarction**.

Small penetrating artery thrombotic strokes affect one or more vessels and are the most common type of ischemic stroke. Small artery thrombotic strokes are also called lacunar strokes because of the cavity that is created once the infarcted brain tissue disintegrates.

Cardiogenic embolic strokes are associated with cardiac dysrhythmias, usually atrial fibrillation. Emboli originate from the heart and circulate to the cerebral vasculature, most commonly the left middle cerebral artery, resulting in a stroke. Embolic strokes may be prevented by the use of anticoagulation therapy in patients with atrial fibrillation.

The last two classifications of ischemic strokes are cryptogenic strokes, which have no known cause, and other strokes, from causes such as cocaine use, coagulopathies, migraine, and spontaneous dissection of the carotid or vertebral arteries (Hock, 1999; Schievink, 2001).

## Pathophysiology

In an ischemic brain attack, there is disruption of the cerebral blood flow due to obstruction of a blood vessel. This disruption in blood flow initiates a complex series of cellular metabolic events referred to as the ischemic cascade (Fig. 62-1).

## Glossary

**agnosia:** failure to recognize familiar objects perceived by the senses

**aneurysm:** a weakening or bulge in an arterial wall

**aphasia:** inability to express oneself or to understand language

**apraxia:** inability to perform previously learned purposeful motor acts on a voluntary basis

**ataxia:** impaired ability to coordinate movement, often seen as a staggering gait or postural imbalance

**dysarthria:** defects of articulation due to neurologic causes

**expressive aphasia:** inability to express oneself; often associated with damage to the left frontal lobe area

**hemianopsia:** blindness of half of the field of vision in one or both eyes

**hemiplegia/hemiparesis:** weakness/paralysis of one side of the body, or part of it, due to an injury to the motor areas of the brain

**infarction:** a zone of tissue deprived of blood supply

**Korsakoff's syndrome:** personality disorder characterized by psychosis, disorientation, delirium, insomnia, and hallucinations

**penumbra region:** area of low cerebral blood flow

**perseveration:** continued and automatic repetition of an activity or word or phrase that is no longer appropriate

**receptive aphasia:** inability to understand what someone else is saying; often associated with damage to the temporal lobe area

## Physiology/Pathophysiology

**FIGURE 62-1** Processes contributing to ischemic brain cell injury. Courtesy of National Stroke Association, Englewood, Colorado.

The ischemic cascade begins when cerebral blood flow falls to less than 25 mL/100 g/min. At this point, neurons can no longer maintain aerobic respiration. The mitochondria must then switch to anaerobic respiration, which generates large amounts of lactic acid, causing a change in the pH level. This switch to the less efficient anaerobic respiration also renders the neuron incapable of producing sufficient quantities of adenosine triphosphate (ATP) to fuel the depolarization processes. Thus, the membrane pumps that maintain electrolyte balances begin to fail and the cells cease to function.

Early in the cascade, an area of low cerebral blood flow, referred to as the penumbra region, exists around the area of infarction. The **penumbra region** is ischemic brain tissue that can be salvaged with timely intervention. The ischemic cascade threatens cells in the penumbra because membrane depolarization of the cell wall leads to an increase in intracellular calcium and the release of glutamate (Hock, 1999). The penumbra area can be revitalized by administration of tissue plasminogen activator (t-PA), and the influx of calcium can be limited with the use of calcium channel blockers. The influx of calcium and the release of glutamate, if continued, activate a number of damaging pathways that result in the destruction of the cell membrane, the release of more calcium and glutamate, vasoconstriction, and the generation of free radicals. These processes enlarge the area of infarction into the penumbra, extending the stroke.

Each step in the ischemic cascade represents an opportunity for intervention to limit the extent of secondary brain damage caused by a stroke. Medications that protect the brain from secondary injury are called neuroprotectants (Reed, 2000). A number of clinical trials are focusing on calcium channel antagonists that block the calcium influx, glutamate antagonists, antioxidants, and other neuroprotectant strategies that will help prevent secondary complications (NINDS, 1999; Reed, 2000).

## Clinical Manifestations

An ischemic stroke can cause a wide variety of neurologic deficits, depending on the location of the lesion (which vessels are obstructed), the size of the area of inadequate perfusion, and the amount of collateral (secondary or accessory) blood flow. The patient may present with any of the following signs or symptoms:

- Numbness or weakness of the face, arm, or leg, especially on one side of the body
- Confusion or change in mental status
- Trouble speaking or understanding speech
- Visual disturbances
- Difficulty walking, dizziness, or loss of balance or coordination
- Sudden severe headache

Motor, sensory, cranial nerve, cognitive, and other functions may be disrupted. Table 62-2 reviews the neurologic deficits frequently seen in patients with strokes. Table 62-3 compares the symptoms seen in right hemispheric stroke with those seen in left hemispheric stroke. Patients exhibit deficits in specific locations as well as different behavior.

### MOTOR LOSS

A stroke is a lesion of the upper motor neurons and results in loss of voluntary control over motor movements. Because the upper motor neurons decussate (cross), a disturbance of voluntary motor control on one side of the body may reflect damage to the upper motor neurons on the opposite side of the brain. The most common motor dysfunction is **hemiplegia** (paralysis of one side of the body) due to a lesion of the opposite side of the brain. **Hemiparesis**, or weakness of one side of the body, is another sign.

In the early stage of stroke, the initial clinical features may be flaccid paralysis and loss of or decrease in the deep tendon reflexes. When these deep reflexes reappear (usually by 48 hours), increased tone is observed along with spasticity (abnormal increase in muscle tone) of the extremities on the affected side.

### COMMUNICATION LOSS

Other brain functions affected by stroke are language and communication. In fact, stroke is the most common cause of aphasia. The following are dysfunctions of language and communication:

- **Dysarthria** (difficulty in speaking), caused by paralysis of the muscles responsible for producing speech
- Dysphasia or **aphasia** (defective speech or loss of speech), which can be **expressive aphasia**, **receptive aphasia**, or global (mixed) aphasia
- **Apraxia** (inability to perform a previously learned action), as may be seen when a patient picks up a fork and attempts to comb his hair with it

### PERCEPTUAL DISTURBANCES

Perception is the ability to interpret sensation. Stroke can result in visual-perceptual dysfunctions, disturbances in visual-spatial relations, and sensory loss.

Visual-perceptual dysfunctions are due to disturbances of the primary sensory pathways between the eye and visual cortex. Homonymous **hemianopsia** (loss of half of the visual field) may occur from stroke and may be temporary or permanent. The affected side of vision corresponds to the paralyzed side of the body.

Disturbances in visual-spatial relations (perceiving the relation of two or more objects in spatial areas) are frequently seen in patients with right hemispheric damage.

**Table 62-2 • Neurologic Deficits of Stroke: Manifestations and Nursing Implications**

NEUROLOGIC DEFICIT	MANIFESTATION	NURSING IMPLICATIONS/PATIENT TEACHING APPLICATIONS
<b>Visual Field Deficits</b>		
Homonymous hemianopsia (loss of half of the visual field)	<ul style="list-style-type: none"> <li>• Unaware of persons or objects on side of visual loss</li> <li>• Neglect of one side of the body</li> <li>• Difficulty judging distances</li> </ul>	<p>Place objects within intact field of vision.            Approach the patient from side of intact field of vision.            Instruct/remind the patient to turn head in the direction of visual loss to compensate for loss of visual field.            Encourage the use of eyeglasses if available.            When teaching the patient, do so within patient's intact visual field.            Avoid night driving or other risky activities in the darkness.            Place objects in center of patient's intact visual field.            Encourage the use of a cane or other object to identify objects in the periphery of the visual field.            Explain to the patient the location of an object when placing it near the patient.            Consistently place patient care items in the same location.</p>
Loss of peripheral vision	<ul style="list-style-type: none"> <li>• Difficulty seeing at night</li> <li>• Unaware of objects or the borders of objects</li> </ul>	
Diplopia	<ul style="list-style-type: none"> <li>• Double vision</li> </ul>	
<b>Motor Deficits</b>		
Hemiparesis	<ul style="list-style-type: none"> <li>• Weakness of the face, arm, and leg on the same side (due to a lesion in the opposite hemisphere)</li> </ul>	<p>Place objects within the patient's reach on the nonaffected side.            Instruct the patient to exercise and increase the strength on the unaffected side.</p>
Hemiplegia	<ul style="list-style-type: none"> <li>• Paralysis of the face, arm, and leg on the same side (due to a lesion in the opposite hemisphere)</li> </ul>	<p>Encourage the patient to provide range-of-motion exercises to the affected side.            Provide immobilization as needed to the affected side.            Maintain body alignment in functional position.            Exercise unaffected limb to increase mobility, strength, and use.            Support patient during the initial ambulation phase.            Provide supportive device for ambulation (walker, cane).            Instruct the patient not to walk without assistance or supportive device.            Provide the patient with alternative methods of communicating.            Allow the patient sufficient time to respond to verbal communication.            Support patient and family to alleviate frustration related to difficulty in communicating.</p>
Ataxia	<ul style="list-style-type: none"> <li>• Staggering, unsteady gait</li> <li>• Unable to keep feet together; needs a broad base to stand</li> </ul>	
Dysarthria	<ul style="list-style-type: none"> <li>• Difficulty in forming words</li> </ul>	
Dysphagia	<ul style="list-style-type: none"> <li>• Difficulty in swallowing</li> </ul>	<p>Test the patient's pharyngeal reflexes before offering food or fluids.            Assist the patient with meals.            Place food on the unaffected side of the mouth.            Allow ample time to eat.</p>
<b>Sensory Deficits</b>		
Paresthesia (occurs on the side opposite the lesion)	<ul style="list-style-type: none"> <li>• Numbness and tingling of extremity</li> <li>• Difficulty with proprioception</li> </ul>	<p>Instruct the patient to avoid using this extremity as the dominant limb due to altered sensation.            Provide range of motion to affected areas and apply corrective devices as needed.</p>
<b>Verbal Deficits</b>		
Expressive aphasia	<ul style="list-style-type: none"> <li>• Unable to form words that are understandable; may be able to speak in single-word responses</li> </ul>	<p>Encourage patient to repeat sounds of the alphabet.</p>
Receptive aphasia	<ul style="list-style-type: none"> <li>• Unable to comprehend the spoken word; can speak but may not make sense</li> </ul>	<p>Speak slowly and clearly to assist the patient in forming the sounds.</p>
Global (mixed) aphasia	<ul style="list-style-type: none"> <li>• Combination of both receptive and expressive aphasia</li> </ul>	<p>Speak clearly and in simple sentences; use gestures or pictures when able.            Establish alternative means of communication.</p>
<b>Cognitive Deficits</b>		
	<ul style="list-style-type: none"> <li>• Short- and long-term memory loss</li> <li>• Decreased attention span</li> <li>• Impaired ability to concentrate</li> <li>• Poor abstract reasoning</li> <li>• Altered judgment</li> </ul>	<p>Reorient patient to time, place, and situation frequently.            Use verbal and auditory cues to orient patient.            Provide familiar objects (family photographs, favorite objects).            Use noncomplicated language.            Match visual tasks with a verbal cue; holding a toothbrush, simulate brushing of teeth while saying, "I would like you to brush your teeth now."            Minimize distracting noises and views when teaching the patient.            Repeat and reinforce instructions frequently.</p>
<b>Emotional Deficits</b>		
	<ul style="list-style-type: none"> <li>• Loss of self-control</li> <li>• Emotional lability</li> <li>• Decreased tolerance to stressful situations</li> <li>• Depression</li> <li>• Withdrawal</li> <li>• Fear, hostility, and anger</li> <li>• Feelings of isolation</li> </ul>	<p>Support patient during uncontrollable outbursts.            Discuss with the patient and family that the outbursts are due to the disease process.            Encourage patient to participate in group activity.            Provide stimulation for the patient.            Control stressful situations, if possible.            Provide a safe environment.            Encourage patient to express feelings and frustrations related to disease process.</p>

**Table 62-3 • Comparison of Left and Right Hemispheric Strokes**

LEFT HEMISPHERIC STROKE	RIGHT HEMISPHERIC STROKE
Paralysis or weakness on right side of body	Paralysis or weakness on left side of body
Right visual field deficit	Left visual field deficit
Aphasia (expressive, receptive, or global)	Spatial-perceptual deficits
Altered intellectual ability	Increased distractibility
Slow, cautious behavior	Impulsive behavior and poor judgment
	Lack of awareness of deficits

### SENSORY LOSS

The sensory losses from stroke may take the form of slight impairment of touch or may be more severe, with loss of proprioception (ability to perceive the position and motion of body parts) as well as difficulty in interpreting visual, tactile, and auditory stimuli.

### COGNITIVE IMPAIRMENT AND PSYCHOLOGICAL EFFECTS

If damage has occurred to the frontal lobe, learning capacity, memory, or other higher cortical intellectual functions may be impaired. Such dysfunction may be reflected in a limited attention span, difficulties in comprehension, forgetfulness, and a lack of motivation, which cause these patients to become frustrated in their rehabilitation program. Depression is common and may be exaggerated by the patient's natural response to this catastrophic event. Other psychological problems are common and are manifested by emotional lability, hostility, frustration, resentment, and lack of cooperation.

### Assessment and Diagnostic Findings

Any patient with neurologic deficits needs a careful history and a complete physical and neurologic examination. Initial assessment will focus on airway patency, which may be compromised by loss of gag or cough reflexes and altered respiratory pattern; cardiovascular status (including blood pressure, cardiac rhythm and rate, carotid bruit), and gross neurologic losses.

Stroke patients may present to the acute care facility at any point along a continuum of neurologic involvement. A system that uses the time course to classify patients along this continuum may be used to guide treatment. Strokes using the time course are commonly classified in the following manner: (1) transient ischemic attack (TIA); (2) reversible ischemic neurologic deficit; (3) stroke in evolution; and (4) completed stroke (Hock, 1999) (Chart 62-1).

The initial diagnostic test for a stroke is a noncontrast computed tomography (CT) scan performed emergently to determine if the event is ischemic or hemorrhagic (which determines treatment). Further diagnostic workup for ischemic stroke involves attempting to identify the source of the thrombi or emboli. A 12-lead electrocardiogram and a carotid ultrasound are standard tests. Other studies may include cerebral angiography, transcranial Doppler flow studies, transthoracic or transesophageal echocardiography, magnetic resonance imaging of the brain and/or neck, xenon CT, and single photon emission CT (Bonnono et al., 2000; Petty et al., 2000).

In a patient with a TIA, a bruit (abnormal sound heard on auscultation resulting from interference with normal blood flow) may be heard over the carotid artery. There are diminished or ab-

Chart  
62-1

### The Stroke Continuum: Time Course Classification

Strokes are commonly classified using the time course in the following manner: (1) transient ischemic attack (TIA), (2) reversible ischemic neurologic deficit, (3) stroke in evolution, and (4) completed stroke (Hock, 1999).

#### Transient Ischemic Attack

Temporary episode of neurologic dysfunction manifested by a sudden loss of motor, sensory, or visual function. It may last a few seconds or minutes but not longer than 24 hours. Complete recovery usually occurs between attacks. The symptoms result from temporary impairment of blood flow to a specific region of the brain due to atherosclerosis, obstruction of cerebral microcirculation by a small embolus, a decrease in cerebral perfusion pressure (CPP), or cardiac dysrhythmias.

A TIA may serve as a warning of impending stroke, which has its greatest incidence in the first month after the first attack. Lack of evaluation and treatment of a patient who has experienced previous TIAs may result in a stroke and irreversible deficits.

#### Reversible Ischemic Neurologic Deficits

Signs and symptoms are consistent with but more pronounced than a TIA and last more than 24 hours. Symptoms resolve in days with no permanent neurologic deficit.

#### Stroke in Evolution

Worsening of neurologic signs and symptoms over several minutes or hours. This is a progressing stroke.

#### Completed Stroke

Stabilization of the neurologic signs and symptoms. This indicates no further progression of the hypoxic insult to the brain from this particular ischemic event.

sent carotid pulsations in the neck. Diagnostic tests for TIA may include carotid phonoangiography; this involves auscultation, direct visualization, and photographic recording of carotid bruits. Oculoplethysmography measures the pulsation of blood flow through the ophthalmic artery. Carotid angiography allows visualization of intracranial and cervical vessels. Digital subtraction angiography is used to define carotid artery obstruction and provides information on patterns of cerebral blood flow.

### Prevention

Primary prevention of ischemic stroke is the best approach. Stroke risk screenings are an ideal opportunity to lower stroke risk by identifying high-risk individuals or groups and educating the patients and the community about recognition and prevention of stroke (Lindsey, 2000; Manzella & Galante, 2000).

Advanced age, gender, and race are well-known non-modifiable risk factors for stroke (American Heart Association, 2000). Specifically, high-risk groups include people over the age of 55, because the incidence of stroke more than doubles in each successive decade, and men, who have a higher rate of stroke than women (due to the higher prevalence of women in the elderly population, however, the absolute numbers of men and women with stroke are similar). Another high-risk group is African Americans: the incidence of first stroke in African Americans is almost twice that in Caucasians. African Americans also suffer more extensive physical impairments and are twice as likely to die from stroke than Caucasians. Hispanic, Native American Indian, Alaska native, and Asian/Pacific Islander ethnic groups also have a higher relative risk of stroke compared to Caucasians.

Modifiable risk factors for ischemic stroke include hypertension, cardiovascular disease, high cholesterol, obesity, smoking, and diabetes (Chart 62-2). For people at high risk, interventions that alter modifiable factors, such as treating hypertension and hyperglycemia and stopping smoking, will reduce stroke risk. Many health promotion efforts involve encouraging a healthy lifestyle, including eating a low-fat, low-cholesterol diet and increasing exercise. Recent evidence suggests that eating fish two or more times per week reduces the risk of thrombotic stroke for women (Iso et al., 2001).

Several methods of preventing recurrent stroke have been identified for patients with TIAs or mild ischemic stroke. Patients with moderate to severe carotid stenosis are treated with carotid endarterectomy (Wolf et al., 1999). In patients with atrial fibrillation, which increases the risk of emboli, administration of warfarin (Coumadin), an anticoagulant that inhibits clot formation, may prevent both thrombotic and embolic strokes.

**NURSING ALERT** Many people take herbal remedies and nutritional supplements but do not think of them as “medications” and do not always report their use to health care providers. Patients receiving anticoagulation following a stroke, TIA, or diagnosis of atrial fibrillation need to be cautioned that two herbs, ginkgo and garlic, have demonstrated effects on warfarin (Coumadin). Ginkgo has been associated with increased bleeding times and increased rates of spontaneous hemorrhage and subdural hematomas. Garlic and warfarin taken together can greatly increase the International Normalized Ratio (INR), increasing the risk for bleeding (Evans, 2000).

## Medical Management

Patients who have experienced a TIA or mild stroke from atrial fibrillation or from suspected embolic or thrombotic causes are candidates for nonsurgical medical management. Those with

Chart 62-2

### Modifiable Risk Factors for Ischemic and Hemorrhagic Stroke

- Hypertension (controlling hypertension, the major risk factor, is the key to preventing stroke)
- Cardiovascular disease (cerebral emboli may originate in the heart)
  - Atrial fibrillation
  - Coronary artery disease
  - Heart failure
  - Left ventricular hypertrophy
  - Myocardial infarction (especially anterior)
  - Rheumatic heart disease
- High cholesterol levels
- Obesity
- Elevated hematocrit (increases the risk of cerebral infarction)
- Diabetes mellitus (associated with accelerated atherogenesis)
- Oral contraceptive use (increases risk, especially with coexisting hypertension, smoking, and high estrogen levels)
- Smoking
- Drug abuse (especially cocaine)
- Excessive alcohol consumption

Hock, 1999; Summers et al., 2000.

atrial fibrillation are treated with dose-adjusted warfarin sodium (Coumadin) unless contraindicated. The INR target is 2.5. When warfarin is contraindicated, aspirin is used in doses between 50 and 325 mg/d (Wolf et al., 1999).

Platelet-inhibiting medications (aspirin, dipyridamole [Persantine], clopidogrel [Plavix], and ticlopidine [Ticlid]) decrease the incidence of cerebral infarction in patients who have experienced TIAs from suspected embolic or thrombotic causes. Currently the most cost-effective antiplatelet regimen is aspirin 50 mg/d and dipyridamole 400 mg/d (Sarasin et al., 2000).

## THROMBOLYTIC THERAPY

Thrombolytic agents are used to treat ischemic stroke by dissolving the blood clot that is blocking blood flow to the brain. Recombinant t-PA is a genetically engineered form of t-PA, a thrombolytic substance made naturally by the body. It works by binding to fibrin and converting plasminogen to plasmin, which stimulates fibrinolysis of the atherosclerotic lesion. Rapid diagnosis of stroke and initiation of thrombolytic therapy (within 3 hours) in patients with ischemic stroke leads to a decrease in the size of the stroke and an overall improvement in functional outcome after 3 months (NINDS t-PA Stroke Study Group, 1995). To realize the full potential of thrombolytic therapy, community education directed at recognizing the symptoms of stroke and obtaining appropriate emergency care is necessary to ensure rapid transport to a hospital and initiation of therapy within the 3-hour time frame (Manzella & Galante, 2000). Delays make the patient ineligible for thrombolytic therapy because revascularization of necrotic tissue (which develops after 3 hours) increases the risk for cerebral edema and hemorrhage.

**Enhancing Prompt Diagnosis.** After being notified by emergency medical service personnel, the emergency department calls the appropriate staff (neurologist, neuroradiologist, radiology department, nursing staff, and electrocardiogram technician) and informs them of the patient’s imminent arrival at the hospital. Many institutions have brain attack teams that respond rapidly, ensuring that treatment occurs within the allotted time frame (Alberts et al., 2000; Bonnono et al., 2000).

Initial management requires the definitive diagnosis of an ischemic stroke by CT scanning and determination of whether the patient meets all the criteria for t-PA therapy (Chart 62-3). Some of the contraindications for thrombolytic therapy include symptom onset greater than 3 hours prior to admission, a patient who is anticoagulated, a patient who has had a recent myocardial infarction, or a patient who has had any type of intracranial pathology (eg, stroke, head injury, trauma). Once it is determined that the patient is a candidate for t-PA therapy, no anticoagulants are to be administered in the next 24 hours.

Before receiving t-PA, the patient should be assessed using the National Institutes of Health Stroke Scale (NIHSS), which contains 42 items evaluating neurologic deficits and is useful in differentiating between ischemic strokes and TIAs (Table 62-4). A patient with an NIHSS score of greater than 22 is not eligible to receive t-PA.

**Dosage and Administration.** The patient is weighed to determine the dose of t-PA. The minimum dose is 0.9 mg/kg; the maximum dose is 90 mg. The loading dose is 10% of the calculated dose and is administered over 1 minute. The remaining dose is administered over 1 hour via an infusion pump. After the infusion is completed, the line is flushed with 20 mL of normal saline solution to ensure that all the medication is administered.

Chart  
62-3

## Eligibility Criteria for t-PA Administration

Age 18 years or older  
 Clinical diagnosis of stroke with NIH stroke scale score under 22  
 Time of onset of stroke known and is 3 hours or less  
 BP systolic  $\leq$  185; diastolic  $\leq$  110  
 Not a minor stroke or rapidly resolving stroke  
 No seizure at onset of stroke  
 Not taking warfarin (Coumadin)  
 Prothrombin time  $\leq$  15 seconds or INR  $\leq$  1.7  
 Not receiving heparin during the past 48 hours with elevated partial thromboplastin time  
 Platelet count  $\geq$  100,000  
 Blood glucose level between 50 and 400 mg/dL  
 No acute myocardial infarction  
 No prior intracranial hemorrhage, neoplasm, arteriovenous malformation, or aneurysm  
 No major surgical procedures within 14 days  
 No stroke or serious head injury within 3 months  
 No gastrointestinal or urinary bleeding within last 21 days  
 Not lactating or postpartum within last 30 days

The patient is admitted to the intensive care unit, where continuous cardiac monitoring is implemented. Vital signs are obtained every 15 minutes for the first 2 hours, every 30 minutes for the next 6 hours, then every hour for 16 hours. Blood pressure should be maintained with the systolic pressure less than 180 mm Hg and the diastolic pressure less than 100 mm Hg. Airway management is instituted based on the patient's clinical condition and arterial blood gas values.

**Side Effects.** Bleeding is the most common side effect of t-PA administration, and the patient should be closely monitored for any bleeding (intracranial, intravenous [IV] insertion sites, urinary catheter site, endotracheal tube, nasogastric tube, urine, stool, emesis, other secretions) (Scroggins, 2000). Intracranial bleeding is a major complication that occurs in approximately 6.5% of patients (NINDS t-PA Stroke Study Group, 1995).

### THERAPY FOR PATIENTS WITH ISCHEMIC STROKE NOT RECEIVING t-PA

Not all patients are candidates for t-PA therapy. Other treatments include anticoagulant administration (IV heparin or low-molecular-weight heparin) for ischemic strokes and careful maintenance of cerebral hemodynamics to maintain cerebral perfusion. Increased intracranial pressure (ICP) and its associated complications may occur following a large ischemic stroke. Interventions during this period include methods to reduce ICP, such as administering an osmotic diuretic (eg, mannitol), maintaining PaCO<sub>2</sub> within the range of 30 to 35 mm Hg, and positioning to avoid hypoxia. Other treatment measures include the following:

- Elevation of the head of the bed to promote venous drainage and to lower increased ICP
- Intubation with an endotracheal tube to establish a patent airway, if necessary
- Continuous hemodynamic monitoring. Systolic pressure should be maintained at less than 180 mm Hg, diastolic pressure at less than 100 mm Hg. Maintaining the blood pressure within this range reduces the potential for additional bleeding or further ischemic damage.

- Neurologic assessment to determine whether the stroke is evolving or whether other acute complications are developing, such as bleeding from anticoagulation or medication-induced bradycardia, which can result in hypotension and subsequent decreases in cardiac output and cerebral perfusion pressure.

See the acute ischemic stroke clinical guidelines in Appendix A.

### MANAGING POTENTIAL COMPLICATIONS

Adequate cerebral blood flow is essential for cerebral oxygenation. If cerebral blood flow is inadequate, the amount of oxygen supplied to the brain will decrease and tissue ischemia will result. Therefore, maintaining cardiac output within the normal range of 4 to 8 L/min, or sometimes greater, can improve the cerebral blood flow and oxygen delivery. Adequate oxygenation begins with pulmonary care, maintenance of a patent airway, and administration of supplemental oxygen as needed. The importance of adequate gas exchange cannot be overemphasized in these patients, many of whom are elderly and more prone to developing pneumonia, which can interfere with gas exchange.

### ENDARTERECTOMY FOR PREVENTION OF ISCHEMIC STROKE

The main surgical procedure for managing TIAs and small stroke is carotid endarterectomy, currently the most frequently performed peripheral vascular procedure in the United States (Krenzer, 1999). A carotid endarterectomy is the removal of an atherosclerotic plaque or thrombus from the carotid artery to prevent stroke in patients with occlusive disease of the extracranial cerebral arteries (Fig. 62-2). This surgery is indicated for patients with symptoms of TIA or mild stroke found to be due to severe (70% to 99%) carotid artery stenosis or moderate (50% to 69%) stenosis with other significant risk factors (Wolf et al., 1999).

**Nursing Management.** The primary complications of carotid endarterectomy are stroke, cranial nerve injuries, infection or hematoma at the incision, and carotid artery disruption. It is important to maintain adequate blood pressure levels in the immediate postoperative period. Hypotension is avoided to prevent cerebral ischemia and thrombosis. Uncontrolled hypertension may precipitate cerebral hemorrhage, edema, hemorrhage at the surgical incision, or disruption of the arterial reconstruction. Sodium nitroprusside is commonly used to reduce the blood pressure to previous levels. Close cardiac monitoring is necessary because these patients have a high incidence of coronary artery disease.

A neurologic flow sheet is used to monitor and document all body systems, with particular attention to neurologic status, following carotid endarterectomy. The neurosurgeon is notified immediately if a neurologic deficit develops. Formation of a thrombus at the site of the endarterectomy is suspected if there is a sudden increase in neurologic deficits, such as weakness on one side of the body. The patient should be prepared for repeat endarterectomy.

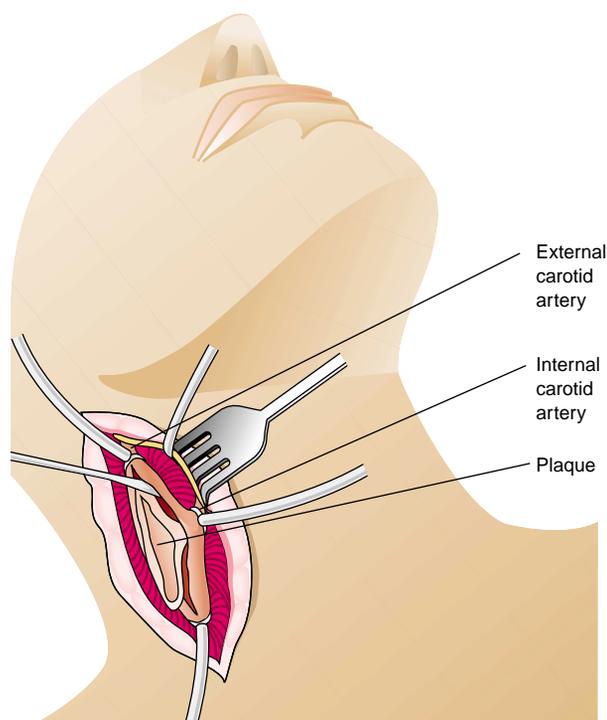

Difficulty in swallowing, hoarseness, or other signs of cranial nerve dysfunction must be assessed. The nurse should focus on assessment of cranial nerves VI, X, XI, and XII (Krenzer, 1999). Some swelling in the neck after surgery is expected; if large enough, however, swelling and hematoma formation can obstruct the airway. Emergency airway supplies, including those needed for a tracheostomy, must be available. Table 62-5 provides more information about potential complications of carotid surgery.

**Table 62-4 • Summary of NIH Stroke Scale**

CATEGORY	DESCRIPTION	SCORE	BASELINE DATE/TIME	DATE/TIME
1a. Level of Consciousness (alert, drowsy, etc)	Alert	0		
	Drowsy	1		
	Stuporous	2		
	Coma	3		
1b. LOC Questions (Month, age)	Answers both correctly	0		
	Answers one correctly	1		
	Incorrect	2		
1c. LOC Commands (Open, close eyes, make fist, let go)	Obeys both correctly	0		
	Obeys one correctly	1		
	Incorrect	2		
2. Best Gaze (Eyes open—patient follows examiner’s finger or face)	Normal	0		
	Partial Gaze Palsy	1		
	Forced Deviation	2		
3. Visual (Introduce visual stimulus/threat to patient’s visual field quadrants)	No Visual Loss	0		
	Partial Hemianopia	1		
	Complete Hemianopia	2		
	Bilateral Hemianopia	3		
4. Facial Palsy (Show teeth, raise eyebrows and squeeze eyes shut)	Normal	0		
	Minor	1		
	Partial	2		
	Complete	3		
5a. Motor Arm—Left (Elevate extremity to 90° and score drift/movement)	No Drift	0		
	Drift	1		
	Can’t Resist Gravity	2		
	No Effort Against Gravity	3		
	No Movement	4		
	Amputation, joint fusion (explain)	9		
5b. Motor arm—Right (Elevate extremity to 90° and score drift/movement)	No Drift	0		
	Drift	1		
	Can’t Resist Gravity	2		
	No Effort Against Gravity	3		
	No Movement	4		
	Amputation, joint fusion (explain)	9		
6a. Motor leg—Left (Elevate extremity to 30° and score drift/movement)	No Drift	0		
	Drift	1		
	Can’t Resist Gravity	2		
	No Effort Against Gravity	3		
	No Movement	4		
	Amputation, joint fusion (explain)	9		
6a. Motor leg—Right (Elevate extremity to 30° and score drift/movement)	No Drift	0		
	Drift	1		
	Can’t Resist Gravity	2		
	No Effort Against Gravity	3		
	No Movement	4		
	Amputation, joint fusion (explain)	9		
7. Limb ataxia (Finger-to-nose and heel-to-shin testing)	Absent	0		
	Present in One limb	1		
	Present in Two Limbs	2		
8. Sensory (Pin prick to face, arm, trunk and leg—compare side to side)	Normal	0		
	Partial Loss	1		
	Severe Loss	2		
9. Best Language (Name items, describe a picture and read sentences)	No Aphasia	0		
	Mild to Moderate Aphasia	1		
	Severe Aphasia	2		
	Mute	3		
10. Dysarthria (Evaluate speech clarity by patient repeating words)	Normal Articulation	0		
	Mild to Moderate Dysarthria	1		
	Near to Unintelligible or Worse	2		
	Intubated or Other Physical Barrier	9		
11. Extinction and Inattention (Use information from LOC and motor testing to identify neglect)	No Neglect	0		
	Partial Neglect	1		
	Complete Neglect	2		

Individual Administering Scale: \_\_\_\_\_

**FIGURE 62-2** Plaque, a potential source of emboli in TIA and stroke, is surgically removed from the carotid artery.

## NURSING PROCESS: THE PATIENT RECOVERING FROM AN ISCHEMIC STROKE

The acute phase of an ischemic stroke may last 1 to 3 days, but ongoing monitoring of all body systems is essential as long as the patient requires care. The patient who has had a stroke is at risk for multiple complications, including deconditioning and other musculoskeletal problems, swallowing difficulties, bowel and bladder dysfunction, inability to perform self-care, and skin breakdown. After the stroke is complete, management focuses on the prompt initiation of rehabilitation for any deficits.

### Assessment

During the acute phase, a neurologic flow sheet is maintained to provide data about the following important measures of the patient's clinical status:

- Change in the level of consciousness or responsiveness as evidenced by movement, resistance to changes of position, and response to stimulation; orientation to time, place, and person
- Presence or absence of voluntary or involuntary movements of the extremities; muscle tone; body posture; and position of the head
- Stiffness or flaccidity of the neck

**Table 62-5 • Selected Complications of Carotid Endarterectomy and Nursing Interventions**

COMPLICATION	CHARACTERISTICS	NURSING INTERVENTIONS
Incision hematoma	Occurs in 5.5% of patients. Large or rapidly expanding hematomas require emergency treatment. If the airway is obstructed by the hematoma, the incision may be opened at the bedside.	Monitor neck discomfort and wound expansion. Report swelling, subjective feelings of pressure in the neck, difficulty breathing.
Hypertension	Poorly controlled hypertension increases the risk of postoperative complications, including hematoma and hyperperfusion syndrome. There is an increased incidence of neurologic impairment and death due to intracerebral hemorrhage. May be related to surgically induced abnormalities of carotid baroreceptor sensitivity.	Risk is highest in the first 48 hours after surgery. Check blood pressure frequently and report deviations from baseline. Observe for and report new onset of neurologic deficits.
Postoperative hypotension	Occurs in approximately 5% of patients. Treated with fluids and low-dose phenylephrine infusion. Usually resolves in 24 to 48 hours. Patients with hypotension should have serial ECGs to rule out myocardial infarction.	Monitor blood pressure and observe for signs and symptoms of hypotension.
Hyperperfusion syndrome	Occurs when cerebral vessel autoregulation fails. Arteries accustomed to diminished blood flow may be permanently dilated; increased blood flow after endarterectomy coupled with insufficient vasoconstriction leads to capillary bed damage, edema, and hemorrhage.	Observe for severe unilateral headache improved by sitting upright or standing.
Intracerebral hemorrhage	Occurs infrequently, but is often fatal (60%) or results in serious neurologic impairment. Can occur secondary to hyperperfusion syndrome. Increased risk with advanced age, hypertension, presence of high-grade stenosis, poor collateral flow, and slow flow in the region of the middle cerebral artery.	Monitor neurologic status and report any changes in mental status or neurologic functioning immediately.

- Eye opening, comparative size of pupils and pupillary reactions to light, and ocular position
- Color of the face and extremities; temperature and moisture of the skin
- Quality and rates of pulse and respiration; arterial blood gas values as indicated, body temperature, and arterial pressure
- Ability to speak
- Volume of fluids ingested or administered; volume of urine excreted each 24 hours
- Presence of bleeding
- Maintenance of blood pressure within the desired parameters

After the acute phase, the nurse assesses mental status (memory, attention span, perception, orientation, affect, speech/language), sensation/perception (usually the patient has decreased awareness of pain and temperature), motor control (upper and lower extremity movement), swallowing ability, nutritional and hydration status, skin integrity, activity tolerance, and bowel and bladder function. Ongoing nursing assessment continues to focus on any impairment of function in the patient's daily activities, because the quality of life after stroke is closely related to the patient's functional status.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the major nursing diagnoses for a patient with a stroke may include:

- Impaired physical mobility related to hemiparesis, loss of balance and coordination, spasticity, and brain injury
- Acute pain (painful shoulder) related to hemiplegia and disuse
- Self-care deficits (hygiene, toileting, grooming, and feeding) related to stroke sequelae
- Disturbed sensory perception related to altered sensory reception, transmission, and/or integration
- Impaired swallowing
- Incontinence related to flaccid bladder, detrusor instability, confusion, or difficulty in communicating
- Disturbed thought processes related to brain damage, confusion, or inability to follow instructions
- Impaired verbal communication related to brain damage
- Risk for impaired skin integrity related to hemiparesis/hemiplegia, or decreased mobility
- Interrupted family processes related to catastrophic illness and caregiving burdens
- Sexual dysfunction related to neurologic deficits or fear of failure

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Potential complications include:

- Decreased cerebral blood flow due to increased ICP
- Inadequate oxygen delivery to the brain
- Pneumonia

## Planning and Goals

Although rehabilitation begins on the day the patient has the stroke, the process is intensified during convalescence and requires a coordinated team effort. It is helpful for the team to know what

the patient was like before the stroke: his or her illnesses, abilities, mental and emotional state, behavioral characteristics, and activities of daily living. It is also helpful for clinicians to be knowledgeable about the relative importance of predictors of stroke outcome (age, gender, NIHSS score at time of admission, to name a few) in order to provide stroke survivors and their families with realistic goals (Demchuk & Buchan, 2000).

The major goals for the patient (and family) may include improved mobility, avoidance of shoulder pain, achievement of self-care, relief of sensory and perceptual deprivation, prevention of aspiration, continence of bowel and bladder, improved thought processes, achieving a form of communication, maintaining skin integrity, restored family functioning, improved sexual function, and absence of complications.

## Nursing Interventions

Nursing care has a significant impact on the patient's recovery. Often many body systems are impaired as a result of the stroke, and conscientious care and timely interventions can prevent debilitating complications. During and after the acute phase, nursing interventions focus on the whole person. In addition to providing physical care, nurses can encourage and foster recovery by listening to patients and asking questions to elicit the meaning of the stroke experience (Eaves, 2000; Pilkington, 1999).

### IMPROVING MOBILITY AND PREVENTING JOINT DEFORMITIES

A hemiplegic patient has unilateral paralysis (paralysis on one side). When control of the voluntary muscles is lost, the strong flexor muscles exert control over the extensors. The arm tends to adduct (adductor muscles are stronger than abductors) and to rotate internally. The elbow and the wrist tend to flex, the affected leg tends to rotate externally at the hip joint and flex at the knee, and the foot at the ankle joint supinates and tends toward plantar flexion.

Correct positioning is important to prevent contractures; measures are used to relieve pressure, assist in maintaining good body alignment, and prevent compressive neuropathies, especially of the ulnar and peroneal nerves. Because flexor muscles are stronger than extensor muscles, a posterior splint applied at night to the affected extremity may prevent flexion and maintain correct positioning during sleep. (See Chap. 11 for additional information.)

#### Preventing Shoulder Adduction

To prevent adduction of the affected shoulder while the patient is in bed, a pillow is placed in the axilla when there is limited external rotation; this keeps the arm away from the chest. A pillow is placed under the arm, and the arm is placed in a neutral (slightly flexed) position, with distal joints positioned higher than the more proximal joints. Thus, the elbow is positioned higher than the shoulder and the wrist higher than the elbow. This helps to prevent edema and the resultant joint fibrosis that will limit range of motion if the patient regains control of the arm (Fig. 62-3).

#### Positioning the Hand and Fingers

The fingers are positioned so that they are barely flexed. The hand is placed in slight supination (palm faces upward), which is its most functional position. If the upper extremity is flaccid, a volar resting splint can be used to support the wrist and hand in a functional position. If the upper extremity is spastic, a hand roll is not used, because it stimulates the grasp reflex. In this instance a dor-

**FIGURE 62-3** Correct positioning to prevent shoulder adduction.

sal wrist splint is useful in allowing the palm to be free of pressure. Every effort is made to prevent hand edema.

Spasticity, particularly in the hand, can be a disabling complication after stroke. Researchers have recently reported that intramuscular injections of botulinum toxin A decreased spasticity in the wrist and fingers and increased functional ability in dressing, washing, and other activities of daily living (Brashear et al., 2002).

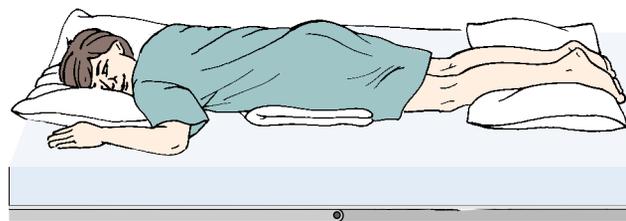

### Changing Positions

The patient's position should be changed every 2 hours. To place a patient in a lateral (side-lying) position, a pillow is placed between the legs before the patient is turned. To promote venous return and prevent edema, the upper thigh should not be acutely flexed. The patient may be turned from side to side, but the amount of time spent on the affected side should be limited if sensation is impaired.

If possible, the patient is placed in a prone position for 15 to 30 minutes several times a day. A small pillow or a support is placed under the pelvis, extending from the level of the umbilicus to the upper third of the thigh (Fig. 62-4). This helps to promote hyperextension of the hip joints, which is essential for normal gait and helps prevent knee and hip flexion contractures. The prone position also helps to drain bronchial secretions and prevents contractural deformities of the shoulders and knees. During positioning, it is important to reduce pressure and change position frequently to prevent pressure ulcers.

### Establishing an Exercise Program

The affected extremities are exercised passively and put through a full range of motion four or five times a day to maintain joint

**FIGURE 62-4** Prone position with pillow support helps prevent hip flexion.

mobility, regain motor control, prevent contractures in the paralyzed extremity, prevent further deterioration of the neuromuscular system, and enhance circulation. Exercise is helpful in preventing venous stasis, which may predispose the patient to thrombosis and pulmonary embolus.

Repetition of an activity forms new pathways in the CNS and therefore encourages new patterns of motion. At first, the extremities are usually flaccid. If tightness occurs in any area, the range-of-motion exercises should be performed more frequently (see Chap. 11).

The patient is observed for signs and symptoms that may indicate pulmonary embolus or excessive cardiac workload during exercise; these include shortness of breath, chest pain, cyanosis, and increasing pulse rate with exercise. Frequent short periods of exercise always are preferable to longer periods at infrequent intervals. Regularity in exercise is most important. Improvement in muscle strength and maintenance of range of motion can be achieved only through daily exercise.

The patient is encouraged and reminded to exercise the unaffected side at intervals throughout the day. It is helpful to develop a written schedule to remind the patient of the exercise activities. The nurse supervises and supports the patient during these activities. The patient can be taught to put the unaffected leg under the affected one to move it when turning and exercising. Flexibility, strengthening, coordination, endurance, and balancing exercises prepare the patient for ambulation. Quadriceps muscle setting and gluteal setting exercises are started early to improve the muscle strength needed for walking; these are performed at least five times daily for 10 minutes at a time.

### Preparing for Ambulation

As soon as possible, the patient is assisted out of bed. Usually, when hemiplegia has resulted from a thrombosis, an active rehabilitation program is started as soon as the patient regains consciousness; a patient who has had a cerebral hemorrhage cannot participate actively until all evidence of bleeding is gone.

The patient is first taught to maintain balance while sitting and then to learn to balance while standing. If the patient has difficulty in achieving standing balance, a tilt table, which slowly brings the patient to an upright position, can be used. Tilt tables are especially helpful for patients who have been on bed rest for prolonged periods and are having orthostatic blood pressure changes.

If the patient needs a wheelchair, the folding type with hand brakes is the most practical because it allows the patient to manipulate the chair. The chair should be low enough to allow the patient to propel it with the uninvolved foot and narrow enough to permit it to be used in the home. When the patient is transferred from the wheelchair, the brakes must be applied and locked on both sides of the chair.

The patient is usually ready to walk as soon as standing balance is achieved. Parallel bars are useful in these first efforts. A chair or wheelchair should be readily available in case the patient suddenly becomes fatigued or feels dizzy.

The training periods for ambulation should be short and frequent. As the patient gains strength and confidence, an adjustable cane can be used for support. Generally, a three- or four-pronged cane provides a stable support in the early phases of rehabilitation.

### PREVENTING SHOULDER PAIN

Up to 70% of stroke patients suffer severe pain in the shoulder that prevents them from learning new skills, because shoulder func-

tion is essential in achieving balance and performing transfers and self-care activities. Three problems can occur: painful shoulder, subluxation of the shoulder, and shoulder–hand syndrome.

A flaccid shoulder joint may be overstretched by the use of excessive force in turning the patient or from overstrenuous arm and shoulder movement. To prevent shoulder pain, the nurse should never lift the patient by the flaccid shoulder or pull on the affected arm or shoulder. If the arm is paralyzed, subluxation (incomplete dislocation) at the shoulder can occur from overstretching the joint capsule and musculature by the force of gravity when the patient sits or stands in the early stages after a stroke. This results in severe pain. Shoulder–hand syndrome (painful shoulder and generalized swelling of the hand) can cause a frozen shoulder and ultimately atrophy of subcutaneous tissues. When a shoulder becomes stiff, it is usually painful.

Medications are helpful in the management of post-stroke pain. Amitriptyline hydrochloride (Elavil) has been used but it can cause cognitive problems, has a sedating effect, and is not effective in all patients. A recent study showed the efficacy of an antiseizure medication lamotrigine (Lamictal) in treating post-stroke pain (Jensen et al., 2001).

Many shoulder problems can be prevented by proper patient movement and positioning. The flaccid arm is positioned on a table or with pillows while the patient is seated. Some clinicians advocate the use of a properly worn sling when the patient first becomes ambulatory to prevent the paralyzed upper extremity from dangling without support. Range-of-motion exercises are important in preventing painful shoulder. Overstrenuous arm movements are avoided. The patient is instructed to interlace the fingers, place the palms together, and push the clasped hands slowly forward to bring the scapulae forward; he or she then raises both hands above the head. This is repeated throughout the day. The patient is instructed to flex the affected wrist at intervals and move all the joints of the affected fingers. He or she is encouraged to touch, stroke, rub, and look at both hands. Pushing the heel of the hand firmly down on a surface is useful. Elevation of the arm and hand is also important in preventing dependent edema of the hand. Patients with continuing pain after movement and positioning have been attempted may require the addition of analgesia to their treatment program.

### ENHANCING SELF-CARE

As soon as the patient can sit up, personal hygiene activities are encouraged. The patient is helped to set realistic goals; if feasible, a new task is added daily. The first step is to carry out all self-care activities on the unaffected side. Such activities as combing the hair, brushing the teeth, shaving with an electric razor, bathing, and eating can be carried out with one hand and are suitable for self-care. Although the patient may feel awkward at first, the various motor skills can be learned by repetition, and the unaffected side will become stronger with use. The nurse must be sure that the patient does not neglect the affected side. Assistive devices will help make up for some of the patient's deficits (Chart 62-4). A small towel is easier to control while drying after bathing, and boxed paper tissues are easier to use than a roll of toilet tissue.

Return of functional ability is important to the patient recovering after a stroke. An early baseline assessment of functional ability with an instrument such as the Functional Independence Measure (FIM) is important in team planning and goal setting for the patient. The FIM is a widely used instrument in stroke rehabilitation and also provides valuable functional information during the acute phase of care (Hinkle, 2000, 2001).

### Chart 62-4

## Assistive Devices to Enhance Self-Care After Stroke

The following list identifies products that may help neurologically impaired patients perform self-care more easily and safely after a stroke or other disorders.

### Eating Devices

- Nonskid mats to stabilize plates
- Plate guards to prevent food from being pushed off plate
- Wide-grip utensils to accommodate a weak grasp

### Bathing and Grooming Devices

- Long-handled bath sponge
- Grab bars, nonskid mats, hand-held shower heads
- Electric razors with head at 90 degrees to handle
- Shower and tub seats, stationary or on wheels

### Toileting Aids

- Raised toilet seat
- Grab bars next to toilet

### Dressing Aids

- Velcro closures
- Elastic shoelaces
- Long-handled shoe horn

### Mobility Aids

- Canes, walkers, wheelchairs
- Transfer devices such as transfer boards and belts

The patient's morale will improve if ambulatory activities are carried out in street clothes. The family is instructed to bring in clothing that is preferably a size larger than that normally worn. Clothing fitted with front or side fasteners or Velcro closures is the most suitable. The patient has better balance if most of the dressing activities are done in a seated position.

Perceptual problems may make it difficult for the patient to dress without assistance because of an inability to match the clothing to the body parts. To assist the patient, the nurse can take steps to keep the environment organized and uncluttered, because the patient with a perceptual problem is easily distracted. The clothing is placed on the affected side in the order in which the garments are to be put on. Using a large mirror while dressing promotes the patient's awareness of what he or she is putting on the affected side. Each garment is put on the affected side first. The patient has to make many compensatory movements when dressing; these can produce fatigue and painful twisting of the intercostal muscles. Support and encouragement are provided to prevent the patient from becoming overly fatigued and discouraged. Even with intensive training, not all patients can achieve independence in dressing.

### MANAGING SENSORY-PERCEPTUAL DIFFICULTIES

Patients with a decreased field of vision should be approached on the side where visual perception is intact. All visual stimuli (clock, calendar, and television) should be placed on this side. The patient can be taught to turn the head in the direction of the defective visual field to compensate for this loss. The nurse should make eye contact with the patient and draw his or her attention to the affected side by encouraging the patient to move the head. The nurse may also want to stand at a position that encourages the patient to move or turn to visualize who is in the room. Increasing the natural or artificial lighting in the room and providing eyeglasses are important in increasing vision.

The patient with homonymous hemianopsia (loss of half of the visual field) turns away from the affected side of the body and tends to neglect that side and the space on that side; this is called *amorphosynthesis*. In such instances, the patient cannot see food on half of the tray, and only half of the room is visible. It is important for the nurse to constantly remind the patient of the other side of the body, to maintain alignment of the extremities, and, if possible, to place the extremities where the patient can see them.

### MANAGING DYSPHAGIA

Stroke can result in swallowing problems (dysphagia) due to impaired function of the mouth, tongue, palate, larynx, pharynx, or upper esophagus. Patients must be observed for paroxysms of coughing, food dribbling out of or pooling in one side of the mouth, food retained for long periods in the mouth, or nasal regurgitation when swallowing liquids. Swallowing difficulties place the patient at risk for aspiration, pneumonia, dehydration, and malnutrition.

A speech therapist will evaluate the patient's gag reflexes and ability to swallow. Even if partially impaired, swallowing function may return in some patients over time, or the patient may be taught alternative swallowing techniques, advised to take smaller boluses of food, and taught about which foods are easier to swallow. The patient may initially be started on a thick liquid or puréed diet because these foods are easier to swallow than thin liquids. Having the patient sit upright, preferably out of bed in a chair, and instructing him or her to tuck the chin toward the chest as he or she swallows, will help prevent aspiration. The diet may be advanced as the patient becomes more proficient at swallowing. If the patient cannot resume oral intake, a gastrointestinal feeding tube will be placed for ongoing tube feedings.

### Managing Tube Feedings

Enteral tubes can be either nasogastric (placed in the stomach) or nasoenteral (placed in the duodenum) to reduce the risk of aspiration. Nursing responsibilities in feeding include elevating the head of the bed at least 30 degrees to prevent aspiration, checking the position of the tube before feeding, ensuring that the cuff of the tracheostomy tube (if in place) is inflated, and giving the tube feeding slowly. The feeding tube is aspirated periodically to ensure that the feedings are passing through the gastrointestinal tract. Retained or residual feedings increase the risk for aspiration. Patients with retained feedings may benefit from the placement of a gastrostomy tube or a percutaneous endoscopic gastrostomy tube. In a patient with a nasogastric tube, the feeding tube should be placed in the duodenum to reduce the risk of aspiration. For long-term feedings, a gastrostomy tube is preferred. Management of patients with tube feedings is discussed in Chapter 36.

### ATTAINING BOWEL AND BLADDER CONTROL

After a stroke, the patient may have transient urinary incontinence due to confusion, inability to communicate needs, and inability to use the urinal or bedpan because of impaired motor and postural control. Occasionally after a stroke, the bladder becomes atonic, with impaired sensation in response to bladder filling. Sometimes control of the external urinary sphincter is lost or diminished. During this period, intermittent catheterization with sterile technique is carried out. When muscle tone increases and deep tendon reflexes return, bladder tone increases and spasticity of the bladder may develop. Because the patient's sense of awareness is clouded, persistent urinary incontinence or urinary retention may be symptomatic of bilateral brain damage. The voiding

pattern is analyzed and the urinal or bedpan offered on this pattern or schedule. The upright posture and standing position are helpful for male patients during this aspect of rehabilitation.

Patients may also have problems with bowel control or constipation, with constipation being more common. Unless contraindicated, a high-fiber diet and adequate fluid intake (2 to 3 L per day) should be provided and a regular time established (usually after breakfast) for toileting. See Chapter 11 for bowel and bladder retraining programs.

### IMPROVING THOUGHT PROCESSES

After a stroke, the patient may have problems with cognitive, behavioral, and emotional deficits related to brain damage. In many instances, however, a considerable degree of function can be recovered because not all areas of the brain are equally damaged; some remain more intact and functional than others.

After assessment that delineates the patient's deficits, the neuropsychologist, in collaboration with the primary care physician, psychiatrist, nurse, and other professionals, structures a training program using cognitive-perceptual retraining, visual imagery, reality orientation, and cueing procedures to compensate for losses.

The role of the nurse is supportive. The nurse reviews the results of neuropsychological testing, observes the patient's performance and progress, gives positive feedback, and, most importantly, conveys an attitude of confidence and hope. Interventions capitalize on the patient's strengths and remaining abilities while attempting to improve performance of affected functions. Other interventions are similar to those for improving cognitive functioning after a head injury (see Chap. 63).

### IMPROVING COMMUNICATION

Aphasia, which impairs the patient's ability to understand what is being said and to express himself or herself, may become apparent in various ways. The cortical area responsible for integrating the myriad of pathways required for the comprehension and formulation of language is called Broca's area. It is located in a convolution adjoining the middle cerebral artery. This area is responsible for control of the combinations of muscular movements needed to speak each word. Broca's area is so close to the left motor area that a disturbance in the motor area often affects the speech area. This is why so many patients paralyzed on the right side (due to damage or injury to the left side of the brain) cannot speak, whereas those paralyzed on the left side are less likely to have speech disturbances.

The speech pathologist assesses the communication needs of the stroke patient, describes the precise deficit, and suggests the best overall method of communication. With many language intervention strategies for the aphasic adult, the program can be individually tailored. The patient is expected to take an active part in establishing goals.

A person with aphasia may become depressed because of the inability to talk. The inability to talk on the telephone, answer a question, or participate in conversation causes anger, frustration, fear of the future, and hopelessness. Nursing interventions include doing everything possible to make the atmosphere conducive to communication. This includes being sensitive to the patient's reactions and needs and responding to them in an appropriate manner, always treating the patient as an adult. The nurse provides strong moral support and understanding to allay anxiety.

A common pitfall is for the nurse or other health care team member to complete the thoughts or sentences of the patient.

This should be avoided because it may cause the patient to feel more frustrated at not being allowed to speak and may deter efforts to practice putting thoughts together and completing the sentence. A consistent schedule, routines, and repetitions help the patient to function despite significant deficits. A written copy of the daily schedule, a folder of personal information (birth date, address, names of relatives), checklists, and an audiotaped list help improve the patient's memory and concentration. The patient may also benefit from a communication board, which has pictures of common needs and phrases. The board may be translated into several languages.

When talking with the patient, it is important to have the patient's attention, speak slowly, and keep the language of instruction consistent. One instruction is given at a time, and time is allowed for the patient to process what has been said. The use of gestures may enhance comprehension. Speaking is thinking out loud, and the emphasis is on thinking. The patient must sort out incoming messages and formulate a response. Listening requires mental effort; the patient must struggle against mental inertia and needs time to organize an answer.

In working with the aphasic patient, the nurse must remember to talk to the patient during care activities. This provides social contact for the patient. Chart 62-5 describes points to keep in mind when communicating with the aphasic patient.

### MAINTAINING SKIN INTEGRITY

The stroke patient may be at risk for skin and tissue breakdown because of altered sensation and inability to respond to pressure and discomfort by turning and moving. Therefore, preventing skin and tissue breakdown requires frequent assessment of the skin, with emphasis on bony areas and dependent parts of the body. During the acute phase, a specialty bed (eg, low-air-loss bed) may be used until the patient can move independently or assist in moving.

A regular turning and positioning schedule must be followed to minimize pressure and prevent skin breakdown. Pressure-relieving devices may be employed but do not replace regular turning and positioning. The turning schedule (at least every 2 hours) must be adhered to even if pressure-relieving devices are used to prevent tissue and skin breakdown. When the patient is positioned or turned, care must be used to minimize shear and friction forces, which cause damage to tissues and predispose the skin to breakdown.

Chart  
62-5

#### Communicating With the Aphasic Patient

- Face the patient and establish eye contact.
- Speak in a normal manner and tone.
- Use short phrases and pause between phrases to allow the patient time to understand what is being said.
- Limit conversation to practical and concrete matters.
- Use gestures, pictures, and objects.
- As the patient uses and handles an object, say what the object is. It helps to match the words with the object or action.
- Be consistent in using the same words and gestures each time you give instructions or ask a question.
- Keep extraneous noises and sounds to a minimum. Too much background noise can distract the patient or make it difficult to sort out the message being spoken.

The patient's skin must be kept clean and dry; gentle massage of healthy (nonreddened) skin and adequate nutrition are other factors that help to maintain normal skin and tissue integrity (see Chap. 11).

### IMPROVING FAMILY COPING

Family members play an important role in the patient's recovery. Some type of counseling and support system should be available to them to prevent the care of the patient from taking a significant toll on their health and interfering too radically with their lives. Involving others in the patient's care and teaching stress management techniques and methods for maintaining personal health also facilitate family coping.

The family may have difficulty accepting the patient's disability and may be unrealistic in their expectations. They are given information about the expected outcomes and are counseled to avoid doing for the patient those things that he or she can do. They are assured that their love and interest are part of the patient's therapy.

The family needs to be informed that the rehabilitation of the hemiplegic patient requires many months; progress may be slow. The gains made by the patient in the hospital or rehabilitation unit must be maintained. All should approach the patient with a supportive and optimistic attitude, focusing on the abilities that remain. The rehabilitation team, the medical and nursing team, the patient, and the family all must be involved in developing attainable goals for the patient at home.

Most relatives of stroke patients handle the physical changes better than the emotional aspects of care. The family should be prepared to expect occasional episodes of emotional lability. The patient may laugh or cry easily and may be irritable and demanding or depressed and confused. The nurse can explain to the family that the patient's laughter does not necessarily connote happiness, nor does crying reflect sadness, and that emotional lability usually improves with time.

### HELPING THE PATIENT COPE WITH SEXUAL DYSFUNCTION

Sexual functioning can be profoundly altered by stroke. Often stroke is such a catastrophic illness that the patient experiences loss of self-esteem and value as a sexual being. Although research in this area of stroke management is limited, it appears that stroke patients consider sexual function to be important, but most have sexual dysfunction. The combined effects of age and stroke cause a marked decline in many aspects of sexuality (Lipski & Alexander, 1997). In-depth assessments to determine sexual history before and after the stroke should be followed by appropriate interventions. Interventions for the patient and partner focus on providing relevant information, education, reassurance, adjustment of medications, counseling regarding coping skills, suggestions for alternative positions, and a means of sexual expression and satisfaction (Lipski & Alexander, 1997).

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

Patient and family education is a fundamental component of rehabilitation, and ample opportunity for learning about stroke, its causes and prevention, and the rehabilitation process should be provided (Mumma, 2001). In both acute care and rehabilitation facilities, the focus is on teaching patients to resume as much self-care as possible. This may entail using assistive devices or modi-

ifying the home environment to help the patient live with a disability.

An occupational therapist may be helpful in assessing the home environment and recommending modifications to help the patient become more independent. For example, a shower is more convenient than a tub for the hemiplegic patient because most patients do not gain sufficient strength to get up and down from a tub. Sitting on a stool of medium height with rubber suction tips permits the patient to wash with greater ease. A long-handled bath brush with a soap container is helpful to the patient who has only one functional hand. If a shower is not available, a stool may be placed in the tub and a portable shower hose attached to the faucet. Handrails may be attached beside the bathtub and the toilet. Other assistive devices include special utensils for eating, grooming, and dressing (see Chart 62-3).

### Continuing Care

The recovery and rehabilitation process after stroke may be prolonged, requiring patience and perseverance on the part of the patient and family. Depending on the specific neurologic deficits resulting from the stroke, the patient at home may require the services of a number of health care professionals. The nurse often coordinates the care of the patient at home. The family (often the spouse) will require assistance in planning and providing care. The caregiver often requires reminders to attend to his or her health problems and well-being.

The family is advised that the patient may tire easily, become irritable and upset by small events, and is likely to show less interest in things. Because a stroke frequently occurs in the later stages of life, there is the possibility of intellectual decline related to dementia.

Emotional problems associated with stroke are often related to speech dysfunction and frustrations about being unable to communicate. A speech therapist who visits the home allows the family to be involved and gives the family practical instructions to help the patient between therapy sessions.

Depression is a common and serious problem in the stroke patient. Antidepressant therapy may help if depression dominates the patient's life. As progress is made in the rehabilitation program, some problems will diminish. The family can help by continuing to support the patient and by giving positive reinforcement for the progress that is being made.

Community-based stroke support groups allow the patient and family to learn from others with similar problems and to share their experiences (Olson, 2001). The patient is encouraged to continue with hobbies, recreational and leisure interests, and contact with friends to prevent social isolation. All nurses coming in contact with the patient should encourage the patient to keep active, adhere to the exercise program, and remain as self-sufficient as possible.

The nurse should recognize the potential effects of caregiving on the family (Teel et al., 2001). Not all families have the adaptive coping skills and psychological functioning necessary for the long-term care of another. The patient's spouse may be elderly, with his or her own health problems; in some instances the stroke patient may have been the provider of care to the spouse. Even healthy caregivers may find it difficult to maintain a schedule that includes being available around the clock. Some effects of sustained caregiving include increased risk for depression and substance abuse, and increased use of health care services by the caregiver (King et al., 2001). Depressed caregivers are more likely to resort to physical or emotional abuse of the patient and are more likely to place the patient in a nursing home. Respite care

(planned short-term care to relieve the family from having to provide continuous 24-hour care) may be available from an adult day care center. Some hospitals also offer weekend respite care that can provide caregivers with needed time to themselves. Nurses should encourage families to arrange for such services and should provide information to assist them.

The nurse involved in home and continuing care also needs to remind patients and family members of the need for continuing health promotion and screening practices. Patients who have not been involved in these practices in the past are educated about their importance and are referred to appropriate health care providers, if indicated.

### NURSING RESEARCH PROFILE 62-1

#### Caregiving Experience

Teel, C. S., Duncan, P., & Lai, S. M., (2001). Caregiving experiences after stroke. *Nursing Research*, 50(1), 53–60.

#### Purpose

Family caregiving is often a source of stress for family members. However, despite the high prevalence of stroke, little is known about the experience of family caregiving after stroke. The primary purpose of this study was to examine relationships between patient characteristics, characteristics of the caregiver, and caregiver coping resources with caregiver physical and mental health outcomes at 3 and 6 months following a stroke.

#### Study Sample and Design

This longitudinal, correlational study was conducted in collaboration with a study of patient outcomes after stroke. The presence of stroke was confirmed by clinical assessment, CT, or MRI; stroke severity was assessed using the Orpington Prognostic Scale. Multiple instruments were used to assess the characteristics of family caregivers as well as their fatigue, vigor, mood disturbances, stress, spirituality, reactions to caregiving situation, coping resources, and physical and mental health status. These instruments were completed at 1, 3, and 6 months after a stroke. The sample for this study consisted of 83 caregivers, the majority of whom were female, Caucasian, and married and had at least a high school education. Their mean age was 57 years.

#### Findings

The caregivers reported stable perceptions of fatigue, vigor, recurrent sorrow, perceived stress, finances, family support, physical health, and depressive symptoms at 1, 3, and 6 months. Caregivers with more fatigue, sorrow, stress, depression, difficulty with scheduling and finances, and difficulty with family support had more physical health problems. Also less vigor, less importance of spirituality, and less perceived self-esteem (a reaction to caregiving) correlated with more physical health issues at 3 and 6 months.

#### Nursing Implications

Nurses working with stroke patients and families should note that comprehensive assessments of caregivers of stroke survivors should include physical and mental health components. Early identification of caregivers with more fatigue, sorrow, stress, depression, problems with scheduling and finances, and difficulty with family support may help identify persons at greater risk for physical health issues in the continuing care role. This would permit nurses to provide assistance, support, and referral to social services to family caregivers at greatest risk for physical and mental health issues.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Achieves improved mobility
  - a. Avoids deformities (contractures and footdrop)
  - b. Participates in prescribed exercise program
  - c. Achieves sitting balance
  - d. Uses unaffected side to compensate for loss of function of hemiplegic side
2. Reports absence of shoulder pain
  - a. Demonstrates shoulder mobility; exercises shoulder
  - b. Elevates arm and hand at intervals
3. Achieves self-care; performs hygiene care; uses adaptive equipment
4. Turns head to see people or objects
5. Demonstrates improved swallowing ability
6. Achieves normal bowel and bladder elimination
7. Participates in cognitive improvement program
8. Demonstrates improved communication
9. Maintains intact skin without breakdown
  - a. Demonstrates normal skin turgor
  - b. Participates in turning and positioning activities
10. Family members demonstrate a positive attitude and coping mechanisms
  - a. Encourage patient in exercise program
  - b. Take an active part in rehabilitation process
  - c. Contact respite care programs or arrange for other family members to assume some responsibilities for care
11. Has positive attitude regarding alternative approaches to sexual expression

## Hemorrhagic Stroke

Hemorrhagic strokes account for 15% of cerebrovascular disorders and are primarily caused by an intracranial or subarachnoid hemorrhage. Each year in the United States there are approximately 50,000 intracerebral hemorrhages and 25,000 cases of subarachnoid hemorrhage from ruptured intracranial **aneurysm** (Pfohman & Criddle, 2001; Qureshi et al., 2001).

Patients generally have more severe deficits and a longer recovery time compared to those with ischemic stroke (AHCPR, 1995). The mean cost per discharge for subarachnoid hemorrhage was estimated at \$39,994, compared to \$21,535 for intracranial hemorrhage. The mean length of stay was 22 days for subarachnoid hemorrhage and 19 for intracranial hemorrhage (Matchar & Samsa, 2000).

Hemorrhagic strokes are caused by bleeding into the brain tissue, the ventricles, or the subarachnoid space. Primary intracerebral hemorrhage from a spontaneous rupture of small vessels accounts for approximately 80% of hemorrhagic strokes and is primarily caused by uncontrolled hypertension (Qureshi et al., 2001). Secondary intracerebral hemorrhage is associated with arteriovenous malformations (AVMs), intracranial aneurysms, or certain medications (eg, anticoagulants and amphetamines) (Qureshi et al., 2001).

## Pathophysiology

The pathophysiology of hemorrhagic stroke depends on the cause and type of cerebrovascular disorder. Symptoms are produced when an aneurysm or AVM enlarges and presses on nearby cranial nerves or brain tissue or, more dramatically, when an

aneurysm or AVM ruptures, causing subarachnoid hemorrhage (hemorrhage into the cranial subarachnoid space). Normal brain metabolism is disrupted by the brain being exposed to blood; by an increase in ICP resulting from the sudden entry of blood into the subarachnoid space, which compresses and injures brain tissue; or by secondary ischemia of the brain resulting from the reduced perfusion pressure and vasospasm that frequently accompany subarachnoid hemorrhage.

### INTRACEREBRAL HEMORRHAGE

An intracerebral hemorrhage, or bleeding into the brain substance, is most common in patients with hypertension and cerebral atherosclerosis because degenerative changes from these diseases cause rupture of the vessel. They also may be due to certain types of arterial pathology, brain tumor, and the use of medications (oral anticoagulants, amphetamines, and illicit drugs such as crack and cocaine).

The bleeding is usually arterial and occurs most commonly in the cerebral lobes, basal ganglia, thalamus, brain stem (mostly the pons), and cerebellum (Qureshi et al., 2001). Occasionally, the bleeding ruptures the wall of the lateral ventricle and causes intraventricular hemorrhage, which is frequently fatal.

### INTRACRANIAL (CEREBRAL) ANEURYSM

An intracranial (cerebral) **aneurysm** is a dilation of the walls of a cerebral artery that develops as a result of weakness in the arterial wall. The cause of aneurysms is unknown, although research is ongoing. An aneurysm may be due to atherosclerosis, resulting in a defect in the vessel wall with subsequent weakness of the wall; a congenital defect of the vessel wall; hypertensive vascular disease; head trauma; or advancing age.

Any artery within the brain can be the site of cerebral aneurysms, but they usually occur at the bifurcations of the large arteries at the circle of Willis (Fig. 62-5). The cerebral arteries most commonly affected by an aneurysm are the internal carotid artery (ICA), anterior cerebral artery (ACA), anterior communicating artery (ACoA), posterior communicating artery (PCoA), posterior cerebral artery (PCA), and middle cerebral artery (MCA). Multiple cerebral aneurysms are not uncommon.

### ARTERIOVENOUS MALFORMATIONS

An AVM is due to an abnormality in embryonal development that leads to a tangle of arteries and veins in the brain without a

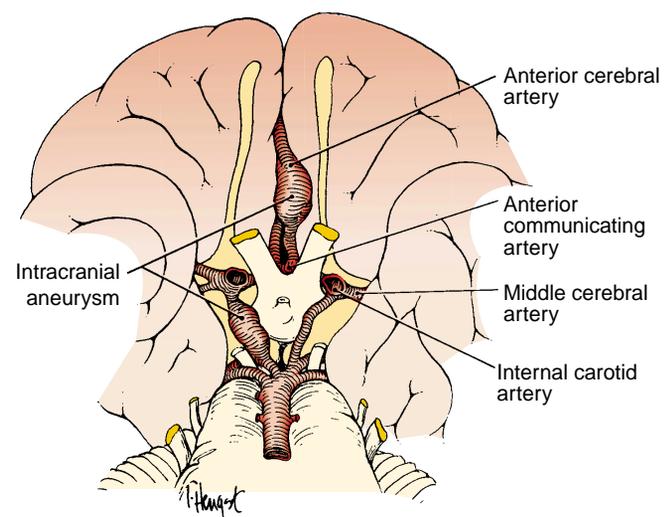

FIGURE 62-5 Intracranial aneurysms.

capillary bed. The absence of a capillary bed leads to dilation of the arteries and veins and eventual rupture. They are commonly a cause of hemorrhage in young people.

### SUBARACHNOID HEMORRHAGE

A subarachnoid hemorrhage (hemorrhage into the subarachnoid space) may occur as a result of an AVM, intracranial aneurysm, trauma, or hypertension. The most common cause is a leaking aneurysm in the area of the circle of Willis or a congenital AVM of the brain.

### Clinical Manifestations

The patient with a hemorrhagic stroke can present with a wide variety of neurologic deficits, similar to the patient with ischemic stroke. A comprehensive assessment will reveal the extent of the neurologic deficits. Many of the same motor, sensory, cranial nerve, cognitive, and other functions that are disrupted following ischemic stroke are altered following a hemorrhagic stroke. Table 62-2 reviews the neurologic deficits frequently seen in stroke patients. Table 62-3 compares the symptoms seen in right hemispheric stroke with those seen in left hemispheric stroke.

In addition to the neurologic deficits that are similar to ischemic stroke, the patient with an intracranial aneurysm or AVM can have some unique clinical manifestations. Rupture of an aneurysm or AVM usually produces a sudden, unusually severe headache and often loss of consciousness for a variable period. There may be pain and rigidity of the back of the neck (nuchal rigidity) and spine due to meningeal irritation. Visual disturbances (visual loss, diplopia, ptosis) occur when the aneurysm is adjacent to the oculomotor nerve. Tinnitus, dizziness, and hemiparesis may also occur.

At times, an aneurysm or AVM leaks blood, leading to the formation of a clot that seals the site of rupture. In this instance, the patient may show little neurologic deficit. In other cases, severe bleeding occurs, resulting in cerebral damage followed rapidly by coma and death.

Prognosis depends on the neurologic condition of the patient, age, associated diseases, and the extent and location of an intracranial aneurysm. Subarachnoid hemorrhage from an aneurysm is a catastrophic event with significant morbidity and mortality (Pfohman & Criddle, 2001). Chart 62-6 discusses ethical issues related to the patient with a severe hemorrhagic stroke.

### Assessment and Diagnostic Findings

Any patient suspected of having a hemorrhagic stroke should undergo CT scanning to determine the size and location of the hematoma as well as the presence or absence of ventricular blood and hydrocephalus (Qureshi et al., 2001). CT scan and cerebral angiography confirm the diagnosis of an intracranial aneurysm or AVM. These tests show the location and size of the lesion and provide information about the affected arteries, veins, adjoining vessels, and vascular branches. Lumbar puncture is performed if there is no evidence of increased ICP, the CT scan results are negative, and subarachnoid hemorrhage must be confirmed. Lumbar puncture in the presence of increased ICP could result in brain stem herniation or rebleeding. In diagnosing a hemorrhagic stroke in a patient younger than 40, some clinicians obtain a toxicology screen for illicit drug use.

The Hunt-Hess classification system guides the physician in diagnosing the severity of subarachnoid hemorrhage after an aneurysmal bleed (Table 62-6). Classifying the patient by severity of neurologic deficit provides a baseline for future comparison.

### Chart 62-6 • Ethics and Related Issues DNR Orders in Severe Stroke

#### Situation

An 85-year-old patient is admitted with a large intracerebral hemorrhage, severe neurologic deficits, and a past medical history of coronary artery bypass graft surgery, hypertension, atrial fibrillation, and gout. The attending physician suggests a do-not-resuscitate (DNR) order to the family.

#### Dilemma

Does the principle of autonomy include death with dignity, or is beneficence keeping the patient alive at all costs? Does the family have the right to refuse? If the patient goes into cardiac arrest and cardiopulmonary resuscitation (CPR) is not provided, have the health care workers “killed” the patient?

#### Discussion

What arguments would you pose in favor of the DNR order?

What arguments would you pose against the DNR order?

Is a DNR order an example of “patient abandonment” by health care workers, or an attempt to limit treatment and avoid CPR in a patient with an anticipated poor outcome?

### Prevention

Primary prevention of hemorrhagic stroke is the best approach and includes managing hypertension and ameliorating other significant risk factors (Pfohman & Criddle, 2001). Control of hypertension, especially in individuals over 55 years of age, clearly reduces the risk for hemorrhagic stroke (Qureshi et al., 2001). Additional factors are similar to the risks for ischemic stroke and include smoking, excessive alcohol intake, and high cholesterol (see Chart 62-2). Stroke risk screenings provide an ideal opportunity to lower hemorrhagic stroke risk by identifying high-risk individuals or groups and educating the patients and the community about recognition and prevention (Pfohman & Criddle, 2001).

A prevention effort unique to hemorrhagic stroke is to increase the public's awareness about the association between phenylpropanolamine (an ingredient found in appetite suppressants as well as cold and cough agents) and hemorrhagic stroke. Recent research has found that phenylpropanolamine is an independent risk factor for hemorrhagic stroke, especially in women (Kernan et al., 2000). Many products have been removed voluntarily from the market, but consumers should continue to look for this ingredient on labels.

## Medical Management

The goals of medical treatment of hemorrhagic stroke are to allow the brain to recover from the initial insult (bleeding), to prevent or minimize the risk for rebleeding, and to prevent or treat complications. Management consists of bed rest with sedation to prevent agitation and stress, management of vasospasm, and surgical or medical treatment to prevent rebleeding. Analgesics (codeine, acetaminophen) may be prescribed for head and neck pain. The patient is fitted with elastic compression stockings to prevent deep vein thrombosis, a threat to any patient on bed rest.

## COMPLICATIONS

Potential complications include rebleeding; cerebral vasospasm resulting in cerebral ischemia; acute hydrocephalus, which results when free blood obstructs the reabsorption of cerebrospinal fluid (CSF) by the arachnoid villi; and seizures.

**Cerebral Hypoxia and Decreased Blood Flow.** Immediate complications of a hemorrhagic stroke include cerebral hypoxia, decreased cerebral blood flow, and extension of the area of injury. Providing adequate oxygenation of blood to the brain minimizes cerebral hypoxia. Brain function is dependent on available oxygen being delivered to the tissues. Administering supplemental oxygen and maintaining the hemoglobin and hematocrit at acceptable levels will assist in maintaining tissue oxygenation.

Cerebral blood flow is dependent on the blood pressure, cardiac output, and integrity of cerebral blood vessels. Adequate hydration (IV fluids) must be ensured to reduce blood viscosity and improve cerebral blood flow. Extremes of hypertension or hypotension need to be avoided to prevent changes in cerebral blood flow and the potential for extending the area of injury.

A seizure can also compromise cerebral blood flow. Seizures occur in approximately 5% of stroke patients (Berges et al., 2000). Observation for and appropriate treatment of seizure activity is an important component of care following a hemorrhagic stroke (Qureshi et al., 2001).

**Vasospasm.** The development of cerebral vasospasm (narrowing of the lumen of the involved cranial blood vessel) is a serious complication of subarachnoid hemorrhage and accounts for 40% to 50% of the morbidity and mortality of those who survive the initial intracranial bleed. The mechanism responsible for the spasm is not clear, but vasospasm is associated with increasing amounts of blood in the subarachnoid cisterns and cerebral fissures, as visualized by CT scan.

Vasospasm leads to increased vascular resistance, which impedes cerebral blood flow and causes brain ischemia and infarction. The signs and symptoms reflect the areas of the brain involved. Vasospasm is often heralded by a worsening headache, a decrease in level of consciousness (confusion, lethargy, and dis-

orientation), or a new focal neurologic deficit (aphasia, hemiparesis [partial paralysis affecting one side of the body]).

Vasospasm frequently occurs 4 to 14 days after initial hemorrhage when the clot undergoes lysis (dissolution), increasing the chances of rebleeding.

It is believed that early surgery to clip the aneurysm prevents rebleeding and that removal of blood from the basal cisterns around the major cerebral arteries may prevent vasospasm. The IV administration of the calcium-channel blocker nimodipine during the critical time in which vasospasm may occur may prevent delayed ischemic deterioration. Advances in technology have led to the introduction of interventional neuroradiology for the treatment of aneurysms. Endovascular techniques may be used in selected patients to occlude the artery supplying the aneurysm with a balloon or to occlude the aneurysm itself. As more studies on these techniques are completed, their use will increase.

Management of vasospasm remains difficult and controversial. Based on one theory that vasospasm is caused by an increased influx of calcium into the cell, medication therapy may be used to block or antagonize this action and prevent or reverse the action of vasospasm already present. Calcium-channel blockers may include nimodipine (Nimotop), verapamil (Isoptin), and nifedipine (Procardia). Other therapy for vasospasm is aimed at minimizing the deleterious effects of the associated cerebral ischemia and includes fluid volume expanders and induced arterial hypertension, normotension, or hemodilution.

**Increased ICP.** An increase in ICP can follow either an ischemic or hemorrhagic stroke but almost always follows a subarachnoid hemorrhage, usually because of disturbed circulation of CSF caused by blood in the basal cisterns. If the patient shows evidence of deterioration from increased ICP (due to cerebral edema, herniation, hydrocephalus, or vasospasm), CSF drainage may be instituted by cautious lumbar puncture or ventricular catheter drainage, and mannitol is given to reduce ICP. When mannitol is used as a long-term measure to control ICP, dehydration and disturbances in electrolyte balance (hyponatremia or hypernatremia; hypokalemia or hyperkalemia) may occur. Mannitol acts by pulling water out of the brain tissue by osmosis as well as by reducing total-body water through diuresis. The patient is monitored for signs of dehydration and for rebound elevation of ICP.

**Systemic Hypertension.** Preventing sudden systemic hypertension is critical in hemorrhagic stroke management. The goal of therapy is to maintain the systolic blood pressure at about 150 mm Hg. If blood pressure is elevated, antihypertensive therapy (labetalol [Normodyne], nicardipine [Cardene], nitroprusside [Nitropress]) may be prescribed. Hemodynamic monitoring by arterial line during the administration of antihypertensives is important to detect and avoid a precipitous drop in blood pressure, which can produce brain ischemia. Because seizures cause blood pressure elevation, antiseizure agents are administered prophylactically. Stool softeners are used to prevent straining, which can also elevate the blood pressure.

## SURGICAL MANAGEMENT

Many patients with a primary intracerebral hemorrhage are not treated surgically. However, surgical evacuation is strongly recommended for the patient with a cerebellar hemorrhage if the diameter exceeds 3 cm and the Glasgow Coma Scale score is below

14 (Qureshi et al., 2001). Surgical evacuation is most frequently accomplished via a craniotomy (see Chap. 61).

The patient with an intracranial aneurysm is prepared for surgical intervention as soon as the condition is considered stable. The Hunt-Hess classification system guides the physician in diagnosing the severity of subarachnoid hemorrhage after an aneurysm bleeds and in timing the surgery (see Table 62-6). Morbidity and mortality from surgery are high if the patient is stuporous or comatose (grade IV or V). Surgical treatment of the patient with an unruptured aneurysm is an option (Pfohman & Criddle, 2001).

The goal of surgery is to prevent bleeding in an unruptured aneurysm and further bleeding in an already ruptured aneurysm. This objective is accomplished by isolating the aneurysm from its circulation or by strengthening the arterial wall. An aneurysm may be excluded from the cerebral circulation by means of a ligature or a clip across its neck. If this is not anatomically possible, the aneurysm can be reinforced by wrapping it with muslin or some other substance to provide support and induce scarring.

An extracranial-intracranial arterial bypass may be performed to establish collateral blood supply to allow surgery on the aneurysm. Alternatively, an extracranial method may be used, whereby the carotid artery is gradually occluded in the neck to reduce pressure within the blood vessel. After ligation of the carotid artery, there is some risk for cerebral ischemia and sudden hemiplegia because during the surgical procedure, there is a temporary occlusion of the blood supply to the brain (unless a temporary bypass shunt is used). In anticipation of these complications, cerebral blood flow and internal carotid pressure may be measured to identify patients at risk for postoperative ischemic episodes.

Several less invasive endovascular treatments are now being used for aneurysms. These procedures are performed by neurosurgeons in neurointerventional radiology suites. Two procedures are endovascular treatment (occlusion of the parent artery) and aneurysm coiling (obstruction of the aneurysm site with a coil). While associated with lower risks than intracranial surgery in general, secondary stroke and rupture of the aneurysm are still potential complications (Pfohman & Criddle, 2001).

Postoperative complications include psychological symptoms (disorientation, amnesia, **Korsakoff's syndrome**, personality changes), intraoperative embolization, postoperative internal artery occlusion, fluid and electrolyte disturbances (from dysfunction of the neurohypophyseal system), and gastrointestinal bleeding.

## NURSING PROCESS: THE PATIENT WITH A HEMORRHAGIC STROKE

### Assessment

A complete neurologic assessment is performed initially and should include evaluation for the following:

- Altered level of consciousness
- Sluggish pupillary reaction
- Motor and sensory dysfunction
- Cranial nerve deficits (extraocular eye movements, facial droop, presence of ptosis)
- Speech difficulties and visual disturbance
- Headache and nuchal rigidity or other neurologic deficits

All patients should be monitored in the intensive care unit following an intracerebral hemorrhage (Qureshi et al., 2001). Neurologic assessment findings are documented and reported as indicated. The frequency of these assessments varies depending on the patient's condition. Any changes in the patient's condition require reassessment and thorough documentation; changes should be reported immediately.

Alteration in level of consciousness often is the earliest sign of deterioration in a patient with a hemorrhagic stroke. Because nurses have the most frequent contact with patients, they are in the best position to detect what may be subtle changes. Mild drowsiness and slight slurring of speech may be early signs that the level of consciousness is deteriorating. Frequent nursing assessment is crucial in the patient with known or suspected cerebral aneurysm.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Ineffective cerebral tissue perfusion related to bleeding
- Disturbed sensory perception related to medically imposed restrictions (aneurysm precautions)
- Anxiety related to illness and/or medically imposed restrictions (aneurysm precautions)

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include the following:

- Vasospasm
- Seizures
- Hydrocephalus
- Rebleeding

## Planning and Goals

The goals for the patient may include improved cerebral tissue perfusion, relief of sensory and perceptual deprivation, relief of anxiety, and the absence of complications.

## Nursing Interventions

### OPTIMIZING CEREBRAL TISSUE PERFUSION

The patient is closely monitored for neurologic deterioration occurring from recurrent bleeding, increasing ICP, or vasospasm. A neurologic flow record is maintained. The blood pressure, pulse, level of responsiveness (an indicator of cerebral perfusion), pupillary responses, and motor function are checked hourly. Respiratory status is monitored because a reduction in oxygen in areas of the brain with impaired autoregulation increases the chances of a cerebral infarction. Any changes are reported immediately.

### Implementing Aneurysm Precautions

Cerebral aneurysm precautions are implemented for the patient with a diagnosis of aneurysm to provide a nonstimulating environment, prevent increases in ICP pressure, and prevent further bleeding. The patient is placed on immediate and absolute bed

rest in a quiet, nonstressful environment because activity, pain, and anxiety elevate the blood pressure, which increases the risk for bleeding. Visitors, except for family, are restricted.

The head of the bed is elevated 15 to 30 degrees to promote venous drainage and decrease ICP. Some neurologists, however, prefer that the patient remain flat to increase cerebral perfusion.

Any activity that suddenly increases the blood pressure or obstructs venous return is avoided. This includes the Valsalva maneuver, straining, forceful sneezing, pushing up in bed, acute flexion or rotation of the head and neck (which compromises the jugular veins), and cigarette smoking. Any activity requiring exertion is contraindicated. The patient is instructed to exhale through the mouth during voiding or defecation to decrease strain. No enemas are permitted, but stool softeners and mild laxatives are prescribed. Both prevent constipation, which would cause an increase in ICP, as would enemas. Dim lighting is helpful because photophobia (visual intolerance of light) is common. Coffee and tea, unless decaffeinated, are usually eliminated.

High-high elastic compression stockings or sequential compression boots may be prescribed to decrease the incidence of deep vein thrombosis resulting from immobility. The legs are observed for signs and symptoms of deep vein thrombosis (tenderness, swelling, warmth, discoloration, positive Homans' sign), and abnormal findings are reported.

The nurse administers all personal care. The patient is fed and bathed to prevent any exertion that might raise the blood pressure. External stimuli are kept to a minimum, including no television, no radio, and no reading. Visitors are restricted in an effort to keep the patient as quiet as possible. This precaution must be individualized based on the patient's condition and response to visitors. A sign indicating this restriction should be placed on the door of the room, and the restrictions should be discussed with both patient and family. The purpose of aneurysm precautions should be thoroughly explained to both the patient (if possible) and family.

### RELIEVING SENSORY DEPRIVATION AND ANXIETY

Sensory stimulation is kept to a minimum for patients on aneurysm precautions. For patients who are awake, alert, and oriented, an explanation of the restrictions helps reduce the patient's sense of isolation. Reality orientation is provided to help maintain orientation.

Keeping the patient well informed of the plan of care provides reassurance and helps minimize anxiety. Appropriate reassurance also helps relieve the patient's fears and anxiety. The family also requires information and support.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

#### Vasospasm

The patient is assessed for signs of possible vasospasm: intensified headaches, a decrease in level of responsiveness (confusion, disorientation, lethargy), or evidence of aphasia or partial paralysis. These signs may develop several days after surgery or on the initiation of treatment and must be reported immediately. If vasospasm is diagnosed, calcium-channel blockers or fluid volume expanders may be prescribed.

#### Seizures

Seizure precautions are maintained for every patient who may be at risk for seizure activity. Should a seizure occur, maintaining the airway and preventing injury are the primary goals. Medication

therapy is initiated at this time if not already prescribed. The medication of choice is phenytoin (Dilantin) because this agent usually provides adequate antiseizure action while causing no drowsiness at therapeutic levels.

#### Hydrocephalus

Blood in the subarachnoid space impedes the circulation of CSF, resulting in hydrocephalus. A CT scan that indicates dilated ventricles confirms the diagnosis. Hydrocephalus can occur within the first 24 hours (acute) after subarachnoid hemorrhage or days (subacute) to several weeks (delayed) later. Symptoms vary according to the time of onset and may be nonspecific. Acute hydrocephalus is characterized by sudden onset of stupor or coma and is managed with a ventriculostomy drain to decrease ICP. Symptoms of subacute and delayed hydrocephalus include gradual onset of drowsiness, behavioral changes, and ataxic gait. A ventriculoperitoneal shunt is surgically placed to treat chronic hydrocephalus. Changes in patient responsiveness are reported immediately.

#### Rebleeding

The rate of recurrent hemorrhage is approximately 2% following a primary intracerebral hemorrhage. Hypertension is the most serious risk factor, suggesting the importance of appropriate antihypertensive treatment (Qureshi et al., 2001).

Aneurysm rebleeding occurs most frequently in the first 2 weeks after the initial hemorrhage and is considered a major complication. Symptoms of rebleeding include sudden severe headache, nausea, vomiting, decreased level of consciousness, and neurologic deficit. A CT scan is performed to confirm rebleeding. Blood pressure is carefully maintained with medications. Antifibrinolytic medications (epsilon-aminocaproic acid) may be administered to delay the lysis of the clot surrounding the rupture. The most effective preventive treatment is early clipping of the aneurysm if the patient is a candidate for surgery.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

The patient and family are provided with information that will enable them to cooperate with the care and restrictions required during the acute phase of hemorrhagic stroke and to prepare them to return home. Patient and family teaching includes information about the causes of hemorrhagic stroke and its possible consequences. In addition, the patient and family are informed about the medical treatments that are implemented, including surgical intervention if warranted, and the importance of interventions taken to prevent and detect complications (ie, aneurysm precautions, close monitoring of the patient). Depending on the presence and severity of neurologic impairment and other complications resulting from the stroke, the patient may be transferred to a rehabilitation unit or center, where additional patient and family teaching will focus on strategies to regain ability to manage self-care. Teaching may also address the use of assistive devices or modification of the home environment to help the patient live with a disability. Modifications of the home may be required to provide a safe environment (Olson, 2001). (See Nursing Research Profile 62-2.)

#### Continuing Care

During the acute and rehabilitation phase of care for the patient with a hemorrhagic stroke, the focus is on obvious needs, issues, and deficits. The patient and family are reminded of the impor-

## NURSING RESEARCH PROFILE 62-2

## The Experience of Stroke for Eight African-American Elders

Eaves, Y. (2000). "What happened to me": Rural African American elders' experiences of stroke. *Journal of Neuroscience Nursing*, 32(1), 37–48.

### Purpose

The rate of stroke is higher in African Americans compared to Caucasians, yet little is known about the subjective experiences of stroke in this group and their families. The purpose of this study was to examine the experience of stroke from the perspective of rural African-American elders and their family members.

### Study Sample and Design

This descriptive, qualitative study was part of a larger study on caregiving. A purposive sample of eight African-American stroke survivors and their families participated. The survivors had each experienced a stroke in the preceding 4 months, were 55 years or older, and recently had been discharged from a rehabilitation center. The qualitative method of descriptive narrative analysis was used to explain the stroke experience. Interactive audiotaped interviews and focused observations with written field notes took place in the home of each participant over several sessions. The qualitative text analysis software MARTIN was used for data analysis of the transcribed audiotaped interviews and written field notes.

### Findings

The eight stroke survivors ranged in age from 56 to 79 years; primary caregivers ranged in age from 21 to 70 years and secondary caregivers

ranged from 8 to 60 years. Five main themes were revealed in this study: (1) discovering stroke, (2) delaying treatment, (3) living with uncertainty, (4) discovering the impact of stroke, and (5) reconstructing life. Each of the five themes revealed at least two patterns; discovering stroke, for example, included stroke signs and explaining stroke. The findings revealed that several of the participants hid their stroke symptoms from family members and delayed seeking treatment for a prolonged time.

### Nursing Implications

Nurses in acute care, home care, rehabilitation, and community settings involved with stroke patients and their families can use this information to better understand how African-American elders live through and respond to the experience of stroke. The identified themes of how, when, and why rural African-American elders seek treatment for stroke symptoms can assist nurses in educating this group about signs and symptoms of stroke, stroke prevention, and the emergent nature of stroke. This would permit the development of appropriate strategies to target this high-risk group.

tance of following recommendations to prevent further hemorrhagic stroke and keeping follow-up appointments with health care providers for monitoring. Referral for home care may be warranted to assess the home environment and the ability of the patient and to ensure that the patient and family are able to manage at home. The physical and psychological status of the patient and ability of the family to cope with any alterations in the patient's status are monitored during home visits. In addition, the nurse involved in home and continuing care needs to remind patients and family members of the need for continuing health promotion and screening practices. Patients who have not been involved in these practices

in the past are educated about their importance and are referred to appropriate health care providers, if indicated. Chart 62-7 lists teaching points for the patient recovering from a stroke.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Demonstrates intact neurologic status and normal vital signs and respiratory patterns

## Chart 62-7

## Home Care Checklist • The Patient Recovering From A Stroke

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Discuss measures to prevent subsequent strokes.	✓	✓
• Identify signs and symptoms of specific complications.	✓	✓
• Identify potential complications and discuss measures to prevent them (blood clots, aspiration, pneumonia, urinary tract infection, fecal impaction, skin breakdown, contracture).	✓	✓
• Identify psychosocial consequences of stroke and appropriate interventions.	✓	✓
• Identify safety measures to prevent falls.	✓	✓
• State names, doses, indications, and side effects of medications.	✓	✓
• Demonstrate adaptive techniques for accomplishing ADLs.	✓	✓
• Demonstrate swallowing techniques (for patients with dysphagia).	✓	✓
• Demonstrate care of enteric feeding tube, if applicable.	✓	✓
• Demonstrate home exercises, use of splints or orthotics, proper positioning, and need for frequent repositioning.	✓	✓
• Describe procedures for maintaining skin integrity.	✓	✓
• Demonstrate indwelling catheter care, if applicable. Describe a bowel and bladder elimination program as appropriate.	✓	✓
• Identify appropriate recreational or diversional activities, support groups, and community resources.	✓	✓

- a. Is alert and oriented to time, place, and person
  - b. Demonstrates normal speech patterns and intact cognitive processes
  - c. Demonstrates normal and equal strength, movement, and sensation of all four extremities
  - d. Exhibits normal deep tendon reflexes and pupillary responses
2. Demonstrates normal sensory perceptions
    - a. States rationale for aneurysm precautions
    - b. Exhibits clear thought processes
  3. Exhibits reduced anxiety level
    - a. Is less restless
    - b. Exhibits absence of physiologic indicators of anxiety (eg, normal vital signs; normal respiratory rate; absence of excessive, fast speech)
  4. Is free of complications
    - a. Exhibits absence of vasospasm
    - b. Exhibits normal vital signs and neuromuscular activity without seizures
    - c. Verbalizes understanding of seizure precautions
    - d. Exhibits normal mental status and normal motor and sensory status
    - e. Reports no visual changes

### Critical Thinking Exercises

1. Your patient had symptoms of an ischemic stroke approximately 2 hours ago and is undergoing a confirmatory CT scan in 30 minutes. You know t-PA must be administered within 3 hours of the symptoms. What actions would you take? What is your rationale for these actions?
2. Your patient has expressive aphasia following an ischemic stroke. How would you explain this phenomenon to the patient and family? Describe appropriate techniques for communicating with a patient with this type of aphasia.
3. Your patient is admitted with hemorrhagic stroke and exhibits homonymous hemianopsia. How would you explain this phenomenon to the patient and family? How would you modify your care for this patient? Describe ways that the patient and family may work together to compensate for this problem.
4. A 50-year-old patient is expected to be discharged to home today following a 5-day stay for an ischemic stroke. He tells you that he lives alone in a small apartment and knows none of his neighbors. He has some residual right-sided weakness. What teaching would be indicated to prevent another stroke? What resources may be needed to enable him to go home as scheduled?

# ● Management of Patients With Neurologic Trauma

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Differentiate among patients with head injuries according to mechanism of injury, clinical signs and symptoms, diagnostic testing, and treatment options.
2. Describe the nursing management of head-injured patients.
3. Use the nursing process as a framework for care of patients with brain injury.
4. Identify the population at risk for spinal cord injury.
5. Describe three clinical features of the patient with neurogenic shock.
6. Discuss the pathophysiology of autonomic dysreflexia and describe the appropriate nursing interventions.
7. Use the nursing process as a framework for care of patients with spinal cord injury.

**T**rauma involving the central nervous system can be life-threatening. Even if not life-threatening, brain and spinal cord injury may result in major physical and psychological dysfunction and can alter the patient's life completely. Neurologic trauma affects the patient, the family, the health care system, and society as a whole because of its major sequelae and the costs of acute and long-term care of patients with trauma to the brain and spinal cord.

## Head Injuries

Head injury is a broad classification that includes injury to the scalp, skull, or brain. It is the most common cause of death from trauma in the United States. Approximately 1 million people receive treatment for head injuries every year. Of these, 230,000 are hospitalized, 80,000 have permanent disabilities, and 50,000 people die (Centers for Disease Control and Prevention [CDC], 2001). Traumatic brain injury is the most serious form of head injury. The most common causes of traumatic brain injury are motor vehicle crashes, violence, and falls. Groups at highest risk for traumatic brain injury are persons age 15 to 24 years and males, who suffer traumatic brain injury at a rate almost twice that of females. The very young (under 5) and the very old (over 75) are also at increased risk. It is estimated that 5.3 million Americans today are living with a disability as a result of a traumatic brain injury (CDC, 2001). The best approach to head injury is prevention (Chart 63-1).

## Pathophysiology

Research suggests that not all brain damage occurs at the moment of impact. Damage to the brain from traumatic injury takes two forms: primary injury and **secondary injury**. Primary injury is the initial damage to the brain that results from the traumatic event. This may include contusions, lacerations, and torn blood vessels from impact, acceleration/deceleration, or foreign object penetration (Blank-Reid & Reid, 2000; Porth, 2002). Secondary injury evolves over the ensuing hours and days after the initial injury and is due primarily to brain swelling or ongoing bleeding.

An injured brain is different from other injured body areas due to its unique characteristics. It resides within the skull, which is a

Chart  
63-1

## Head and Spinal Cord Injury Prevention

The most effective treatment for brain and spinal cord injury is prevention. To decrease the incidence of these devastating and catastrophic injuries, the following steps should be taken:

- Drivers should obey traffic laws, particularly not speeding or driving when under the influence of drugs or alcohol.
- All drivers and passengers should wear seat belts and shoulder harnesses. Children under 12 should be restrained in an age/size-appropriate system in the back seat.
- Passengers should not ride in the back of pick-up trucks.
- Motorcyclists, scooterists, bicyclists, skateboarders, and roller skaters should wear helmets.
- Educational programs should be directed toward violence and suicide prevention in the community.
- Water safety instruction should be provided.
- Steps should be taken to prevent falls, particularly in the elderly.
- Athletes should use protective devices; coaches should be educated in proper coaching techniques.
- Owners of firearms should keep them locked in a secure area where children cannot access them.

rigid closed compartment (Bader & Palmer, 2000). Unlike an injured ankle, in which the covering skin expands with swelling, the confines of the skull do not allow for the expansion of cranial contents. Thus, any bleeding or swelling within the skull increases the volume of contents within a container of fixed size and so can cause increased intracranial pressure (ICP) (see Chap. 61). If the increased pressure is high enough, it can cause a downward or lateral displacement of the brain through or against the rigid structures of the skull. This causes restriction of blood flow to the brain, decreasing oxygen delivery and waste removal. Cells within the brain become anoxic and cannot metabolize properly, producing ischemia, infarction, irreversible brain damage, and eventually brain death (Fig. 63-1).

## SCALP INJURY

Isolated scalp trauma is generally classified as a minor head injury. Because its many blood vessels constrict poorly, the scalp bleeds

## Glossary

**autonomic dysreflexia:** a life-threatening emergency in spinal cord injury patients that causes a hypertensive emergency; also called autonomic hyperreflexia

**brain injury:** an injury to the skull or brain that is severe enough to interfere with normal functioning

**brain injury, closed (blunt):** occurs when the head accelerates and then rapidly decelerates or collides with another object and brain tissue is damaged, but there is no opening through the skull and dura

**brain injury, open:** occurs when an object penetrates the skull, enters the brain, and damages the soft brain tissue in its path (penetrating injury), or when blunt trauma to the head is so severe that it opens the scalp, skull, and dura to expose the brain

**concussion:** a temporary loss of neurologic function with no apparent structural damage to the brain

**contusion:** bruising of the brain surface

**complete spinal cord lesion:** a condition that involves total loss of sensation and voluntary muscle control below the lesion

**halo vest:** a lightweight vest with an attached halo that stabilizes the cervical spine

**incomplete spinal cord lesion:** a condition where there is preservation of the sensory or motor fibers, or both, below the lesion

**neurogenic bladder:** bladder dysfunction that results from a disorder or dysfunction of the nervous system; may result in either urinary retention or bladder overactivity

**paraplegia:** paralysis of the lower extremities with dysfunction of the bowel and bladder from a lesion in the thoracic, lumbar, or sacral regions of the spinal cord

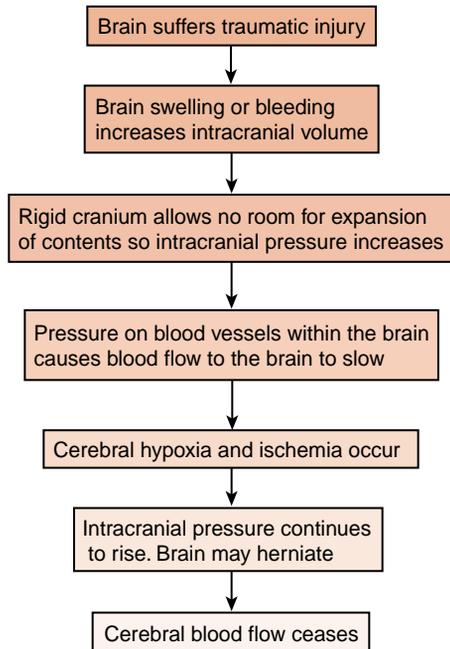

**quadriplegia (tetraplegia):** paralysis of both arms and legs, with dysfunction of bowel and bladder from a lesion of the cervical segments of the spinal cord

**secondary injury:** an insult to the brain subsequent to the original traumatic event

**spinal cord injury (SCI):** an injury to the spinal cord, vertebral column, supporting soft tissue, or intervertebral disks caused by trauma

**transection:** severing of the spinal cord itself; transection can be complete (all the way through the cord) or incomplete (partially through)

## Physiology/Pathophysiology

**FIGURE 63-1** Pathophysiology of traumatic brain injury.

profusely when injured. Trauma may result in an abrasion (brush wound), contusion, laceration, or hematoma beneath the layers of tissue of the scalp (subgaleal hematoma). Large avulsions of the scalp may be potentially life-threatening and are true emergencies. Diagnosis of any scalp injury is based on physical examination, inspection, and palpation. Scalp wounds are potential portals of entry of organisms that cause intracranial infections. Therefore, the area is irrigated before the laceration is sutured to remove foreign material and to reduce the risk for infection. Subgaleal hematomas (hematomas below the outer covering of the skull) usually absorb on their own and do not require any specific treatment.

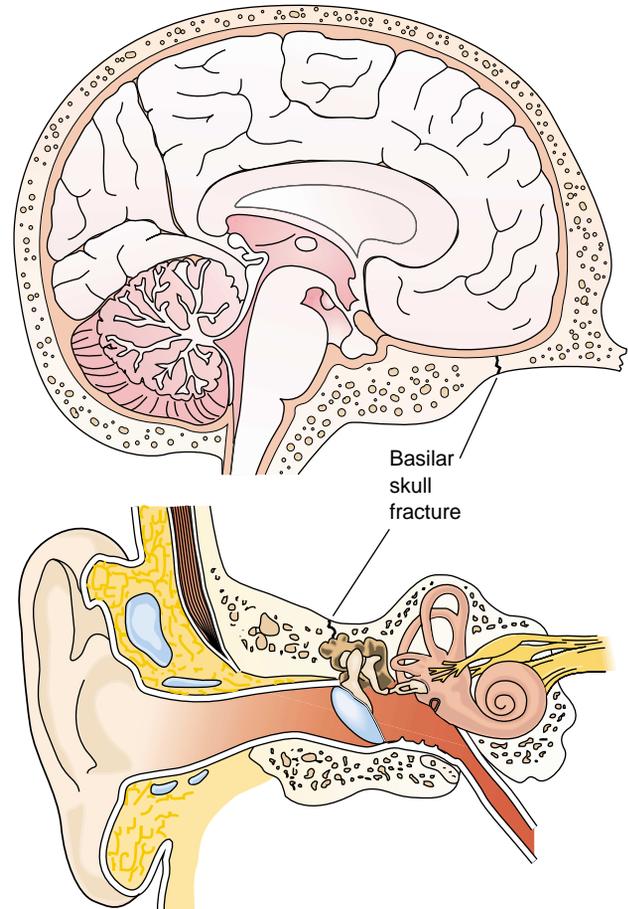

### SKULL FRACTURES

A skull fracture is a break in the continuity of the skull caused by forceful trauma. It may occur with or without damage to the brain. Skull fractures are classified as linear, comminuted, depressed, or basilar. A fracture may be open, indicating a scalp laceration or tear in the dura (eg, from a bullet or an ice pick), or closed, in which the dura is intact (Fig. 63-2).

### Clinical Manifestations

The symptoms, apart from those of the local injury, depend on the severity and the distribution of brain injury. Persistent, localized pain usually suggests that a fracture is present. Fractures of the cranial vault may or may not produce swelling in the region of the fracture; therefore, an x-ray is needed for diagnosis.

Fractures of the base of the skull tend to traverse the paranasal sinus of the frontal bone or the middle ear located in the temporal bone (see Fig. 63-2). Thus, they frequently produce hemorrhage from the nose, pharynx, or ears, and blood may appear under the conjunctiva. An area of ecchymosis (bruising) may be

**FIGURE 63-2** Basilar fractures allow cerebrospinal fluid to leak from the nose and ears. Adapted from Hickey, J. V. (2003). *The clinical practice of neurological and neurosurgical nursing* (5th ed.). Philadelphia: Lippincott Williams & Wilkins.

seen over the mastoid (Battle's sign). Basal skull fractures are suspected when cerebrospinal fluid escapes from the ears (CSF otorrhea) and the nose (CSF rhinorrhea). A halo sign (a blood stain surrounded by a yellowish stain) may be seen on bed linens or the head dressing and is highly suggestive of a CSF leak. Drainage of CSF is a serious problem because meningeal infection can occur if organisms gain access to the cranial contents through the nose, ear, or sinus through a tear in the dura. Bloody CSF suggests a brain laceration or contusion.

### Assessment and Diagnostic Findings

Although a rapid physical examination and evaluation of neurologic status detect the more obvious brain injuries, a computed tomography (CT) scan can detect less apparent abnormalities by the degree to which the soft tissue absorbs the x-rays. It is a fast, accurate, and safe diagnostic study that shows the presence, nature, location, and extent of acute lesions. It is also helpful in the ongoing management of patients with head injury as it can disclose cerebral edema, contusion, intracerebral or extracerebral hematoma, subarachnoid and intraventricular hemorrhage, and late changes (infarction, hydrocephalus). Magnetic resonance imaging (MRI) is used to evaluate patients with head injury when a more accurate picture of the anatomic nature of the injury is warranted and when the patient is stable enough to undergo this longer diagnostic study.

Cerebral angiography may also be used; it identifies supratentorial, extracerebral, and intracerebral hematomas and cerebral contusions. Lateral and anteroposterior views of the skull are obtained.

## Medical Management

Nondepressed skull fractures generally do not require surgical treatment; however, close observation of the patient is essential. Nursing personnel may observe the patient in the hospital, but if no underlying brain injury is present, the patient may be allowed to return home. If the patient is discharged home, specific instructions (see the section on concussions below) must be given to the family. Many depressed skull fractures are managed conservatively; only contaminated or deforming fractures require surgery.

If surgery is necessary, the scalp is shaved and cleansed with copious amounts of saline to remove debris. The fracture is then exposed. After the skull fragments are elevated, the area is debrided. Large defects can be repaired immediately with bone or artificial grafts; if significant cerebral edema is present, repair of the defect can be delayed for 3 to 6 months. Penetrating wounds require surgical debridement to remove foreign bodies and devitalized brain tissue and to control hemorrhage (Blank-Reid & Reid, 2000). Antibiotic treatment is instituted immediately, and blood component therapy is administered if indicated.

As stated previously, fractures of the base of the skull are serious because they are usually open (involving the paranasal sinuses or middle or external ear) and result in CSF leakage. The nasopharynx and the external ear should be kept clean. Usually a piece of sterile cotton is placed loosely in the ear, or a sterile cotton pad may be taped loosely under the nose or against the ear to collect the draining fluid. The patient who is conscious is cautioned against sneezing or blowing the nose. The head is elevated 30 degrees to reduce ICP and promote spontaneous closure of the leak (Sullivan, 2000), although some neurosurgeons prefer that the bed be kept flat. Persistent CSF rhinorrhea or otorrhea usually requires surgical intervention.

## Brain Injury

The most important consideration in any head injury is whether or not the brain is injured. Even seemingly minor injury can cause significant brain damage secondary to obstructed blood flow and decreased tissue perfusion. The brain cannot store oxygen and glucose to any significant degree. Because the cerebral cells need an uninterrupted blood supply to obtain these nutrients, irreversible brain damage and cell death occur when the blood supply is interrupted for even a few minutes. Clinical manifestations of **brain injury** are listed in Chart 63-2. **Closed (blunt) brain injury** occurs when the head accelerates and then rapidly decelerates or collides with another object (eg, a wall or dashboard of a car) and brain tissue is damaged, but there is no opening through the skull and dura. **Open brain injury** occurs when an object penetrates the skull, enters the brain, and damages the soft brain tissue in its path (penetrating injury), or when blunt trauma to the head is so severe that it opens the scalp, skull, and dura to expose the brain.

## Concussion

A cerebral **concussion** after head injury is a temporary loss of neurologic function with no apparent structural damage. A concussion generally involves a period of unconsciousness lasting

Chart  
63-2

### Clinical Manifestations of Brain Injury

- Altered level of consciousness
- Confusion
- Pupillary abnormalities (changes in shape, size, and response to light)
- Altered or absent gag reflex
- Absent corneal reflex
- Sudden onset of neurologic deficits
- Changes in vital signs (altered respiratory pattern, hypertension, bradycardia, tachycardia, hypothermia or hyperthermia)
- Vision and hearing impairment
- Sensory dysfunction
- Spasticity
- Headache
- Vertigo
- Movement disorders
- Seizures

from a few seconds to a few minutes. The jarring of the brain may be so slight as to cause only dizziness and spots before the eyes (“seeing stars”), or it may be severe enough to cause complete loss of consciousness for a time. If the brain tissue in the frontal lobe is affected, the patient may exhibit bizarre irrational behavior, whereas involvement of the temporal lobe can produce temporary amnesia or disorientation.

The patient may be hospitalized overnight for observation or discharged from the hospital in a relatively short time after a concussion. Treatment involves observing the patient for headache, dizziness, lethargy, irritability, and anxiety. The occurrence of these symptoms after injury is referred to as postconcussion syndrome. Giving the patient information, explanations, and encouragement may reduce some of the problems of postconcussion syndrome. The patient is advised to resume normal activities slowly, and the family is instructed to observe for the following signs and symptoms and to notify the physician or clinic (or bring the patient to the emergency department) if they occur:

- Difficulty in awakening
- Difficulty in speaking
- Confusion
- Severe headache
- Vomiting
- Weakness of one side of the body

A concussion was once thought of as a minor head injury without significant sequelae. However, studies have demonstrated that there are often disturbing and sometimes residual effects, including headache, lethargy, personality and behavior changes, attention deficits, difficulty with memory, and disruption in work habits (Ponsford et al., 1999).

### Gerontologic Considerations

Elderly patients must be assessed very carefully. Even given similar mechanisms of injury, an elderly person will often suffer more severe injury than a young person and will often recover more slowly and with more complications (Perdue et al., 1998). The elderly patient with confusion or behavioral disturbances should be assessed for head injury, because unrecognized “minor” head trauma may account for behavioral and confusional episodes in some elderly people (Walshaw, 2000). A misdiagnosed or untreated episode of confusion in an elderly patient may result in

long-term disability that might have been avoided if the injury had been detected and treated promptly.

## Contusion

Cerebral **contusion** is a more severe injury in which the brain is bruised, with possible surface hemorrhage. The patient is unconscious for more than a few seconds or minutes. Clinical signs and symptoms depend on the size of the contusion and the amount of associated cerebral edema. The patient may lie motionless, with a faint pulse, shallow respirations, and cool, pale skin. Often there is involuntary evacuation of the bowels and the bladder. The patient may be aroused with effort but soon slips back into unconsciousness. The blood pressure and the temperature are subnormal, and the picture is somewhat similar to that of shock.

In general, patients with severe brain injury who have abnormal motor function, abnormal eye movements, and elevated ICP have poor outcomes—that is, brain damage, disability, or death. Conversely, the patient may recover consciousness but pass into a stage of cerebral irritability. In this stage, the patient is conscious and easily disturbed by any form of stimulation such as noises, light, and voices; he or she may become hyperactive at times. Gradually, the pulse, respirations, temperature, and other body functions return to normal, but full recovery can be delayed for months. Residual headache and vertigo are common, and impaired mental function or seizures may occur as a result of irreparable cerebral damage.

## Diffuse Axonal Injury

Diffuse axonal injury involves widespread damage to axons in the cerebral hemispheres, corpus callosum, and brain stem. It can be seen in mild, moderate, or severe head trauma and results in axonal swelling and disconnection (Porth, 2002). Clinically, with severe injury, the patient has no lucid intervals and experiences immediate coma, decorticate and decerebrate posturing (see Fig. 61-1 in Chap. 61 and discussion in Chap. 60), and global cerebral edema. Diagnosis is made by clinical signs in conjunction with a CT scan or MRI. Recovery depends on the severity of the axonal injury.

## Intracranial Hemorrhage

Hematomas (collections of blood) that develop within the cranial vault are the most serious brain injuries (Porth, 2002). A hematoma may be epidural (above the dura), subdural (below the dura), or intracerebral (within the brain) (Fig. 63-3). Major symptoms are frequently delayed until the hematoma is large enough to cause distortion of the brain and increased ICP. The signs and symptoms of cerebral ischemia resulting from the com-

pression by a hematoma are variable and depend on the speed with which vital areas are affected and the area that is injured. In general, a rapidly developing hematoma, even if small, may be fatal, whereas a larger but slowly developing collection of blood may allow compensation for increases in ICP.

## EPIDURAL HEMATOMA (EXTRADURAL HEMATOMA OR HEMORRHAGE)

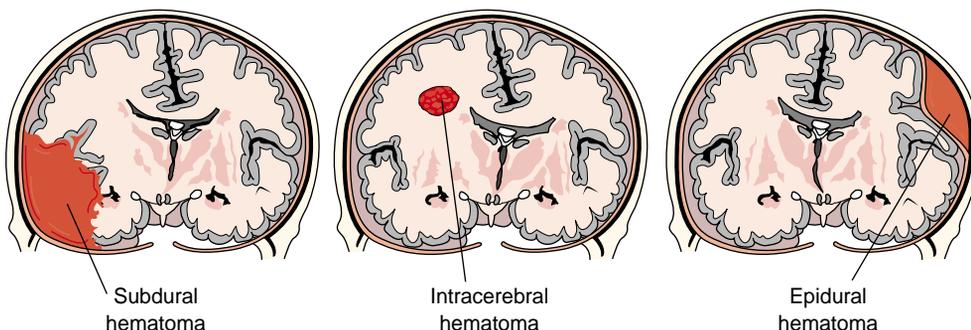

After a head injury, blood may collect in the epidural (extradural) space between the skull and the dura. This can result from a skull fracture that causes a rupture or laceration of the middle meningeal artery, the artery that runs between the dura and the skull inferior to a thin portion of temporal bone. Hemorrhage from this artery causes rapid pressure on the brain.

Symptoms are caused by the expanding hematoma. Usually, there is a momentary loss of consciousness at the time of injury, followed by an interval of apparent recovery (lucid interval). Although the lucid interval is considered a classic characteristic of an epidural hematoma, no lucid interval has been reported in many patients with this lesion (Servadei, 1997), and thus it should not be considered a critical defining criterion. During the lucid interval, compensation for the expanding hematoma takes place by rapid absorption of CSF and decreased intravascular volume, both of which help maintain a normal ICP. When these mechanisms can no longer compensate, even a small increase in the volume of the blood clot produces a marked elevation in ICP. Then, often suddenly, signs of compression appear (usually deterioration of consciousness and signs of focal neurologic deficits such as dilation and fixation of a pupil or paralysis of an extremity), and the patient deteriorates rapidly.

An epidural hematoma is considered an extreme emergency; marked neurologic deficit or even respiratory arrest can occur within minutes. Treatment consists of making openings through the skull (burr holes) to decrease ICP emergently, remove the clot, and control the bleeding. A craniotomy may be required to remove the clot and control the bleeding. A drain is usually inserted after creation of burr holes or a craniotomy to prevent reaccumulation of blood.

## SUBDURAL HEMATOMA

A subdural hematoma is a collection of blood between the dura and the brain, a space normally occupied by a thin cushion of fluid. The most common cause of subdural hematoma is trauma, but it may also occur from coagulopathies or rupture of an aneurysm. A subdural hemorrhage is more frequently venous in origin and is due to the rupture of small vessels that bridge the subdural space. A subdural hematoma may be acute, subacute, or chronic, depending on the size of the involved vessel and the amount of bleeding present.

**FIGURE 63-3** Locations of intracranial hemorrhages.

**Acute and Subacute Subdural Hematoma.** Acute subdural hematomas are associated with major head injury involving contusion or laceration. Clinical symptoms develop over 24 to 48 hours. Signs and symptoms include changes in the level of consciousness (LOC), pupillary signs, and hemiparesis. There may be minor or even no symptoms with small collections of blood. Coma, increasing blood pressure, decreasing heart rate, and slowing respiratory rate are all signs of a rapidly expanding mass requiring immediate intervention.

Subacute subdural hematomas are the result of less severe contusions and head trauma. Clinical manifestations usually appear between 48 hours and 2 weeks after the injury. Signs and symptoms are similar to those of an acute subdural hematoma.

If the patient can be transported rapidly to the hospital, an immediate craniotomy is performed to open the dura, allowing the subdural clot to be evacuated. Successful outcome also depends on the control of ICP and careful monitoring of respiratory function (see “The Patient Undergoing Intracranial Surgery” in Chap. 61). The mortality rate for patients with acute and subacute subdural hematomas is high because of associated brain damage.

**Chronic Subdural Hematoma.** Chronic subdural hematomas can develop from seemingly minor head injuries and are seen most frequently in the elderly. The elderly are prone to this type of head injury secondary to brain atrophy, which is an expected consequence of the aging process. Seemingly minor head trauma may produce enough impact to shift the brain contents abnormally. The time between injury and onset of symptoms may be lengthy (eg, 3 weeks to months), so the actual insult may be forgotten.

A chronic subdural hematoma resembles other conditions and may be mistaken for a stroke. The bleeding is less profuse and there is compression of the intracranial contents. The blood within the brain changes in character in 2 to 4 days, becoming thicker and darker. In a few weeks, the clot breaks down and has the color and consistency of motor oil. Eventually, calcification or ossification of the clot takes place. The brain adapts to this foreign body invasion, and the clinical signs and symptoms fluctuate. There may be severe headache, which tends to come and go; alternating focal neurologic signs; personality changes; mental deterioration; and focal seizures. Unfortunately, the patient may be labeled neurotic or psychotic if the cause of the symptoms is overlooked.

The treatment of a chronic subdural hematoma consists of surgical evacuation of the clot. The procedure may be carried out through multiple burr holes, or a craniotomy may be performed for a sizable subdural mass that cannot be suctioned or drained through burr holes.

### INTRACEREBRAL HEMORRHAGE AND HEMATOMA

Intracerebral hemorrhage is bleeding into the substance of the brain. It is commonly seen in head injuries when force is exerted to the head over a small area (missile injuries or bullet wounds; stab injury). These hemorrhages within the brain may also result from systemic hypertension, which causes degeneration and rupture of a vessel; rupture of a saccular aneurysm; vascular anomalies; intracranial tumors; systemic causes, including bleeding disorders such as leukemia, hemophilia, aplastic anemia, and thrombocytopenia; and complications of anticoagulant therapy. Nontraumatic causes of intracerebral hemorrhage are discussed in Chapter 62.

The onset may be insidious, beginning with the development of neurologic deficits followed by headache. Management in-

cludes supportive care, control of ICP, and careful administration of fluids, electrolytes, and antihypertensive medications. Surgical intervention by craniotomy or craniectomy permits removal of the blood clot and control of hemorrhage but may not be possible because of the inaccessible location of the bleeding or the lack of a clearly circumscribed area of blood that can be removed.

### Management of Brain Injuries

Assessment and diagnosis of the extent of injury are accomplished by the initial physical and neurologic examinations. CT and MRI are the primary neuroimaging diagnostic tools and are useful in evaluating soft tissue injuries. Positron emission tomography (PET scan) is available in some trauma centers; this method of scanning examines brain function rather than structure. A flowchart developed by the Brain Trauma Foundation for the initial management of brain-injured patients is presented in Figure 63-4 (Brain Trauma Foundation, 2000).

Any individual with a head injury is presumed to have a cervical spine injury until proven otherwise. From the scene of the injury, the patient is transported on a board with the head and neck maintained in alignment with the axis of the body. A cervical collar should be applied and maintained until cervical spine x-rays have been obtained and the absence of cervical spinal cord injury documented.

All therapy is directed toward preserving brain homeostasis and preventing secondary brain injury. “Secondary injury” is a term used to describe injury to the brain subsequent to the original traumatic event (Bader & Palmer, 2000). Common causes of secondary injury are cerebral edema, hypotension, and respiratory depression that may lead to hypoxemia and electrolyte imbalance. Treatments to prevent this include stabilization of cardiovascular and respiratory function to maintain adequate cerebral perfusion, control of hemorrhage and hypovolemia, and maintenance of optimal blood gas values (Wong, 2000).

### TREATMENT OF INCREASED INTRACRANIAL PRESSURE

As the damaged brain swells with edema or as blood collects within the brain, a rise in ICP occurs; this requires aggressive treatment. See Chapter 61 for a discussion of the relationship of ICP to cerebral perfusion pressure (CPP). If the ICP remains elevated, it can decrease the CPP. Initial management is based on the principle of preventing secondary injury and maintaining adequate cerebral oxygenation (see Fig. 63-4).

Surgery is required for evacuation of blood clots, débridement and elevation of depressed fractures of the skull, and suture of severe scalp lacerations. ICP is monitored closely; if increased, it is managed by maintaining adequate oxygenation, elevating the head of the bed, and maintaining normal blood volume. Devices to monitor ICP or drain CSF can be inserted during surgery or at the bedside using aseptic technique. The patient is cared for in the intensive care unit, where expert nursing care and medical treatment are readily available.

### SUPPORTIVE MEASURES

Treatment also includes ventilatory support, seizure prevention, fluid and electrolyte maintenance, nutritional support, and pain and anxiety management. Comatose patients are intubated and mechanically ventilated to ensure adequate oxygenation and protect the airway.

Because seizures are common after head injury and can cause secondary brain damage from hypoxia, antiseizure agents may be administered. If the patient is very agitated, benzodiazepines may

be prescribed to calm him or her without decreasing LOC. These medications do not affect ICP or CPP, making them good choices for the head-injured patient.

A nasogastric tube may be inserted because reduced gastric motility and reverse peristalsis are associated with head injury, making regurgitation and aspiration common in the first few hours.

### **BRAIN DEATH**

When a patient has sustained a severe head injury incompatible with life, the nurse may assist in the clinical examination for

determination of brain death and in the process of organ procurement. Since 1981, all 50 states have recognized the Uniform Determination of Brain Death Act (Lovasik, 2000). This act states that death will be determined with accepted medical standards and that death will indicate irreversible loss of all brain function. The patient has no neurologic activity upon clinical examination; adjunctive tests such as EEG and cerebral blood flow (CBF) studies are often used to confirm brain death (Lovasik, 2000). Many of these patients are potential organ donors, and the nurse may provide information to the family

**FIGURE 63-4** Initial management of the severe head injury patient (treatment option). Copyright © 1998 Brain Trauma Foundation, Inc.

and assist them with this decision-making process about organ donation.

## NURSING PROCESS: THE PATIENT WITH A BRAIN INJURY

### Assessment

Depending on the patient's neurologic status, the nurse may elicit information from the patient, family, or witnesses or from emergency rescue personnel (Munro, 2000). Although it may not be possible to obtain all usual baseline data initially, the immediate health history should include the following questions:

- When did the injury occur?
- What caused the injury? A high-velocity missile? An object striking the head? A fall?
- What was the direction and force of the blow?

Since a history of unconsciousness or amnesia after a head injury indicates a significant degree of brain damage, and since changes that occur minutes to hours after the initial injury can reflect recovery or indicate the development of secondary brain damage, the nurse should try to determine if there was a loss of consciousness, what the duration of the unconscious period was, and if the patient could be aroused.

In addition to questions that establish the nature of the injury and the patient's condition immediately after the injury, the nurse should examine the patient thoroughly. This assessment should include determining the patient's LOC, ability to respond to verbal commands (if conscious), response to tactile stimuli (if unconscious), pupillary response to light, status of corneal and gag reflexes, motor function, and Glasgow Coma Scale score (Chart 63-4).

Additional detailed neurologic and systems assessments are made initially and at frequent intervals throughout the acute phase of care (Dibsie, 1998). The baseline and ongoing assessments are critical nursing interventions for the brain-injured pa-

Chart  
63-4

### Glasgow Coma Scale

The Glasgow Coma Scale is a tool for assessing a patient's response to stimuli. Scores range from 3 (deep coma) to 15 (normal).

Eye opening response	Spontaneous	4
	To voice	3
	To pain	2
	None	1
Best verbal response	Oriented	5
	Confused	4
	Inappropriate words	3
	Incomprehensible sounds	2

Best motor response	Obeys command	6
	Localizes pain	5
	Withdraws	4
	Flexion	3
	Extension	2
	None	1
Total		3 to 15

tient, whose condition can worsen dramatically and irrevocably if subtle signs are overlooked. More information on assessment is provided below and in Figure 63-5 and Table 63-1.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Ineffective airway clearance and impaired gas exchange related to brain injury
- Ineffective cerebral tissue perfusion related to increased ICP and decreased CPP
- Deficient fluid volume related to decreased LOC and hormonal dysfunction
- Imbalanced nutrition, less than body requirements, related to metabolic changes, fluid restriction, and inadequate intake
- Risk for injury (self-directed and directed at others) related to seizures, disorientation, restlessness, or brain damage
- Risk for imbalanced (increased) body temperature related to damaged temperature-regulating mechanism
- Potential for impaired skin integrity related to bed rest, hemiparesis, hemiplegia, and immobility
- Disturbed thought processes (deficits in intellectual function, communication, memory, information processing) related to brain injury
- Potential for disturbed sleep pattern related to brain injury and frequent neurologic checks
- Potential for compromised family coping related to unresponsiveness of patient, unpredictability of outcome, prolonged recovery period, and the patient's residual physical and emotional deficit
- Deficient knowledge about recovery and the rehabilitation process

The nursing diagnoses for the unconscious patient and the patient with increased ICP also apply (see Chap. 61).

### Chart 63-3 • Ethics and Related Issues

#### What If a Family Does Not Want Life Support Stopped?

##### Situation

A 16-year-old involved in a motor vehicle crash suffered a severe closed head injury. Extensive medical tests have determined conclusively that he is brain dead. He remains in the ICU on a mechanical ventilator with multiple medications to keep his heart beating. The patient's medical condition and ultimate physical death cannot be prevented by any medical interventions, yet the family refuses to discontinue any of the medical treatments, hoping for a "miracle."

##### Dilemma

The family's wish to continue care for their son conflicts with the medical reality of the patient's condition.

##### Discussion

What arguments could you make in favor of the family's position to continue life support? What arguments could you make in favor of withdrawal of life support?

**FIGURE 63-5** Assessment parameters for the patient with a head injury include (A) eye opening and responsiveness, (B) vital signs, and (C, D) motor response reflected in hand strength or response to painful stimulus. Photo © B. Proud.

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on all the assessment data, the major complications include the following:

- Decreased cerebral perfusion
- Cerebral edema and herniation
- Impaired oxygenation and ventilation
- Impaired fluid, electrolyte, and nutritional balance
- Risk of post-traumatic seizures

### Planning and Goals

The goals for the patient may include maintenance of a patent airway, adequate CPP, fluid and electrolyte balance, adequate nutritional status, prevention of secondary injury, maintenance of normal body temperature, maintenance of skin integrity, improvement of cognitive function, prevention of sleep deprivation, effective family coping, increased knowledge about the rehabilitation process, and absence of complications.

### Nursing Interventions

The nursing interventions for the patient with a head injury are extensive and diverse; they include making nursing assessments, setting priorities for nursing interventions, anticipating needs and complications, and initiating rehabilitation.

### MONITORING FOR DECLINING NEUROLOGIC FUNCTION

The importance of ongoing assessment and monitoring of the brain-injured patient cannot be overstated. The following parameters are assessed initially and as frequently as the patient's condition requires. As soon as the initial assessment is made, the use of a neurologic flow chart is started and maintained.

#### Level of Consciousness

The LOC is regularly assessed because changes in it precede all other changes in vital and neurologic signs. The Glasgow Coma Scale, which is used to assess LOC, is based on the three criteria of eye opening, verbal responses, and motor responses to verbal commands or painful stimuli. It is particularly useful for monitoring changes during the acute phase, the first few days after a head injury. It does not take the place of an in-depth neurologic assessment; rather, it is used to monitor the patient's motor, verbal, and eye-opening responses. The patient's best responses to predetermined stimuli are recorded (see Chart 63-4). Each response is scored (the greater the number the better the functioning), and the sum of these scores gives an indication of the severity of coma and a prediction of possible outcome. The lowest score is 3 (least responsive); the highest is 15 (most responsive). A score of 8 or less is generally accepted as indicating a severe head injury (Teasdale & Jennett, 1974).

**Table 63-1 • Summary of Multisystem Assessment Measures for the Brain-Injured Patient**

SYSTEM-SPECIFIC CONSIDERATIONS	ASSESSMENT DATA
<p><b>Neurologic System</b></p> <ul style="list-style-type: none"> <li>• Severe head injury will result in unconsciousness and will alter many neurologic functions.</li> <li>• All body functions must be supported.</li> <li>• Increased ICP and herniation syndromes are life-threatening</li> <li>• Measures are instituted to control elevated ICP.</li> </ul> <p><b>Integumentary System (Skin and Mucous Membranes)</b></p> <ul style="list-style-type: none"> <li>• Immobility secondary to injury and unconsciousness contributes to the development of pressure areas and skin breakdown.</li> <li>• Intubation causes irritation of the mucous membrane.</li> </ul> <p><b>Musculoskeletal System</b></p> <ul style="list-style-type: none"> <li>• Immobility contributes to musculoskeletal changes.</li> <li>• Decerebrate or decorticate posturing makes proper positioning difficult.</li> </ul> <p><b>Gastrointestinal System</b></p> <ul style="list-style-type: none"> <li>• Administration of corticosteroids places the patient at high risk for GI hemorrhage.</li> <li>• Injury to the GI tract can result in paralytic ileus.</li> <li>• Constipation can result from bed rest, NPO status, fluid restriction, and opioids given for pain control.</li> <li>• Bowel incontinence is related to the patient's unconscious state or altered mental state.</li> </ul> <p><b>Genitourinary System</b></p> <ul style="list-style-type: none"> <li>• Fluid restriction or use of diuretics can alter the amount of urinary output.</li> <li>• Urinary incontinence is related to the patient's unconscious state.</li> </ul> <p><b>Metabolic (Nutritional) System</b></p> <ul style="list-style-type: none"> <li>• The patient receives all fluids intravenously for the first few days until the GI tract is functioning.</li> <li>• A nutritional consultation is initiated within the first 24–48 h; ### Vital Signs

Although a change in LOC is the most sensitive neurologic indication of deterioration of the patient's condition, vital signs are monitored at frequent intervals also to assess the intracranial status. Table 63-1 depicts the general assessment parameters for the patient with a head injury.

Signs of increasing ICP include slowing of the heart rate (bradycardia), increasing systolic blood pressure, and widening pulse pressure. As brain compression increases, respirations become rapid, the blood pressure may decrease, and the pulse slows further. This is an ominous development, as is a rapid fluctuation of vital signs (March, 2000). A rapid rise in body temperature is regarded as unfavorable because hyperthermia increases the metabolic demands of the brain and may indicate brain stem damage, a poor prognostic sign. The temperature is maintained at less than 38°C (100.4°F). Tachycardia and arterial hypotension may indicate that bleeding is occurring elsewhere in the body.

### Motor Function

Motor function is assessed frequently by observing spontaneous movements, asking the patient to raise and lower the extremities, and comparing the strength and equality of the hand grasp and pedal push at periodic intervals. To assess the hand grasp, the nurse instructs the patient to squeeze the examiner's fingers tightly. The nurse assesses lower extremity motor strength (pedal push) by placing the hands on the soles of the patient's feet and asking the patient to push down against the examiner's hands. Motor assessment is discussed in Chapter 60 in more detail. The presence or absence of spontaneous movement of each extremity is also noted, and speech and eye signs are assessed.

If the patient does not demonstrate spontaneous movement, responses to painful stimuli are assessed. Motor response to pain is assessed by applying a central stimulus, such as pinching the pectoralis major muscle, to determine the patient's best response. Peripheral stimulation may provide inaccurate assessment data because it may result in a reflex movement rather than a voluntary motor response. Abnormal responses (lack of motor response; extension responses) are associated with a poorer prognosis.

### Other Neurologic Signs

In addition to the patient's spontaneous eye opening evaluated with the Glasgow Coma Scale, the size and equality of the pupils and their reaction to light are assessed. A unilaterally dilated and poorly responding pupil may indicate a developing hematoma, with subsequent pressure on the third cranial nerve due to shifting of the brain. If both pupils become fixed and dilated, this indicates overwhelming injury and intrinsic damage to the upper brain stem and is a poor prognostic sign.

The patient with a head injury may develop focal nerve palsies such as anosmia (lack of sense of smell) or eye movement abnormalities and focal neurologic deficits such as aphasia, memory deficits, and post-traumatic seizures or epilepsy. Patients may be left with residual organic psychological deficits (impulsiveness, emotional lability, or uninhibited, aggressive behaviors) and, as a consequence of the impairment, lack insight into their emotional responses (Davis, 2000).

### MAINTAINING THE AIRWAY

One of the most important nursing goals in the management of the patient with a head injury is to establish and maintain an adequate airway. The brain is extremely sensitive to hypoxia, and a

neurologic deficit can worsen if the patient is hypoxic. Therapy is directed toward maintaining optimal oxygenation to preserve cerebral function. An obstructed airway causes CO<sub>2</sub> retention and hypoventilation, which can produce cerebral vessel dilation and increased ICP.

Interventions to ensure an adequate exchange of air are discussed in Chapter 61 and include the following:

- Keep the unconscious patient in a position that facilitates drainage of oral secretions, with the head of the bed elevated about 30 degrees to decrease intracranial venous pressure (Bader & Palmer, 2000).
- Establish effective suctioning procedures (pulmonary secretions produce coughing and straining, which increase ICP).
- Guard against aspiration and respiratory insufficiency.
- Closely monitor arterial blood gas values to assess the adequacy of ventilation. The goal is to keep blood gas values within the normal range to ensure adequate cerebral blood flow.
- Monitor the patient who is receiving mechanical ventilation.
- Monitor for pulmonary complications such as acute respiratory distress syndrome (ARDS) and pneumonia (Munro, 2000).

### MONITORING FLUID AND ELECTROLYTE BALANCE

Brain damage can produce metabolic and hormonal dysfunctions. The monitoring of serum electrolyte levels is important, especially in patients receiving osmotic diuretics, those with inappropriate antidiuretic hormone secretion, and those with post-traumatic diabetes insipidus.

Serial studies of blood and urine electrolytes and osmolality are carried out because head injuries may be accompanied by disorders of sodium regulation. Hyponatremia is common following head injury due to shifts in extracellular fluid, electrolytes, and volume. Hyperglycemia, for example, may cause an increase in extracellular fluid that lowers sodium (Hickey, 2003). Hypernatremia may also occur due to sodium retention that may last several days, followed by sodium diuresis. Increasing lethargy, confusion, and seizures may be due to electrolyte imbalance.

Endocrine function is evaluated by monitoring serum electrolytes, blood glucose values, and intake and output. Urine is tested regularly for acetone. A record of daily weights is maintained, especially if the patient has hypothalamic involvement and is at risk for the development of diabetes insipidus.

### PROMOTING ADEQUATE NUTRITION

Head injury results in metabolic changes that increase calorie consumption and nitrogen excretion (Donaldson et al., 2000). There is an increased demand for protein. As soon as possible, nutrition should be provided. Early initiation of nutritional therapy has been shown to improve outcomes in head-injured patients (Bader & Palmer, 2000). Parenteral nutrition via a central line or enteral feedings administered via a nasogastric or nasojejunal feeding tube may be used. If there is discharge of CSF from the nose (CSF rhinorrhea), an oral feeding tube should be inserted in place of a nasal tube.

Laboratory values should be monitored closely in patients receiving parenteral nutrition. Elevating the head of the bed and aspirating the enteral tube for evidence of residual feeding before administering additional feedings can help prevent distention, regurgitation, and aspiration. A continuous-drip infusion or pump

may be used to regulate the feeding. The principles and technique of enteral feedings are discussed in Chapter 36. Enteral or parenteral feedings are usually continued until the swallowing reflex returns and the patient can meet caloric requirements orally.

### PREVENTING INJURY

As the patient emerges from coma, there is often a period of lethargy and stupor followed by a period of agitation. Each phase is variable and depends on the individual, the location of the injury, the depth and duration of coma, and the patient's age. The patient emerging from a coma may become increasingly agitated toward the end of the day. Restlessness may be due to hypoxia, fever, pain, or a full bladder. It may indicate injury to the brain but may also be a sign that the patient is regaining consciousness. (Some restlessness may be beneficial because the lungs and extremities are exercised.) Agitation may also be due to discomfort from catheters, intravenous lines, restraints, and repeated neurologic checks. Alternatives to restraints must be used whenever possible.

Strategies to prevent injury include the following:

- Assess the patient to ensure that oxygenation is adequate and the bladder is not distended. Check dressings and casts for constriction.
- To protect the patient from self-injury and dislodging of tubes, use padded side rails or wrap the patient's hands in mitts (Fig. 63-6). Restraints are avoided because straining against them can increase ICP or cause other injury. Enclosed or floor-level specialty beds may be indicated.
- Avoid using opioids as a means of controlling restlessness because these medications depress respiration, constrict the pupils, and alter responsiveness.
- Minimize environmental stimuli by keeping the room quiet, limiting visitors, speaking calmly, and providing frequent orientation information (eg, explaining where the patient is and what is being done).
- Provide adequate lighting to prevent visual hallucinations.
- Minimize disruption of the patient's sleep/wake cycles.
- Lubricate the skin with oil or emollient lotion to prevent irritation due to rubbing against the sheet.

**FIGURE 63-6** Hands of the patient with a head injury may be placed in a Posey mitt to prevent self-injury. This mitt has finger holes so that circulation can be assessed without removing the mitt. Photo courtesy of Sarah Trainer, RN, Roxborough Memorial Hospital, Philadelphia.

- If incontinence occurs, consider use of an external sheath catheter on a male patient. Because prolonged use of an indwelling catheter inevitably produces infection, the patient may be placed on an intermittent catheterization schedule.

### MAINTAINING BODY TEMPERATURE

An increase in body temperature in the head-injured patient can be the result of damage to the hypothalamus, cerebral irritation from hemorrhage, or infection. The nurse monitors the patient's temperature every 4 hours. If the temperature rises, efforts are undertaken to identify the cause and to control it using acetaminophen and cooling blankets as prescribed (Bader & Palmer, 2000). Cooling blankets should be used with caution so as not to induce shivering, which increases ICP. If infection is suspected, potential sites of infection are cultured and antibiotics are prescribed and administered.

### MAINTAINING SKIN INTEGRITY

Patients with traumatic head injury often require assistance in turning and positioning because of immobility or unconsciousness. Prolonged pressure on the tissues will decrease circulation and lead to tissue necrosis. Potential areas of breakdown need to be identified early to avoid the development of pressure ulcers. Specific nursing measures include the following:

- Assess all body surfaces and document skin integrity at least every 8 hours.
- Turn and reposition the patient every 2 hours.
- Provide skin care every 4 hours.
- Assist patient to get out of bed to a chair three times a day if physically able.

### IMPROVING COGNITIVE FUNCTIONING

Although many patients with head injury survive because of resuscitative and supportive technology, they frequently have significant cognitive sequelae that may not be detected during the acute phase of injury. Cognitive impairment includes memory deficits, decreased ability to focus and sustain attention to a task (distractibility), reduced ability to process information, and slowness in thinking, perceiving, communicating, reading, and writing. Psychiatric or emotional problems develop in as many as 44% of patients with head injury (van Reekum et al., 2000). Resulting psychosocial, behavioral, emotional, and cognitive impairments are devastating to the family as well as to the patient (Davis, 2000; Perlesz, Kinsella, & Crowe, 1999).

These problems require collaboration among many disciplines (Bader & Palmer, 2000). A neuropsychologist (specialist in evaluating and treating cognitive problems) plans a program and initiates therapy or counseling to help the patient reach maximal potential. Cognitive rehabilitation activities help the patient to devise new problem-solving strategies. The retraining is carried out over an extended period and may include the use of sensory stimulation and reinforcement, behavior modification, reality orientation, computer-training programs, and video games. Assistance from many disciplines is necessary during this phase of recovery. Even if intellectual ability does not improve, social and behavioral abilities may.

The patient recovering from a brain injury may experience fluctuations in the level of cognitive function, with orientation, attention, and memory frequently affected. When pushed to a level greater than the impaired cortical functioning allows, the patient

may show symptoms of fatigue, anger, and stress (headache, dizziness). The Rancho Los Amigos Level of Cognitive Function is a scale frequently used to assess cognitive function and evaluate ongoing recovery from head injury. Nursing management and a description of each level are included in Table 63-2.

### PREVENTING SLEEP PATTERN DISTURBANCE

Patients who require frequent monitoring of neurologic status may experience sleep deprivation. They are awakened hourly to assess LOC and as a result are deprived of long periods of sleep and rest. In an effort to allow the patient longer times of uninterrupted sleep and rest, the nurse can group nursing care activities so that the patient is disturbed less frequently. Environmental noise is decreased and the room lights are dimmed. Back rubs and other activities to increase comfort can assist in promoting sleep and rest.

### SUPPORTING FAMILY COPING

Having a loved one sustain a serious head injury can produce a great deal of prolonged stress in the family. This stress can result from the patient's physical and emotional deficits, the unpredictable outcome, and altered family relationships. Families report difficulties in coping with changes in the patient's temperament, behavior, and personality. Such changes are associated with disruption in family cohesion, loss of leisure pursuits, and loss of work capacity, as well as social isolation of the caretaker. The family may experience anger, grief, guilt, and denial in recurring cycles (Perlesz et al., 1999).

To promote effective coping, the nurse can ask the family how the patient is different at this time: What has been lost? What is most difficult about coping with this situation? Helpful interventions include providing family members with accurate and honest information and encouraging them to continue to set well-defined, mutual, short-term goals. Family counseling helps address the family members' overwhelming feelings of loss and helplessness and gives them guidance for the management of inappropriate behaviors. Support groups help the family members share problems, develop insight, gain information, network, and gain assistance in maintaining realistic expectations and hope.

The National Head Injury Foundation serves as a clearinghouse for information and resources for patients with head injuries and their families, including specific information on coma, rehabilitation, behavioral consequences of head injury, and family issues. This organization can provide names of facilities and professionals who work with patients with head injuries and can assist families in organizing local support groups. See the end of this chapter for more information on resources.

Many patients with severe head injury die of their injuries, and many of those who survive experience long-term problems that prevent them from resuming their previous roles and functions. During the most acute phase of injury, family members need support and facts from the health care team.

Many individuals with severe head injuries that result in brain death are young and otherwise healthy and are therefore considered for organ donation. Family members of patients with such injuries need support during this extremely stressful time and assistance in making decisions to end life support and permit donation of organs. They need to know that the brain-dead patient whose respiratory and cardiovascular systems are maintained through life support is not going to survive and that the severe head injury, not the removal of the patient's organs or the removal of life support, is the cause of patient's death. Bereavement counselors and members of the organ procurement team are

often very helpful to family members in making decisions about organ donation and in helping them cope with stress.

## MONITORING AND MANAGING POTENTIAL COMPLICATIONS

### Decreased Cerebral Perfusion

Maintenance of adequate CPP is important to prevent serious complications of head injury due to decreased cerebral perfusion (Bader & Palmer, 2000; March, 2000). Adequate CPP is greater than 70 mm Hg. Any decrease in this pressure can impair cerebral perfusion and cause brain hypoxia and ischemia, leading to permanent damage. Therapy (eg, elevation of the head of the bed and increased intravenous fluids) is directed toward decreasing cerebral edema and increasing venous outflow from the brain. Systemic hypotension, which causes vasoconstriction and a significant decrease in CPP, is treated with increased intravenous fluids.

### Cerebral Edema and Herniation

The patient with a head injury is at risk for additional complications such as increased ICP and brain stem herniation. Cerebral edema is the most common cause of increased ICP in the patient with a head injury, with the swelling peaking approximately 48 to 72 hours after injury. Bleeding also may increase the volume of contents within the rigid closed compartment of the skull, causing increased ICP and herniation of the brain stem and resulting in irreversible brain anoxia and brain death. Measures to control ICP are listed in Chart 63-5 (Zafonte et al., 1999) and discussed in Chapter 61.

### Impaired Oxygenation and Ventilation

Impaired oxygen and ventilation may necessitate mechanical ventilatory support. The patient must be monitored for a patent airway, altered breathing patterns, and hypoxemia and pneumonia. Interventions may include endotracheal intubation, mechanical ventilation, and positive end-expiratory pressure. These topics are discussed in further detail in Chapters 25 and 61.

### Impaired Fluid, Electrolyte, and Nutritional Balance

Fluid, electrolyte, and nutritional imbalances are common in the patient with a head injury. Common imbalances may include hyponatremia, which is often associated with the syndrome of inappropriate secretion of antidiuretic hormone (see Chaps. 14 and 42), hypokalemia, and hyperglycemia (Hickey, 2003). Modifications in fluid intake with tube feedings or intravenous fluids may be necessary to treat these imbalances. Insulin administration may be prescribed to treat hyperglycemia.

Undernutrition is also a common problem in response to the increased metabolic needs associated with severe head injury. If the patient cannot eat, enteral feedings or parenteral nutrition may be initiated within 24 hours of injury to provide adequate calories and nutrients.

### Post-traumatic Seizures

Patients with head injury are at an increased risk for post-traumatic seizures. Post-traumatic seizures are classified as immediate (within 24 hours of injury), early (within 1 to 7 days of injury), or late (more than 7 days following injury) (Kado & Patel, 1999). Seizure prophylaxis refers to the practice of administering antiseizure medications to patients following head injury to prevent seizures. It is important to prevent post-traumatic seizures,

**Table 63-2 • Rancho Los Amigos Scale: Levels of Cognitive Function**

COGNITIVE LEVEL	DESCRIPTION	NURSING MANAGEMENT
<b>For levels I–III, the key approach is to provide stimulation.</b>		
I: No response	Completely unresponsive to all stimuli, including painful stimuli	Multiple modalities of sensory input should be used. Examples are listed below, but should be individualized and expanded based on available materials and patient preferences (determined by obtaining information from the family). <i>Olfactory:</i> perfumes, flowers, shaving lotion <i>Visual:</i> family pictures, card, personal items
II: Generalized response	Nonpurposeful response; responds to pain, but in a nonpurposeful manner	<i>Auditory:</i> radio, television, tapes of family voices or favorite recordings, talking to patient (nurse, family members). The nurse should tell patient what is going to be done, discuss the environment, provide encouragement.
III: Localized response	Responses more focused: withdraws to pain; turns toward sound; follows moving objects that pass within visual field; pulls on sources of discomfort (eg, tubes, restraints); may follow simple commands but inconsistently and in a delayed manner	<i>Tactile:</i> touching of skin, rubbing various textures on skin <i>Movement:</i> range of motion exercises, turning, repositioning, use of water mattress
<b>For levels IV–VI, the key approach is to provide structure.</b>		
IV: Confused, agitated response	Alert, hyperactive state in which patient responds to internal confusion/agitation; behavior nonpurposeful in relation to the environment; aggressive, bizarre behavior common	For level IV, which lasts 2–4 weeks, interventions are directed at decreasing agitation, increasing environmental awareness, and promoting safety. <ul style="list-style-type: none"> <li>• Approach patient in a calm manner, and use a soft voice.</li> <li>• Screen patient from environmental stimuli (eg, sounds, sights); provide a quiet, controlled environment.</li> <li>• Remove devices that contribute to agitation (eg, tubes), if possible.</li> <li>• Functional goals cannot be set, because the patient is unable to cooperate.</li> </ul>
V: Confused, inappropriate response	When agitation occurs, it is the result of external rather than internal stimuli; focused attention is difficult; memory is severely impaired; responses are fragmented and inappropriate to the situation; there is no carryover of learning from one situation to the other.	For levels V and VI, interventions are directed at decreasing confusion, improving cognitive function, and improving independence in performing ADLs. <ul style="list-style-type: none"> <li>• Provide supervision.</li> <li>• Use repetition and cues to teach ADLs. Focus the patient's attention and help to increase his or her concentration.</li> </ul>
VI: Confused, appropriate response	Follows simple directions consistently but is inconsistently oriented to time and place; short-term memory worse than long-term memory; can perform some ADLs	<ul style="list-style-type: none"> <li>• Help the patient organize activity.</li> <li>• Clarify misinformation and reorient when confused.</li> <li>• Provide a consistent, predictable schedule (eg, post daily schedule on large poster board).</li> </ul>
<b>For levels VII–X, the key approach is integration into the community.</b>		
VII: Automatic, appropriate response	Appropriately responsive and oriented within the hospital setting; needs little supervision in ADLs; some carryover of learning; patient has superficial insight into disabilities; has decreased judgment and problem-solving abilities; lacks realistic planning for future	For levels VII–X, interventions are directed at increasing the patient's ability to function with minimal or no supervision in the community. <ul style="list-style-type: none"> <li>• Reduce environmental structure.</li> <li>• Help the patient plan for adapting ADLs for self into the home environment.</li> <li>• Discuss and adapt home living skills (eg, cleaning, cooking) to patient's ability.</li> </ul>
VIII: Purposeful, appropriate	Alert, oriented, intact memory; has realistic goals for the future. Able to complete familiar tasks for 1 hour in a distracting environment; overestimates or underestimates abilities, argumentative, easily frustrated, self-centered. Uncharacteristically dependent/independent.	<ul style="list-style-type: none"> <li>• Provide stand-by assistance as needed for ADLs and home living skills.</li> </ul>

(continued)

Table 63-2 • Rancho Los Amigos Scale: Levels of Cognitive Function (Continued)

COGNITIVE LEVEL	DESCRIPTION	NURSING MANAGEMENT
IX: Purposeful, appropriate	Independently shifts back and forth between tasks and completes them accurately for at least two consecutive hours. Uses assistive memory devices to recall schedule and activities. Aware of and acknowledges impairments and disabilities when they interfere with task completion. Depression may continue. May be easily irritable and have a low frustration tolerance.	<ul style="list-style-type: none"> <li>• Provide assistance on request for adapting ADLs and home living skills.</li> </ul>
X: Purposeful, appropriate	Able to handle multiple tasks simultaneously in all environments but may require periodic breaks. Independently initiates and carries out familiar and unfamiliar tasks but may require more than usual amount of time and/or compensatory strategies to complete them. Accurately estimates abilities and independently adjusts to task demands. Periodic periods of depression may occur. Irritability and low frustration tolerance when sick, fatigued and/or under stress.	<ul style="list-style-type: none"> <li>• Monitor for signs and symptoms of depression.</li> <li>• Help the patient plan, anticipate concerns, and solve problems.</li> </ul>

especially in the immediate and early phase of recovery, as seizures may increase ICP and decrease oxygenation. Many antiseizure medications impair cognitive performance, prolonging the duration of rehabilitation. Therefore, it is important to weigh the overall benefit of these medications against their side effects. Currently, there is no conclusive evidence that long-term anti-

seizure prophylaxis improves outcomes in patients with head injury. Research evidence supports the use of prophylactic antiseizure agents to prevent immediate and early seizure after head injury, but not for prevention of late seizures (Brain Trauma Foundation, American Association of Neurological Surgeons, Joint Section on Neurotrauma and Critical Care, 2000).

### NURSING RESEARCH PROFILE 63-1

#### *The Experience of Hope for the Relatives of Head-Injured Patients*

Gelling, L. (1999). The experience of hope for the relatives of head-injured patients admitted to a neuroscience critical care unit: A phenomenological study. *Nursing in Critical Care*, 4(5), 214–221.

#### Background

Helping the family members of patients with their emotional needs is a crucial aspect of ICU care. Previous research has demonstrated that meeting needs can be beneficial to both families and patients. One of the most important needs families have identified is to maintain hope. The purpose of this study was to develop a better understanding of what hope means to family members in order to help nurses better meet their needs.

#### Study Methods and Design

Participants were selected by approaching family members of consecutive patients admitted to a neuroscience ICU. Family members were approached after the patient had been in the ICU at least 48 hours. A total of seven patients had family members who agreed to participate. In this phenomenologic study family members were interviewed about their experiences using a semi-structured format. The interviews were transcribed and returned to the informants for verification of content. Data were analyzed for emergent themes. A summary of the findings was returned to the participants for verification.

#### Results

Seven themes emerged from analysis of the interview data. The themes that relatives felt most influenced their experience of hope when they had a loved one admitted to the ICU were: 1) Relationships—The positive relationships between the family members and

nurses helped the family members to feel comfortable and safe with the care their loved ones were receiving; 2) Information—Inadequate or poorly delivered information led to uncertainty and difficulty in maintaining hope; 3) The Past—Lack of knowledge and initial negative experiences in the hospital made hope more difficult; 4) The Present—Unfamiliar terminology, devices, and situations needed to be assimilated by the family before they could become hopeful; 5) The future—Goal setting helped the family members have hope for a future for the patient; 6) Loss of control—Relatives felt that though they were asked by the nurses to participate in decisions, they often felt ill equipped to do so, leading to feelings of hopelessness; 7) Emotions—Family members were often so fearful for the patient that it was difficult to have hope.

#### Nursing Implications

Meeting the needs of families is a key part of nursing care of the patients in a neuroscience unit and furthermore an important component of a holistic nursing approach. Nurses need to be acutely aware of the pivotal role they play in helping the family members to cope and maintain hope in a difficult situation. Nurses should encourage supportive relationships with the families, and maintain an open and honest dialogue. Families need accurate, current information on a level they can understand and assimilate. Nurses need to be cognizant that their care is crucial not just for the patient, but for the entire family.

Chart  
63-5**Controlling ICP in Severely Brain-Injured Patients**

- Elevate the head of bed 30 degrees.
- Maintain the patient's head and neck in neutral alignment (no twisting).
- Initiate measures to prevent the Valsalva maneuver (eg, stool softeners).
- Maintain normal body temperature.
- Administer O<sub>2</sub> to maintain PaO<sub>2</sub> > 90 mm Hg.
- Maintain fluid balance with normal saline solution.
- Avoid noxious stimuli (eg, excessive suctioning, painful procedures).
- Administer sedation to reduce agitation.
- Maintain cerebral perfusion pressure > 70 mm Hg.

Nurses must assess patients carefully for the development of post-traumatic seizures. Risk factors that increase the likelihood of seizures are brain contusion with subdural hematoma, skull fracture, loss of consciousness or amnesia of 1 day or more, and age over 65 years (Annegers & Coan, 2000). The nursing management of seizures is addressed in Chapter 61.

Other complications after traumatic head injury include systemic infections (pneumonia, urinary tract infection [UTI], septicemia), neurosurgical infections (wound infection, osteomyelitis, meningitis, ventriculitis, brain abscess), and heterotrophic ossification (painful bone overgrowth in weight-bearing joints).

**PROMOTING HOME AND COMMUNITY-BASED CARE****Teaching Patients Self-Care**

Teaching early in the course of head injury often focuses on reinforcing information given to the family about the patient's condition and prognosis. As the patient's status and expected outcome change over time, family teaching may focus on interpretation and explanation of changes in the patient's physical and psychological responses.

If the patient's physical status allows him or her to be discharged home, the patient and family are instructed about limitations that can be expected and complications that may occur. Monitoring for complications that merit contacting the neurosurgeon is explained to the patient and family verbally and in

writing. Depending on the patient's prognosis and physical and cognitive status, the patient may be included in teaching about self-care management strategies.

Because of the risk for post-traumatic seizures, antiseizure medications may be prescribed for 1 to 2 years after injury. The patient and family require instruction about the side effects of these medications and about the importance of continuing to take them as prescribed.

**Continuing Care**

Rehabilitation of the patient with a head injury begins at the time of injury and extends into the home and community. Depending on the degree of brain damage, the patient may be referred to a rehabilitation setting that specializes in cognitive restructuring of the brain-injured patient. The patient is encouraged to continue the rehabilitation program after discharge because improvement in status may continue 3 or more years after injury. Changes in the head-injured patient and the effects of long-term rehabilitation on the family and their coping abilities need frequent assessment. Teaching and continued support of the patient and family are essential as their needs and the patient's status change. Teaching points to address with the family of the head-injured patient who is about to return home are described in Chart 63-6.

Depending on his or her status, the patient is encouraged to return to normal activities gradually. Referral to support groups and the National Head Injury Foundation may be warranted.

During the acute and rehabilitation phase of care, the focus of teaching is on obvious needs, issues, and deficits. The nurse needs to remind patients and family members of the need for continuing health promotion and screening practices following these initial phases. Patients who have not been involved in these practices in the past are educated about their importance and are referred to appropriate health care providers.

**Evaluation****EXPECTED PATIENT OUTCOMES**

Expected patient outcomes may include:

1. Attains or maintains effective airway clearance, ventilation, and brain oxygenation
  - a. Achieves normal blood gas values and has normal breath sounds on auscultation
  - b. Mobilizes and clears secretions

Chart 63-6

**Home Care Checklist • The Patient With a Head Injury**

*At the completion of the home care instruction, the patient or caregiver will be able to:*

	Patient	Caregiver
• Explain the need for monitoring for changes in neurologic status and for complications	✓	✓
• Identify changes in neurologic status and signs and symptoms of complications that should be reported to the neurosurgeon or nurse		✓
• Demonstrate safe techniques to assist patient with self-care, hygiene, and ambulation		✓
• Demonstrate safe technique for eating, feeding patient, or assisting patient with eating	✓	✓
• Explain rationale for taking medications as prescribed	✓	✓
• Identify need for close monitoring of behavior due to changes in cognitive functioning		✓
• Describe household modifications needed to ensure safe environment for the patient		✓
• Describe strategies for reinforcing positive behaviors		✓
• State importance of continuing follow-up by health care team	✓	✓

2. Achieves satisfactory fluid and electrolyte balance
  - a. Demonstrates serum electrolytes within normal range
  - b. Has no clinical signs of dehydration or overhydration
3. Attains adequate nutritional status
  - a. Has less than 50 mL of aspirate in stomach before each tube feeding
  - b. Is free of gastric distention and vomiting
  - c. Shows minimal weight loss
4. Avoids injury
  - a. Shows lessening agitation and restlessness
  - b. Is oriented to time, place, and person
5. Does not have a fever
6. Demonstrates intact skin integrity
  - a. Exhibits no redness or breaks in skin integrity
  - b. Exhibits no pressure ulcers
7. Shows improvement in cognitive function and improved memory
8. Demonstrates normal sleep/wake cycle
9. Demonstrates absence of complications
  - a. Exhibits normal ICP, normal vital signs and body temperature, and increasing orientation to time, place, and person
  - b. Demonstrates reduced ICP
10. Patient experiences no post-traumatic seizures
  - a. Takes antiseizure medications as prescribed
  - b. Identifies side effects/adverse effects of antiseizure medications
11. Demonstrate adaptive coping mechanisms for family members
  - a. Join support group
  - b. Share feelings with appropriate health care personnel
  - c. Make end-of-life decisions, if needed
12. Participate in rehabilitation process as indicated for patient and family members
  - a. Take active role in identifying rehabilitation goals and participating in recommended patient care activities
  - b. Prepare for discharge of patient

## Spinal Cord Injury

**Spinal cord injury (SCI)** is a major health problem. Nearly 200,000 people in the United States live each day with a disability from SCI, with an estimated 11,000 new injuries occurring each year. SCI occurs almost four times more often in males than females. Young people aged 16 to 30 suffer more than half of the new SCIs each year. African Americans are at a higher risk than Caucasians, with the incidence rising in recent years. The most common cause of SCI is motor vehicle crashes, which account for 35% of the injuries. Violence-related injuries account for nearly as many SCIs (30%), with falls causing 19% and sports-related injuries causing 8% (CDC, 2001). There is a high frequency of associated injuries and medical complications.

The predominant risk factors for SCI include age, gender, and alcohol and drug use. The frequency with which these risk factors are associated with SCI serves to emphasize the importance of primary prevention. The same interventions suggested earlier in this chapter for head injury prevention will serve to decrease the incidence of SCI as well (see Chart 63-1) (CDC, 2001; Elovic & Kirschblum, 1999).

The vertebrae most frequently involved in SCI are the 5th, 6th, and 7th cervical (neck), the 12th thoracic, and the 1st lumbar vertebrae. These vertebrae are the most susceptible because

there is a greater range of mobility in the vertebral column in these areas (Dibsie, 1998).

## Pathophysiology

Damage to the spinal cord ranges from transient concussion (from which the patient fully recovers) to contusion, laceration, and compression of the cord substance (either alone or in combination), to complete **transection** of the cord (which renders the patient paralyzed below the level of the injury).

SCIs can be separated into two categories: primary injuries and secondary injuries (Porth, 2002). Primary injuries are the result of the initial insult or trauma and are usually permanent. Secondary injuries are usually the result of a contusion or tear injury, in which the nerve fibers begin to swell and disintegrate. A secondary chain of events produces ischemia, hypoxia, edema, and hemorrhagic lesions, which in turn result in destruction of myelin and axons (Hickey, 2003). These secondary reactions, believed to be the principal causes of spinal cord degeneration at the level of injury, are now thought to be reversible 4 to 6 hours after injury. Therefore, if the cord has not suffered irreparable damage, some method of early treatment is needed to prevent partial damage from developing into total and permanent damage (see the section on management) (Zafonte et al., 1999).

## Clinical Manifestations

Manifestations depend on the type and level of injury (Chart 63-7). The type of injury refers to the extent of injury to the spinal cord itself. **Incomplete spinal cord lesions** are classified according to the area of spinal cord damage: central, lateral, anterior, or peripheral. The American Spinal Injury Association (ASIA) provides another standard classification of SCI according to the degree of sensory and motor function present after injury (Chart 63-8). “Neurologic level” refers to the lowest level at which sensory and motor functions are normal. Below the neurologic level, there is total sensory and motor paralysis, loss of bladder and bowel control (usually with urinary retention and bladder distention), loss of sweating and vasomotor tone, and marked reduction of blood pressure from loss of peripheral vascular resistance. A **complete spinal cord lesion** can result in **paraplegia** (paralysis of the lower body) or **quadriplegia** (paralysis of all four extremities).

If conscious, the patient usually complains of acute pain in the back or neck, which may radiate along the involved nerve. Absence of pain, however, does not rule out spinal injury, and a careful assessment of the spine should be done in the face of any significant mechanism of injury. Often the patient speaks of fear that the neck or back is broken.

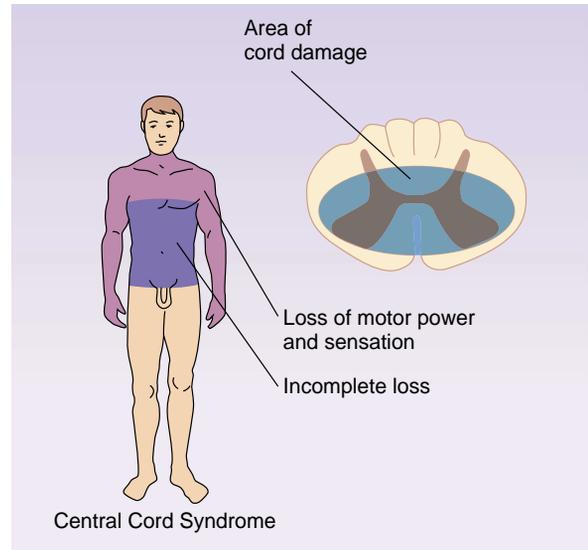

Respiratory dysfunction is related to the level of injury. The muscles contributing to respiration are the abdominals and intercostals (T1 to T11) and the diaphragm. In high cervical cord injury, acute respiratory failure is the leading cause of death.

## Assessment and Diagnostic Findings

A detailed neurologic examination is performed. Diagnostic x-rays (lateral cervical spine x-rays) and CT scanning are usually performed initially. An MRI scan may be ordered as a further work-up if a ligamentous injury is suspected, since significant spinal cord damage may exist even in the absence of bony injury. A search is made for other injuries, because spinal trauma often is accompanied by concomitant injuries, commonly to the head

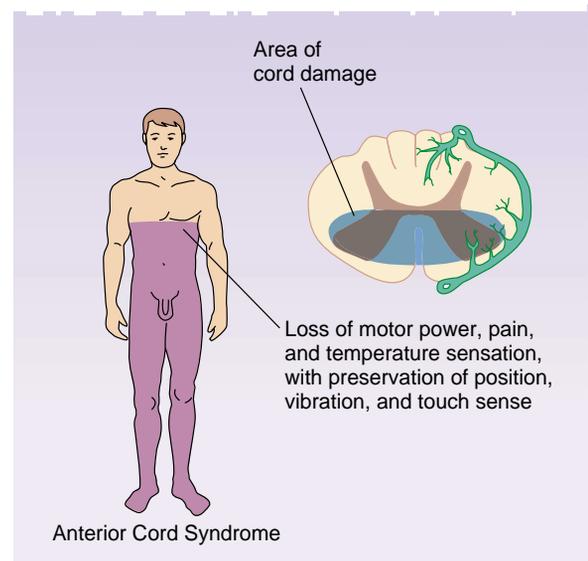

**Central Cord Syndrome**

- Characteristics: Motor deficits (in the upper extremities compared to the lower extremities; sensory loss varies but is more pronounced in the upper extremities); bowel/bladder dysfunction is variable, or function may be completely preserved.
- Cause: Injury or edema of the central cord, usually of the cervical area.

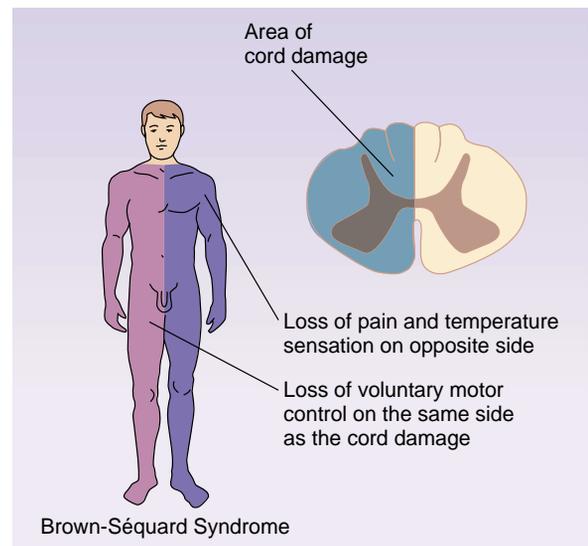

**Anterior Cord Syndrome**

- Characteristics: Loss of pain, temperature, and motor function is noted below the level of the lesion; light touch, position, and vibration sensation remain intact.
- Cause: The syndrome may be caused by acute disk herniation or hyperflexion injuries associated with fracture-dislocation of vertebra. It also may occur as a result of injury to the anterior spinal artery, which supplies the anterior two thirds of the spinal cord.

**Brown-Sequard Syndrome (Lateral Cord Syndrome)**

- Characteristics: Ipsilateral paralysis or paresis is noted, together with ipsilateral loss of touch, pressure, and vibration and contralateral loss of pain and temperature.
- Cause: The lesion is caused by a transverse hemisection of the cord (half of the cord is transected from north to south), usually as a result of a knife or missile injury, fracture-dislocation of a unilateral articular process, or possibly an acute ruptured disk.

Chart  
63-8

## ASIA Impairment Scale

- A = Complete:** No motor or sensory function is preserved in the sacral segments S4-S5.
- B = Incomplete:** Sensory but not motor function is preserved below the neurologic level, and includes the sacral segments S4-S5.
- C = Incomplete:** Motor function is preserved below the neurologic level, and more than half of key muscles below the neurologic level have a muscle grade less than 3.
- D = Incomplete:** Motor function is preserved below the neurologic level, and at least half of key muscles below the neurologic level have a muscle grade of 3 or greater.
- E = Normal:** Motor and sensory function are normal.

and chest. Continuous electrocardiographic monitoring may be indicated if a cord injury is suspected since bradycardia (slow heart rate) and asystole (cardiac standstill) are common in acute spinal injuries.

## Emergency Management

The immediate management of the patient at the scene of the injury is critical, because improper handling can cause further damage and loss of neurologic function. Any patient involved in a motor vehicle or diving injury, a contact sports injury, a fall, or any direct trauma to the head and neck must be considered to have SCI until such an injury is ruled out. Initial care must include a rapid assessment, immobilization, extrication, stabilization or control of life-threatening injuries, and transportation to the most appropriate medical facility.

At the scene of the injury, the patient must be immobilized on a spinal (back) board, with head and neck in a neutral position, to prevent an incomplete injury from becoming complete. One member of the team must assume control of the patient's head to prevent flexion, rotation, or extension; this is done by placing the hands on both sides of the patient's head at about the ear to limit movement and maintain alignment while a spinal board or cervical immobilizing device is applied. If possible, at least four people should slide the victim carefully onto a board for transfer to the hospital. Any twisting movement may irreversibly damage the spinal cord by causing a bony fragment of the vertebra to cut into, crush, or sever the cord completely.

The patient must be referred to a regional spinal injury or trauma center because of the multidisciplinary personnel and support services required to counteract the destructive changes that occur in the first few hours after injury. During treatment in the emergency and x-ray departments, the patient is kept on the transfer board. The patient must always be maintained in an extended position. No part of the body should be twisted or turned, nor should the patient be allowed to sit up. Once the extent of the injury has been determined, the patient may be placed on a rotating bed (Fig. 63-7) or in a cervical collar (Fig. 63-8). Later, if SCI and bone instability have been ruled out, the patient can be moved to a conventional bed or the collar removed without harm. If a rotating bed is needed but not available, the patient should be placed in a cervical collar and on a firm mattress with a bedboard under it.

## Management of Spinal Cord Injuries (Acute Phase)

The goals of management are to prevent further SCI and to observe for symptoms of progressive neurologic deficits. The patient is resuscitated as necessary, and oxygenation and cardiovascular stability are maintained. Many changes in the treatment of SCI have occurred during the past 20 years. Treatments such as hypothermia, corticosteroids, and naloxone were investigated and used during the 1980s; of these, high-dose corticosteroids have shown the most promise, but their use remains controversial (Short et al., 2000). Currently, regeneration therapy is being investigated; this involves transplanting fetal tissue into the injured spinal cord in hopes of regenerating the damaged tissue (Vacanti et al., 2001). SCI continues to be a devastating event, and new treatment methods are continually being investigated.

### PHARMACOLOGIC THERAPY

In some studies, the administration of high-dose corticosteroids, specifically methylprednisolone, has been found to improve motor and sensory outcomes at 6 weeks, 6 months, and 1 year if given within 8 hours of injury (Hickey, 2003). In other studies, little improvement was found (Short et al., 2000). Use of high-dose methylprednisolone, a corticosteroid, is accepted as standard therapy in many countries and remains an established clinical practice in most institutions in the United States (Bracken, 2000; Hickey, 2003).

### RESPIRATORY THERAPY

Oxygen is administered to maintain a high arterial PO<sub>2</sub> because hypoxemia can create or worsen a neurologic deficit of the spinal cord. If endotracheal intubation is necessary, extreme care is taken to avoid flexing or extending the patient's neck, which can result in an extension of a cervical injury.

In high cervical spine injuries, spinal cord innervation to the phrenic nerve, which stimulates the diaphragm, is lost. Di-

**FIGURE 63-7** Roto Rest® bed. Courtesy of Kinetic Concepts, San Antonio, TX.

**FIGURE 63-8** Cervical collar. Courtesy of Aspen Medical Products.

aphragmatic pacing (electrical stimulation of the phrenic nerve) attempts to stimulate the diaphragm to help the patient breathe. Diaphragmatic pacing may be considered for the patient with a high cervical lesion but is usually carried out after the acute phase.

### SKELETAL FRACTURE REDUCTION AND TRACTION

Management of SCI requires immobilization and reduction of dislocations (restoration of normal position) and stabilization of the vertebral column.

Cervical fractures are reduced and the cervical spine is aligned with some form of skeletal traction, such as skeletal tongs or calipers, or with use of the halo device. Early surgical stabilization has reduced the need for cervical traction in many patients with cervical spine injuries (Gaebler et al., 1999). A variety of skeletal tongs are available, all of which involve fixation in the skull in some manner (Fig. 63-9). The Gardner-Wells tongs require no predrilled holes in the skull. Crutchfield and Vinke tongs are inserted through holes made in the skull with a special drill under local anesthesia.

Traction is applied to the tongs by weights, the amount depending on the size of the patient and the degree of fracture dis-

placement. The traction force is exerted along the longitudinal axis of the vertebral bodies, with the patient's neck in a neutral position. The traction is then gradually increased by adding more weights. As the amount of traction is increased, the spaces between the intervertebral disks widen and the vertebrae may slip back into position. Reduction usually takes place after correct alignment has been restored. Once reduction is achieved, as verified by cervical spine x-rays and neurologic examination, the weights are gradually removed until the amount of weight needed to maintain the alignment is identified. The weights should hang freely so as not to interfere with the traction. Traction is sometimes supplemented with manual manipulation of the neck by a surgeon to help achieve realignment of the vertebral bodies.

A halo device may be used initially with traction or may be applied after removal of the tongs. It consists of a stainless-steel halo ring that is fixed to the skull by four pins. The ring is attached to a removable **halo vest**, which suspends the weight of the unit circumferentially around the chest. A metal frame connects the ring to the chest. Halo devices provide immobilization of the cervical spine while allowing early ambulation (Fig. 63-10).

Thoracic and lumbar injuries are usually treated with surgical intervention followed by immobilization with a fitted brace. Traction is not indicated either before or after surgery.

### Surgical Management

Surgery is indicated in any of the following instances:

- Compression of the cord is evident.
- The injury results in a fragmented or unstable vertebral body.
- The injury involves a wound that penetrates the cord.
- There are bony fragments in the spinal canal.
- The patient's neurologic status is deteriorating.

Surgery is performed to reduce the spinal fracture or dislocation or to decompress the cord. A laminectomy (excision of the posterior arches and spinous processes of a vertebra) may be indicated in the presence of progressive neurologic deficit, suspected epidural hematoma, bony fragments, or penetrating injuries that require surgical débridement, or to permit direct visualization and exploration of the cord. Vertebral bodies may also be surgically fused to create a stable spinal column.

### Management of Complications of Spinal Cord Injury

#### SPINAL AND NEUROGENIC SHOCK

The spinal shock associated with SCI represents a sudden depression of reflex activity in the spinal cord (areflexia) below the level of injury. The muscles innervated by the part of the spinal cord segment below the level of the lesion are without sensation, paralyzed, and flaccid, and the reflexes are absent. In particular, the reflexes that initiate bladder and bowel function are affected. Bowel distention and paralytic ileus can be caused by depression of the reflexes and are treated with intestinal decompression by insertion of a nasogastric tube (Hickey, 2003).

Neurogenic shock develops due to the loss of autonomic nervous system function below the level of the lesion (Hickey, 2003). The vital organs are affected, causing the blood pressure and heart rate to fall. This loss of sympathetic innervation causes a variety

**FIGURE 63-9** Traction for cervical fractures may be applied with tongs.

A

B

**FIGURE 63-10** Halo systems for cervical and thoracic vertebral injuries. (A) Halo cervical skeletal traction. Courtesy of Acromed Corp., Cleveland, OH. (B) Halo and vest. Courtesy of Bremer Medical, Inc., Darwin Road, Jacksonville, FL.

of other clinical manifestations, including a decrease in cardiac output, venous pooling in the extremities, and peripheral vasodilation. In addition, the patient does not perspire on the paralyzed portions of the body because sympathetic activity is blocked; therefore, close observation is required for early detection of an abrupt onset of fever. (A discussion of neurogenic shock can be found in Chap. 15.)

**NURSING ALERT** The patient's vital organ functions and body defenses must be supported and maintained until spinal and neurogenic shock abates and the neurologic system has recovered from the traumatic insult; that can take up to 4 months (Hickey, 2003).

With injuries to the cervical and upper thoracic spinal cord, innervation to the major accessory muscles of respiration is lost and respiratory problems develop. These include decreased vital capacity, retention of secretions, increased PaCO<sub>2</sub> levels and decreased oxygen levels, respiratory failure, and pulmonary edema.

**NURSING ALERT** Special attention also must be directed to the respiratory system. The patient may be unable to generate sufficient intrathoracic pressure to cough effectively. Chest physical therapy and suctioning may assist in clearance of pulmonary secretions.

### DEEP VEIN THROMBOSIS

Deep vein thrombosis (DVT) is a potential complication of immobility and is common in patients with SCI. Patients who develop DVT are at risk for pulmonary embolism (PE), a life-threatening complication. One estimate from a meta-analysis of recent studies of the incidence of DVT and PE in SCI patients put the rate at 6.3% for PE and 17.4% for DVT (Velmahos et al., 2000). Manifestations of PE include pleuritic chest pain, anxiety, shortness of breath, and abnormal blood gas values (increased PaCO<sub>2</sub> and decreased PaO<sub>2</sub>). Thigh and calf measurements are made daily. The patient is evaluated for the presence of DVT if there is a significant increase in the circumference of one extremity. Low-dose anticoagulation therapy usually is initiated to prevent DVT and PE, along with thigh-high elastic compression stockings or pneumatic compression devices. In some cases, permanent indwelling filters (see Chap. 31) may be placed in the vena cava to prevent dislodged clots (emboli) from migrating to the lungs and causing pulmonary emboli (Velmahos et al., 2000).

### OTHER COMPLICATIONS

In addition to respiratory complications (respiratory failure, pneumonia) and **autonomic dysreflexia** (characterized by pounding headache, profuse sweating, nasal congestion, piloerection ["goose bumps"], bradycardia, and hypertension), other complications that may occur include pressure ulcers and infection (urinary, respiratory, and local infection at the skeletal traction pin sites) (Sullivan, 1999).

## NURSING PROCESS: THE PATIENT WITH ACUTE SPINAL CORD INJURY

### Assessment

The breathing pattern is observed, the strength of the cough is assessed, and the lungs are auscultated, because paralysis of abdominal and respiratory muscles diminishes coughing and makes it difficult to clear bronchial and pharyngeal secretions. Reduced excursion of the chest also results.

The patient is monitored closely for any changes in motor or sensory function and for symptoms of progressive neurologic damage. It may be impossible in the early stages of SCI to determine whether the cord has been severed, because signs and symptoms of cord edema are indistinguishable from those of cord transection. Edema of the spinal cord may occur with any severe cord injury and may further compromise spinal cord function.

Motor and sensory functions are assessed through careful neurologic examination. These findings are recorded most often on a flow sheet so that changes in the baseline neurologic status can be closely monitored accurately. The American Spinal Injury Association (ASIA) classification is commonly used to describe level of function for SCI patients. Chart 63-7 also gives an example of nursing assessment of spinal cord function.

- Motor ability is tested by asking the patient to spread the fingers, squeeze the examiner's hand, and move the toes or turn the feet.
- Sensation is evaluated by gently pinching the skin or touching it lightly with a small object such as a tongue blade, starting at shoulder level and working down both sides of the extremities. The patient should have both eyes closed so that the examination reveals true findings, not what the patient hopes to feel. The patient is asked where the sensation is felt.
- Any decrease in neurologic function is reported immediately.

The patient is also assessed for spinal shock, a complete loss of all reflex, motor, sensory, and autonomic activity below the level of the lesion that causes bladder paralysis and distention. The lower abdomen is palpated for signs of urinary retention and overdistention of the bladder. Further assessment is made for gastric dilation and ileus due to an atonic bowel, a result of autonomic disruption.

Temperature is monitored because the patient may have periods of hyperthermia as a result of alteration in temperature control due to autonomic disruption.

### Diagnosis

#### NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Ineffective breathing patterns related to weakness or paralysis of abdominal and intercostal muscles and inability to clear secretions
- Ineffective airway clearance related to weakness of intercostal muscles
- Impaired physical mobility related to motor and sensory impairment
- Disturbed sensory perception related to motor and sensory impairment
- Risk for impaired skin integrity related to immobility and sensory loss

- Urinary retention related to inability to void spontaneously
- Constipation related to presence of atonic bowel as a result of autonomic disruption
- Acute pain and discomfort related to treatment and prolonged immobility

#### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include:

- DVT
- Orthostatic hypotension
- Autonomic dysreflexia

### Planning and Goals

The goals for the patient may include improved breathing pattern and airway clearance, improved mobility, improved sensory and perceptual awareness, maintenance of skin integrity, relief of urinary retention, improved bowel function, promotion of comfort, and absence of complications.

### Nursing Interventions

#### PROMOTING ADEQUATE BREATHING AND AIRWAY CLEARANCE

Possible impending respiratory failure is detected by observing the patient, measuring vital capacity, monitoring oxygen saturation through pulse oximetry, and monitoring arterial blood gas values. Early and vigorous attention to clearing bronchial and pharyngeal secretions can prevent retention of secretions and atelectasis. Suctioning may be indicated, but caution must be used during suctioning because this procedure can stimulate the vagus nerve, producing bradycardia, which can result in cardiac arrest.

If the patient cannot cough effectively because of decreased inspiratory volume and inability to generate sufficient expiratory pressure, chest physical therapy and assisted coughing may be indicated. Specific breathing exercises are supervised by the nurse to increase the strength and endurance of the inspiratory muscles, particularly the diaphragm. Assisted coughing promotes clearing of secretions from the upper respiratory tract and is similar to using abdominal thrusts to clear an airway (see Chap. 25). It is important to ensure proper humidification and hydration to prevent secretions from becoming thick and difficult to remove even with coughing. The patient is assessed for signs of respiratory infection (cough, fever, dyspnea). Smoking is discouraged because it increases bronchial and pulmonary secretions and impairs ciliary action.

Ascending edema of the spinal cord in the acute phase may cause respiratory difficulty that requires immediate intervention. Therefore, the patient's respiratory status must be monitored frequently.

#### IMPROVING MOBILITY

Proper body alignment is maintained at all times. The patient is repositioned frequently and is assisted out of bed as soon as the spinal column is stabilized. The feet are prone to footdrop; therefore, various types of splints are used to prevent footdrop. When used, the splints are removed and reapplied every 2 hours. Trochanter rolls, applied from the crest of the ilium to the mid thigh of both legs, help prevent external rotation of the hip joints.

Patients with lesions above the midthoracic level have loss of sympathetic control of peripheral vasoconstrictor activity, leading to hypotension. These patients may tolerate changes in position poorly and require monitoring of blood pressure when positions are changed. Usually the patient is turned every 2 hours. If not on a rotating bed, the patient should not be turned unless the spine is stable and the physician has indicated that it is safe to do so.

Contractures develop rapidly with immobility and muscle paralysis. A joint that is immobilized too long becomes fixed as a result of contractures of the tendon and joint capsule. Atrophy of the extremities results from disuse. Contractures and other complications may be prevented by range-of-motion exercises that help preserve joint motion and stimulate circulation. Passive range-of-motion exercises should be implemented as soon as possible after injury. Toes, metatarsals, ankles, knees, and hips should be put through a full range of motion at least four, and ideally five, times daily.

For most patients with a cervical fracture without neurologic deficit, reduction in traction followed by rigid immobilization for about 6 to 8 weeks restores skeletal integrity. These patients are allowed to move gradually to an erect position. A four-poster neck brace or molded collar is applied when the patient is mobilized after traction is removed (see Fig. 63-8).

### PROMOTING ADAPTATION TO SENSORY AND PERCEPTUAL ALTERATIONS

The nurse assists the patient to compensate for sensory and perceptual alterations that occur with SCI. The intact senses above the level of the injury are stimulated through touch, aromas, flavorful food and beverages, conversation, and music. Additional strategies include the following:

- Providing prism glasses to enable the patient to see from the supine position
- Encouraging use of hearing aids, if indicated, to enable the patient to hear conversations and environmental sounds
- Providing emotional support to the patient
- Teaching the patient strategies to compensate for or cope with these deficits

### MAINTAINING SKIN INTEGRITY

Because the patient with SCI is immobilized and has loss of sensation below the level of the lesion, there is an ever-present, life-threatening risk of pressure ulcers. In areas of local tissue ischemia, where there is continuous pressure and where the peripheral circulation is inadequate as a result of the spinal shock and recumbent position, pressure ulcers have developed within 6 hours. Prolonged immobilization of the patient on a transfer board increases the risk of pressure ulcers. The most common sites are over the ischial tuberosity, the greater trochanter, and the sacrum. In addition, patients who wear cervical collars for prolonged periods may develop breakdown from the pressure of the collar under the chin, on the shoulders, and at the occiput.

The patient's position is changed at least every 2 hours. Turning not only assists in the prevention of pressure ulcers but also prevents the pooling of blood and tissue fluid in the dependent areas.

Careful inspection of the skin is made each time the patient is turned. The skin over the pressure points is assessed for redness or breaks; the perineum is checked for soilage and the catheter is observed for adequate drainage. The patient's general body alignment and comfort are assessed. Special attention should be given to pressure areas in contact with the transfer board.

The patient's skin should be kept clean by washing with a mild soap, rinsed well, and blotted dry. Pressure-sensitive areas should be kept well lubricated and soft with bland cream or lotion. The patient is informed about the danger of pressure ulcers to encourage understanding of the reason for preventive measures. See Chapter 11 for other aspects of the prevention of pressure ulcers.

**NURSING ALERT** Never massage the calves or thighs due to the danger of dislodging an undetected DVT.

### MAINTAINING URINARY ELIMINATION

Immediately after SCI, the urinary bladder becomes atonic and cannot contract by reflex activity. Urinary retention is the immediate result. Because the patient has no sensation of bladder distention, overstretching of the bladder and detrusor muscle may occur, delaying the return of bladder function.

Intermittent catheterization is carried out to avoid overdistention of the bladder and UTI. If this is not feasible, an indwelling catheter is inserted temporarily. At an early stage, family members are shown how to carry out intermittent catheterization and are encouraged to participate in this facet of care, because they will be involved in long-term follow-up and must be able to recognize complications so that treatment can be instituted.

The patient is taught to record fluid intake, voiding pattern, amounts of residual urine after catheterization, characteristics of urine, and any unusual sensations that may occur. The management of a **neurogenic bladder** is discussed in detail in Chapter 11.

### IMPROVING BOWEL FUNCTION

Immediately after SCI, a paralytic ileus usually develops due to neurogenic paralysis of the bowel; therefore, a nasogastric tube is often required to relieve distention and prevent aspiration.

Bowel activity usually returns within the first week. As soon as bowel sounds are heard on auscultation, the patient is given a high-calorie, high-protein, high-fiber diet, with the amount of food gradually increased. The nurse administers prescribed stool softeners to counteract the effects of immobility and pain medications. A bowel program is instituted as early as possible.

### PROVIDING COMFORT MEASURES

After cervical injury, if pins, tongs, or calipers are in place, the skull is assessed for signs of infection, including drainage. The back of the head is checked periodically for signs of pressure, with care taken not to move the neck. The hair around the tongs usually is shaved to facilitate inspection. Probing under encrusted areas is avoided.

### The Patient in Halo Traction

Patients who have been placed in a halo device after cervical stabilization may have a slight headache or discomfort around the skull pins for several days after the pins are inserted. The patient initially may be bothered by the rather startling appearance of this apparatus but usually readily adapts to it because the device provides comfort for the unstable neck. The patient may complain of being caged in and of noise created by any object coming in contact with the steel frame, but he or she can be reassured that adaptation to such annoyances will occur.

The areas around the pin sites are cleansed daily and observed for redness, drainage, and pain. The pins are observed for loosening, which may contribute to infection. If one of the pins becomes detached, the head is stabilized in a neutral position by one

person while another notifies the neurosurgeon. A torque screwdriver should be readily available should the screws on the frame need tightening.

The skin under the halo vest is inspected for excessive perspiration, redness, and skin blistering, especially on the bony prominences. The vest is opened at the sides to allow the torso to be washed. The liner of the vest should not become wet, because dampness causes skin excoriation. Powder is not used inside the vest, because it may contribute to the development of pressure ulcers. The liner should be changed periodically to promote hygiene and good skin care. If the patient is to be discharged with the vest, detailed instructions must be given to the family and time allowed for them to return demonstrate the necessary skills (Chart 63-9).

## MONITORING AND MANAGING POTENTIAL COMPLICATIONS

### Thrombophlebitis

Thrombophlebitis is a relatively common complication in patients after SCI. DVT occurs in a high percentage of SCI patients; thus, they are at risk for PE. The patient must be assessed for symptoms of thrombophlebitis and PE: chest pain, shortness of breath, and changes in arterial blood gas values must be reported promptly to the physician. The circumferences of the thighs and calves are measured and recorded daily; further diagnostic studies will be performed if a significant increase is noted. Patients remain at high risk for thrombophlebitis for several months after the initial injury. Patients with paraplegia or quadriplegia are at increased risk for the rest of their lives. Immobilization and the associated venous stasis, as well as varying degrees of autonomic disruption, contribute to the high risk and susceptibility for DVT (Zafonte et al., 1999).

Anticoagulation is initiated once head and other systemic injuries have been ruled out. Low-dose fractionated or unfractionated heparin may be followed by long-term oral anticoagulation (ie, warfarin) or subcutaneous fractionated heparin injections. Additional measures such as range-of-motion exercises, thigh-high elastic compression stockings, and adequate hydration are important preventive measures. Pneumatic compression devices may also be used to reduce venous pooling and promote venous return. It is also important to avoid external pressure on the lower extremities that may result from flexion of the knees while the patient is in bed.

### Orthostatic Hypotension

For the first 2 weeks after SCI, the blood pressure tends to be unstable and quite low. There is a gradual return to preinjury levels, but periodic episodes of severe orthostatic hypotension frequently interfere with efforts to mobilize the patient. Interruption in the reflex arcs that normally produce vasoconstriction in the upright position, coupled with vasodilation and pooling in abdominal and lower extremity vessels, can result in blood pressure readings of 40 mm Hg systolic and 0 mm Hg diastolic. Orthostatic hypotension is a particularly common problem for patients with lesions above T7. In some quadriplegic patients, even slight elevations of the head can result in dramatic changes in blood pressure.

A number of techniques can be used to reduce the frequency of hypotensive episodes. Close monitoring of vital signs before and during position changes is essential. Vasopressor medication can be used to treat the profound vasodilation. Thigh-high elastic compression stockings should be applied to improve venous return from the lower extremities. Abdominal binders may also be used to encourage venous return and provide diaphragmatic support when upright. Activity should be planned in advance and adequate time given for a slow progression of position changes from recumbent to sitting and upright. Tilt tables frequently are helpful in assisting patients to make this transition.

### Autonomic Dysreflexia

**Autonomic dysreflexia** (autonomic hyperreflexia) is an acute emergency that occurs as a result of exaggerated autonomic responses to stimuli that are harmless in normal people. It occurs only after spinal shock has resolved. This syndrome is characterized by a severe, pounding headache with paroxysmal hypertension, profuse diaphoresis (most often of the forehead), nausea, nasal congestion, and bradycardia. It occurs among patients with cord lesions above T6 (the sympathetic visceral outflow level) after spinal shock has subsided. The sudden rise in blood pressure may cause a rupture of one or more cerebral blood vessels or lead to increased ICP. A number of stimuli may trigger this reflex: distended bladder (the most common cause); distention or contraction of the visceral organs, especially the bowel (from constipation, impaction); or stimulation of the skin (tactile, pain, thermal stimuli, pressure ulcer). Because this is an emergency situation, the objective is to remove the triggering stimulus and to avoid the possibly serious complications.

Chart 63-9

### Home Care Checklist • The Patient With a Halo Vest

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Describe the rationale for use of the halo vest	✓	✓
• Demonstrate assessment of frame, traction, tongs, and pins		✓
• Describe emergency measures if respiratory or other complications develop while patient is in halo vest or if frame becomes dislodged		✓
• Demonstrate pin care using correct technique		✓
• Identify signs and symptoms of infection	✓	✓
• Assess the skin for reddened or irritated areas and breakdown		✓
• Demonstrate care of skin		✓
• Explain the reasons for and the method for changing the vest liner	✓	✓
• Demonstrate safe techniques to assist patient with self-care, hygiene, and ambulation		✓
• Identify signs and symptoms of complications (deep venous thrombosis, respiratory impairment, urinary tract infection)	✓	✓

The following measures are carried out:

- The patient is placed immediately in a sitting position to lower blood pressure.
- Rapid assessment to identify and alleviate the cause is imperative.
- The bladder is emptied immediately via a urinary catheter. If an indwelling catheter is not patent, it is irrigated or replaced with another catheter.
- The rectum is examined for a fecal mass. If one is present, a topical anesthetic is inserted 10 to 15 minutes before the mass is removed, because visceral distention or contraction can cause autonomic dysreflexia.
- The skin is examined for any areas of pressure, irritation, or broken skin.
- Any other stimulus that can be the triggering event, such as an object on the skin or a draft of cold air, must be removed.
- If these measures do not relieve the hypertension and excruciating headache, a ganglionic blocking agent (hydralazine hydrochloride [Apresoline]) is prescribed and given slowly intravenously.
- The medical record or chart should be labeled with a clearly visible note about the risk for autonomic dysreflexia.
- The patient is instructed about prevention and management measures.
- Any patient with a lesion above the T6 segment is informed that such an episode is possible and may even occur many years after the initial injury.

The rehabilitation of the patient with a SCI (ie, the quadriplegic or paraplegic patient) is discussed below.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

In most cases, SCI patients need long-term rehabilitation. The process begins during hospitalization as acute symptoms begin to subside or come under better control and the overall deficits and long-term effects of the injury become clear. The goals begin to shift from merely surviving the injury to learning strategies necessary to cope with the alterations that injury imposes on activities of daily living. The emphasis shifts from ensuring that the patient is stable and free of complications to specific assessment and planning designed to meet the patient's rehabilitation needs. Patient teaching may initially focus on the injury and its effects on mobility, dressing, and bowel, bladder, and sexual function. As the patient and family acknowledge the consequences of the injury, the focus of teaching may broaden to address issues necessary to carry out the tasks of daily living. Teaching begins in the acute phase and continues throughout rehabilitation and throughout the patient's life as changes occur, the patient ages, and problems arise.

Caring for the SCI patient at home may at first seem a daunting task to the family. They will require dedicated nursing support to gradually assume full care of the patient (Craig et al., 1999).

Although maintaining function and preventing complications will remain important, goals regarding self-care and preparation for discharge will assist in a smooth transition to rehabilitation and eventually to the community.

### Continuing Care

The ultimate goal of the rehabilitation process is independence. The nurse becomes a support to both the patient and the family,

assisting them to assume responsibility for increasing aspects of patient care and management. Care for the SCI patient involves members of all the health care disciplines; these may include nursing, medicine, rehabilitation, respiratory therapy, physical and occupational therapy, case management, social services, and so forth. The nurse often serves as coordinator of the management team and as a liaison with rehabilitation centers and home care agencies. The patient and family often require assistance in dealing with the psychological impact of the injury and its consequences; referral to a psychiatric clinical nurse specialist or other mental health care professional often is helpful.

The nurse should reassure female SCI patients that pregnancy is not contraindicated, but pregnant women with acute or chronic SCI pose unique management challenges. The normal physiologic changes of pregnancy may predispose women with SCI to many potentially life-threatening complications, including autonomic dysreflexia, pyelonephritis, respiratory insufficiency, thrombophlebitis, PE, and unattended delivery (Atterbury & Groome, 1998).

As more patients survive acute SCI, they will face the changes associated with aging with a disability. Thus, teaching in the home and community focuses on health promotion and addresses the need to minimize risk factors (eg, smoking, alcohol and drug abuse, obesity). Home care nurses and others who have contact with patients with SCI are in a position to teach patients about healthy lifestyles, remind them of the need for health screenings, and make referrals as appropriate. Assisting patients to identify accessible health care providers and imaging centers may increase the likelihood that they will participate in health screening (eg, gynecologic examinations, mammograms, etc.).

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Demonstrates improvement in gas exchange and clearance of secretions, as evidenced by normal breath sounds on auscultation
  - a. Breathes easily without shortness of breath
  - b. Performs hourly deep-breathing exercises, coughs effectively, and clears pulmonary secretions
  - c. Is free of respiratory infection (ie, has normal temperature, respiratory rate, and pulse, normal breath sounds, absence of purulent sputum)
2. Moves within limits of the dysfunction and demonstrates completion of exercises within functional limitations
3. Demonstrates adaptation to sensory and perceptual alterations
  - a. Uses assistive devices (eg, prism glasses, hearing aids, computers) as indicated
  - b. Describes sensory and perceptual alterations as a consequence of injury
4. Demonstrates optimal skin integrity
  - a. Exhibits normal skin turgor; skin is free of reddened areas or breaks
  - b. Participates in skin care and monitoring procedures within functional limitations
5. Regains urinary bladder function
  - a. Exhibits no signs of UTI (ie, has normal temperature; voids clear, dilute urine)
  - b. Has adequate fluid intake

- c. Participates in bladder training program within functional limitations
- 6. Regains bowel function
  - a. Reports regular pattern of bowel movement
  - b. Consumes adequate dietary fiber and oral fluids
  - c. Participates in bowel training program within functional limitations
- 7. Reports absence of pain and discomfort
- 8. Is free of complications
  - a. Demonstrates no signs of thrombophlebitis, DVT, or PE
  - b. Exhibits no manifestations of pulmonary embolism (eg, no chest pain or shortness of breath; arterial blood gas values are normal)
  - c. Maintains blood pressure within normal limits
  - d. Has no lightheadedness with position changes
  - e. Exhibits no manifestations of autonomic dysreflexia (ie, no headache, diaphoresis, nasal congestion, bradycardia, or diaphoresis)

### Management of the Quadriplegic or Paraplegic Patient

Quadriplegia refers to the loss of movement and sensation in all four extremities and the trunk, associated with injury to the cervical spinal cord. Paraplegia refers to loss of motion and sensation in the lower extremities and all or part of the trunk as a result of damage to the thoracic or lumbar spinal cord or to the sacral root. Both conditions most frequently follow trauma such as falls, injuries, and gunshot wounds, but they may also be the result of spinal cord lesions (intervertebral disk, tumor, vascular lesions), multiple sclerosis, infections and abscesses of the spinal cord, and congenital disorders.

The patient faces a lifetime of great disability, requiring ongoing follow-up and care and the expertise of a number of health professionals, including physicians (specifically a physiatrist), rehabilitation nurses, occupational therapist, physical therapist, psychologist, social worker, rehabilitation engineer, and vocational counselor at different times as the need arises.

As the years go by, these patients also have the same medical problems as others in the aging population. In addition, they face the threat of complications associated with their disability. Usually the patient is encouraged to attend a spinal clinic when complications and other issues arise. Lifetime care includes assessment of the urinary tract at prescribed intervals, because there is the likelihood of continuing alteration in detrusor and sphincter function and the patient is prone to UTI.

Long-term problems and complications of SCI include disuse syndrome, autonomic dysreflexia (discussed earlier), bladder and kidney infections, spasticity, and depression. Pressure ulcers with potential complications of sepsis, osteomyelitis, and fistulas occur in about 10% of patients. Flexor muscle spasms may be particularly disabling and occur in up to 25% of patients (Sullivan, 1999). Heterotopic ossification (overgrowth of bone) in the hips, knees, shoulders, and elbows occurs in up to 30% of SCI patients. This complication is painful and can produce a loss of range of motion (Mitcho & Yanko, 1999; Subbarao & Garrison, 1999). Management includes observing for and addressing any alteration in physiologic status and psychological outlook, and the prevention and treatment of long-term complications. The nursing role involves emphasizing the need for vigilance in self-assessment and care.

## NURSING PROCESS: THE PATIENT WITH QUADRIPLEGIA OR PARAPLEGIA

### Assessment

Assessment focuses on the patient's general condition, complications, and how the patient is managing at that particular point in time. A head-to-toe assessment and review of systems should be part of the database, with emphasis on the areas prone to problems in this population. A thorough inspection of all areas of the skin for redness or breakdown is critical. It is also important to review with the patient the established bowel and bladder program, because the program must continue uninterrupted. Patients with quadriplegia or paraplegia have varying degrees of loss of motor power, deep and superficial sensation, vasomotor control, bladder and bowel control, and sexual function. They are faced with potential complications related to immobility, skin breakdown and pressure ulcers, recurring UTI, contractures, and psychosocial disruptions. Knowledge about these particular issues can further guide the assessment in any setting. Nurses in all settings, including home care, must be aware of these potential complications in the lifetime management of these patients.

An understanding of the emotional and psychological responses to quadriplegia or paraplegia is achieved by observing the responses and behaviors of the patient and family and by listening to their concerns (see Chart 63-10 for a discussion of ethical issues). Documenting these assessments and reviewing the plan with the entire team on a regular basis provide insight into how both the patient and the family are coping with the changes in lifestyle and body functioning. Additional information frequently can be gathered from the social worker or psychiatric/mental health worker.

### Chart 63-10 • Ethics and Related Issues

#### When the Patient Wants to Die . . .

##### Situation

A 70-year-old man has been in neurologic intensive care since he suffered a complete C1-C2 cervical fracture 2 weeks ago, which left him quadriplegic and ventilator-dependent. Since his admission, he has asked to be allowed to die. He has a living will and his wife is his designated durable power of attorney for health care. Before his injury, his health was exceptional. He played golf daily and was very active. He is awake, alert, and oriented and can communicate by letter board. He states that he does not want to spend his life unable to do the things he enjoys. He continues to request extubation so that he can die. His family and friends are with him, and he has asked his attorneys to tend to his affairs. With the loving support of his family, the decision to remove the ventilator has been made. Sedatives will be administered to help him deal with hypoxia and anoxia.

##### Dilemma

What is the nurse's role in caring for this patient at this time?

##### Discussion

Is the removal of the ventilator an act of assisted suicide? Is it active or passive euthanasia? What is the nurse's role in caring for the patient if this action conflicts with his/her personal beliefs? If no other nurse is available to provide care? If the physician writes the order for the nurse to remove the ventilator?

It takes time for the patient and family to comprehend the magnitude of the disability. They may go through stages of grief, including shock, disbelief, denial, anger, depression, and acceptance. During the acute phase of the injury, denial can be a protective mechanism to shield patients from the overwhelming reality of what has happened. As they realize the permanent nature of paraplegia or quadriplegia, the grieving process may be prolonged and all-encompassing because of the recognition that long-held plans and expectations may be interrupted or permanently altered. A period of depression often follows as the patient experiences a loss of self-esteem in areas of self-identity, sexual functioning, and social and emotional roles. Exploration and assessment of these issues can assist in developing a meaningful plan of care.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the major nursing diagnoses of the patient with quadriplegia or paraplegia may include the following:

- Impaired physical mobility related to loss of motor function
- Risk for disuse syndrome
- Risk for impaired skin integrity related to permanent sensory loss and immobility
- Urinary retention related to level of injury
- Constipation related to effects of spinal cord disruption
- Sexual dysfunction related to neurologic dysfunction
- Ineffective coping related to impact of dysfunction on daily living
- Deficient knowledge about requirements for long-term management

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on all the assessment data, potential complications of quadriplegia or paraplegia that may develop include:

- Spasticity
- Infection and sepsis

## Planning and Goals

The goals for the patient may include attainment of some form of mobility, maintenance of healthy, intact skin, achievement of bladder management without infection, achievement of bowel control, achievement of sexual expression, strengthening of coping mechanisms, and absence of complications.

## Nursing Interventions

The patient requires extensive rehabilitation, which is less difficult if appropriate nursing management has been carried out during the acute phase of the injury or illness. Nursing care is one of the key factors determining the success of the rehabilitation program. The main objective is for the patient to live as independently as possible in the home and community.

### INCREASING MOBILITY

#### Exercise Programs

The unaffected parts of the body are built up to optimal strength to promote maximal self-care. The muscles of the hands, arms,

shoulders, chest, spine, abdomen, and neck must be strengthened in the paraplegic patient because he or she must bear full weight on these muscles to ambulate. The triceps and the latissimus dorsi are important muscles used in crutch walking. The muscles of the abdomen and the back also are necessary for balance and for maintaining the upright position.

To strengthen these muscles, the patient can do push-ups when in a prone position and sit-ups when in a sitting position. Extending the arms while holding weights (traction weights can be used) also develops muscle strength. Squeezing rubber balls or crumpling newspaper promotes hand strength.

With encouragement from all members of the rehabilitation team, the paraplegic patient can develop the increased exercise tolerance needed for gait training and ambulation activities. The importance of maintaining cardiovascular fitness is stressed to the patient. Alternative exercises to increase the heart rate to target levels must be designed within the patient's abilities.

### Mobilization

When the spine is stable enough to allow the patient to assume an upright posture, mobilization activities are initiated. A brace or vest may be used, depending on the level of the lesion. A patient whose paralysis is due to complete transection of the cord can begin weight-bearing early because no further damage can be incurred. The sooner muscles are used, the less chance there is of disuse atrophy. The earlier the patient is brought to a standing position, the less opportunity for osteoporotic changes to take place in the long bones. Weight-bearing also reduces the possibility of renal calculi and enhances many other metabolic processes.

Braces and crutches enable some paraplegic patients to ambulate for short distances. Ambulation using crutches requires a high expenditure of energy. Motorized wheelchairs and specially equipped vans can provide greater independence and mobility for patients with high-level SCI or other lesions. Every effort should be made to encourage the patient to be as mobile and active as possible.

### PREVENTING DISUSE SYNDROME

Patients are at high risk for developing contractures as a result of disuse syndrome due to the musculoskeletal system changes (atrophy) brought about by the loss of motor and sensory functions below the level of injury. Range-of-motion exercises must be provided at least four times a day, and care is taken to stretch the Achilles tendon with exercises (Hickey, 2003). The patient is repositioned frequently and maintained in proper body alignment whether in bed or in a wheelchair (Hickey, 2003).

### PROMOTING SKIN INTEGRITY

Because these patients spend a great portion of their lives in wheelchairs, pressure ulcers are an ever-present threat. Contributing factors are permanent sensory loss over pressure areas; immobility, which makes relief of pressure difficult; trauma from bumps (against the wheelchair, toilet, furniture, and so forth) that cause unperceived abrasions and wounds; loss of protective function of the skin from excoriation and maceration due to excessive perspiration and possible urinary and fecal incontinence; and poor general health (anemia, edema, malnutrition), leading to poor tissue perfusion. The prevention and management of pressure ulcers are discussed in detail in Chapter 11.

The person with quadriplegia or paraplegia must take responsibility for monitoring (or directing) his or her skin status. This

involves relieving pressure and not remaining in any position for longer than 2 hours, in addition to ensuring that the skin receives meticulous attention and cleansing. The patient is taught that ulcers develop over bony prominences exposed to unrelieved pressure in the lying and sitting positions. The most vulnerable areas are identified. The paraplegic patient is instructed to use mirrors, if possible, to inspect these areas morning and night, observing for redness, slight edema, or any abrasions. While in bed, the patient should turn at 2-hour intervals and then inspect the skin again for redness that does not fade on pressure. The bottom sheet should be checked for wetness and for creases. The quadriplegic or paraplegic patient who cannot perform these activities is encouraged to direct others to check these areas and prevent ulcers from developing.

The patient is taught to relieve pressure while in the wheelchair by doing push-ups, leaning from side to side to relieve ischial pressure, and tilting forward while leaning on a table. The caregiver for the quadriplegic patient will need to perform these activities if the patient cannot do so independently. A wheelchair cushion is prescribed to meet individual needs, which may change in time with changes in posture, weight, and skin tolerance. A referral can be made to a rehabilitation engineer, who can measure pressure levels while the patient is sitting and then tailor the cushion and other necessary aids and assistive devices to the patient's needs.

The diet for the patient with quadriplegia or paraplegia should be high in protein, vitamins, and calories to ensure minimal wasting of muscle and the maintenance of healthy skin, and high in fluids to maintain well-functioning kidneys. Excessive weight gain and obesity should be avoided because they limit mobility.

### IMPROVING BLADDER MANAGEMENT

The effect of the spinal cord lesion on the bladder depends on the level of injury, the degree of cord damage, and the length of time after injury. A patient with quadriplegia or paraplegia usually has either a reflex or a nonreflex bladder (see Chaps. 11 and 44). Both bladder types increase the risk of UTI.

The nurse emphasizes the importance of maintaining an adequate flow of urine by encouraging a fluid intake of about 2.5 L daily. The patient should empty the bladder frequently so there is minimal residual urine and should pay attention to personal hygiene, because infection of the bladder and kidneys almost always occurs by the ascending route. The perineum must be kept clean and dry and attention given to the perianal skin after defecation. Underwear should be cotton (more absorbent) and changed at least once a day.

If an external catheter (condom catheter) is used, the sheath is removed nightly; the penis is cleansed to remove urine and is dried carefully, because warm urine on the periurethral skin promotes the growth of bacteria. Attention also is given to the collection bag. The nurse emphasizes the importance of monitoring for indications of UTI: cloudy, foul-smelling urine or hematuria (blood in the urine), fever, or chills.

The female patient who cannot achieve reflex bladder control or self-catheterization may need to wear pads or waterproof undergarments. Surgical intervention may be indicated in some patients to create a urinary diversion.

### ESTABLISHING BOWEL CONTROL

The objective of a bowel training program is to establish bowel evacuation through reflex conditioning. This technique is described in Chapter 38. If a cord injury occurs above the sacral segments or nerve roots and there is reflex activity, the anal sphincter may be massaged (digital stimulation) to stimulate defecation. If

the cord lesion involves the sacral segment or nerve roots, anal massage is not performed because the anus may be relaxed and lack tone. Massage is also contraindicated if there is spasticity of the anal sphincter. The anal sphincter is massaged by inserting a gloved finger (which has been adequately lubricated) 2.5 to 3.7 cm (1 to 1.5 in) into the rectum and moving it in a circular motion or from side to side. It soon becomes apparent which area triggers the defecation response. This procedure should be performed at the same time (usually every 48 hours), after a meal, and at a time that will be convenient for the patient at home. The patient also is taught the symptoms of impaction (frequent loose stools; constipation) and cautioned to watch for hemorrhoids. A diet with sufficient fluids and fiber is essential to a successful bowel training program, avoiding constipation, and decreasing the risk of autonomic dysreflexia.

### COUNSELING ON SEXUAL EXPRESSION

Many paraplegic and quadriplegic patients can have some form of meaningful sexual relationship, although some modifications will be necessary. The patient and partner benefit from counseling about the range of sexual expression possible, special techniques and positions, exploration of body sensations offering sensual feelings, and urinary and bowel hygiene as related to sexual activity. For men with erectile failure, penile prostheses enable them to have and sustain an erection. Sildenafil (Viagra) is an oral smooth muscle relaxant that causes blood to flow into the penis, resulting in an erection (see Chap. 49).

Sexual education and counseling services are included in the rehabilitation services at spinal centers. Small-group meetings in which the patients can share their feelings, receive information, and discuss sexual concerns and practical aspects are helpful in producing effective attitudes and adjustments (Sipski & Alexander, 1997).

### ENHANCING COPING MECHANISMS

The impact of the disability and loss becomes marked when patients return home. Each time something new enters their lives (eg, a new relationship, going to work), they are reminded anew of their limitations. Grief reactions and depression are common.

To work through this depression, patients must have some hope for relief in the future. Thus, the nurse can encourage them to feel confident in their ability to achieve self-care and relative independence. The role of the nurse ranges from caretaker during the acute phase to teacher, counselor, and facilitator as patients gain mobility and independence.

The patient's disability affects not only the patient, but also the entire family. In many cases, family therapy is helpful to help work through issues as they arise.

Adjustment to the disability leads to the development of realistic goals for the future, making the best of the abilities that are left intact and reinvesting in other activities and relationships. Rejection of the disability causes self-destructive neglect and noncompliance with the therapeutic program, which leads to more frustration and depression. Crises for which interventions may be sought include social, psychological, marital, sexual, and psychiatric problems. The family usually requires counseling, social services, and other support systems to help them cope with the changes in their lifestyle and socioeconomic status.

A major goal of nursing management is to help patients overcome their sense of futility and to encourage them in the emotional adjustment that must be made before they are willing to venture into the outside world. However, an excessively sympathetic attitude on the part of the nurse may cause patients to

develop an overdependence that defeats the purpose of the entire rehabilitation program. Patients are taught and assisted when necessary, but the nurse should avoid performing activities that patients can do for themselves with a little effort. This approach to care more than repays itself in the satisfaction of seeing a completely demoralized and helpless patient become independent and find meaning in a newly emerging lifestyle.

## MONITORING AND MANAGING POTENTIAL COMPLICATIONS

### Spasticity

Muscle spasticity is one of the most problematic complications of quadriplegia and paraplegia. These incapacitating flexor or extensor spasms, which occur below the level of the spinal cord lesion, interfere with both the rehabilitation process and activities of daily living. Spasticity results from an imbalance between the facilitatory and inhibitory effects on neurons that exist normally. The area of the cord distal to the site of injury or lesion becomes disconnected from the higher inhibitory centers located in the brain. Facilitatory impulses, which originate from muscles, skin, and ligaments, thus predominate.

Spasticity is defined as a condition of increased muscle tone in a muscle that is weak. Initial resistance to stretching is quickly followed by sudden relaxation. The stimulus that precipitates spasm can be either obvious, such as movement or a position change, or subtle, such as a slight jarring of the wheelchair. Most patients with quadriplegia or paraplegia have some degree of spasticity. With SCI, the onset of spasticity usually occurs from a few weeks to 6 months after the injury. The same muscles that are flaccid during the period of spinal shock will develop spasticity during recovery. The intensity of spasticity tends to peak around 2 years after the injury, after which the spasms tend to regress.

Management of spasticity is based on the severity of symptoms and the degree of incapacitation. Antispasmodic medications such as diazepam (Valium), baclofen (Lioresal), and dantrolene (Dantrium) are frequently effective in controlling spasm but cause drowsiness, weakness, and vertigo in some patients. Passive range-of-motion exercises and frequent turning and repositioning are helpful because stiffness tends to increase spasticity. These activities also are essential in the prevention of contractures, pressure ulcers, and bowel and bladder dysfunction.

Contractures can complicate day-to-day care, increasing the difficulty with positioning and decreasing mobility. A number of surgical procedures have been tried with varying degrees of success. These techniques are used if more conservative approaches fail. The best treatment is prevention.

### Infection and Sepsis

Patients with quadriplegia and paraplegia are at increased risk for infection and sepsis from a variety of sources: urinary tract, respiratory tract, and pressure ulcers. Sepsis remains a major cause of death and complications in these patients. Prevention of infection and sepsis is essential through maintenance of skin integrity, complete emptying of the bladder at regular intervals, and prevention of urinary and fecal incontinence. The risk of respiratory infection can be decreased by avoiding contact with people with symptoms of respiratory infection, performing coughing and deep-breathing exercises to prevent pooling of respiratory secretions, receiving yearly influenza vaccines, and giving up smoking. A high-protein diet is important in maintaining an adequate immune system, as is avoiding factors that may reduce immune

system function (eg, excessive stress, drug abuse, excessive alcohol intake).

If infection occurs, the patient requires thorough assessment and prompt treatment. Antibiotic therapy and adequate hydration, in addition to local measures (depending on the site of infection), are initiated immediately.

UTIs are minimized or prevented by:

- Aseptic technique in catheter management
- Adequate hydration
- Bladder training program
- Prevention of overdistention of the bladder and stasis

Skin breakdown and infection are prevented by:

- Maintenance of a turning schedule
- Frequent back care
- Regular assessment of all skin areas
- Regular cleansing and lubrication of the skin
- Passive range-of-motion exercise to prevent contractures
- Pressure relief, particularly over broken skin areas, bony prominences, and heels
- Wrinkle-free bed linen

Pulmonary infections are managed and prevented by:

- Frequent coughing, turning, and deep-breathing exercises and chest physiotherapy
- Aggressive respiratory care and suctioning of the airway if a tracheostomy is present
- Assisted coughing
- Adequate hydration

Infections of any kind can be life-threatening. Therefore, aggressive nursing interventions are key to their prevention and management.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

Patients with quadriplegia or paraplegia are at risk for complications for the rest of their lives. Thus, a major aspect of nursing care is teaching patients and their families about these complications and about strategies to minimize this risk. UTIs, contractures, infected pressure ulcers, and sepsis may necessitate hospitalization. Other late complications that may occur include lower extremity edema, joint contractures, respiratory dysfunction, and pain. To avoid these and other complications, the patient and a family member are taught skin care, catheter care, range-of-motion exercises, breathing exercises, and other care techniques. Teaching is initiated as soon as possible and extends into the rehabilitation or long-term care facility and home.

### Continuing Care

Referral for home care is often appropriate for assessment of the home setting, patient teaching, and evaluation of the patient's physical and emotional status. During visits by the home care nurse, teaching about strategies to prevent or minimize potential complications is reinforced. The home environment is assessed for adequacy for care and for safety. Environmental modifications are made and specialized equipment is obtained, ideally before the patient goes home.

The home care nurse also assesses the patient's and the family's adherence to recommendations and their use of coping strategies. The use of inappropriate coping strategies such as drug and alcohol use is assessed and referrals to counseling are made for the

patient and family. Appropriate and effective coping strategies are reinforced. The nurse reviews previous teaching and determines the need for further physical or psychological assistance. The patient's self-esteem and body image may be very poor at this time. Because people with high levels of social support often report feelings of well-being despite major physical disability, it is beneficial for the nurse to assess and promote further development of the support system and effective coping strategies of each patient.

The patient requires continuing, life-long follow-up by the physician, physical therapist, and other rehabilitation team members because the neurologic deficit is usually permanent and new deficits and complications can develop. These require prompt attention before they take their toll in additional physical impairment, time, morale, and financial costs. The local counselor for the Office of Vocational Rehabilitation works with the patient with respect to job placement or additional educational or vocational training.

The nurse is in a good position to remind patients and family members of the need for continuing health promotion and screening practices. Referral to accessible health care providers and imaging centers is important in health promotion.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Attains some form of mobility
2. Contractures do not develop
3. Maintains healthy, intact skin
4. Achieves bladder control, absence of UTI
5. Achieves bowel control
6. Reports sexual satisfaction
7. Shows improved adaptation to environment and others
8. Exhibits reduction in spasticity
  - a. Reports understanding of the precipitating factors
  - b. Reports understanding of measures to reduce spasticity
9. Describes long-term management required
10. Exhibits absence of complications

### Critical Thinking Exercises

**1.** A patient has been brought to the emergency department after he was hit in the head with a bat during a company baseball game. His coworkers report that he was unconscious for about 3 minutes. He now seems alert and oriented. What type of injury has he most likely sustained? What discharge instructions are warranted for this patient's family? How would you modify your discharge instructions if the patient lives alone?

**2.** A 25-year-old man with paraplegia secondary to SCI is scheduled to return home after an 8-month stay in a rehabilitation facility. What health promotion strategies are relevant to teach the patient prior to discharge? What modifications in patient teaching would be indicated if the patient were a 50-year-old woman?

**3.** A patient with a T4 SCI has just returned to the nursing unit from physical therapy. He reports a severe, pounding headache and nausea. His blood pressure is very elevated and his pulse is slow. What are the possible causes of these signs and symptoms? What immediate actions should you take? What treatments can you anticipate? What teaching is warranted, and why?

# ● Management of Patients With Neurologic Infections, Autoimmune Disorders, and Neuropathies

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Differentiate among the infectious disorders of the nervous system according to causes, manifestations, medical care, and nursing management.
2. Describe the pathophysiology, clinical manifestations, and medical and nursing management of multiple sclerosis, myasthenia gravis, and Guillain-Barré syndrome.
3. Use the nursing process as a framework for care of patients with multiple sclerosis, myasthenia gravis, and Guillain-Barré syndrome.
4. Describe disorders of the cranial nerves, their manifestations, and indicated nursing interventions.
5. Develop a plan of nursing care for the patient with a cranial nerve disorder.

The diverse group of neurologic disorders that make up infectious and autoimmune disorders, and cranial and peripheral neuropathies present unique challenges for nursing care. Infectious processes of the nervous system sometimes cause death or permanent dysfunction. Autoimmune disorders usually have a slow, progressive course, requiring the nurse to manage symptoms and facilitate patients' and families' understanding of the disease process. Cranial and peripheral nerve disorders may affect the patient's comfort, functional independence, and self-esteem.

The nurse who cares for patients with these disorders must have a clear understanding of the pathologic processes and the clinical outcomes. Some of the issues nurses must help patients and families confront include adaptation to the effects of the disease, potential changes in family dynamics, and, possibly, end-of-life issues.

## Infectious Neurologic Disorders

The infectious disorders of the nervous system include meningitis, brain abscesses, various types of encephalitis, and Creutzfeldt-Jakob and new-variant Creutzfeldt-Jakob disease. The clinical manifestations, assessment, and diagnostic findings as well as the medical and nursing management are related to the specific infectious process.

### MENINGITIS

Meningitis is an inflammation of the meninges, the protective membranes that surround the brain and spinal cord. Meningitis is classified as aseptic or septic. In aseptic meningitis, bacteria are not the cause of the inflammation; the cause is viral or secondary to lymphoma, leukemia, or brain abscess. Septic meningitis refers to meningitis caused by bacteria, most commonly *Neisseria meningitidis*, although *Haemophilus influenzae* and *Streptococcus pneumoniae* are also causative agents.

Outbreaks of *N. meningitidis* infection are most likely to occur in dense community groups, such as college campuses and military installations. Though infections occur year round, the peak incidence is in the winter and early spring. Factors that increase the risk for developing bacterial meningitis include tobacco use and viral upper respiratory infection because they increase the amount of droplet production. Otitis media and mastoiditis increase the risk of bacterial meningitis because the bacteria can cross the epithelium membrane and enter the subarachnoid space. Persons with immune system deficiencies are also at greater risk for developing bacterial meningitis. Between 1992 and 1996 there was a 28% increase in the number of new cases reported in the 12-to-29-year-old age group (Rosenstein, Perkins, Stephens et al.,

2001). This increase focused attention on the need to develop a vaccine for high-risk populations.

### Pathophysiology

Meningeal infections generally originate in one of two ways: through the bloodstream as a consequence of other infections, or by direct extension, such as might occur after a traumatic injury to the facial bones, or secondary to invasive procedures.

*N. meningitidis* concentrates in the nasopharynx and is transmitted by secretion or aerosol contamination. Bacterial or meningococcal meningitis also occurs as an opportunistic infection in patients with acquired immunodeficiency syndrome (AIDS) and as a complication of Lyme disease (Chart 64-1). *S. pneumoniae* is the most frequent causative agent of bacterial meningitis associated with AIDS (Rosenstein, Perkins, Stephens et al., 2001).

Once the causative organism enters the bloodstream, it crosses the blood-brain barrier and causes an inflammatory reaction in the meninges. Independent of the causative agent, inflammation of the subarachnoid space and pia mater occurs. Since there is little room for expansion within the cranial vault, the inflammation may cause increased intracranial pressure. Cerebrospinal fluid (CSF) flows in the subarachnoid space, where inflammatory cellular material from the affected meningeal tissue enters and accumulates in the subarachnoid space, thereby increasing the CSF cell count (Coyle, 1999).

The prognosis for bacterial meningitis depends on the causative organism, the severity of the infection and illness, and the timeliness of treatment. In acute fulminant presentations there may be adrenal damage, circulatory collapse, and widespread hemorrhages (Waterhouse-Friderichsen syndrome). This syndrome is the result of endothelial damage and vascular necrosis caused by the bacteria. Complications include visual impairment, deafness, seizures, paralysis, hydrocephalus, and septic shock.

### Clinical Manifestations

Headache and fever are frequently the initial symptoms. Fever tends to remain high throughout the course of the illness. The headache is usually severe as a result of meningeal irritation. Meningeal irritation results in a number of other well-recognized signs common to all types of meningitis:

- Nuchal rigidity (stiff neck) is an early sign. Any attempts at flexion of the head are difficult because of spasms in the muscles of the neck. Forceful flexion causes severe pain.
- Positive Kernig's sign: When the patient is lying with the thigh flexed on the abdomen, the leg cannot be completely extended (Fig. 64-1).

## Glossary

**ataxia:** impaired coordination of movements

**bulbar paralysis:** immobility of muscles innervated by cranial nerves with their cell bodies in the lower portion of the brain stem

**diplopia:** double vision, or the awareness of two images of the same object occurring in one or both eyes

**dyskinesia:** impaired ability to execute voluntary movements

**dysphagia:** difficulty swallowing, causing the patient to be at risk for aspiration

**dysphonia:** voice impairment or altered voice production

**myoclonus:** spasms of a single muscle or group of muscles

**neuropathy:** general term indicating a disorder of the nervous system

**paresthesia:** a sensation of numbness or tingling or a "pins and needles" sensation

**prion:** a particle smaller than a virus that is resistant to standard sterilization procedures

**spasticity:** muscular hypertonicity with increased resistance to stretch often associated with weakness, increased deep tendon reflexes, and diminished superficial reflexes

**spongiform:** having the appearance or quality of a sponge

Chart  
64-1

## Meningitis in Specific Populations

Meningitis can occur as a complication of other diseases and is an opportunistic infection seen with greater frequency in patients with acquired immunodeficiency syndrome (AIDS)

## Meningitis in AIDS Patients

- Aseptic, cryptococcal, and tuberculous forms of meningitis have been reported in patients with AIDS.
- Acute and chronic forms of aseptic meningitis may occur with AIDS; both are accompanied by headache, but signs of meningeal irritation generally occur with the acute form.
- Aseptic meningitis may be accompanied by cranial nerve palsies. The meningitis is thought to be related to direct infection of the central nervous system by human immunodeficiency virus (HIV) because it can be isolated from the cerebrospinal fluid (CSF).
- Cryptococcal meningitis is the most common fungal infection of the central nervous system in patients with AIDS and has a 50% to 60% relapse rate. Patients may experience headache, nausea, vomiting, seizures, confusion, and lethargy. Treatment consists of IV administration of amphotericin B followed by fluconazole. Maintenance therapy with fluconazole may be necessary to prevent relapse.
- Some immunosuppressed patients develop few if any symptoms because of blunted inflammatory responses; others develop atypical features.

## Meningitis in Lyme Disease

- Lyme disease is a multisystem inflammatory process caused by the tick-transmitted spirochete *Borrelia burgdorferi*.
- Neurologic abnormalities are seen in later stages (stages 2 or 3). Stage 2 occurs either with the characteristic rash or from 1 to 6 months after it has disappeared.
- Neurologic abnormalities include aseptic meningitis, chronic lymphocytic meningitis, and encephalitis.
- Cranial nerve inflammation, including Bell's palsy and other peripheral neuropathies, is common.
- Stage 3 (the chronic form of the disease) begins years after the initial tick infection and is characterized by arthritis, skin lesions, and neurologic abnormalities.
- Most patients with stage 2 and 3 Lyme disease are treated with intravenous antibiotics, usually ceftriaxone or penicillin G.
- Meningeal and systemic symptoms begin to improve within days, although other symptoms, such as headache, may persist for weeks.

- Positive Brudzinski's sign: When the patient's neck is flexed, flexion of the knees and hips is produced; when passive flexion of the lower extremity of one side is made, a similar movement is seen in the opposite extremity (see Fig. 64-1).
- Photophobia: extreme sensitivity to light; this finding is common, although the cause is unclear.

A rash can be a striking feature of *N. meningitidis* infection, occurring in about half of patients with this type of meningitis. Skin lesions develop, ranging from a petechial rash with purpuric lesions to large areas of ecchymosis.

Disorientation and memory impairment are common early in the course of the illness. The changes depend on the severity of the infection as well as the individual response to the physiologic processes. Behavioral manifestations are also common. As the illness progresses, lethargy, unresponsiveness, and coma may develop.

Seizures and increased intracranial pressure (ICP) are also associated with meningitis. Seizures occur secondary to focal areas of cortical irritability. Intracranial pressure increases secondary to accumulation of purulent exudate. The initial signs of increased ICP include decreased level of consciousness and focal motor deficits. If ICP is not controlled, the uncus of the temporal lobe may herniate through the tentorium into the brain stem. Brain stem herniation is a life-threatening event causing cranial nerve dysfunction and depressing the centers of vital functions, such as the medulla (Rowland, 2000). (See Chap. 61 for discussion of the patient with a change in level of consciousness or increased ICP.)

A fulminating infection occurs in about 10% of patients with meningococcal meningitis, with signs of overwhelming septicemia: an abrupt onset of high fever, extensive purpuric lesions (over the face and extremities), shock, and signs of disseminated intravascular coagulopathy (DIC). Death may occur within a few hours of onset of the infection.

## Assessment and Diagnostic Findings

When the clinical presentation points to meningitis, diagnostic testing to identify the causative organism is conducted. Bacterial culture and Gram staining of CSF and blood are key diagnostic tests (Fischbach, 2002). The presence of polysaccharide antigen in CSF further supports the diagnosis of bacterial meningitis (Rosenstein et al., 2001).

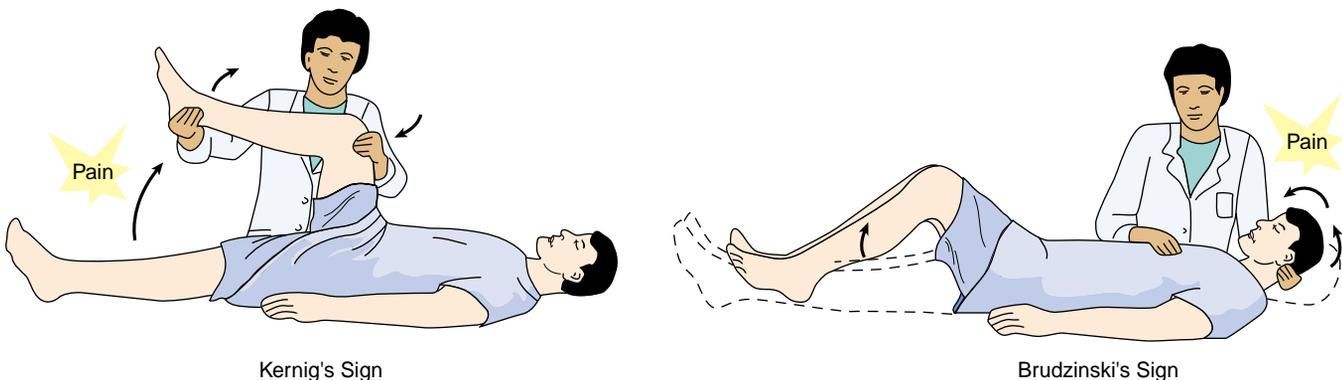

FIGURE 64-1 Testing for meningeal irritation. (A) Kernig's sign. (B) Brudzinski's sign.

## Prevention

In 1971, the military began vaccinating all new recruits against meningococcal meningitis, resulting in a dramatic decrease in the incidence. Researchers suggested vaccination of college freshmen as surveillance studies indicated that freshmen living in dormitories were at highest risk for developing meningococcal meningitis. At this time vaccination is not required for college freshmen; however, the American Academy of Pediatrics provides information to college freshmen and their parents about the risk of disease and the availability of vaccination (Bruce et al., 2001; Centers for Disease Control and Prevention [CDC], 2000).

People in close contact with patients with meningococcal meningitis should be treated with antimicrobial chemoprophylaxis using rifampin (Rifadin), ciprofloxacin hydrochloride (Cipro), or ceftriaxone sodium (Rocephin) (CDC, 2000). Therapy should be started as soon as possible after contact; a delay in the initiation of therapy will limit the effectiveness of the prophylaxis (Rosenstein et al., 2001). Vaccination should also be considered as an adjunct to antibiotic chemoprophylaxis for anyone living with a person who develops meningococcal infection. Vaccination for children and at-risk adults should be encouraged to avoid meningitis caused by *H. influenzae* and *S. pneumoniae*.

## Medical Management

Successful outcomes depend on the early administration of an antibiotic that crosses the blood–brain barrier into the subarachnoid space in sufficient concentration to halt the multiplication of bacteria. Penicillin antibiotics (eg, ampicillin, piperacillin) or one of the cephalosporins (eg, ceftriaxone sodium, cefotaxime sodium) may be used. Vancomycin hydrochloride alone or in combination with rifampin may be used if resistant strains of bacteria are identified. High doses of the appropriate antibiotic are administered intravenously.

Dexamethasone has been shown to be beneficial as adjunct therapy in the treatment of acute bacterial meningitis and in pneumococcal meningitis if given 15 to 20 minutes before the first dose of antibiotic and every 6 hours for the next 4 days. Studies indicate that dexamethasone improves the outcome in adults and does not increase the risk of gastrointestinal bleeding (de Gans & van de Beek, 2002).

Dehydration and shock are treated with fluid volume expanders. Seizures, which may occur in the early course of the disease, are controlled with phenytoin (Dilantin). Increased ICP is treated as necessary (see Chap. 61).

## Nursing Management

The patient may be critically ill; therefore, so many of the nursing interventions are collaborative with those of the physician, respiratory therapist, and other members of the health care team. The patient's prognosis may depend on the supportive care provided.

Neurologic status and vital signs are continually assessed. Pulse oximetry and arterial blood gas values are used to quickly identify the need for respiratory support as the increasing ICP compromises the brain stem. Insertion of a cuffed endotracheal tube (or tracheotomy) and mechanical ventilation may be necessary to maintain adequate tissue oxygenation.

Arterial blood pressures are monitored to assess for incipient shock, which precedes cardiac or respiratory failure. Rapid intravenous (IV) fluid replacement may be prescribed, but care is taken

to prevent fluid overload. Fever also will increase the workload of the heart and cerebral metabolism. ICP will increase in response to increased cerebral metabolic demands. Therefore, measures are taken to reduce body temperature as quickly as possible.

Other important components of nursing care include:

- Monitoring body weight, serum electrolytes, and urine volume, specific gravity, and osmolality, especially if the syndrome of inappropriate antidiuretic hormone (SIADH) secretion is suspected
- Protecting the patient from injury secondary to seizure activity or altered level of consciousness
- Preventing complications associated with immobility, such as pressure ulcers and pneumonia
- Instituting droplet precautions until 24 hours after the initiation of antibiotic therapy (oral and nasal discharge is considered infectious)

Any sudden, critical illness can be devastating to the family. Because the patient's condition is often critical and the prognosis guarded, the family needs to be informed about the patient's condition and permitted to see the patient at intervals, even though the priority is to address the patient's need for immediate and intensive treatment. An important aspect of the nurse's role is to support the patient and to assist the family in identifying others who can be supportive to them during the crisis.

## BRAIN ABSCESS

Although brain abscess is relatively rare, it is a complication encountered increasingly in patients whose immune systems have been suppressed either through therapy or disease.

## Pathophysiology

A brain abscess is a collection of infectious material within the tissue of the brain. It may occur by direct invasion of the brain from intracranial trauma or surgery; by spread of infection from nearby sites, such as the sinuses, ears, and teeth (paranasal sinus infections, otitis media, dental sepsis); or by spread of infection from other organs (lung abscess, infective endocarditis) (Hickey, 2003). To prevent brain abscess, otitis media, mastoiditis, sinusitis, dental infections, and systemic infections should be treated promptly.

## Clinical Manifestations

The clinical manifestations of a brain abscess result from alterations in intracranial dynamics (edema, brain shift), infection, or the location of the abscess (Chart 64-2). Headache, usually worse in the morning, is the most prevailing symptom. Vomiting is also common. Focal neurologic signs (weakness of an extremity, decreasing vision, seizures) may occur, depending on the site of the abscess. There may be a change in mental status, as reflected in lethargic, confused, irritable, or disoriented behavior. Fever may or may not be present.

## Assessment and Diagnostic Findings

Repeated neurologic examinations and continuing assessment of the patient are necessary to determine the location of the abscess. A computed tomography (CT) scan is invaluable in locating the site of the abscess, after the evolution and resolution of suppurative lesions, and in determining the optimal time for surgical inter-

Chart

vention. A magnetic resonance imaging (MRI) scan is useful to obtain images of the brain stem and posterior fossa if an abscess is suspected in these areas.

**Medical Management**

Brain abscess is treated with antimicrobial therapy and surgical incision or aspiration. If the abscess is encapsulated, CT-guided stereotactic needle aspiration under local anesthesia may be performed. Antimicrobial treatment is prescribed to eliminate the causative organism or reduce its virulence.

Penicillin G (20 million U) and chloramphenicol (Chloromycetin) (4 to 6 g/day given intravenously in divided doses) are usually prescribed because anaerobic streptococci and *Bacterioides* are the most common causative organisms (Hickey, 2003). Large IV doses are usually prescribed preoperatively to penetrate the blood-brain barrier and reach the abscess. The therapy is continued postoperatively. Corticosteroids may be prescribed to help reduce the inflammatory cerebral edema if the patient shows evidence of an increasing neurologic deficit. Antiseizure medications (phenytoin, phenobarbital) may be prescribed to prevent seizures. Multiple abscesses may be treated with appropriate antimicrobial therapy alone, with close monitoring by CT scans.

**Nursing Management**

Nursing care focuses on ongoing assessment of the neurologic status, administering medications, assessing the response to treatment, and providing supportive care.

Ongoing neurologic assessment alerts the nurse to changes in ICP, which may indicate a need for more aggressive intervention. The nurse also assesses and documents the responses to medications. Blood laboratory test results, specifically blood glucose and serum potassium levels, need to be closely monitored when corticosteroids are prescribed. Medical intervention may be required to return these values to normal or acceptable levels.

Patient safety is also a key nursing responsibility. Injury may result from decreased level of consciousness and falls related to motor weakness or seizures.

The patient with a brain abscess is extremely ill, and neurologic deficits may remain after treatment, such as hemiparesis, seizures, visual deficits, and cranial nerve palsies. Focal seizures are the most common sequelae, occurring in about 30% of patients (Hickey, 2003). The nurse must assess the family's ability to express their distress at the patient's condition, cope with the patient's illness and deficits, and obtain support.

**HERPES SIMPLEX VIRUS ENCEPHALITIS**

Encephalitis is an acute inflammatory process of the brain tissue. Herpes simplex virus (HSV) is the most common cause of acute encephalitis in the United States (Levitz, 1998). There are two herpes simplex viruses, HSV-1 and HSV-2. HSV-1 typically affects children and adults.

**Pathophysiology**

There are two possible modes of HSV-1 infection. In most cases, primary HSV-1 infection of the buccal mucosa occurs, followed by retrograde spread along the trigeminal nerve to the brain. It is also believed that latent virus in brain tissue may reactivate and result in encephalitis (Roos, 1999). HSV-2 most commonly affects neonates and is discussed in pediatric textbooks (Gutierrez & Prober, 1998).

**Clinical Manifestations**

HSV-1 encephalitis causes inflammation and necrosis in the temporal lobe, frontal lobe, and limbic system. The initial symptoms include fever, headache, confusion, and behavioral abnormalities (Roos, 1999). Focal neurologic symptoms reflect the areas of cerebral inflammation and necrosis and include behavioral change, focal seizures, dysphasia, hemiparesis, and altered level of consciousness. Focal symptoms are present within 7 days of infection and progress for 14 to 21 days.

**Assessment and Diagnostic Findings**

Neuroimaging studies, electroencephalography (EEG), and CSF examination are used to diagnose HSV encephalitis. MRI is the neuroimaging study of choice in the diagnosis of HSV encephalitis as it can help identify lesions in the temporal lobe.

The EEG demonstrates a specific wave pattern in 66% of cases of biopsy-proven HSV encephalitis. CSF reveals a high opening pressure and low glucose and high protein levels. Viral cultures are almost always negative. Since 1996, the polymerase chain reaction (PCR) technique has been used to diagnose HSV encephalitis (Roos, 1999). PCR will identify the DNA bands of the HSV specifically. The validity of PCR is very high between the third and tenth day of symptom onset.

**Medical Management**

Acyclovir (Zovirax), an antiviral agent, is the medication of choice in HSV treatment (Karch, 2002). The mode of action is the inhibition of viral DNA replication. It is usually well tolerated by the patient. To prevent relapse, treatment should continue for up to 3 weeks. Slow administration over 1 hour will prevent crystallization of the medication in the urine. The usual dose of acyclovir is decreased if the patient has a history of renal insufficiency (Karch, 2002). In the rare case of acyclovir resistance, foscarnet sodium (Foscavir) is prescribed (Roos, 1999).

## Nursing Management

Assessment of neurologic function is key to monitoring the progression of disease. Comfort measures to reduce headache include dimming the lights, limiting noise, and administering analgesic agents. Opioid analgesic medications may mask neurologic symptoms; therefore, they are used cautiously. Focal seizures and altered level of consciousness require care directed at injury prevention and safety. Nursing care addressing patient and family anxiety is ongoing throughout the illness. Monitoring of blood chemistry test results and urinary output will alert the nurse to the presence of renal complications related to acyclovir therapy.

## ARTHROPOD-BORNE VIRUS ENCEPHALITIS

Arthropod vectors transmit several types of viruses that cause encephalitis. The primary vector in North America is the mosquito. Arbovirus infection occurs in specific geographic areas during the summer and fall. The four types of arboviral encephalitis that occur in North America are LaCrosse encephalitis, St. Louis encephalitis, Western equine encephalitis, and Eastern equine encephalitis (Roos, 1999).

## Pathophysiology

Viral replication occurs at the site of the mosquito bite. If adequate virus is inoculated, a viremia ensues. The virus gains access to the central nervous system (CNS) via the cerebral capillaries. It spreads from neuron to neuron, predominantly affecting the cortical gray matter, the brain stem, and the thalamus. Meningeal exudates compound the clinical presentation by irritating the meninges and increasing ICP (Roos, 1999).

## Clinical Manifestations

All arboviral encephalitis begins with a flu-like prodrome, but specific neurologic manifestations depend on the viral type. LaCrosse encephalitis, for example, may present with focal neurologic symptoms and seizures. Mortality is low but residual seizures may occur. A unique clinical feature of St. Louis encephalitis is SIADH with hyponatremia. The mortality rate is 10% to 20%. The clinical manifestations of Eastern equine encephalitis are acute and carry a high mortality rate of 50% to 75% (Roos, 1999). Although the clinical manifestations of Western equine encephalitis are nonspecific, the morbidity rate is high.

## Assessment and Diagnostic Findings

Neuroimaging is not useful in diagnosing many types of encephalitis. In Eastern equine encephalitis, however, CT scan and MRI may reveal lesions in the basal ganglia and thalamus (Roos, 1999). The CSF analysis shows a normal glucose level, elevated protein level, and polymorphonuclear leukocytic pleocytosis. St. Louis, Eastern equine, and Western equine encephalitis viruses are rarely isolated in the CSF (Roos, 1999).

The age of the patient is important information in making a specific viral diagnosis. La Crosse virus encephalitis is the most common pediatric arboviral encephalitis. St. Louis encephalitis affects adults over 50 years of age; Eastern equine encephalitis is not age-specific (Roos, 1999). Western equine encephalitis can present as pediatric encephalitis but is less prevalent.

## Medical Management

There is no specific medication for arboviral encephalitis. Medical management is aimed at controlling seizures and increased ICP (Roos, 1999)

## Nursing Management

If the patient is very ill, hospitalization may be required. The nurse carefully assesses neurologic status and identifies improvement or deterioration in the patient's condition. Injury prevention is key in light of the potential for falls or seizures. Arboviral encephalitis may result in death or life-long residual health issues. The family will need support and teaching to cope with these outcomes.

Public education addressing the prevention of arboviral encephalitis is a key nursing role. Clothing that provides coverage and insect repellents should be used in high-risk areas. Community mosquito control is advocated.

## FUNGAL ENCEPHALITIS

Fungal infections of the CNS occur rarely in healthy people. The presentation of fungal encephalitis is related to geographic area and a compromised immune system (Leedom & Underman, 2000). The common fungi found around the world that can infect the CNS include *Cryptococcus neoformans*, *Histoplasma capsulatum*, *Aspergillus*, and *Candida albicans* (Davis, 1999). Other fungi are found only in certain regions: *Coccidioides immitis*, for example, is found in soil in central California, the southwest United States, northern Mexico, and areas of Argentina (Davis, 1999).

## Pathophysiology

The fungal spores enter the body via inhalation. They initially infect the lungs, causing vague respiratory symptoms. In some cases, the fungi may enter the bloodstream, causing a fungemia. If the fungemia overcomes the person's immune system, the fungus may spread to the CNS. The initial presentation is meningitis followed by encephalitis and brain abscesses. In addition to infecting the brain, the fungi may infect the spinal cord, producing an abscess. The abscess will produce symptoms of spinal cord compression (Davis, 1999).

## Clinical Manifestations

The common symptoms of fungal encephalitis include fever, malaise, headache, nuchal rigidity, lethargy, and mental status changes (Davis, 1999). *C. neoformans* is the most common fungus to infect the CNS. Symptoms of increased ICP related to hydrocephalus often occur (Go et al., 2000). Vascular changes are associated with *C. immitis* and *Aspergillus* (Leedom & Underman, 2000). Manifestations of vascular change may include arteritis or cerebral infarction.

## Assessment and Diagnostic Findings

CNS fungal infections present a diagnostic challenge because their presentations mimic other causes of encephalitis. The symptoms develop over a 2-week period. Fungal infection may also be present in organs such as the lungs or kidney (Davis, 1999). The presence of a compromised immune system and a history of living

in or recently having traveled to a geographic area where specific fungi are found in the soil may suggest fungal encephalitis (Davis, 1999; Leedom & Underman, 2000). Laboratory evaluation of blood shows an elevated white cell count and anemia. In some cases, serologic tests may show fungal antibodies in serum (Davis, 1999). The CSF shows an elevated white cell count and protein levels. *C. neoformans* is readily identified in the CSF fungal culture. The CSF culture is positive for other fungi in 50% of cases (Davis, 1999).

Neuroimaging is used to identify CNS changes related to fungal infection and will demonstrate fungal foci in organs initially invaded by the fungus. Although both MRI and CT scan are used in the workup for fungal encephalitis, MRI is more sensitive. The MRI may indicate lesions in the basal ganglia or thalamus, as well as hemorrhage, vascular complications, ischemia, aneurysm formation, or hydrocephalus (Go et al., 2000).

## Medical Management

Medical management is directed at the causative fungus and the neurologic consequences of the infection. Seizures are controlled by standard antiseizure medications. Increased ICP is controlled by repeated lumbar punctures or shunting of CSF. In contrast to patients with cryptococcal meningitis, the use of repeated (once or twice daily) lumbar punctures in patients with fungal infections has been an effective strategy to control increased ICP and has been associated with improved survival with fewer neurologic sequelae (Davis, 1999).

Antifungal agents are given for a specific period of time to cure the infection in patients with competent immune systems. Patients with compromised immune systems will receive antifungal therapy until the infection is controlled, after which they will receive a maintenance dose of the medication for an indefinite period of time.

Although the dose and duration of treatment depend on the causative fungi, amphotericin B (Abelcet, AmBisome, Amphocin, Amphotec, Fungizone, and Fungizone IV) is the standard antifungal agent used in treatment (Karch, 2002). Dosing must be high enough to penetrate the blood–brain barrier without causing renal toxicity.

Fluconazole (Diflucan) or flucytosine (5-FC, 5-fluorocytosine, Ancobon) may be administered in conjunction with amphotericin B. Both can be given orally and may be used as maintenance therapy. Potential side effects of fluconazole include nausea, abdominal pain, headache, dizziness, rash, reversible alopecia, and a transient increase in liver enzymes. When flucytosine is prescribed in conjunction with amphotericin B, bone marrow suppression may occur. Therefore, patients receiving these medications in combination should have leukocyte and platelet counts monitored twice a week (Davis, 1999).

## Nursing Management

If hydrocephalus develops and inflammation progresses, ICP will rise. Nursing assessment aimed at early identification of increased ICP is necessary to ensure early control and management. (See Chap. 61 for management of the patient with increased ICP.) Patient comfort may be optimized by administering nonopioid analgesics, limiting environmental stimuli, and positioning. Administration of amphotericin B may cause fever, chills, and body aches. Giving diphenhydramine (Benadryl) and acetaminophen (Tylenol) approximately 30 minutes before giving amphotericin B may prevent these side effects. Renal toxicity due to

amphotericin B is dose-limiting. Monitoring the serum creatinine and blood urea nitrogen levels may alert the nurse to the development of renal insufficiency and the need to address the patient's renal status.

Providing support will assist the patient and family to cope with the illness. Work-up of the patient for immunodeficiency diseases such as AIDS may put additional stress on the family. The nurse may need to mobilize community support systems for the patient and family.

## CREUTZFELDT-JAKOB AND NEW-VARIANT CREUTZFELDT-JAKOB DISEASE

Creutzfeldt-Jakob disease (CJD) and new-variant Creutzfeldt-Jakob (nvCJD) disease belong to a group of degenerative, infectious neurologic disorders called transmissible spongiform encephalopathies (TSE). Although CJD and nvCJD have distinct clinical and histologic differences, they have many features in common. Both are rare and have incubation periods ranging from months to decades. In both, the symptoms are progressive, there is no definitive treatment, and the outcome is fatal.

CJD occurs primarily in adults ages 50 to 70. The incidence of disease is 1 per million worldwide (Weihl & Roos, 1999). nvCJD occurs in younger patients and has a prolonged duration of illness compared to CJD. The risk of nvCJD in the United States is thought to be low as cattle are fed primarily with soy-derived feed (see Pathophysiology, below). Only a few rare cases of TSE have occurred in the United States to date (Weihl & Roos, 1999).

## Pathophysiology

Although still debated, the causative agent appears to be a **prion**, a proteinaceous, infectious particle smaller than a virus (Davis & Kennedy, 2000). The prion converts a normal cellular protein to an abnormal form, thus destroying neurons and glial cells. The gray matter takes on a spongy appearance (**spongiform** changes). Lesions, or plaques, also appear in various locations in the CNS (Weihl & Roos, 1999).

In CJD, the method of transmission is frequently unknown; however, direct transmission (by contact with infected animals) of the prion to humans may initiate the degenerative neurologic process. The disease is also heritable, and familial groups account for approximately 15% of cases, clustering in certain parts of the world. Iatrogenic transmission accounts for approximately 5% of cases and is due to contaminated neurosurgical devices and blood transfusions and the use of cadaver-derived growth hormone (growth hormone is now created synthetically) (World Health Organization, 2001).

Based primarily on an outbreak of cases in England in the late 1980s and through the 1990s, it was discovered that in nvCJD, the primary mode of transmission appeared to be the ingestion of CNS tissue of infected cattle. However, in 1998, additional concerns were raised about the safety of the English blood supply. The prion exists in lymphoid tissue and blood in all of the TSEs, but the incidence is higher in nvCJD. In light of the rising incidence of nvCJD, concern arose about the risk of infection through transfusion of blood products. There is no method available to screen blood for infectivity. All blood must be leukocyte-depleted prior to transfusion. In 1998, the use of plasma derived from citizens of the United Kingdom for use in manufacturing blood-derived products was banned in the U.S. (Weihl & Roos, 1999).

## Clinical Manifestations

Many patients with CJD have vague prodromal symptoms prior to specific neurologic changes. Symptoms usually include behavioral changes, dementia, mutism, visual changes, cerebellar, pyramidal, and extrapyramidal signs, and myoclonic jerks. The myoclonic jerks may be spontaneous or precipitated by auditory or tactile stimuli. The **myoclonus** (spasms) may involve a single muscle group, a limb, or the entire body. The symptoms progress until the patient is completely unaware of the environment and immobilized.

Although the same type of agent, a prion, causes nvCJD, there are distinct differences in the clinical manifestations of nvCJD and CJD. In nvCJD, there are more prion-reactive plaques, referred to as florid plaques, surrounding spongiform tissue throughout the cerebrum and cerebellum. The characteristic EEG changes present in CJD are absent in nvCJD. Anxiety, depression, and behavioral changes are the initial symptoms of nvCJD. Cerebellar symptoms occur, with gait changes and **ataxia**. Myoclonus is present in most patients diagnosed with nvCJD. Memory and cognitive impairments occur late in the course of nvCJD. Mutism occurs in both nvCJD and CJD (Almond, 1998).

## Assessment and Diagnostic Findings

Historically, sharp waves and spikes on the EEG were the only features available to support the diagnosis of CJD. Recent detection of a polyclonal antibody (protein 14-3-3) in CSF has enabled the diagnosis of CJD (Poser, Mollenhauder, Krab et al., 1999). In addition to the presence of a polyclonal antibody in CSF, a protein increase is demonstrated along with the presence of enzymes indicative of neuronal loss. CT scan is used to rule out disorders that may mimic the symptoms of CJD. MRI scans are useful, identifying lesions in the basal ganglia in most cases of CJD. Definitive diagnosis is made by brain biopsy or at autopsy.

## Medical Management

After the onset of specific neurologic symptoms, progression of disease occurs quickly. There is no effective treatment for CJD or nvCJD. The care of the patient is supportive and palliative. Goals of care include prevention of injury related to immobility and dementia, promotion of patient comfort, and provision of support and education for the family. The duration of disease is 4 to 5 months in CJD and 16 months in nvCJD, with death occurring as a result of respiratory failure or sepsis (Weihl & Roos, 1999).

## Nursing Management

As with medical management, the nursing care of patients is primarily supportive and palliative. Psychological and emotional support of patients and families throughout the course of the illness is needed. This care extends to providing for a dignified death and supporting the family through the processes of grief and loss. Hospice care should be used either at home or at an inpatient facility. (See Chap. 17 for an in-depth discussion of end-of-life issues.)

Prevention of disease transmission is an important part of nursing care. Although patient isolation is not necessary, use of standard precautions is important. Institutional protocols are followed for blood and body fluid exposure and decontamination of equipment. Conventional methods of sterilization do not destroy the prion. The CDC guidelines (based on WHO guidelines) out-

line the stringent sterilization methods that must be used to destroy the prion on surfaces.

## Autoimmune Processes

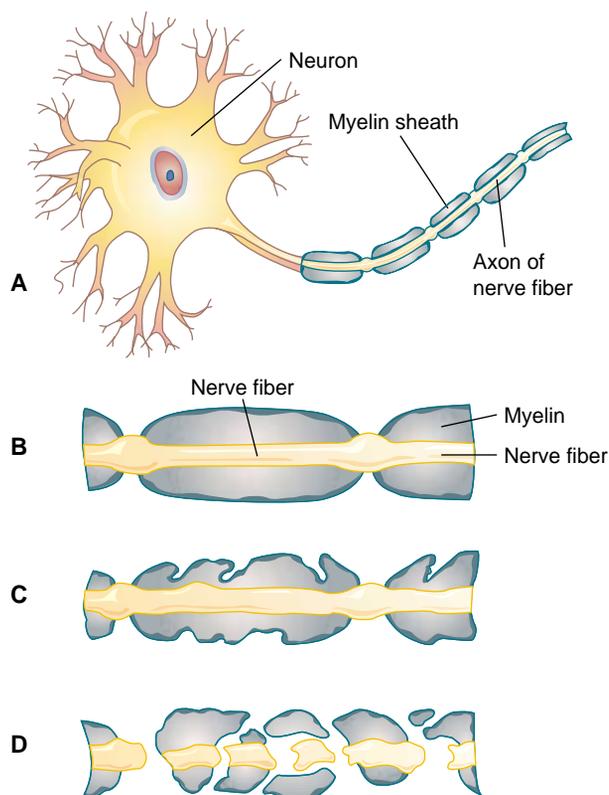

Autoimmune nervous system disorders include multiple sclerosis, myasthenia gravis, and Guillain-Barré syndrome.

## MULTIPLE SCLEROSIS

Multiple sclerosis (MS) is an immune-mediated progressive demyelinating disease of the CNS. Demyelination refers to the destruction of myelin, the fatty and protein material that surrounds certain nerve fibers in the brain and spinal cord; it results in impaired transmission of nerve impulses (Fig. 64-2). MS typically presents in young adults ages 20 to 40, and it affects women more frequently than men (Boyden, 2000).

The cause of MS is an area of ongoing research. Autoimmune activity results in demyelination, but the sensitized antigen has not been identified. Multiple factors play a role in the initiation of the immune process. Geographic prevalence is highest in northern Europe, southern Australia, the northern United States, and southern Canada (Noseworthy, Lucchinetti, Rodriguez et al., 2000). It is believed that an environmental exposure at a young age may play a role in the development of MS later in life.

Genetic predisposition is indicated by the presence of a specific cluster (haplotype) of human leukocyte antigens (HLA) on the cell wall. The presence of this haplotype may promote susceptibility to factors, such as viruses, that trigger the autoimmune response activated in MS. A specific virus capable of initiating the

**FIGURE 64-2** The process of demyelination. **A** and **B** depict a normal nerve cell and axon with myelin. **C** and **D** show the slow disintegration of myelin, resulting in a disruption in axon function.

autoimmune response has not been identified. It is believed that DNA on the virus mimics the amino acid sequence of myelin, resulting in an immune system cross-reaction in the presence of a defective immune system (Boyden, 2000).

## Pathophysiology

Sensitized T cells typically cross the blood–brain barrier; their function is to check the CNS for antigens and then leave. In MS, the sensitized T cells remain in the CNS and promote the infiltration of other agents that damage the immune system. The immune system attack leads to inflammation that destroys myelin (which normally insulates the axon and speeds the conduction of impulses along the axon) and oligodendroglial cells that produce myelin in the CNS.

Plaques of sclerotic tissue appear on demyelinated axons, further interrupting the transmission of impulses. Demyelination interrupts the flow of nerve impulses and results in a variety of manifestations, depending on which nerves are affected. Demyelinated axons are scattered irregularly throughout the CNS (Fig. 64-3). The areas most frequently affected are the optic nerves, chiasm, and tracts; the cerebrum; the brain stem and cerebellum; and the spinal cord. Eventually the axons themselves begin to degenerate, resulting in permanent and irreversible damage (Bashir & Whitaker, 2002; Halper, 2001).

## Clinical Manifestations

The course of MS may assume many different patterns (Fig. 64-4). In some patients, the disease follows a benign course, with a normal life span and symptoms so mild that patients do not seek

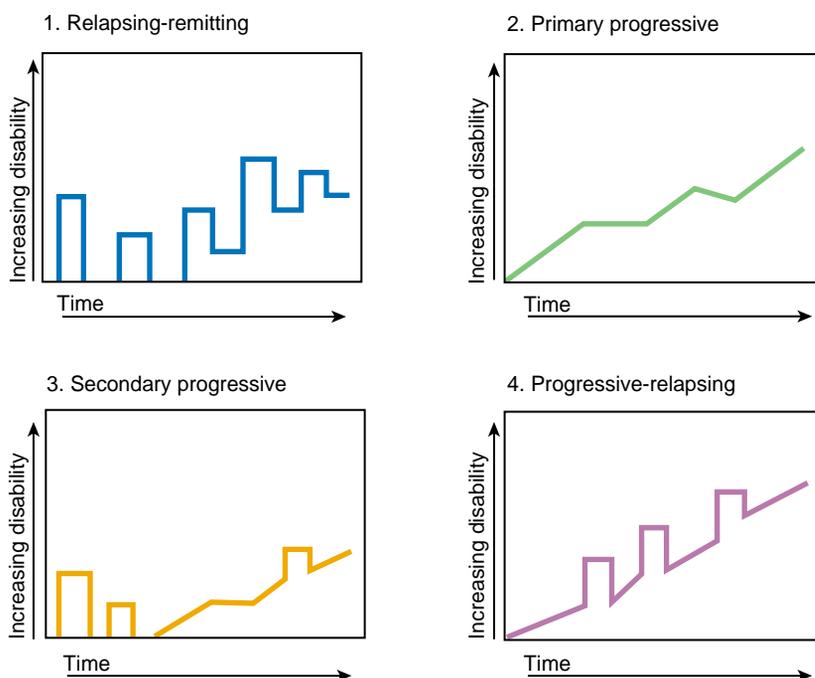

health care and treatment. Eighty percent to 85% of cases of MS begin with a relapsing–remitting course, with complete recovery between clearly defined symptomatic exacerbations (Noseworthy et al., 2000). This form of the disease does not progress between relapses, although the majority of cases with this initial type of course change to a secondary–progressive course after some years (Halper, 2001). Secondary–progressive MS begins as relapsing–remitting disease but changes to a course in which there is not full recovery but rather continued progression between defined relapses. Ten percent to 20% percent of patients have a primary progressive course (Noseworthy et al., 2000; Halper, 2001), in which symptoms progress throughout the disease, with increasing disability. Primary progressive MS is characterized by continuous decline, with the potential development of quadriplegia, cognitive dysfunction, visual loss, and brain stem syndromes.

The signs and symptoms of MS are varied and multiple, reflecting the location of the lesion (plaque) or combination of lesions. The primary symptoms most commonly reported are fatigue, depression, weakness, numbness, difficulty in coordination, loss of balance, and pain. Visual disturbances due to lesions in the optic nerves or their connections may include blurring of vision, **diplopia**, patchy blindness (scotoma), and total blindness.

Fatigue impairs optimal function throughout the course of the disease. Fatigue is exacerbated when febrile illness, environmental temperature, hot showers, and normal circadian rhythms during the afternoon elevate body temperature. Depression may relate to the pathophysiology or may occur as a reaction to the diagnosis. Suicide as the cause of death occurs 7.5 times more frequently among persons diagnosed with MS than among the age-matched general population. If suicide occurs, it is likely to occur within the first 5 years of diagnosis (Walther & Hohlfield, 1999).

**FIGURE 64-3** Multiple sclerosis. (A) A CT scan of brain demonstrates an area of demyelination in the periventricular white matter of the right frontal lobe. The plaque is perpendicular to the lateral ventricle, a typical finding in MS. (B) An MRI of the spinal cord in the same patient highlights another typical finding: a flame-shaped area of demyelination within the midcervical region of the spinal cord. Courtesy of the Danbury Hospital Department of Radiology.

**FIGURE 64-4** Types and courses of MS. 1. Relapsing remitting (RR) MS is characterized by clearly acute attacks with full recovery or with sequelae and residual deficit upon recovery. Periods between disease relapses are characterized by lack of disease progression. 2. Primary progressive (PP) MS is characterized by disease showing progression of disability from onset, without plateaus or remissions or with occasional plateaus and temporary minor improvements. 3. Secondary progressive (SP) MS begins with an initial RR course, followed by progression of variable rate, which may also include occasional relapses and minor remissions. 4. Progressive-relapsing (PR) MS shows progression from onset but with clear acute relapses with or without recovery. Lublin, F. D., Reingold, F. C., et al. (1996). Defining the clinical course of multiple sclerosis: Results of an international survey. *Neurology*, 46(64), 907–911. Used with permission from Lippincott Williams & Wilkins.

Pain occurs in 66% of patients with MS. Pain may be due to demyelination of pain fibers, mechanical stress on muscles, bones, and joints due to disability, or treatment measures (Maloni, 2000).

**Spasticity** (muscle hypertonicity) of the extremities and loss of the abdominal reflexes are due to involvement of the main motor pathways (pyramidal tracts) of the spinal cord. Disruption of the sensory axons may produce sensory dysfunction (paresthesias, pain). Cognitive and psychosocial problems may reflect frontal or parietal lobe involvement; some degree of cognitive change (eg, memory loss, decreased concentration) occurs in about half of patients, but severe cognitive changes with dementia (progressive organic mental disorder) are rare. Involvement of the cerebellum or basal ganglia can produce ataxia (impaired coordination of movements) and tremor. Loss of the control connections between the cortex and the basal ganglia may occur and cause emotional lability and euphoria. Bladder, bowel, and sexual dysfunctions are common.

Secondary complications of MS include urinary tract infections, constipation, pressure ulcers, contracture deformities, dependent pedal edema, pneumonia, reactive depression, and decreased bone mass. Emotional, social, marital, economic, and vocational problems may also be a consequence of the disease.

Exacerbations and remissions are characteristic of MS. During exacerbations, new symptoms appear and existing ones worsen; during remissions, symptoms decrease or disappear. Relapses may be associated with periods of emotional and physical stress. MRI studies demonstrate that many plaques do not produce serious symptoms; however, the disease may be very active, as demonstrated by MRI. There also is evidence that remyelination actually occurs in some patients.

### Assessment and Diagnostic Findings

MRI is the primary diagnostic tool for visualizing plaques, documenting disease activity, and evaluating the effect of treatment. Electrophoresis of CSF identifies the presence of oligoclonal banding (several bands of immunoglobulin G bonded together,

indicating an immune system abnormality). Evoked potential studies can help define the extent of the disease process and monitor changes. Underlying bladder dysfunction is diagnosed by urodynamic studies. Neuropsychological testing may be indicated to assess cognitive impairment. A sexual history helps to identify changes in sexual function.

### Gerontologic Considerations

Due to improved treatment and an increase in the average life span for patients with MS, more individuals are living to become elderly. These patients may have chronic health problems for which they may be taking additional medications that could interact with medications prescribed for MS. The absorption, distribution, metabolism, and excretion of medications are altered in the elderly as a result of age-related changes in renal and liver functions. Therefore, the elderly must be monitored closely for adverse and toxic effects of MS medications and for osteoporosis (particularly with frequent corticosteroid use, which may be required for exacerbations). The cost of medications could lead to poor adherence to the prescribed regimen in elderly patients on fixed incomes.

Elderly MS patients have specific physical and psychosocial challenges. Physical challenges include impaired mobility, spasticity, pain and bladder dysfunction, impaired sleep, and an increased need for assistance with self-care (Klewer et al., 2001). Psychosocial issues include depression and suicidal thoughts (Klewer et al., 2001).

### Medical Management

No cure exists for MS. An individualized, organized, and rational treatment program is indicated to relieve the patient's symptoms and provide continuing support, particularly for individuals with cognitive changes (50%), who may need more structure and support. The goals of treatment are to delay the progression of the disease, manage chronic symptoms, and treat acute exacerbations. Many patients with MS have stable disease and require

only intermittent treatment, whereas others experience steady progression of their disease. Symptoms requiring intervention include spasticity, fatigue, bladder dysfunction, and ataxia. Management strategies target the various motor and sensory symptoms and effects of immobility that can occur.

### PHARMACOLOGIC THERAPY

Three medications, referred to as the “ABC (and R) drugs,” are currently the main pharmacologic therapy for MS. The interferons beta-1a (Avonex) and beta-1b (Betaseron) reduce the frequency of relapse by 30% and decrease the appearance of new lesions on MRI by 80% (Tselis & Lisak, 1999). Glatiramer acetate (Copaxone) also reduces the number of lesions on MRI and the relapse rate. In March 2002, the FDA approved a fourth agent, Rebif, for the treatment of relapsing MS (PRISMS Study Group, 2001).

All of these medications have multiple immune activities. The interferons reduce T-cell proliferation; glatiramer acetate inhibits antigen-specific T-cell activation (Noseworthy et al., 2000). All of the disease-modifying medications, the “ABC (and R) drugs,” require injections. Interferon beta-1b (Betaseron) is administered subcutaneously every other day, interferon beta-1a (Avonex) is given by intramuscular injection once a week, and glatiramer acetate (Copaxone) is administered by subcutaneous injection every day. Rebif is administered subcutaneously three times a week. Seventy-five percent of patients taking one of the interferons experience flu-like symptoms; these symptoms can be controlled with nonsteroidal anti-inflammatory drugs (NSAIDs) and usually resolve after a few months of therapy (Walther & Hohlfeld, 1999). Patients receiving these injectable medications and their families must be instructed in injection technique and must become knowledgeable about site reactions and other possible side effects (Ross, 2001).

Mitoxantrone (Novantrone), which received FDA approval in 2000 (Rolak, 2001), is an antineoplastic agent used primarily to treat leukemia and lymphoma. It received approval to treat secondary progressive MS due to its immunosuppressive qualities (Rolak, 2001). Patients need to have laboratory tests (complete blood count) performed, and the results must be closely monitored due to the potential for leukopenia and cardiac toxicity. A few patients (2% to 3%) will develop signs and symptoms of cardiomyopathy and heart failure due to cardiac toxicity (Rolak, 2001).

Corticosteroids modulate the immune response and are used to limit the severity and duration of exacerbations. These agents suppress the immune response and decrease inflammatory change. Nerve conduction is restored with variable degrees of symptomatic recovery. Typically the patient receives high-dose IV methylprednisolone followed by an oral prednisone taper. The nurse must carefully monitor the patient for side effects related to corticosteroids such as mood changes and fluid and electrolyte alterations and teach the patient and family about side effects.

Researchers continue to investigate other possible treatments for MS. Many agents that have been investigated have proven to be too toxic for clinical use. Researchers are studying strategies that facilitate the proliferation of anti-inflammatory cytokines. T-cell vaccination and agents that inhibit oxygen radicals and proteases are under study (Noseworthy et al., 2000).

Medications are also prescribed for management of specific symptoms. Baclofen (Lioresal), a GABA agonist, is the medication of choice in treating spasms. It can be administered orally or by intrathecal injection. Benzodiazepines (Valium), tizanidine (Zanaflex), and dantrolene (Dantrium) may also be used to treat spasms. Patients with disabling spasms and contractures may re-

quire nerve blocks or surgical intervention. Fatigue that interferes with activities of daily living may be treated with amantadine (Symmetrel), pemoline (Cylert), or fluoxetine (Prozac). Ataxia is a chronic problem most resistant to treatment. Medications used to treat ataxia include beta-adrenergic blockers (Inderal), anti-seizure agents (Neurontin), and benzodiazepines (Klonopin).

Various strategies for pain management can be implemented, based on the type of pain that exists. Acute pain may be treated with antidepressants, opiates, or antiseizure medications. Surgical procedures may be required to interrupt the pain pathway. Subacute pain as well as chronic back pain can be effectively treated with NSAIDs. Physical therapy may also benefit the patient by improving posture and strength.

Pain may also be due to osteoporosis (Maloni, 2000). Perimenopausal women with MS are more likely to develop osteoporosis than those without MS. Immobility, corticosteroid therapy, and estrogen loss play a role in the development of osteoporosis in women with MS. Bone mineral density testing is recommended for this high-risk group (Smeltzer, Zimmerman, Capriotti & Fernandes, 2002). Diagnosis and treatment of osteoporosis are discussed at length in Chapter 68.

Management of bladder and bowel control is often among the patient’s most difficult problems and a variety of medications (anticholinergics, alpha-adrenergic blockers, or antispasmodic agents) may be prescribed. Nonpharmacologic strategies also assist in establishing effective bowel and bladder elimination (see Nursing Process section).

Urinary tract infection is often superimposed on the underlying neurologic dysfunction. Ascorbic acid (vitamin C) may be prescribed to acidify the urine, making bacterial growth less likely. Antibiotics are prescribed when appropriate.

## NURSING PROCESS: THE PATIENT WITH MULTIPLE SCLEROSIS

### Assessment

Nursing assessment addresses actual and potential problems associated with the disease, including neurologic problems, secondary complications, and the impact of the disease on the patient and family. The patient’s movements and walking are observed to determine if there is danger of falling. Assessment of function is carried out both when the patient is well rested and when fatigued. The patient is assessed for weakness, spasticity, visual impairment, incontinence, and disorders of swallowing and speech. Additional areas of assessment include the following: How has MS affected the patient’s lifestyle? How well is the patient coping? What would the patient like to do better?

### Diagnosis

#### NURSING DIAGNOSES

Based on the assessment data, the patient’s major nursing diagnoses may include the following:

- Impaired physical mobility related to weakness, muscle paresis, spasticity
- Risk for injury related to sensory and visual impairment
- Impaired urinary and bowel elimination (urgency, frequency, incontinence, constipation) related to nervous system dysfunction
- Impaired speech and swallowing related to cranial nerve involvement

- Disturbed thought processes (loss of memory, dementia, euphoria) related to cerebral dysfunction
- Ineffective individual coping related to uncertainty of course of MS
- Impaired home maintenance management related to physical, psychological, and social limits imposed by MS
- Potential for sexual dysfunction related to spinal cord involvement or psychological reactions to condition

## Planning and Goals

The major goals for the patient may include promotion of physical mobility, avoidance of injury, achievement of bladder and bowel continence, promotion of speech and swallowing mechanisms, improvement of cognitive function, development of coping strengths, improved home maintenance management, and adaptation to sexual dysfunction.

## Nursing Interventions

An individualized program of physical therapy, rehabilitation, and education is combined with emotional support. The nursing interventions include face-to-face and telephone interactions that address patient education to enable the person with MS to deal with the physiologic, social, and psychological problems that accompany chronic disease (Madonna & Keating, 1999).

### PROMOTING PHYSICAL MOBILITY

Relaxation and coordination exercises promote muscle efficiency. Progressive resistive exercises are used to strengthen weak muscles because diminishing muscle strength is often significant in MS.

#### Exercises

Walking improves the gait, particularly when there is loss of position sense of the legs and feet. If certain muscle groups are irreversibly affected, other muscles can be trained to take over their actions. Instruction in the use of assistive devices may be needed to ensure their correct and safe use.

### Minimizing Spasticity and Contractures

Muscle spasticity is common and, in its later stages, is characterized by severe adductor spasm of the hips with flexor spasm of the hips and knees. If this is not relieved, fibrous contractures of these joints with resultant pressure ulcers over the sacrum and hips (due to diminished sensation and the inability to position the patient properly) occur. Warm packs may be beneficial, but hot baths should be avoided because of risk for burn injury secondary to sensory loss and increasing symptoms that may occur with an elevation of the body temperature.

Daily exercises for muscle stretching are prescribed to minimize joint contractures. Special attention is given to the hamstrings, gastrocnemius muscles, hip adductors, biceps, and wrist and finger flexors. Muscle spasticity is common and interferes with normal function. A stretch–hold–relax routine is helpful for relaxing and treating muscle spasticity. Swimming and stationary bicycling are useful, and progressive weight-bearing can relieve spasticity in the legs. The patient should not be hurried in any of these activities because this often increases spasticity.

### Activity And Rest

The patient is encouraged to work to a point just short of fatigue. Very strenuous physical exercise is not advisable because it raises the body temperature and may aggravate symptoms. The patient

is advised to take frequent short rest periods, preferably lying down. Extreme fatigue may contribute to the exacerbation of symptoms.

### Minimizing Effects of Immobility

Because of the decrease in physical activity that often occurs with MS, complications associated with immobility, including pressure ulcers, expiratory muscle weakness, and accumulation of bronchial secretions, need to be considered and steps taken to prevent them. Measures to prevent such complications include assessment and maintenance of skin integrity and coughing and deep-breathing exercises.

### PREVENTING INJURY

If motor dysfunction causes problems of incoordination and clumsiness, or if ataxia is apparent, the patient is at risk for falling. To overcome this disability, the patient is taught to walk with feet wide apart to widen the base of support and to increase walking stability. If there is loss of position sense, the patient is taught to watch the feet while walking. Gait training may require assistive devices (walker, cane, braces, crutches, parallel bars) and instruction about their use by a physical therapist. If the gait remains inefficient, a wheelchair or motorized scooter may be the solution. The occupational therapist is a valuable resource person in suggesting and securing aids to promote independence. If incoordination is a problem and tremor of the upper extremities occurs when voluntary movement is attempted (intention tremor), weighted bracelets or wrist cuffs are helpful. The patient is trained in transfer and activities of daily living.

Because sensory loss may occur in addition to motor loss, pressure ulcers are a continuing threat to skin integrity. Confinement to a wheelchair increases the risk. See Chapter 11 for a discussion of the prevention and treatment of pressure ulcers.

### ENHANCING BLADDER AND BOWEL CONTROL

Generally, bladder symptoms fall into the following categories: (1) inability to store urine (hyperreflexic, uninhibited); (2) inability to empty the bladder (hyporeflexic, hypotonic); and (3) a mixture of both types. The patient with urinary frequency, urgency, or incontinence requires special support. The sensation of the need to void must be heeded immediately, so the bedpan or urinal should be readily available. A voiding time schedule is set up (every 1.5 to 2 hours initially, with gradual lengthening of the interval). The patient is instructed to drink a measured amount of fluid every 2 hours and then attempt to void 30 minutes after drinking. Using a timer or wristwatch with an alarm may be helpful for the patient who does not have enough sensation to signal the need to empty the bladder. The nurse encourages the patient to take the prescribed medications to treat bladder spasticity because this allows greater independence. Intermittent self-catheterization has been successful in maintaining bladder control in patients with MS. (See Chap. 11 for a discussion of intermittent self-catheterization.) If the female patient has permanent urinary incontinence, urinary diversion procedures may be considered. The male patient may wear a condom appliance for urine collection.

Bowel problems include constipation, fecal impaction, and incontinence. Adequate fluids, dietary fiber, and a bowel-training program are frequently effective in solving these problems. (See Chap. 11 for a discussion of promoting bowel continence.)

### MANAGING SPEECH AND SWALLOWING DIFFICULTIES

When the cranial nerves controlling the mechanisms of speech and swallowing are involved, dysarthrias (defects of articulation) marked by slurring, low volume of speech, and difficulties in

phonation may occur. Swallowing disturbances (**dysphagia**) may also occur. A speech therapist evaluates speech and swallowing and instructs the patient, family, and health team members about strategies to compensate for speech and swallowing problems. The nurse reinforces this instruction and encourages the patient and family to adhere to the plan. Impaired swallowing increases the patient's risk for aspiration; therefore, strategies (eg, having suction apparatus available, careful feeding, proper positioning for eating) are needed to reduce that risk (Galvan, 2001).

### IMPROVING SENSORY AND COGNITIVE FUNCTION

Measures may be taken if visual defects (the cranial nerves affecting vision may be affected by MS) or changes in cognitive status occur.

#### Vision

An eye patch or a covered eyeglass lens may be used to block visual impulses of one eye when the patient has diplopia (double vision). Prism glasses may be helpful for the bedridden patient who is having difficulty reading in the supine position. People unable to read regular-print materials are eligible for the free talking book services of the Library of Congress or may obtain large-type books from local libraries.

#### Cognition and Emotional Responses

Cognitive impairment and emotional lability may occur early in MS in some patients and may impose numerous stresses on the patient and family. Some patients with MS are forgetful and easily distracted and may exhibit emotional lability.

Patients adapt to illness in a variety of ways, which may include denial, depression, withdrawal, and hostility. Emotional support assists patients and their families to adapt to the changes and uncertainties associated with MS and to cope with the disruption in their lives. The patient is assisted to set meaningful and realistic goals to achieve a sense of purpose, to remain as active as possible, and to keep up social interests and activities. Hobbies may help the patient's morale and provide satisfying interests if the disease progresses to the stage in which formerly enjoyed activities can no longer be pursued.

The family should be made aware of the nature and degree of cognitive impairment. The environment is kept structured, and lists and other memory aids are used to help the patient with cognitive changes to maintain a daily routine. The occupational therapist can be helpful in formulating a structured daily routine.

#### Strengthening Coping Mechanisms

The diagnosis of MS is always distressing to the patient and family. They need to know that no two patients with MS have identical symptoms or courses of illness. Although some patients do experience significant disability early, others have a near-normal life span with minimal disability. Some families, however, face overwhelming frustrations and problems. MS affects people who are often in a productive stage of life and concerned about career and family responsibilities. Family conflict, disintegration, separation, and divorce are not uncommon. Often, very young family members assume the responsibility of caring for a parent with MS. Nursing interventions in this area include alleviating stress and making appropriate referrals for counseling and support to minimize the adverse effects of dealing with chronic illness.

The nurse, mindful of these complex problems, initiates home care and coordinates a network of services, including social services, speech therapy, physical therapy, and homemaker services. To strengthen the patient's coping skills, as much information as possible is provided. People who live with chronic illness need an

updated list of the assistive devices, services, and resources that are available.

Coping through problem solving involves helping the patient define the problem and develop alternatives for its management. Careful planning and maintaining flexibility and a hopeful attitude are useful for psychological and physical adaptation.

### IMPROVING SELF-CARE ABILITIES

MS can affect every facet of daily living. After certain abilities are lost, they are often impossible to regain. Physical function may vary from day to day. Modifications that allow independence in self-care should be implemented (eg, assistive eating devices, raised toilet seat, bathing aids, telephone modifications, long-handled comb, tongs, modified clothing). Physical and emotional stresses should be avoided as much as possible because these may worsen symptoms and impair performance. Exposure to heat increases fatigue and muscle weakness, so air conditioning in at least one room is recommended. Exposure to extreme cold may increase spasticity.

### PROMOTING SEXUAL FUNCTIONING

Patients with MS and their partners face problems that interfere with sexual activity, arising not only as a direct consequence of nerve damage but also from psychological reactions to the disease. Easy fatigability, conflicts arising from dependency and depression, emotional lability, loss of self-esteem, and feelings of low self-worth compound the problem. Erectile and ejaculatory disorders in men and orgasmic dysfunction and adductor spasms of the thigh muscles in women can make sexual intercourse difficult or impossible. Bladder and bowel incontinence and urinary tract infections add to the difficulties.

An experienced sexual counselor helps bring into focus the patient's or partner's sexual resources and suggests relevant information and supportive therapy (Sipski & Alexander, 1997). Sharing and communicating feelings, planning for sexual activity (to minimize the effects of fatigue), and exploring alternative methods of sexual expression may open up a wide range of sexual enjoyment and experiences.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

As the disease progresses, the patient and family need to learn new strategies to maintain optimal independence. Teaching of new self-care techniques may be initiated in the hospital or clinic setting and reinforced in the home. Teaching about self-care may address the use of assistive devices, self-catheterization, and administration of medications that affect the course of the disease or treat complications. Although the disease-modifying medications (the "ABC and R medications") may slow the progression of disease and disability in many persons with MS, they are not effective in all patients. Patients who receive these medications will require teaching and support, while those unable to take them or for whom the medications have not been effective need continued support and assistance in coping with this reality. Exercises that enable the patient to continue some form of activity or that maintain or improve swallowing, speech, or respiratory function may be taught to the patient and family (Chart 64-3).

#### Continuing Care

After discharge, the home care nurse often provides teaching and reinforcement of these new techniques in the patient's home. Nurses in the home setting assess for changes in the patient's

## Chart 64-3

## Home Care Checklist • The Patient With Multiple Sclerosis

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• State how to access the local chapter of the National MS Society and available resources.	✓	✓
• Discuss the clinical course of MS.	✓	✓
• Identify strategies to manage symptoms (pain, cognitive responses, dysphagia, tremors, visual disturbances).	✓	✓
• State how to prevent complications (pressure ulcers, pneumonia, depression).	✓	✓
• Identify coping strategies.	✓	✓
• Identify ways to minimize fatigue.	✓	✓
• Explain how to prevent injury.	✓	✓
• State ways to adapt to sexual dysfunction.	✓	✓
• Discuss ways to control bowel and bladder function.	✓	✓
• Name benefits of exercise and physical activity.	✓	✓
• Identify ways to minimize immobility and spasticity.	✓	✓
• Describe medication regimen and potential adverse effects.	✓	✓
• Demonstrate correct techniques of administering injectable medications, if prescribed.	✓	✓

physical and emotional status, provide physical care to the patient if required, coordinate outpatient services and resources, and encourage health promotion, appropriate health screenings, and adaptation. If changes in the disease or its course are noted, the home care nurse encourages the patient to contact the primary care provider because treatment of an acute exacerbation or new problem may be indicated. Continuing health care and follow-up are recommended.

The patient with MS is encouraged to contact the local chapter of the National Multiple Sclerosis Society for services, publications, and contact with others with MS. Local chapters also provide direct services to patients. Through group participation, the patient has an opportunity to meet others with similar problems, to share experiences, and to learn self-help methods in a social environment.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Improved physical mobility
  - a. Participates in gait-training and rehabilitation program
  - b. Establishes a balanced program of rest and exercise
  - c. Uses assistive devices correctly and safely
2. Is free of injury
  - a. Uses visual cues to compensate for decreased sense of touch or position
  - b. Asks for assistance when necessary
3. Attains or maintains control of bladder and bowel patterns
  - a. Monitors self for urine retention and employs intermittent self-catheterization technique, if indicated

## NURSING RESEARCH PROFILE 64-1

### Quality of Life for People With Multiple Sclerosis

Stuifbergen, A., Seraphine, A., & Roberts, G. (2000). An explanatory model of health promotion and quality of life in chronic disabling conditions. *Nursing Research*, 49(3), 122–129.

#### Purpose

The purpose of this study was to test an explanatory model of variables influencing health promotion and quality of life in persons with multiple sclerosis (MS). This was the second phase of a project designed to investigate the issues surrounding the health-promotion needs of individuals with chronic disabling conditions and the outcomes associated with the performance of health-promoting behaviors.

#### Study Sample and Design

This was a one-time cross-sectional design using mailed questionnaires. Participants were recruited for the study using targeted mailings to individuals with MS on the mailing lists of national MS Society chapters. The study sample included 786 persons with MS (630 women and 156 men) who returned surveys. Instruments used included the Incapacity Status Scale (ISS), Barriers to Health Promoting Activities for Disabled Persons Scale, Personal Resource Questionnaire, Acceptance of Illness Scale, Self-Rated Abilities for Health Practices scale, Health Promoting Lifestyle Profile-II (HPLP-II), and the Quality of Life Index (QLI).

#### Findings

The analysis revealed that the original model was generally well specified, with an adequate fit to the data. The model supported the hypothesis that quality of life is the outcome of a complex interplay between contextual factors (severity of illness), antecedent variables, and health-promoting behaviors. The revised model, with the addition of two paths between personal resources and barriers, had an improved fit of the data compared to the original model. The original and revised models are depicted in the article. Resources, barriers, self-efficacy, and acceptance accounted for 58% of the variance in the frequency of health-promoting behaviors and 66% of the variance in perceived quality of life.

#### Nursing Implications

Further testing of the model was recommended, especially in samples of differing ethnic and cultural backgrounds. Nurses working with MS patients should be aware that quality of life is the outcome of the interaction of many variables. The authors suggest that nurses can improve health-promoting behaviors and quality of life using interventions that enhance social support, decrease barriers, and increase specific self-efficacy for health behaviors.

- b. Identifies the signs and symptoms of urinary tract infection
- c. Maintains adequate fluid and fiber intake
4. Participates in strategies to improve speech and swallowing
  - a. Practices exercises recommended by speech therapist
  - b. Maintains adequate nutritional intake without aspiration
5. Compensates for altered thought processes
  - a. Uses lists and other aids to compensate for memory losses
  - b. Discusses problems with trusted advisor or friend
  - c. Substitutes new activities for those that are no longer possible
6. Demonstrates effective coping strategies
  - a. Maintains sense of control
  - b. Modifies lifestyle to fit goals and limitations
  - c. Verbalizes desire to pursue goals and developmental tasks of adulthood
  - d. Adheres to plan for home maintenance management
  - e. Uses appropriate self-care techniques to maintain independence
  - f. Engages in health promotion activities and health screenings as appropriate
8. Adapts to changes in sexual function
  - a. Is able to discuss problem with partner and appropriate health professional
  - b. Identifies alternate means of sexual expression

## MYASTHENIA GRAVIS

Myasthenia gravis, an autoimmune disorder affecting the myoneuronal junction, is characterized by varying degrees of weakness of the voluntary muscles. Women tend to develop the disease at an earlier age (20 to 40 years of age) compared to men (60 to 70 years of age), and women are affected more frequently (Heitmiller, 1999).

### Pathophysiology

Normally, a chemical impulse precipitates the release of acetylcholine from vesicles on the nerve terminal at the myoneuronal junction. The acetylcholine attaches to receptor sites on the motor end plate, stimulating muscle contraction. Continuous binding of acetylcholine to the receptor site is required for muscular contraction to be sustained.

In myasthenia gravis, autoantibodies directed at the acetylcholine receptor sites impair transmission of impulses across the

myoneuronal junction. Therefore, fewer receptors are available for stimulation, resulting in voluntary muscle weakness that escalates with continued activity (Fig. 64-5). These antibodies are found in 80% to 90% of the people with myasthenia gravis. Eighty percent of persons with myasthenia gravis have either thymic hyperplasia or a thymic tumor (Roos, 1999), and the thymus gland is believed to be the site of antibody production. In patients who are antibody negative, it is believed that the offending antibody is directed at a portion of the receptor site rather than the whole complex.

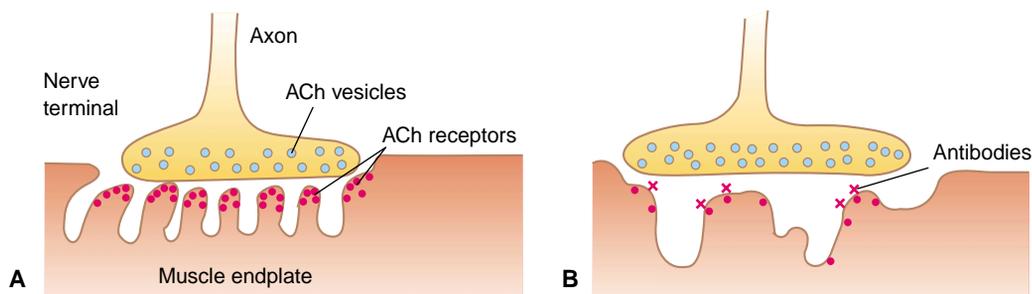

### Clinical Manifestations

The initial manifestation of myasthenia gravis usually involves the ocular muscles. Diplopia (double vision) and ptosis (drooping of the eyelids) are common. However, the majority of patients also experience weakness of the muscles of the face and throat (bulbar symptoms) and generalized weakness. Weakness of the facial muscles will result in a bland facial expression. Laryngeal involvement produces **dysphonia** (voice impairment) and increases the patient's risk for choking and aspiration. Generalized weakness affects all the extremities and the intercostal muscles, resulting in decreasing vital capacity and respiratory failure. Myasthenia gravis is purely a motor disorder with no effect on sensation or coordination.

### Assessment and Diagnostic Findings

An anticholinesterase test is used to diagnose myasthenia gravis. Anticholinesterase agents stop the breakdown of acetylcholine, thereby increasing acetylcholine availability. Edrophonium chloride (Tensilon) is injected intravenously, 2 mg at a time to a total of 10 mg. Thirty seconds after injection, facial muscle weakness and ptosis should resolve for about 5 minutes. This immediate improvement in muscle strength after administration of this agent represents a positive test and usually confirms the diagnosis. Atropine 0.4 mg should be available to control the side effects of edrophonium, which include bradycardia, sweating, and cramping (Roos, 1999).

The acetylcholine receptor antibody titers are elevated as indicated previously. Repetitive nerve stimulation tests record the electrical activity in targeted muscles after nerve stimulation. A 15% decrease in successive action potentials is observed in patients with myasthenia gravis (Heitmiller, 1999). The thymus gland, which is a site of acetylcholine receptor antibody production, is enlarged in myasthenia gravis. MRI demonstrates this enlargement in 90% of cases (Wilkins & Bulkley, 1999).

**FIGURE 64-5** Myasthenia gravis. (A) Normal ACh receptor site. (B) ACh receptor site in myasthenia gravis.

## Medical Management

Management of myasthenia gravis is directed at improving function and reducing and removing circulating antibodies. Therapeutic modalities include administration of anticholinesterase agents and immunosuppressive therapy, plasmapheresis, and thymectomy.

### PHARMACOLOGIC THERAPY

Anticholinesterase agents such as pyridostigmine bromide (Mestinon) and neostigmine bromide (Prostigmin) provide symptomatic relief by increasing the relative concentration of available acetylcholine at the neuromuscular junction. Dosage is increased gradually until maximal benefits (improved strength, less fatigue) are obtained. Adverse effects of anticholinesterase therapy include abdominal pain, diarrhea, nausea, and increased oropharyngeal secretions. Pyridostigmine tends to have fewer side effects (Chart 64-4). Improvement with anticholinesterase therapy is not complete or long-lasting (Heitmiller, 1999).

**NURSING ALERT** Maintenance of stable blood levels of anticholinergic medication is imperative to stabilize muscle strength. Therefore, the anticholinesterase medications must be given on time. Any delay in administration of medications may exacerbate muscle weakness and make it impossible for the patient to take medications orally.

The goal of immunosuppressive therapy is to reduce the production of the antibody. Corticosteroids suppress the patient's immune response, thus decreasing the amount of antibody production. As the corticosteroid dosage is gradually increased, the anticholinesterase dosage is lowered. The patient's ability to maintain effective respirations and to swallow is monitored throughout. Prednisone, taken on alternate days to lower the incidence of side effects, appears to be successful in suppressing the disease. The patient sometimes shows a marked decrease in muscle strength right after therapy is started, but this is usually only temporary.

**Chart 64-4 • PHARMACOLOGY**  
Potential Adverse Effects  
of Anticholinesterase Medications

#### CNS

Irritability  
Anxiety  
Insomnia  
Headache  
Dysarthria  
Syncope

Anorexia  
Increased salivation

#### Skeletal Muscles

Fasciculations  
Spasms  
Weakness

#### Genitourinary

Frequency  
Urgency

#### Integumentary

Rash  
Flushing

Cytotoxic medications have also been used, although the precise mechanism of action in myasthenia is not fully understood. Medications such as azathioprine (Imuran), cyclophosphamide (Cytoxan), and cyclosporine reduce the circulating antiacetylcholine receptor antibody titers. Side effects are significant; therefore, these agents are reserved for patients who do not respond to other forms of therapy.

A number of medications are contraindicated for patients with myasthenia gravis because they worsen myasthenic symptoms. Risks and benefits should be weighed by the physician and the patient before taking any new medications, including antibiotics, cardiovascular medications, antiseizure and psychotropic medications, morphine, quinine and related agents, beta-blockers, and nonprescription medications. Procaine (Novocain) should be avoided, and the patient's dentist is so advised.

### PLASMAPHERESIS

Plasma exchange (plasmapheresis) is a technique used to treat exacerbations. The patient's plasma and plasma components are removed through a centrally placed large-bore double-lumen catheter. The blood cells and antibody-containing plasma are separated; then the cells and a plasma substitute are reinfused. Plasma exchange produces a temporary reduction in the titer of circulating antibodies. Plasma exchange improves the symptoms in 75% of patients, although improvement lasts only a few weeks unless plasmapheresis is continued or other forms of treatment such as immunosuppression with corticosteroids are initiated (Bedlack & Sanders, 2000). IV immune globulin (IVIG) has recently been shown to be nearly as effective as plasmapheresis in controlling symptom exacerbation (Qureshi, Choudhry, Akbar et al., 1999). However, neither therapy is a cure as it does not stop the production of the acetylcholine receptor antibodies.

### SURGICAL MANAGEMENT

Thymectomy (surgical removal of the thymus gland) can produce antigen-specific immunosuppression and result in clinical improvement. It can decrease or eliminate the need for medication. In one study 92% of post-thymectomy patients had symptomatic improvement, with 50% of them no longer requiring pharmacologic therapy (Wilkins & Bulkley, 1999). The entire gland must be removed for optimal clinical outcomes; therefore, surgeons prefer the transsternal surgical approach. After surgery, the patient is monitored in an intensive care unit, with special attention to respiratory function. After the thymus gland is removed, it may take up to 1 year for the patient to benefit from the procedure due to the long life of circulating T cells (Wilkins & Bulkley, 1999).

### Complications: Myasthenic Crisis Versus Cholinergic Crisis

A myasthenic crisis is an exacerbation of the disease process characterized by severe generalized muscle weakness and respiratory and bulbar weakness that may result in respiratory failure. Crisis may result from disease exacerbation or a specific precipitating event. The most common precipitator is infection; others include medication change, surgery, pregnancy, and high environmental temperature (Bella & Chad, 1998).

Symptoms of anticholinergic overmedication (cholinergic crisis) may mimic the symptoms of exacerbation. Differentiation can be achieved with the edrophonium chloride (Tensilon) test. The patient with myasthenic crisis improves immediately following administration of edrophonium, while the patient with

cholinergic crisis may experience no improvement or deteriorate. If myasthenic crisis is diagnosed, neostigmine methylsulfate (PMS-Neostigmine, Prostigmin) is administered intramuscularly or intravenously until the patient is able to swallow oral anticholinesterase medications. Plasmapheresis and IVIG, which reduce the antibody load, also may be used to treat myasthenic crisis. If cholinergic crisis is identified, all anticholinesterase medications are stopped. The patient receives atropine (Atropine sulfate), the antidote for the anticholinesterase medications.

Neuromuscular respiratory failure is the critical complication of crisis. Respiratory muscle and bulbar weakness combine to cause respiratory compromise. Weak respiratory muscles will not support inhalation. An inadequate cough and an impaired gag reflex caused by bulbar weakness result in poor airway clearance. Values on two respiratory function tests, the negative inspiratory force and vital capacity, will be the first clinical signs to deteriorate. Careful monitoring of these values enables the nurse to monitor for impending respiratory failure. Respiratory support and airway protection are key interventions for the nurse caring for the patient in crisis. Endotracheal intubation and mechanical ventilation may be needed (see Chap. 25). Nutritional support may be needed if the patient is intubated for a long period.

## Nursing Management

Because myasthenia gravis is a chronic disease and most patients are seen on an outpatient basis, much of the nursing care focuses on patient and family teaching. Educational topics for outpatient self-care include medication management, energy conservation, strategies to help with ocular manifestations, and prevention and management of complications.

Medication management is a crucial component of ongoing care. Understanding the action of the medications and taking them on schedule is emphasized, as are the consequences of delaying medication and the signs and symptoms of myasthenic and cholinergic crisis. The patient can determine the best times for daily dosing by keeping a diary to determine fluctuation of symptoms and to learn when the medication is wearing off. The medication schedule can then be manipulated to maximize strength throughout the day.

The patient is also taught strategies to conserve energy. To do this, the nurse helps the patient identify the best times for rest periods throughout the day. If the patient lives in a two-story home, the nurse can suggest that frequently used items such as hygiene products, cleaning products, and snacks be kept on each floor to minimize travel between floors. The patient is encouraged to apply for a handicapped license plate to minimize walking from parking spaces and to schedule activities to coincide with peak energy and strength levels.

To minimize the risk of aspiration, mealtimes should coincide with the peak effects of anticholinesterase medication. In addition, rest before meals is encouraged to reduce muscle fatigue. The patient is advised to sit upright during meals with the neck slightly flexed to facilitate swallowing. Soft foods in gravy or sauces can be swallowed more easily; if choking occurs frequently, the nurse can suggest pureeing food to a pudding consistency. Suction should be available at home and the patient and family instructed in its use. Gastrostomy feedings may be necessary in some patients to ensure adequate nutrition.

Impaired vision results from ptosis of one or both eyelids, decreased eye movement, or double vision. To prevent corneal damage when the eyelids do not close completely, the patient is instructed to tape the eyes closed for short intervals and regularly

instill artificial tears. Patients who wear eyeglasses can have “crutches” attached to help lift the eyelids. Patching one eye can help with double vision.

The patient is reminded of the importance of maintaining health promotion practices and of following health care screening recommendations. Factors that will exacerbate symptoms and potentially cause crisis should be noted and avoided: emotional stress, infections (particularly respiratory infections), vigorous physical activity, some medications, and high environmental temperature. The Myasthenia Gravis Foundation of America provides support groups, services, and educational materials for patients, families, and health care providers.

## MANAGING MYASTHENIC AND CHOLINERGIC CRISES

Respiratory distress and varying degrees of dysphagia (difficulty swallowing), dysarthria (difficulty speaking), eyelid ptosis, diplopia, and prominent muscle weakness are symptoms of myasthenic and cholinergic crisis. The patient is placed in an intensive care unit for constant monitoring because of associated intense and sudden fluctuations in clinical condition.

IV edrophonium chloride (Tensilon) is used to differentiate the type of crisis. It improves the condition of the patient in myasthenic crisis and temporarily worsens that of the patient in cholinergic crisis. If the patient is in true myasthenic crisis, neostigmine methylsulfate is administered intramuscularly or intravenously. If the edrophonium test is inconclusive or there is increasing respiratory weakness, all anticholinesterase medications are stopped, and atropine sulfate is given to reduce excessive secretions.

Providing ventilatory assistance takes precedence in the immediate management of the patient with myasthenic crisis. Ongoing assessment for respiratory failure is essential. The nurse assesses the respiratory rate, depth, and breath sounds and monitors pulmonary function parameters (vital capacity and negative inspiratory force) to detect pulmonary problems before respiratory dysfunction progresses. Blood is drawn for arterial blood gas analysis. Endotracheal intubation and mechanical ventilation may be needed (see Chap. 25).

When there is severe weakness of the abdominal, intercostal, and pharyngeal muscles, the patient cannot cough, take deep breaths, or clear secretions. Chest physical therapy, including postural drainage to mobilize secretions, and suctioning to remove secretions may have to be performed frequently. (Postural drainage should not be performed for 30 minutes after feeding.)

Assessment strategies and supportive measures include the following:

- Arterial blood gases, serum electrolytes, input and output, and daily weight are monitored.
- If the patient cannot swallow, nasogastric tube feedings may be prescribed.
- Sedatives and tranquilizers are avoided because they aggravate hypoxia and hypercapnia and can cause respiratory and cardiac depression.

## GUILLAIN-BARRÉ SYNDROME

Guillain-Barré syndrome is an autoimmune attack of the peripheral nerve myelin. The result is acute, rapid segmental demyelination of peripheral nerves and some cranial nerves, producing ascending weakness with **dyskinesia** (inability to execute voluntary movements), hyporeflexia, and **paresthesias** (numbness). In 66% of cases, there is a predisposing event, most often a respiratory or gastrointestinal infection, although vaccination, pregnancy,

and surgery have also been identified as antecedent events (Bella & Chad, 1998). Infection with *Campylobacter jejuni* (a relatively common gastrointestinal bacterial pathogen) precedes Guillain-Barré syndrome in a few cases (Ho & Griffin, 1999; Lindenbaum, Kissel & Mendel, 2001).

The antecedent event usually occurs 2 weeks before symptoms begin. Weakness usually begins in the legs and progresses upward for about 1 month. Maximum weakness varies but usually includes neuromuscular respiratory failure and bulbar weakness. The duration of the symptoms is variable: complete functional recovery may take up to 2 years (Hickey, 2003). Any residual symptoms are permanent and reflect axonal damage from demyelination.

The annual incidence of Guillain-Barré is 0.6 to 1.9 cases per 100,000. Eighty-five percent of patients recover with minimal residual symptoms. Severe residual deficits occur in up to 10% of patients. Residual deficits are most likely in patients with rapid disease progression, those who require mechanical ventilation, or those 60 years of age or older. Death occurs in 3% to 8% of cases, resulting from respiratory failure, autonomic dysfunction, sepsis, or pulmonary emboli (Bella & Chad, 1998).

## Pathophysiology

Myelin is a complex substance that covers nerves, providing insulation and speeding the conduction of impulses from the cell body to the dendrites. The cell that produces myelin in the peripheral nervous system is the Schwann cell. In Guillain-Barré the Schwann cell is spared, allowing for remyelination in the recovery phase of the disease.

Guillain-Barré is the result of a cell-mediated immune attack on peripheral nerve myelin proteins (Ho & Griffin, 1999). The best-accepted theory is that an infectious organism contains an amino acid that mimics the peripheral nerve myelin protein. The immune system cannot distinguish between the two proteins and attacks and destroys peripheral nerve myelin. Studies indicate that an exact location within the peripheral nervous system, the ganglioside GM1b, is the most likely target of the immune attack (Yuki, Ang, Koga et al., 2000). With the autoimmune attack there is an influx of macrophages and other immune-mediated agents that attack myelin, cause inflammation and destruction, and leave the axon unable to support nerve conduction.

## Clinical Manifestations

Classic Guillain-Barré begins with muscle weakness and diminished reflexes of the lower extremities. Hyporeflexia and weakness progress and may result in quadriplegia. Demyelination of the nerves that innervate the diaphragm and intercostal muscles results in neuromuscular respiratory failure. Twenty-five percent of patients will require mechanical ventilation within 18 days of symptom onset (Bella & Chad, 1998). Sensory symptoms include paresthesias of the hands and feet and pain related to the demyelination of sensory fibers.

Cranial nerve demyelination can result in a variety of clinical manifestations. Optic nerve demyelination may result in blindness. Bulbar muscle weakness related to demyelination of the glossopharyngeal and vagus nerves results in an inability to swallow or clear secretions. Vagus nerve demyelination results in autonomic dysfunction, manifested by instability of the cardiovascular system. The presentation is variable and may include tachycardia, bradycardia, hypertension, or orthostatic hypotension. The symptoms of autonomic dysfunction occur and resolve

rapidly. Guillain-Barré does not affect cognitive function or level of consciousness.

While the classic clinical features include areflexia and ascending weakness, variation in presentation occurs. There may be a sensory presentation, with progressive sensory symptoms, an atypical axonal destruction, and the Miller-Fisher variant, which includes paralysis of the ocular muscles, ataxia, and areflexia (Ho & Griffin, 1999).

## Assessment and Diagnostic Findings

The patient presents with symmetric weakness, diminished reflexes, and upward progression of motor weakness. A history of a viral illness in the previous few weeks suggests the diagnosis. Changes in vital capacity and negative inspiratory force are assessed to identify impending neuromuscular respiratory failure. Serum laboratory tests are not useful in the diagnosis. However, elevated protein levels are detected in CSF evaluation, without an increase in other cells. Evoked potential studies demonstrate a progressive loss of nerve conduction velocity (Bella & Chad, 1999).

## Medical Management

Because of the possibility of rapid progression and neuromuscular respiratory failure, Guillain-Barré is a medical emergency, requiring intensive care unit management. Careful assessment of changes in motor weakness and respiratory function alert the clinician to the physical and respiratory needs of the patient. Respiratory therapy or mechanical ventilation may be necessary to support pulmonary function and adequate oxygenation. Mechanical ventilation may be required for an extended period. The patient is weaned from mechanical ventilation when the respiratory muscles can again support spontaneous respiration and maintain adequate tissue oxygenation.

Other interventions are aimed at preventing the complications of immobility. These may include the use of anticoagulant agents and thigh-high elastic compression stockings or sequential compression boots to prevent thrombosis and pulmonary emboli.

Plasmapheresis and IVIG are used to directly affect the peripheral nerve myelin antibody level. Both therapies decrease circulating antibody levels and reduce the amount of time the patient is immobilized and dependent on mechanical ventilation. Studies indicate that IVIG and plasmapheresis are equally effective in treating Guillain-Barré (Bella & Chad, 1999; Winer, 2002).

The cardiovascular risks posed by autonomic dysfunction require continuous ECG monitoring. Tachycardia and hypertension are treated with short-acting medications such as alpha-adrenergic blocking agents. Hypotension is managed by increasing the amount of IV fluid administered. The use of short-acting agents is important because autonomic dysfunction is very labile.

## NURSING PROCESS: THE PATIENT WITH GUILLAIN-BARRÉ SYNDROME

### Assessment

Ongoing assessment for disease progression is critical. The patient is monitored for life-threatening complications (respiratory failure, cardiac dysrhythmias, DVTs) so that appropriate interventions can be initiated. Because of the threat to the patient in this sudden, potentially life-threatening disease, the nurse must assess the patient's and family's ability to cope and their use of appropriate coping strategies.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Ineffective breathing pattern and impaired gas exchange related to rapidly progressive weakness and impending respiratory failure
- Impaired physical mobility related to paralysis
- Imbalanced nutrition, less than body requirements, related to inability to swallow
- Impaired verbal communication related to cranial nerve dysfunction
- Fear and anxiety related to loss of control and paralysis

### COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include the following:

- Respiratory failure
- Autonomic dysfunction

## Planning and Goals

The major goals for the patient may include improved respiratory function, increased mobility, improved nutritional status, effective communication, decreased fear and anxiety, and absence of complications.

## Nursing Interventions

### MAINTAINING RESPIRATORY FUNCTION

Respiratory function can be maximized with incentive spirometry and chest physiotherapy. Monitoring for changes in vital capacity and negative inspiratory force are key to early intervention for neuromuscular respiratory failure. Mechanical ventilation is required if the vital capacity falls, making spontaneous breathing impossible and tissue oxygenation inadequate.

Parameters for determining the appropriate time to begin mechanical ventilation include a vital capacity of 12 to 15 mL/kg, downward vital capacity trend over 4 to 6 hours, and an inability to clear secretions (Bella & Chad, 1999). The potential need for mechanical ventilation should be discussed with the patient and family on admission to provide time for psychological preparation and decision-making. Intubation and mechanical ventilation will result in less anxiety if it is initiated on a nonemergent basis to a well-informed patient. The patient may require mechanical ventilation for a long period. Nursing management of the patient requiring mechanical ventilation is discussed in Chapter 25.

Bulbar weakness that impairs the ability to swallow and clear secretions is another factor in the development of respiratory failure in the patient with Guillain-Barré. Suctioning may be needed to maintain a clear airway.

The nurse assesses the blood pressure and heart rate frequently to identify autonomic dysfunction so that interventions can be initiated quickly if needed. Medications are administered or a temporary pacemaker is placed for clinically significant bradycardia (Winer, 2002).

### ENHANCING PHYSICAL MOBILITY

Nursing interventions to enhance physical mobility and prevent the complications of immobility are key to the function and survival of these patients. The paralyzed extremities are supported in

functional positions, and passive range-of-motion exercises are performed at least twice daily.

DVT and pulmonary embolism are threats to the paralyzed patient. Nursing interventions are aimed at preventing DVT. Range-of-motion exercises, altering positioning, anticoagulation, thigh-high elastic compression stockings or sequential compression boots, and adequate hydration will decrease the risk for DVT.

Padding may be placed over bony prominences such as the elbows and heels to reduce the risk for pressure ulcers. The need for consistent position changes every 2 hours cannot be overemphasized. The nurse evaluates laboratory test results that may indicate malnutrition or dehydration, both of which increase the risk for pressure ulcers. Collaboration with the physician and dietitian will result in a plan to meet the patient's nutritional and hydration needs.

### PROVIDING ADEQUATE NUTRITION

Paralytic ileus may result from insufficient parasympathetic activity. In this event, the nurse administers IV fluids and parenteral nutrition as prescribed and monitors for the return of bowel sounds. If the patient cannot swallow due to **bulbar paralysis** (immobility of muscles), a gastrostomy tube may be placed to administer nutrients. The nurse carefully assesses the return of the gag reflex and bowel sounds before resuming oral nutrition.

### IMPROVING COMMUNICATION

Because of paralysis and ventilator management, the patient cannot talk, laugh, or cry and thus has no method for communicating needs or expressing emotion. Establishing some form of communication with picture cards or an eye blink system will provide a means of communication. Collaboration with the speech therapist may be helpful in developing a communication mechanism that is most effective for a specific patient.

### DECREASING FEAR AND ANXIETY

The patient and family are faced with a sudden, potentially life-threatening disease, and anxiety and fear are constant themes for them. The impact of disease on the family will depend on the patient's age and role within the family. Referral to a support group may provide information and support to the patient and family.

The family may feel helpless in caring for the patient. Mechanical ventilation and monitoring devices may frighten and intimidate them. Family members often want to participate in physical care; with instruction and support by the nurse, they should be allowed to do so.

In addition to fear, the patient may experience isolation, loneliness, and lack of control. Nursing interventions that increase the patient's sense of control include providing information about the condition, emphasizing a positive appraisal of coping resources, and teaching relaxation exercises and distraction techniques. The positive attitude and atmosphere of the multidisciplinary team are important to promote a sense of well-being.

Diversional activities are encouraged to decrease loneliness and isolation. Encouraging visitors, engaging visitors or volunteers to read to the patient, listening to music or books on tape, and watching television are ways to alleviate the patient's sense of isolation.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Thorough assessment of respiratory function at regular intervals is essential because respiratory insufficiency and subsequent fail-

ure due to weakness or paralysis of the intercostal muscles and diaphragm may develop quickly. Respiratory failure is the major cause of mortality, which is reported to be as high as 10% to 20%. Vital capacity is monitored frequently and at regular intervals in addition to respiratory rate and the quality of respirations, so that respiratory insufficiency can be anticipated. Decreasing vital capacity associated with weakness of the muscles used in swallowing, which causes difficulty in both coughing and swallowing, indicates impending respiratory failure. Signs and symptoms include breathlessness while speaking, shallow and irregular breathing, use of accessory muscles, tachycardia, and changes in respiratory pattern.

Parameters for determining the onset of respiratory failure are established on admission, allowing intubation and the initiation of mechanical ventilation on a nonemergent basis. This also allows the patient to be prepared for the procedure in a controlled manner, which reduces anxiety and complications.

Other complications include cardiac dysrhythmias, which necessitate ECG monitoring, transient hypertension, orthostatic hypotension, DVT, pulmonary embolism, urinary retention, and other threats to any immobilized and paralyzed patient. These require monitoring and attention to prevent them and prompt treatment if indicated.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

Patients with Guillain-Barré syndrome and their families are usually frightened by the sudden onset of life-threatening symptoms and their severity. Therefore, teaching the patient and family about the disorder and its generally favorable prognosis is important (Chart 64-5). During the acute phase of the illness, the patient and family are instructed about strategies they can implement to minimize the effects of immobility and other complications. As function begins to return, family members and other home care providers are instructed about care of the patient and their role in the rehabilitation process. Preparation for discharge is an interdisciplinary effort requiring family or caregiver education by all team members, including the nurse, physician, occupational and physical therapists, speech therapist, and respiratory therapist.

## Continuing Care

Most patients with Guillain-Barré syndrome experience complete recovery. Patients who have experienced total or prolonged paralysis require intensive rehabilitation; the extent depends on the patient's needs. Approaches include a comprehensive inpatient program if deficits are significant, an outpatient program if the patient can travel by car, or a home program of physical and occupational therapy. The recovery phase may be long and will require patience as well as involvement on the part of the patient and family.

During acute care the focus is on obvious needs, issues, and deficits. The nurse needs to remind or instruct patients and family members of the need for continuing health promotion and screening practices following this initial phase of care.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Maintains effective respirations and airway clearance
  - a. Has normal breath sounds on auscultation
  - b. Demonstrates gradual improvement in respiratory function
2. Shows increasing mobility
  - a. Regains use of extremities
  - b. Participates in rehabilitation program
  - c. Demonstrates no contractures and minimal muscle atrophy
3. Receives adequate nutrition and hydration
  - a. Consumes diet adequate to meet nutritional needs
  - b. Swallows without aspiration
4. Demonstrates recovery of speech
  - a. Can communicate needs through alternative strategies
  - b. Practices exercises recommended by the speech therapist
5. Shows lessening fear and anxiety
6. Absence of complications
  - a. Breathes spontaneously
  - b. Has vital capacity within normal range
  - c. Exhibits normal arterial blood gases and oximetry

Chart 64-5

### Home Care Checklist • The Patient With Guillain-Barré Syndrome

*At the completion of the home care instruction, the patient or caregiver will be able to:*

	Patient	Caregiver
• Describe the disease process of Guillain-Barré syndrome.	✓	✓
• Manage respiratory needs: tracheostomy care, suctioning.		✓
• Demonstrate proper body mechanics regarding lifting and transfers.		✓
• Practice gait training and strength endurance.	✓	✓
• Perform range-of-motion exercises.	✓	✓
• Perform activities of daily living and manage self-care:		
• Nutrition	✓	✓
• Bowel and bladder management	✓	✓
• Skin care	✓	✓
• Adaptive equipment for bathing, hygiene, grooming, dressing	✓	✓
• Operate and explain function of medical equipment and mobility aids: walkers, wheelchairs, bedside commodes, tub transfer benches, adaptive devices	✓	✓
• Use coping mechanisms and diversional activities appropriately.	✓	✓
• Implement safety measures in the home.	✓	✓
• Know how to contact and use community resources and the Guillain-Barré Syndrome Foundation International.	✓	✓

## Cranial Nerve Disorders

Because the brain stem and cranial nerves involve vital motor, sensory, or autonomic functions of the body, these nerves may be affected by conditions arising primarily within these structures or in secondary extension from adjacent disease processes. The cranial nerves (Fig. 64-6) are examined separately and in sequence (see Chap. 60). Some cranial nerve deficits can be detected by observing the patient's face, eye movements, speech, and swallowing. Electromyography (EMG) is used to investigate motor and sensory dysfunction. MRI is used to obtain images of the cranial nerves and brain stem. An overview of disorders that may affect each of the cranial nerves, including clinical manifestations and nursing interventions, is presented in Table 64-1. The following discussion centers on trigeminal neuralgia, a condition affecting the fifth cranial nerve, and Bell's palsy, caused by involvement of the seventh cranial nerve. These are the most common disorders of the cranial nerves.

### TRIGEMINAL NEURALGIA (TIC DOULOUREUX)

Trigeminal neuralgia is a condition of the fifth cranial nerve characterized by paroxysms of pain in the area innervated by any of the three branches, but it most commonly occurs in the second and third branches of the trigeminal nerve (Maloni, 2000) (Fig. 64-7). The pain ends as abruptly as it starts and is described as a unilateral shooting and stabbing sensation. The unilateral nature of the pain is an important diagnostic characteristic (Preul, 2001). Associated involuntary contraction of the facial muscles can cause sudden closing of the eye or a twitch of the mouth, hence the name *tic douloureux* (painful twitch). The cause is not certain, but chronic compression or irritation of the trigeminal nerve or de-

generative changes in the gasserian ganglion are suggested causes. Vascular pressure from structural abnormalities (loop of an artery) encroaching on the trigeminal nerve, gasserian ganglion, or root entry zone has also been suggested as a cause.

Trigeminal neuralgia is 400 times more common in patients with MS than in the general population. The pain is more often cyclic and affects men with MS at a higher rate than women with MS (Maloni, 2000).

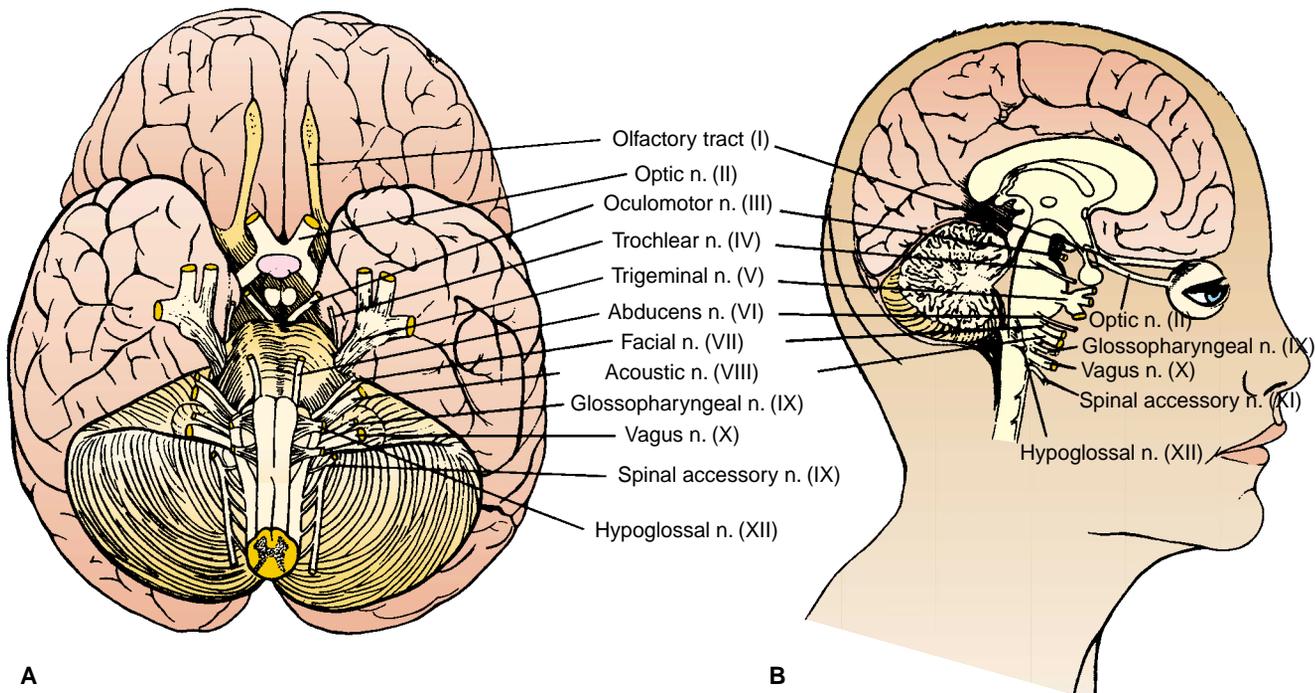

Early attacks, appearing most often in the fifth decade of life, are usually mild and brief. Pain-free intervals may be measured in terms of minutes, hours, days, or longer. With advancing years, the painful episodes tend to become more frequent and agonizing. The patient lives in constant fear of attacks.

Paroxysms can occur with any stimulation of the terminals of the affected nerve branches, such as washing the face, shaving, brushing the teeth, eating, and drinking. A draft of cold air and direct pressure against the nerve trunk may also cause pain. Certain areas are called trigger points because the slightest touch immediately starts a paroxysm or episode. To avoid stimulating these areas, patients with trigeminal neuralgia try not to touch or wash their faces, shave, chew, or do anything else that might cause an attack. These behaviors are a clue to diagnosis.

### Medical Management

#### PHARMACOLOGIC THERAPY

Antiseizure agents, such as carbamazepine (Tegretol), relieve pain in most patients with trigeminal neuralgia by reducing the transmission of impulses at certain nerve terminals. Carbamazepine is taken with meals. Serum levels must be monitored to avoid toxicity in patients who require high doses to control the pain. Side effects include nausea, dizziness, drowsiness, and aplastic anemia. The patient is monitored for bone marrow depression during long-term therapy. Gabapentin (Neurontin) and baclofen (Lioresal)

**FIGURE 64-6** The cranial nerves. (A) Inferior view of the brain showing the cranial nerve. (B) Lateral view showing a schematic version of the cranial nerves.

Table 64-1 • Disorders of Cranial Nerves

DISORDER	CLINICAL MANIFESTATIONS	NURSING INTERVENTIONS
<b>Olfactory Nerve—I</b> Head trauma Intracranial tumor Intracranial surgery	Unilateral or bilateral anosmia (temporary or persistent) Diminished taste for food	Assess sense of smell. Assess for cerebrospinal fluid rhinorrhea if patient has sustained head trauma.
<b>Optic Nerve—II</b> Optic neuritis Increased intracranial pressure Pituitary tumor	Lesions of optic tract producing homonymous hemianopsia	Assess visual acuity. Restructure environment to prevent injuries. Teach patient to accommodate for visual loss.
<b>Oculomotor Nerve—III</b> <b>Trochlear Nerve—IV</b> <b>Abducens Nerve—VI</b> Vascular Brain stem ischemia Hemorrhage and infarction Neoplasm Trauma Infection	Dilation of pupil with loss of light reflex on one side Impairment of ocular movement Diplopia Gaze palsies Ptosis of eyelid	Assess extraocular movement and for non-reactive pupil.
<b>Trigeminal Nerve—V</b> Trigeminal neuralgia Head trauma Cerebellopontine lesion Sinus tract tumor and metastatic disease Compression of trigeminal root by tumor	Pain in face Diminished or loss of corneal reflex Chewing dysfunction	Assess for pain and triggering mechanisms for pain. Assess for difficulty in chewing. Discuss trigger zones and pain precipitants with patient. Protect cornea from abrasion. Ensure good oral hygiene. Educate patient about medication regimen.
<b>Facial Nerve—VII</b> Bell's palsy Facial nerve tumor Intracranial lesion Herpes zoster	Facial dysfunction; weakness and paralysis Hemifacial spasm Diminished or absent taste Pain	Recognize facial paralysis as emergency; refer for treatment as soon as possible. Teach protective care for eyes. Select easily chewed foods; patient should eat and drink from unaffected side of mouth. Emphasize importance of oral hygiene. Provide emotional support for changed appearance of face.
<b>Acoustic Nerve—VIII</b> Tumors and acoustic neuroma Vascular compression of nerve Ménière's syndrome	Tinnitus Vertigo Hearing difficulties	Assess pattern of vertigo. Provide for safety measures to prevent falls. Ensure that patient can obtain balance before ambulating. Caution patient to change positions slowly. Assist with ambulation. Encourage use of activity of daily living aids.
<b>Glossopharyngeal Nerve—IX</b> Glossopharyngeal neuralgia from neurovascular compression of cranial nerves IX and X Trauma Inflammatory conditions Tumor Vertebral artery aneurysms	Pain at base of tongue Difficulty in swallowing Loss of gag reflex Palatal, pharyngeal, and laryngeal paralysis	Assess for paroxysmal pain in throat, decreased or absent swallowing, gag and cough reflexes. Monitor for dysphagia, aspiration, nasal dysarthric speech. Position patient upright for eating or tube feeding.
<b>Vagus Nerve—X</b> Spastic palsy of larynx; bulbar paralysis; high vagal paralysis Guillain-Barré syndrome Vagal body tumors Nerve paralysis from malignancy, surgical trauma such as carotid endarterectomy	Voice changes (temporary or permanent hoarseness) Vocal paralysis Dysphagia	Assess for airway obstruction/provide airway management. Prevent aspiration. Support patient having voice reconstruction procedures.

(continued)

Table 64-1 • Disorders of Cranial Nerves (Continued)

DISORDER	CLINICAL MANIFESTATIONS	NURSING INTERVENTIONS
<b>Spinal Accessory Nerve—XI</b> Spinal cord disorder Amyotrophic lateral sclerosis Trauma Guillain-Barré syndrome	Drooping of affected shoulder with limited shoulder movement Weakness or paralysis of head rotation, flexion, extension; shoulder elevation	Support patient undergoing diagnostic tests.
<b>Hypoglossal Nerve—XII</b> Medullary lesions Amyotrophic lateral sclerosis Polio and motor system disease, which may destroy hypoglossal nuclei Multiple sclerosis Trauma	Abnormal movements of tongue Weakness or paralysis of tongue muscles Difficulty in talking, chewing, and swallowing	Observe swallowing ability. Observe speech pattern. Be aware of swallowing or vocal difficulties. Prepare for alternate feeding methods (tube feeding) to maintain nutrition.

are also used for pain control. If pain control is still not achieved, phenytoin (Dilantin) may be used as adjunctive therapy (Rowland, 2000).

Alcohol or phenol injection of the gasserian ganglion and peripheral branches of the trigeminal nerve relieves pain for several months. However, the pain returns with nerve regeneration.

#### SURGICAL MANAGEMENT

When these methods fail to relieve pain, a number of surgical options are available. The choice of procedure depends on the patient's preference and health status.

**Microvascular Decompression of the Trigeminal Nerve.** An intracranial approach can be used to decompress the trigeminal nerve. The pain may be caused by vascular compression of the entry zone of the trigeminal root by an arterial loop and occa-

sionally by a vein. With the aid of an operating microscope, the artery loop is lifted from the nerve to relieve the pressure, and a small prosthetic device is inserted to prevent recurrence of impingement on the nerve. This procedure relieves facial pain while preserving normal sensation, but it is a major procedure, involving a craniotomy. The postoperative management is the same as for other intracranial surgeries (see Chap. 61).

**Percutaneous Radiofrequency Trigeminal Gangliolysis.** Percutaneous radiofrequency interruption of the gasserian ganglion, in which the small unmyelinated and thinly myelinated fibers that conduct pain are thermally destroyed, is the surgical procedure of choice for trigeminal neuralgia (Tronnier, Rasche, Hamer et al., 2001). Use of stereotactic MRI for identification of the trigeminal nerve followed by gamma knife radiosurgery is being used at some centers with good results (Maesawa et al., 2001).

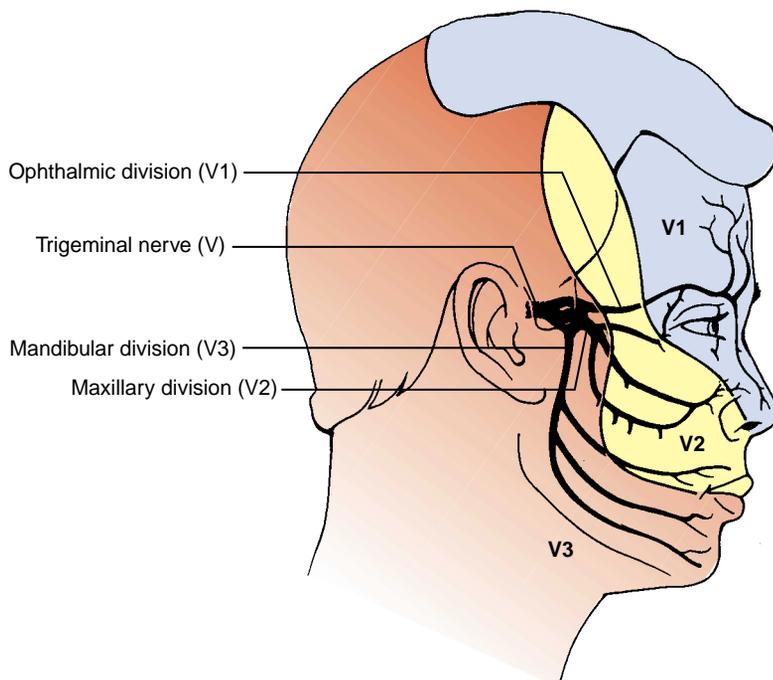

FIGURE 64-7 Distribution of trigeminal nerve branches.

Under local anesthesia, the needle is introduced through the cheek on the affected side. Under fluoroscopic guidance, the needle electrode is guided through the foramen magnum into the gasserian ganglion. The divisions of the gasserian ganglion (mandibular, maxillary, and ophthalmic) are encountered sequentially. The nerve is stimulated with a small current while the patient is awake. The patient reports when a tingling sensation is felt. When the electrode needle is in the desired position, the patient is anesthetized briefly and a radiofrequency current (heating current to destroy the nerve) is passed in a controlled manner to injure the trigeminal ganglion and rootlets thermally. The patient is then awakened from the anesthesia and examined for sensory deficits. This is repeated until the desired effect is achieved. The procedure takes less than 1 hour and provides permanent pain relief in most patients. Touch and proprioceptive functions are left intact.

In the patient with trigeminal neuralgia and MS who is refractory to medical pain management, the surgical treatment of choice is trigeminal rhizotomy (Maloni, 2000). See Chapter 13 for care of the patient following a rhizotomy.

## Nursing Management

### PREVENTING PAIN

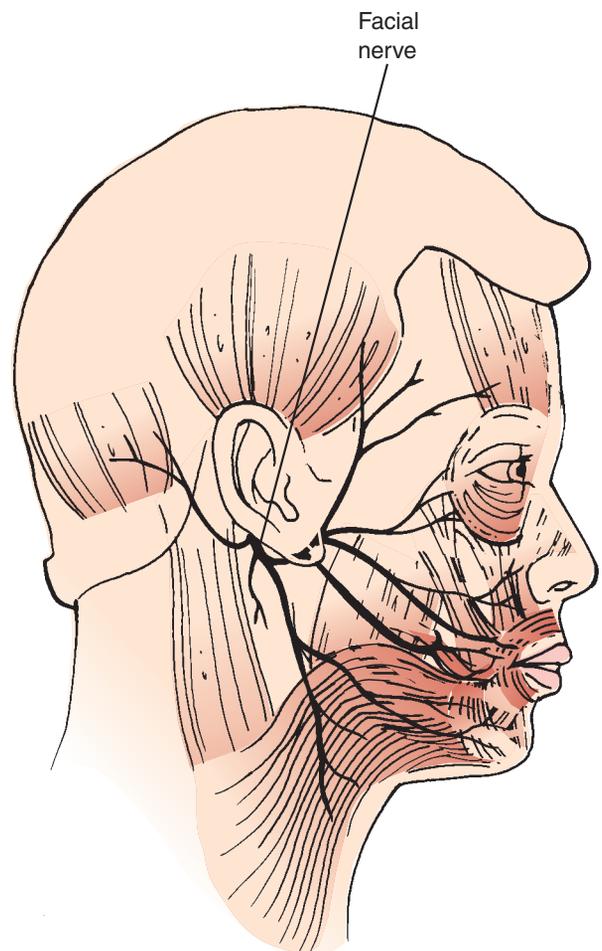

Preoperative management of a patient with trigeminal neuralgia occurs mostly on an outpatient basis and includes recognizing factors that may aggravate excruciating facial pain, such as food that is too hot or too cold or jarring the patient's bed or chair. Even washing the face, combing the hair, or brushing the teeth may produce acute pain. The nurse can assist the patient in preventing or reducing this pain by providing instructions about preventive strategies. Providing cotton pads and room-temperature water for washing the face, instructing the patient to rinse with mouthwash after eating when tooth-brushing causes pain, and performing personal hygiene during pain-free intervals are all effective strategies. The patient is instructed to take food and fluids at room temperature, to chew on the unaffected side, and to ingest soft foods. The nurse recognizes that anxiety, depression, and insomnia often accompany chronic painful conditions and uses appropriate interventions and referrals. (See Chap. 13 for management of patients with chronic pain.)

### PROVIDING POSTOPERATIVE CARE

Postoperative neurologic assessments are conducted to evaluate the patient for facial motor and sensory deficits in each of the three branches of the trigeminal nerve. If the surgery results in sensory deficits to the affected side of the face, the patient is instructed not to rub the eye, because pain will not be felt if there is injury. The eye is assessed for irritation or redness. Artificial tears may be prescribed to prevent dryness in the affected eye. The patient is cautioned not to chew on the affected side until numbness has diminished. The patient is observed carefully for any difficulty in eating and swallowing foods of different consistency.

## BELL'S PALSY

Bell's palsy (facial paralysis) is due to unilateral inflammation of the seventh cranial nerve, which results in weakness or paralysis of the facial muscles on the affected side (Fig. 64-8). The cause is unknown, although possible causes may include vascular ischemia, viral disease (herpes simplex, herpes zoster), autoimmune disease, or a combination of all of these factors. The incidence is 13 to

**FIGURE 64-8** Distribution of facial nerve.

34 cases per 100,000; it increases with age and among pregnant women in the third trimester (Campbell & Brundage, 2002; Shmorgun, Chan & Ray, 2002).

Bell's palsy is considered by some to represent a type of pressure paralysis. The inflamed, edematous nerve becomes compressed to the point of damage, or its nutrient vessel is occluded, producing ischemic necrosis of the nerve. There is distortion of the face from paralysis of the facial muscles; increased lacrimation (tearing); and painful sensations in the face, behind the ear, and in the eye. The patient may experience speech difficulties and may be unable to eat on the affected side because of weakness or paralysis of the facial muscles.

## Management

The objectives of treatment are to maintain the muscle tone of the face and to prevent or minimize denervation. The patient should be reassured that no stroke has occurred and that spontaneous recovery occurs within 3 to 5 weeks in most patients.

Corticosteroid therapy (prednisone) may be prescribed to reduce inflammation and edema; this reduces vascular compression and permits restoration of blood circulation to the nerve. Early administration of corticosteroid therapy appears to diminish the severity of the disease, relieve the pain, and prevent or minimize denervation.

Facial pain is controlled with analgesic agents. Heat may be applied to the involved side of the face to promote comfort and blood flow through the muscles.

Electrical stimulation may be applied to the face to prevent muscle atrophy. Although most patients recover with conservative treatment, surgical exploration of the facial nerve may be indicated in patients who are suspected of having a tumor or for surgical decompression of the facial nerve and for surgical treatment of a paralyzed face.

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** While the paralysis lasts, the involved eye must be protected. Frequently, the eye does not close completely and the blink reflex is diminished, so the eye is vulnerable to dust and foreign particles. Corneal irritation and ulceration may occur if the eye is unprotected. Distortion of the lower lid alters the proper drainage of tears. To prevent injury, the eye should be covered with a protective shield at night. The eye patch may abrade the cornea, however, because there is some difficulty in keeping the partially paralyzed eyelids closed. The application of eye ointment at bedtime causes the eyelids to adhere to one another and remain closed during sleep. The patient can be taught to close the paralyzed eyelid manually before going to sleep. Wrap-around sunglasses or goggles may be worn to decrease normal evaporation from the eye.

**Continuing Care.** When the sensitivity of the nerve to touch decreases and the patient can tolerate touching the face, the nurse can suggest massaging the face several times daily, using a gentle upward motion, to maintain muscle tone. Facial exercises, such as wrinkling the forehead, blowing out the cheeks, and whistling, may be performed with the aid of a mirror in an effort to prevent muscle atrophy. Exposure of the face to cold and drafts is avoided.

## Disorders of the Peripheral Nervous System

### PERIPHERAL NEUROPATHIES

A peripheral **neuropathy** (disorder of the nervous system) is a disorder affecting the peripheral motor, sensory, or autonomic nerves. Peripheral nerves connect the spinal cord and brain to all other organs. They transmit motor impulses from the brain and relay sensory impulses to the brain. A mononeuropathy affects a single peripheral nerve; multiple mononeuropathy or mononeuritis multiplex indicates the involvement of multiple single peripheral nerves or their branches. Polyneuropathies are characterized by bilateral and symmetric disturbance of function, usually beginning in the feet and hands. (Most nutritional, metabolic, and toxic neuropathies take this form.)

The most common causes of peripheral neuropathy are diabetes, alcoholism, and occlusive vascular disease. These disorders result in hypoxia or atrophy of the peripheral nerve. Many bacterial and metabolic toxins and exogenous poisons also cause peripheral neuropathy. Because of the growing use of chemicals in industry, agriculture, and medicine, the number of substances causing peripheral neuropathies and the incidence of peripheral neuropathies have increased. In developing countries, leprosy is a major cause of severe nerve disease because *Mycobacterium leprae* invade the peripheral nervous system.

The major symptoms of peripheral nerve disorders are loss of sensation, muscle atrophy, weakness, diminished reflexes, pain, and paresthesia (numbness, tingling) of the extremities. The pa-

tient frequently describes some part of the extremity as numb. Autonomic features include decreased or absent sweating, orthostatic hypotension, nocturnal diarrhea, tachycardia, impotence, and atrophic skin and nail changes.

Peripheral nerve disorders are diagnosed by history, physical examination, EMG, and somatosensory evoked potentials.

### MONONEUROPATHY

Mononeuropathy is limited to a single peripheral nerve and its branches. It arises when the trunk of the nerve is compressed or entrapped (as in carpal tunnel syndrome); traumatized, as when bruised by a blow, or overstretched, as in joint dislocation; punctured by a needle used to inject a drug or damaged by the drugs thus injected; or inflamed because an adjacent infectious process extends to the nerve trunk. Mononeuropathy frequently is seen in patients with diabetes.

Pain is seldom a major symptom of mononeuropathy when the condition is due to trauma, but in patients with complicating inflammatory conditions such as arthritis, pain is prominent. Pain is increased by all body movements that tend to stretch, strain, or cause pressure on the injured nerve and by sudden jarring of the body (eg, coughing and sneezing). The skin in the areas supplied by nerves that are injured or diseased may become reddened and glossy; the subcutaneous tissue may become edematous, and the nails and hair in this area become defective. Chemical injuries to a nerve trunk, such as those caused by drugs injected into or near it, are often permanent.

The objective of treatment of mononeuropathy is to remove the cause, if possible, such as by freeing the compressed nerve. Local corticosteroid injections may reduce inflammation and the pressure on the nerve. Aspirin or codeine may be used to relieve pain.

### Critical Thinking Exercises

1. A 19-year-old college student is suspected of having meningococcal meningitis. Identify two neurologic changes that may reflect increased ICP. What interventions would be included in your plan of care to protect the patient from injury? The patient's family has many questions about the disease and their risk of contracting meningitis. Develop a teaching plan that would describe meningococcal meningitis and prophylactic therapy for the patient's family and close contacts.
2. Your patient has been receiving one of the injectable interferon medications for the treatment of MS for about 6 months. She reports that she is becoming very discouraged because the medication does not seem to improve her symptoms. In addition, she reports that she has developed skin lesions at the injection sites. Identify the areas of assessment that are of priority at this time. Describe nursing interventions, including teaching and referral, that you would consider at this time. Provide the rationale for your interventions.
3. Your patient has been admitted to the hospital with a diagnosis of possible Guillain-Barré. Identify the priorities of assessment for this patient and the nursing and medical interventions that you would anticipate.
4. Your patient has myasthenia gravis. Although she reports that her condition has been stable and that she has been able

to manage without assistance, she reports increasing weakness and fatigue. What nursing assessments and interventions are warranted for her? What discharge plans are indicated if she is to return home to the care of her family? How would your discharge planning change if she lives alone in an apartment on the second floor of a building without an elevator?

**5.** A 52-year-old man has just been diagnosed with trigeminal neuralgia. Tegretol has been prescribed for pain management. Develop a teaching plan that explains the nature of trigeminal neuralgia, the side effects of Tegretol, and measures he can take to avoid triggering a painful episode. How would you evaluate the outcome of your teaching plan?

# ● Management of Patients With Oncologic or Degenerative Neurologic Disorders

## **LEARNING OBJECTIVES**

*On completion of this chapter, the learner will be able to:*

1. Identify the pathophysiologic processes responsible for oncologic disorders.
2. Describe brain and spinal cord tumors: their classification, clinical manifestations, diagnosis, and medical and nursing management.
3. Use the nursing process as a framework for care of patients with cerebral metastases or inoperable brain tumors.
4. Identify the pathophysiologic processes responsible for various degenerative neurologic disorders.
5. Use the nursing process as a framework for care of patients with degenerative neurologic disorders.
6. Identify resources for patients and families with oncologic and degenerative neurologic disorders.

**D**isease processes that are oncologic or degenerative produce a unique set of problems when they occur in the neurologic system. Oncologic processes include brain and spinal cord tumors. Degenerative neurologic disorders include Parkinson's disease, Huntington's disease, Alzheimer's disease, amyotrophic lateral sclerosis, muscular dystrophies, and degenerative disc disease. A relatively new phenomenon, post-polio syndrome, may be degenerative in nature and is therefore included in this chapter.

## Oncologic Disorders of the Brain and Spinal Cord

Oncologic disorders in the brain and spinal cord include several types of neoplasms, each with its own biology, prognosis, and treatment options. Because of the unique anatomy and physiology of the central nervous system (CNS), this collection of neoplasms is challenging to diagnose and treat. The pathophysiology, clinical manifestations, assessment findings, and medical and nursing management of brain tumors and spinal cord tumors are discussed in the following sections.

### PRIMARY BRAIN TUMORS

A brain tumor is a localized intracranial lesion that occupies space within the skull. Tumors usually grow as a spherical mass, but they can grow diffusely and infiltrate tissue. The effects of neoplasms occur from the compression and infiltration of tissue. A variety of physiologic changes result, causing any or all of the following pathophysiologic events:

- Increased intracranial pressure (ICP) and cerebral edema
- Seizure activity and focal neurologic signs
- Hydrocephalus
- Altered pituitary function

Primary brain tumors originate from cells and structures within the brain. Secondary, or metastatic, brain tumors develop from structures outside the brain and occur in 20% to 40% of all patients with cancer. Brain tumors rarely metastasize outside the CNS, but metastatic lesions to the brain occur commonly from the lung, breast, lower gastrointestinal tract, pancreas, kidney, and skin (melanomas).

The cause of primary brain tumors is unknown. The only known risk factor is exposure to ionizing radiation. Both glial and meningeal neoplasms have been linked to irradiation of the cranium, with a latency period of 10 to 20 years after exposure

(DeAngelis, 2001). Additional possible causes have been investigated, but results of studies are conflicting and unconvincing; suggested causes have included use of cellular telephones, exposure to high-tension wires, use of hair dyes, head trauma, dietary exposure to such factors as nitrates (found in some processed and barbecued foods), and other sources (DeAngelis, 2001).

The incidence of brain tumors appears to have increased in the past few decades. Epidemiologic data, however, suggest that this is due more to aggressive and accurate diagnosis rather than to an actual rise in incidence. It is estimated that there are about 17,000 new cases of primary brain tumors per year, 9,600 in men and 7,400 in women (American Cancer Society, 2002). Secondary tumors or metastases to the brain from a systemic primary cancer are more common (DeAngelis, 2001). The highest incidence of brain tumors in adults occurs in the fifth, sixth, and seventh decades, with a slightly higher incidence in men. In adults, most brain tumors originate from glial cells (glial cells make up the structure and support system of the brain and spinal cord) and are supratentorial (located above the covering of the cerebellum). Neoplastic lesions in the brain ultimately cause death by impairing vital functions, such as respiration, or by increasing intracranial pressure (ICP).

### Pathophysiology

Brain tumors may be classified into several groups: those arising from the coverings of the brain (eg, dural meningioma), those developing in or on the cranial nerves (eg, acoustic neuroma), those originating within brain tissue (eg, gliomas), and metastatic lesions originating elsewhere in the body. Tumors of the pituitary and pineal glands and of cerebral blood vessels are also types of brain tumors. Relevant clinical considerations include the location and the histologic character of the tumor. Tumors may be benign or malignant. A benign tumor can occur in a vital area and can grow large enough to have effects as serious as those of a malignant tumor.

### GLIOMAS

Glial tumors, the most common type of brain neoplasm, are divided into many categories (DeAngelis, 2001). See Chart 65-1 for the classification of brain tumors. Astrocytomas are the most common type of glioma and are graded from I to IV, indicating the degree of malignancy. The grade is based on cellular density, cell mitosis, and appearance. Usually, these tumors spread by infiltrating into the surrounding neural connective tissue and therefore cannot be totally removed without causing considerable damage to vital structures.

## Glossary

**akathisia:** restlessness, urgent need to move around, and agitation

**bradykinesia:** very slow voluntary movements and speech

**chorea:** rapid, jerky, involuntary, purposeless movements of the extremities or facial muscles, including facial grimacing

**dementia:** a progressive organic mental disorder characterized by personality changes, confusion, disorientation, and deterioration of intellect associated with impaired memory and judgment

**dyskinesia:** impaired ability to execute voluntary movements

**dysphonia:** abnormal voice quality caused by weakness and incoordination of muscles responsible for speech

**micrographia:** very minute and often illegible handwriting

**neurodegenerative:** a disease, process, or condition that leads to deterioration of normal cells or function of the nervous system

**papilledema:** edema of the optic nerve

**paresthesia:** a sensation of numbness, tingling, or a "pins and needles" sensation

**radiculopathy:** disease of a spinal nerve root, often resulting in pain and extreme sensitivity to touch

**sciatica:** inflammation of the sciatic nerve, resulting in pain and tenderness along the nerve through the thigh and leg

**spondylosis:** degenerative arthritis or osteoarthritis of the cervical or lumbar vertebrae, resulting in stiffness of the vertebral joint

Chart  
65-1**Classification of Adult Brain Tumors****I. Intracerebral Tumors**

- A. Gliomas—infiltrate any portion of the brain; most common type of brain tumor
  1. Astrocytomas (grades I and II)
  2. Glioblastoma multiforme (astrocytoma grades III and IV)
  3. Oligodendrocytoma (low and high grades)
  4. Ependymoma (grades I to IV)
  5. Medulloblastoma

**II. Tumors Arising From Supporting Structures**

- A. Meningiomas
- B. Neuromas (acoustic neuroma, schwannoma)
- C. Pituitary adenomas

**III. Developmental Tumors**

- A. Angiomas
- B. Dermoid, epidermoid, teroma, craniopharyngioma

**IV. Metastatic Lesions**

Oligodendroglial tumors are another type of glial tumor, representing 20% of gliomas (DeAngelis, 2001). The histologic distinction between astrocytomas and oligodendrogliomas is difficult to make but important, as recent research shows that oligodendrogliomas are more sensitive to chemotherapy than astrocytomas. These tumors are categorized as low-grade and high-grade (anaplastic).

**MENINGIOMAS**

Meningiomas, which represent 20% of all primary brain tumors, are common benign encapsulated tumors of arachnoid cells on the meninges (DeAngelis, 2001). They are slow-growing and occur most often in middle-aged adults (more often in women). Meningiomas most often occur in areas proximal to the venous sinuses. Manifestations depend on the area involved and are the result of compression rather than invasion of brain tissue. Standard treatment is surgery with complete removal or partial dissection.

**ACOUSTIC NEUROMAS**

An acoustic neuroma is a tumor of the eighth cranial nerve, the cranial nerve most responsible for hearing and balance. It usually arises just within the internal auditory meatus, where it frequently expands before filling the cerebellopontine recess.

An acoustic neuroma may grow slowly and attain considerable size before it is correctly diagnosed. The patient usually experiences loss of hearing, tinnitus, and episodes of vertigo and staggering gait. As the tumor becomes larger, painful sensations of the face may occur on the same side as a result of the tumor's compression of the fifth cranial nerve.

With improved imaging techniques and the use of the operating microscope and microsurgical instrumentation, even large tumors can be removed through a relatively small craniotomy. Some of these tumors may be suitable for stereotactic radiotherapy rather than surgery. See the discussion of stereotactic radiotherapy later in this chapter.

**PITUITARY ADENOMAS**

Pituitary tumors represent about 8% to 12% of all brain tumors and cause symptoms as a result of pressure on adjacent structures or hormonal changes (hyperfunction or hypofunction of the pituitary). The pituitary gland, also called the hypophysis, is a relatively small gland located in the sella turcica. It is attached to the

hypothalamus by a short stalk (hypophyseal stalk) and is divided into two lobes: the anterior (adenohypophysis) and the posterior (neurohypophysis).

**Pressure Effects of Pituitary Adenomas.** Pressure from a pituitary adenoma may be exerted on the optic nerves, optic chiasm, or optic tracts or on the hypothalamus or the third ventricle when the tumor invades the cavernous sinuses or expands into the sphenoid bone. These pressure effects produce headache, visual dysfunction, hypothalamic disorders (eg, disorders of sleep, appetite, temperature and emotions), increased ICP, and enlargement and erosion of the sella turcica.

**Hormonal Effects of Pituitary Adenomas.** Functioning pituitary tumors can produce one or more hormones normally produced by the anterior pituitary. These hormones may cause prolactin-secreting pituitary adenomas (prolactinomas), growth hormone-secreting pituitary adenomas that produce acromegaly in adults, and adrenocorticotrophic hormone (ACTH)-producing pituitary adenomas that result in Cushing's disease. Adenomas that secrete thyroid-stimulating hormone or follicle-stimulating hormone and luteinizing hormone occur infrequently, whereas adenomas that produce both growth hormone and prolactin are relatively common.

The female patient whose pituitary gland is secreting excessive quantities of prolactin presents with amenorrhea or galactorrhea (excessive or spontaneous flow of milk). Male patients with prolactinomas may present with impotence and hypogonadism. Acromegaly, caused by excess growth hormone, produces enlargement of the hands and feet, distortion of the facial features, and pressure on peripheral nerves (entrapment syndromes). The clinical features of Cushing's disease, a condition associated with prolonged overproduction of cortisol, occur with excessive production of ACTH. Manifestations include a form of obesity with redistribution of fat to the facial, supraclavicular, and abdominal areas; hypertension; purple striae and ecchymoses; osteoporosis; elevated blood glucose levels; and emotional disorders.

**ANGIOMAS**

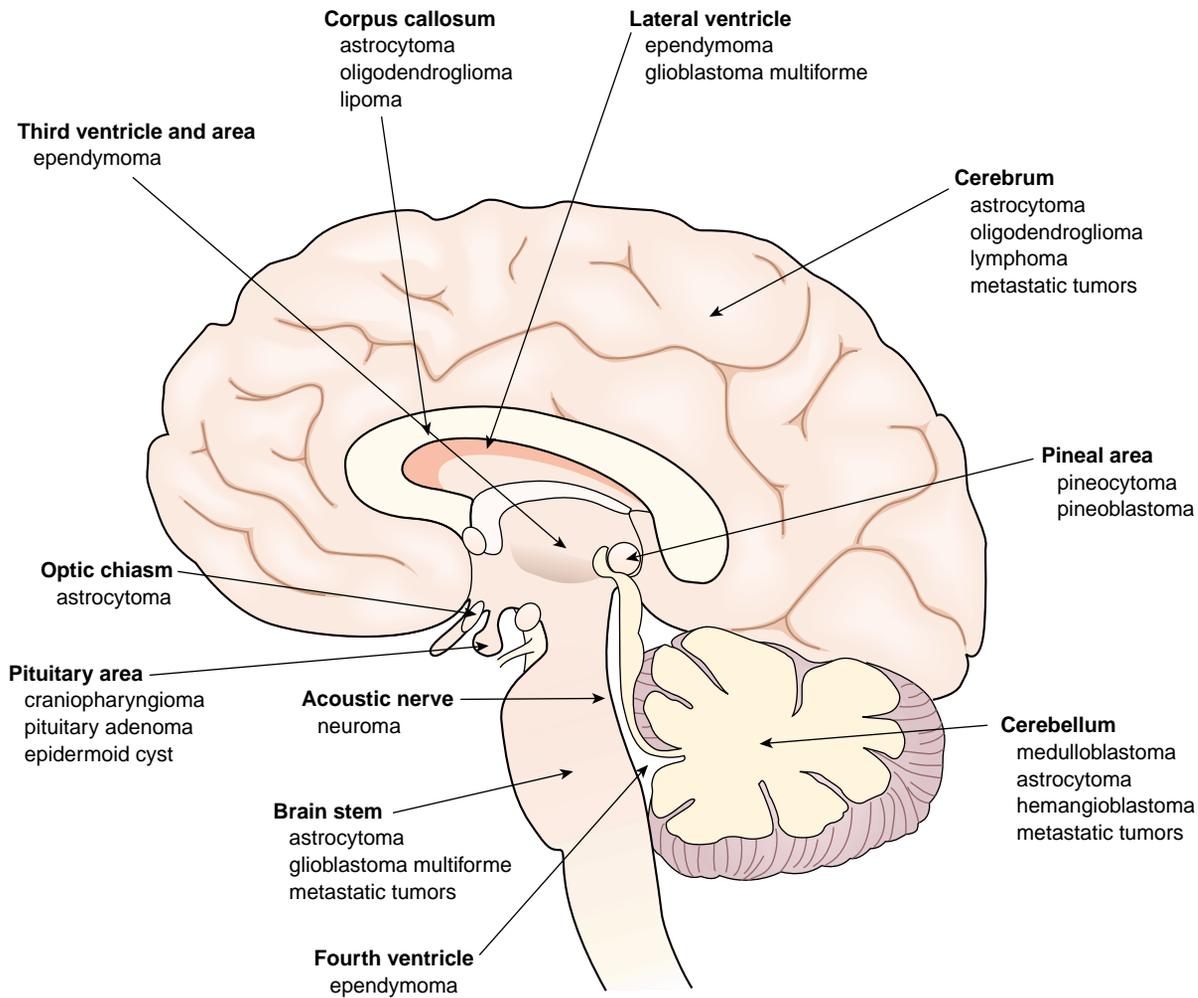

Brain angiomas (masses composed largely of abnormal blood vessels) are found either in or on the surface of the brain. They occur in the cerebellum in 83% of cases. Some persist throughout life without causing symptoms; others cause symptoms of a brain tumor. Occasionally, the diagnosis is suggested by the presence of another angioma somewhere in the head or by a bruit (an abnormal sound) audible over the skull. Because the walls of the blood vessels in angiomas are thin, these patients are at risk for a cerebral vascular accident (stroke). In fact, cerebral hemorrhage in people younger than 40 years of age should suggest the possibility of an angioma.

**Clinical Manifestations**

Brain tumors can produce either focal or generalized neurologic signs and symptoms. Generalized symptoms reflect increased ICP, and the most common focal or specific signs and symptoms result from tumors interfering with functions in specific brain regions. Figure 65-1 indicates common tumor sites in the brain.

**INCREASING ICP**

As discussed in Chapter 61, the skull is a rigid compartment containing essential noncompressible contents: brain matter, intravascular blood, and cerebrospinal fluid (CSF). According to the modified Monro-Kellie hypothesis, if any one of these skull

**FIGURE 65-1** Common brain tumor sites.

components increases in volume, ICP increases unless one of the other components decreases in volume. Consequently, any change in volume occupied by the brain (as occurs with disorders such as brain tumor or cerebral edema) produces signs and symptoms of increased ICP.

Symptoms of increased ICP result from a gradual compression of the brain by the enlarging tumor. The effect is a disruption of the equilibrium that exists between the brain, the CSF, and the cerebral blood, all located within the skull. As the tumor grows, compensatory adjustments may occur through compression of intracranial veins, reduction of CSF volume (by increased absorption or decreased production), a modest decrease of cerebral blood flow, and reduction of intracellular and extracellular brain tissue mass. When these compensatory mechanisms fail, the patient develops signs and symptoms of increased ICP. The three most common signs of increased ICP are headache, nausea and vomiting, and a sixth-nerve palsy (DeAngelis, 2001). Personality changes and a variety of focal deficits, including motor, sensory, and cranial nerve dysfunction, are also common.

**Headache.** Headache, although not always present, is most common in the early morning and is made worse by coughing, straining, or sudden movement. It is thought to be caused by the tumor invading, compressing, or distorting the pain-sensitive structures or by edema that accompanies the tumor. Headaches are usually

described as deep or expanding or as dull but unrelenting. Frontal tumors usually produce a bilateral frontal headache; pituitary gland tumors produce pain radiating between the two temples (bitemporal); in cerebellar tumors, the headache may be located in the suboccipital region at the back of the head.

**Vomiting.** Vomiting, seldom related to food intake, is usually due to irritation of the vagal centers in the medulla. If the vomiting is of the forceful type, it is described as projectile vomiting.

**Visual Disturbances.** **Papilledema** (edema of the optic nerve) is present in 70% to 75% of patients and is associated with visual disturbances such as decreased visual acuity, diplopia (double vision), and visual field deficits.

#### LOCALIZED SYMPTOMS

The most common focal or localized symptoms are hemiparesis, seizures, and mental status changes (DeAngelis, 2001). When specific regions of the brain are affected, additional local signs and symptoms occur, such as sensory and motor abnormalities, visual alterations, alterations in cognition, and language disturbances such as aphasia. The progression of the signs and symptoms is important because it indicates tumor growth and expansion. For example, a rapidly developing hemiparesis is more typical of a highly malignant glioma than a low-grade tumor (DeAngelis, 2001).

Although some tumors are not easily localized because they lie in so-called silent areas of the brain (ie, areas in which functions are not definitely determined), many tumors can be localized by correlating the signs and symptoms to known areas of the brain, as follows:

- A motor cortex tumor produces seizure-like movements localized on one side of the body, called Jacksonian seizures.
- An occipital lobe tumor produces visual manifestations: contralateral homonymous hemianopsia (visual loss in half of the visual field on the opposite side of the tumor) and visual hallucinations.
- A cerebellar tumor causes dizziness, an ataxic or staggering gait with a tendency to fall toward the side of the lesion, marked muscle incoordination, and nystagmus (involuntary rhythmic eye movements), usually in the horizontal direction.
- A frontal lobe tumor frequently produces personality disorders, changes in emotional state and behavior, and an uninterested mental attitude. The patient often becomes extremely untidy and careless and may use obscene language.
- A cerebellopontine angle tumor usually originates in the sheath of the acoustic nerve and gives rise to a characteristic sequence of symptoms. Tinnitus and vertigo appear first, soon followed by progressive nerve deafness (eighth cranial nerve dysfunction). Numbness and tingling of the face and the tongue occur (due to involvement of the fifth cranial nerve). Later, weakness or paralysis of the face develops (seventh cranial nerve involvement). Finally, because the enlarging tumor presses on the cerebellum, abnormalities in motor function may be present.

## Assessment and Diagnostic Findings

The history of the illness and the manner and time frame in which the symptoms evolved are key components in the diagnosis of brain tumors. A neurologic examination indicates the areas of the CNS involved. To assist in the precise localization of the lesion, a battery of tests is performed. Computed tomography (CT) scans, enhanced by a contrast agent, can give specific information concerning the number, size, and density of the lesions and the extent of secondary cerebral edema. CT scans can provide information about the ventricular system. Magnetic resonance imaging (MRI) is the most helpful diagnostic tool for detecting brain tumors, particularly smaller lesions, and tumors in the brain stem and pituitary regions, where bone interferes with CT (Fig. 65-2). In a few instances, the appearance of a brain tumor on an MRI is so characteristic that a biopsy is unnecessary, especially when the tumor is located in a part of the brain that is difficult to biopsy (American Cancer Society, 2001).

In centers where positron emission tomography (PET) is available, it is used to supplement MRI. On PET scans, low-grade tumors are associated with hypometabolism and high-grade tumors show hypermetabolism. This information can be useful in treatment decisions (DeAngelis, 2001). Computer-assisted stereotactic (three-dimensional) biopsy is being used to diagnose deep-seated brain tumors and to provide a basis for treatment and prognosis. Cerebral angiography provides visualization of cerebral blood vessels and can localize most cerebral tumors.

An electroencephalogram (EEG) can detect an abnormal brain wave in regions occupied by a tumor and is used to evaluate temporal lobe seizures and assist in ruling out other disorders.

Cytologic studies of the CSF may be performed to detect malignant cells because CNS tumors can shed cells into the CSF.

**FIGURE 65-2** Low-grade glioma. MRI of the brain shows a mass of abnormal density in the right temporal lobe. Courtesy of the Hospital of the University of Pennsylvania, Nuclear Medicine Section, Philadelphia, Pennsylvania.

## Gerontologic Considerations

Intracranial tumors can produce personality changes, confusion, speech dysfunction, or disturbances of gait. In elderly patients early signs and symptoms of intracranial tumors can be easily overlooked and incorrectly attributed to cognitive and neurologic changes associated with normal aging. The most frequent tumor types in the elderly are anaplastic astrocytoma, glioblastoma multiforme, and cerebral metastases from other sites. The incidence of primary brain tumors and the likelihood of malignancy increase with age. Signs and symptoms in the elderly must be carefully evaluated because 10% of brain metastases occur in patients with a history of prior cancer (Rude, 2000).

## Medical Management

A variety of medical treatment modalities, including chemotherapy and external-beam radiation therapy, are used alone or in combination with surgical resection. Radiation therapy, the cornerstone of treatment of many brain tumors, decreases the incidence of recurrence of incompletely resected tumors. Brachytherapy (the surgical implantation of radiation sources to deliver high doses at a short distance) has had promising results for primary malignancies. It is generally used as an adjunct to conventional radiation therapy or as a rescue measure for recurrent disease.

Intravenous (IV) autologous bone marrow transplantation is used in some patients who will receive chemotherapy or radiation therapy because it has the potential to “rescue” the patient from the bone marrow toxicity associated with high doses of chemotherapy and radiation. A fraction of the patient’s bone marrow is aspirated, usually from the iliac crest, and stored. The patient receives large doses of chemotherapy or radiation therapy to destroy large

numbers of malignant cells. The marrow is then reinfused intravenously after treatment is completed.

Corticosteroids may be used before and after treatment to reduce cerebral edema and promote a smoother, more rapid recovery. Gene-transfer therapy uses retroviral vectors to carry genes to the tumor, reprogramming the tumor tissue for susceptibility to treatment. This approach is being tested.

A new technique being investigated is photodynamic therapy. This is a treatment of primary malignant brain tumors that delivers a targeted therapy while conserving healthy brain tissue (Goodell & Muller, 2001).

### SURGICAL MANAGEMENT

The objective of surgical management is to remove or destroy the entire tumor without increasing the neurologic deficit (paralysis, blindness) or to relieve symptoms by partial removal (decompression). A variety of treatment modalities may be used; the specific approach depends on the type of tumor, its location, and accessibility. In many patients, combinations of these modalities may be used. Most pituitary adenomas are treated by transsphenoidal microsurgical removal (see Chap. 61), whereas the remainder of tumors that cannot be removed completely are treated by radiation. An untreated brain tumor ultimately leads to death, either from increasing ICP or from the damage to brain tissue it causes.

Conventional surgical approaches require an incision into the skull (craniotomy). See Chapter 61 for a discussion of care of the patient following craniotomy. This approach is used in patients with meningiomas, acoustic neuromas, cystic astrocytomas of the cerebellum, colloid cysts of the third ventricle, congenital tumors such as dermoid cyst, and some of the granulomas. For patients with malignant glioma, complete removal of the tumor and cure are not possible, but the rationale for resection includes relieving ICP, removing any necrotic tissue, and reducing the bulk of the

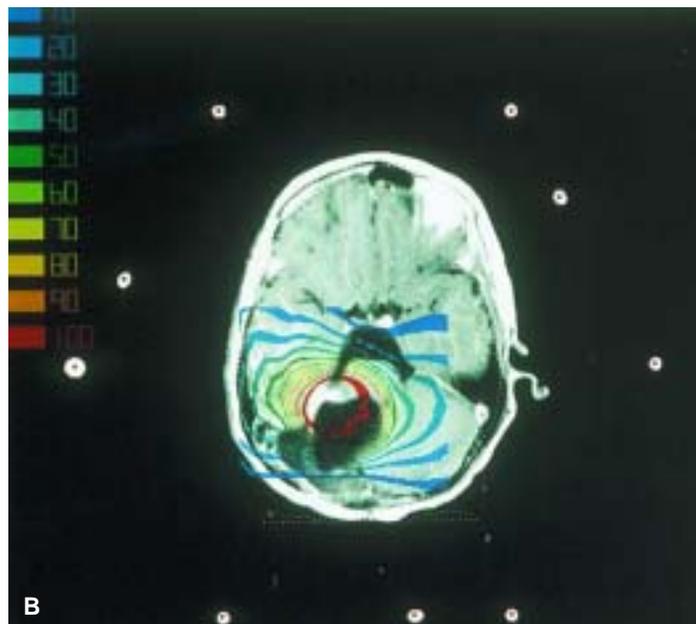

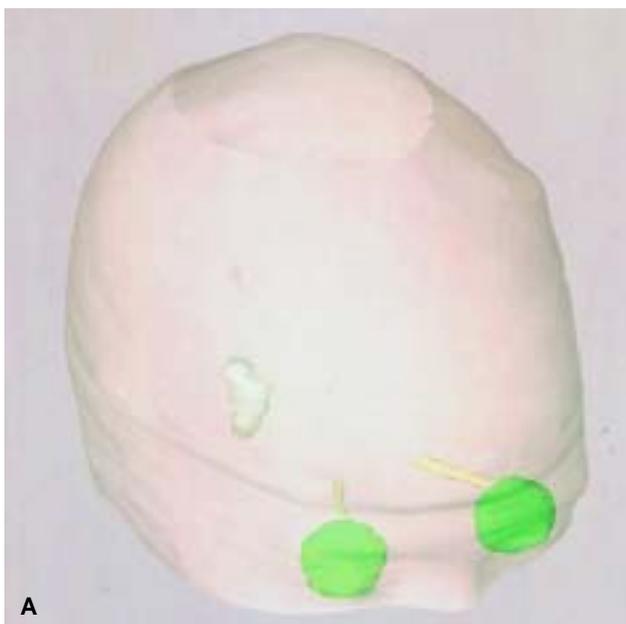

tumor, which theoretically leaves behind fewer cells to become resistant to radiation or chemotherapy.

Stereotactic approaches involve use of a three-dimensional frame that allows very precise localization of the tumor; a stereotactic frame and multiple imaging studies (x-rays, CT scans) are used to localize the tumor and verify its position (Fig. 65-3). New brain-mapping technology helps determine how close diseased areas of the brain are to structures essential for normal brain function. Lasers or radiation can be delivered with stereotactic approaches. Radioisotopes such as iodine 131 ( $^{131}\text{I}$ ) can also be implanted directly into the tumor to deliver high doses of radiation to the tumor (brachytherapy) while minimizing effects on surrounding brain tissue.

The use of the gamma knife to perform radiosurgery allows deep, inaccessible tumors to be treated, often in a single session. Precise localization of the tumor is accomplished using the stereotactic approach and by minute measurements and precise positioning of the patient. Multiple narrow beams then deliver a very high dose of radiation. An advantage of this method is that no surgical incision is needed; a disadvantage is the lag time between treatment and the desired result (Rafferty-Mitchell, Scanlon & Laskowski-Jones, 1999).

### Nursing Management

The patient with a brain tumor may be at an increased risk for aspiration due to cranial nerve dysfunction. Preoperatively, the gag reflex and ability to swallow are evaluated. In patients with diminished gag response, care includes teaching the patient to direct food and fluids toward the unaffected side, having the patient sit upright to eat, offering a semisoft diet, and having suction readily available. Function should be reassessed postoperatively because changes can occur.

**FIGURE 65-3** (A) Using stereotactic or “brain-mapping” guided approach, a 3-D computer image fuses the CT and MRI to pinpoint the exact location of the brain tumor. This low-grade astrocytoma is localized adjacent to the brain stem, is nonoperable, and is treated with radiation. Note the optic chiasm and optic nerves. (B) Computerized image of the prescribed radiation dose.

The effects of increased ICP caused by the tumor mass are reviewed in Chapter 61. The nurse performs neurologic checks, monitors vital signs, maintains a neurologic flow chart, spaces nursing interventions to prevent rapid increase in ICP, and reorients the patient when necessary to person, time, and place. Patients with changes in cognition caused by the lesion require frequent reorientation and the use of orienting devices (personal possessions, photographs, lists, clock), supervision of and assistance with self-care, and ongoing monitoring and intervention for prevention of injury. Patients with seizures are carefully monitored and protected from injury.

Motor function is checked at intervals because specific motor deficits may occur, depending on the tumor's location. Sensory disturbances are assessed. Speech is evaluated. Eye movement and pupillary size and reaction may be affected by cranial nerve involvement. In one study that examined the experience of brain tumor patients 3 to 5 days postoperatively, the basic needs of patients were met, but changes suggested included minimizing the atmosphere of urgency and hurry, appointing a primary nurse for each patient, and giving more postoperative information (Lepola et al., 2001). The nursing process for patients undergoing neurosurgery is discussed in Chapter 61.

## CEREBRAL METASTASES

A significant number of patients with cancer experience neurologic deficits caused by metastasis to the brain. Metastatic lesions to the brain constitute the most common neurologic complication, occurring in 20% to 30% of patients with cancer (Nevidjon & Sowers, 2000). This becomes important clinically as more patients with all forms of cancer live longer as a result of improved therapies. Neurologic signs and symptoms include headache, gait disturbances, visual impairment, personality changes, altered mentation (memory loss and confusion), focal weakness, paralysis, aphasia, and seizures. These signs and symptoms can be devastating to both patient and family.

## Medical Management

The treatment of metastatic brain cancer is palliative and involves eliminating or reducing serious symptoms. Even when palliation is the goal, distressing signs and symptoms can be relieved, thereby improving the quality of life for both the patient and family. Patients with intracerebral metastases who are not treated have a steady downhill course with a limited survival time, whereas those who are treated may survive for slightly longer periods. The median survival for patients with no treatment for brain metastases is 1 month; with corticosteroid treatment alone it is 2 months; radiation therapy extends the median survival to 3 to 6 months (Nevidjon & Sowers, 2000).

The therapeutic approach includes radiation therapy (the foundation of treatment), surgery (usually for a single intracranial metastasis), and chemotherapy; more often some combination of these treatments is the optimal method. Gamma knife radiosurgery is considered when three or fewer lesions are present.

## PHARMACOLOGIC THERAPY

Corticosteroids are useful in relieving headache and alterations in level of consciousness. It is thought that corticosteroids (dexamethasone, prednisone) reduce inflammation around the metastatic deposits and decrease the edema surrounding them. Other medications used include osmotic agents (mannitol, glycerol) to decrease the fluid content of the brain, which leads to a decrease

in ICP. Antiseizure agents (eg, phenytoin) are used to prevent and treat seizures (Nevidjon & Sowers, 2000). Venous thromboembolic events, such as deep vein thrombosis (DVT) and pulmonary embolism (PE), occur in about 15% of patients and are associated with significant morbidity. Anticoagulants are generally not prescribed because of the risk for CNS hemorrhage; however, prophylactic therapy with low-molecular-weight heparin is under investigation.

Chemotherapy plays a small role in managing brain metastasis as a result of poor penetration across the blood-brain barrier. Poor drug penetration and sensitivity of brain cells are two factors that determine the responsiveness of metastatic brain tumors to chemotherapy. Research is being directed at multidrug regimens and drug resistance (American Cancer Society, 2001). Encouraging results have been seen with chemotherapeutic agents such as carmustine (BCNU), lomustine (CCNU), and PCV (a triple-drug combination of procarbazine hydrochloride, lomustine, and vincristine). Promising results have been seen with the use of topotecan (Hycamtin), another chemotherapy agent.

Pain is managed in a step-ladder progression in the doses and type of analgesic agents needed for relief. If the patient has severe pain, morphine can be infused into the epidural or subarachnoid space through a spinal needle and a catheter as near as possible to the spinal segment where the pain is projected. Small doses of morphine are administered at prescribed intervals (see Chap. 13).

## NURSING PROCESS: THE PATIENT WITH CEREBRAL METASTASES OR INCURABLE BRAIN TUMOR

### Assessment

The nursing assessment includes a baseline neurologic examination and focuses on how the patient is functioning, moving, and walking; adapting to weakness or paralysis and to visual and speech loss; and dealing with seizures. Assessment addresses symptoms that cause distress to the patient, including pain, respiratory problems, bowel and bladder disorders, sleep disturbances, and impairment of skin integrity, fluid balance, and temperature regulation. Tumor invasion, compression, or obstruction may cause these disorders.

Nutritional status is assessed because cachexia (weak and emaciated condition) is common in patients with metastases. The nurse explores changes associated with poor nutritional status (anorexia, pain, weight loss, altered metabolism, muscle weakness, malabsorption, and diarrhea) and asks the patient about altered taste sensations that may be secondary to dysphagia, weakness, and depression and about distortions and impaired sense of smell (anosmia).

The nurse takes a dietary history to assess food intake, intolerance, and preferences. Calculation of body mass index can confirm the loss of subcutaneous fat and lean body mass (see Chap. 5). Biochemical measurements (albumin, transferrin, total lymphocyte count, creatinine index, and urinary tests) are reviewed to assess the degree of malnutrition, impaired cellular immunity, and electrolyte balance. A dietitian assists in determining the caloric needs of the patient.

The nurse works with other members of the health care team to assess the impact of the illness on the family in terms of home care, altered relationships, financial problems, time pressures, and family problems. This information is important in helping family members cope with the diagnosis and changes associated with it.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Self-care deficit (feeding, bathing, and toileting) related to loss or impairment of motor and sensory function and decreased cognitive abilities
- Imbalanced nutrition, less than body requirements, related to cachexia due to treatment and tumor effects, decreased nutritional intake, and malabsorption
- Anxiety related to fear of dying, uncertainty, change in appearance, altered lifestyle
- Interrupted family processes related to anticipatory grief and the burdens imposed by the care of the person with a terminal illness

Other nursing diagnoses of the patient with cerebral metastases may include acute pain related to tumor compression; impaired gas exchange related to dyspnea; constipation related to decreased fluid and dietary intake and medications; impaired urinary elimination related to reduced fluid intake, vomiting, and reactions to medications; sleep pattern disturbances related to discomfort and fear of dying; impairment of skin integrity related to cachexia, poor tissue perfusion, and decreased mobility; deficient fluid volume related to fever, vomiting, and low fluid intake; and ineffective thermoregulation related to hypothalamic involvement, fever, and chills. See Chapter 16 for assessment and nursing interventions for the patient with cancer.

## Planning and Goals

The goals for the patient may include compensating for self-care deficits, improving nutrition, reducing anxiety, enhancing family coping skills, and absence of complications.

## Nursing Interventions

### COMPENSATING FOR SELF-CARE DEFICITS

The patient may have difficulty participating in goal setting as the tumor metastasizes and affects cognitive function. It is important to encourage the family to keep the patient as independent as possible for as long as possible. Increasing assistance with self-care activities is required. Because the patient with cerebral metastasis and the family live with uncertainty, they are encouraged to plan for each day and to make the most of each day. The tasks and challenges are to assist the patient to find useful coping mechanisms, adaptations, and compensations in solving problems that arise. This helps patients maintain some sense of control. An individualized exercise program helps maintain strength, endurance, and range of motion. Eventually, referral for home or hospice care may be necessary (see Chap. 17).

### IMPROVING NUTRITION

Patients with nausea, vomiting, diarrhea, breathlessness, and pain are rarely interested in eating (Wilkes, 2000). These symptoms are managed or controlled through assessment, planning, and care. The nurse teaches the family how to position the patient for comfort during meals. Meals are planned for the times the patient is rested and in less distress from pain or the effects of treatment.

The patient needs to be clean, comfortable, and free of pain for meals, in an environment that is as attractive as possible. Oral hygiene before meals helps to improve intake. Offensive sights, sounds, and odors are eliminated. Creative strategies may be required to make food more palatable, provide enough fluids, and increase opportunities for socialization during meals. The family may be asked to keep a daily weight chart and to record the quantity of food eaten to determine the daily calorie count. Dietary supplements, if acceptable to the patient, can be provided to meet increased caloric needs. If the patient is not interested in most usual foods, those foods preferred by the patient should be offered. When the patient shows marked deterioration as a result of tumor growth and effects, some other form of nutritional support (eg, tube feeding, parenteral nutrition) may be indicated if consistent with the patient's end-of-life preferences. Nursing interventions include assessing the patency of the central and IV line or feeding tube, monitoring the insertion site for infection, checking the infusion rate, monitoring intake and output, and changing the IV tubing and dressing. Family members are instructed in these techniques if they will be providing care at home. Parenteral nutrition can also be provided at home if indicated.

The patient's quality of life may guide the selection, initiation, and maintenance of nutritional support. The nurse and family should not place too much emphasis on eating or on discussions about food as the patient may not desire aggressive nutritional intervention. The subsequent course of action must be congruent with the wishes and choices of the patient and family.

### RELIEVING ANXIETY

Patients with cerebral metastases may be restless, with changing moods that may include intense depression, euphoria, paranoia, and severe anxiety. The response of patients to terminal illness reflects their pattern of reaction to other crisis situations. Serious illness imposes additional strains that often bring other unresolved problems to light. The patient's own coping strategies can help deal with anxious and depressed feelings. Caregivers need to be sensitive to the patient's concerns and fears.

Patients need the opportunity to exercise some control over their situation. A sense of mastery can be gained as they learn to understand the disease and its treatment and how to deal with their feelings. The presence of family, friends, a spiritual advisor, and health professionals may be supportive. Support groups such as the Brain Tumor Support Group may provide a feeling of support and strength.

Spending time with patients allows them time to talk and to communicate their fears and concerns. Open communication and acknowledging fears are often therapeutic. Touch is also a form of communication. These patients need reassurance that continuing care will be provided and that they will not be abandoned. The situation becomes more endurable when others share in the experience of dying. If a patient's emotional reactions are very intense or prolonged, additional help from a spiritual advisor, social worker, or mental health professional may be indicated.

### ENHANCING FAMILY PROCESSES

The family needs to be reassured that their loved one is receiving optimal care and that attention will be paid to the patient's changing symptoms and to their concerns. When the patient can no longer carry out self-care, the family, additional support systems (social worker, home health aid, home care nurse, hospice nurse) may be needed. A nursing goal is to keep anxiety at a manageable level.

Chart 65-2

## Home Care Checklist • The Patient With Cerebral Metastases

At the completion of home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• State effects of the tumor according to its location in the brain and type.	✓	✓
• Describe side effects of treatment.	✓	✓
• Identify community resources, including:		
• Home health services	✓	✓
• Hospices	✓	✓
• Support groups	✓	✓
• Identify coping strategies, such as:		
• Taking control, setting daily goals, and staying positive	✓	✓
• Rehabilitation to improve self-care	✓	✓
• Relaxation techniques	✓	✓
• Family support		✓
• Verbalize an understanding of the treatment plan for:		
• Medications and pain control	✓	✓
• Nutritional needs	✓	✓
• Contacting the health care provider	✓	✓

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

The patient and family often have major responsibility for care at home. Therefore, teaching includes strategies of pain management, prevention of complications related to treatment strategies, and methods to ensure adequate fluid and food intake (Chart 65-2). Teaching needs of the patient and family regarding care priorities are likely to change as the disease progresses. It is important to assess the changing needs of the patient and the family and to inform them about resources and services early to assist them to deal with changes in the patient's condition.

### Continuing Care

Home care nursing and hospice services are valuable resources that should be made available to the patient and the family early in the course of a terminal illness. Anticipating needs before they occur can assist in smooth initiation of services. Home care needs and interventions focus on four major areas: palliation of symptoms and pain control, assistance in self-care, control of treatment complications, and administration of specific forms of treatment, such as parenteral nutrition. The home care nurse assesses pain management, respiratory status, complications of the disorder and its treatment, and the patient's cognitive and emotional status. Additionally, the nurse assesses the family's ability to perform necessary care and notifies the physician about changing needs or complications if indicated.

The patient and family who elect to care for the patient at home as the disease progresses benefit from the care and support provided through hospice services. Steps to initiate hospice care, including discussion of hospice care as an option, should not be postponed until death is imminent. Exploration of hospice care as an option should be initiated at a time when hospice care can provide support and care to the patient and family consistent with their end-of-life decisions and assist in allowing death with dignity. End-of-life care is further described in Chapter 13.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Engages in self-care activities as long as possible
  - a. Uses assistive devices or accepts assistance as needed
  - b. Schedules periodic rest periods to permit maximal participation in self-care
2. Maintains as optimal a nutritional status as possible
  - a. Eats and accepts food within limits of condition and preferences
  - b. Accepts alternative methods of providing nutrition if indicated
3. Reports being less anxious
  - a. Is less restless and is sleeping better
  - b. Verbalizes concerns and fears about death
  - c. Participates in activities of personal importance as long as feasible
4. Family members seek help as needed
  - a. Demonstrate ability to bathe, feed, and care for the patient and participate in pain management and prevention of complications
  - b. Express feelings and concerns to appropriate health professionals
  - c. Discuss and seek hospice care as an option

## SPINAL CORD TUMORS

Tumors within the spine are classified according to their anatomic relation to the spinal cord. They include intramedullary lesions (within the spinal cord), extramedullary-intradural lesions (within or under the spinal dura), and extramedullary-extradural lesions (outside the dural membrane). Tumors occurring within the spinal cord or exerting pressure on it cause symptoms ranging from localized or shooting pains and weakness and loss of reflexes above the tumor level to progressive loss of motor function and

paralysis. Usually, sharp pain occurs in the area innervated by the spinal roots that arise from the cord in the region of the tumor. In addition, increasing sensory deficits develop below the level of the lesion.

## Assessment and Diagnostic Findings

Neurologic examination and diagnostic studies are used to make the diagnosis. Neurologic examination includes assessment of pain, loss of reflexes, loss of sensation or motor function, and the presence of weakness and paralysis. Helpful diagnostic studies include x-rays, radionuclide bone scans, and MRI. MRI is the most sensitive diagnostic tool and is particularly helpful in detecting epidural spinal cord compression and vertebral bone metastases (Jacobs & Perrin, 2001; Nevidjon & Sowers, 2000).

## Medical Management

Treatment of specific intraspinal tumors depends on the type and location of the tumor and the presenting symptoms and physical status of the patient. Surgical intervention is the primary treatment for most spinal cord tumors. Other treatment modalities include partial removal of the tumor, decompression of the spinal cord, chemotherapy, and radiation therapy, particularly for intramedullary tumors and metastatic lesions (Jacobs & Perrin, 2001).

Epidural spinal cord compression occurs in approximately 5% of patients who die of cancer and is considered a neurologic emergency (Nevidjon & Sowers, 2000). In the patient with epidural spinal cord compression resulting from metastatic cancer (most commonly from breast, prostate, or lung), high-dose dexamethasone combined with radiation therapy is effective in relieving pain (Nevidjon & Sowers, 2000).

## SURGICAL MANAGEMENT

Tumor removal is desirable but not always possible. The goal is to remove as much tumor as possible while sparing uninvolved portions of the spinal cord. Microsurgical techniques have improved the prognosis for patients with intramedullary tumors. Prognosis is related to the degree of neurologic impairment at the time of surgery, the speed with which symptoms occurred, and the tumor origin. Patients with extensive neurologic deficits before surgery usually do not make significant functional recovery even after successful tumor removal.

## Nursing Management

### PROVIDING PREOPERATIVE CARE

The objectives of preoperative care include recognition of neurologic changes through ongoing assessments, pain control, and management of altered activities of daily living due to sensory and motor deficits and bowel and bladder dysfunction. The nurse assesses for weakness, muscle wasting, spasticity, sensory changes, bowel and bladder dysfunction, and potential respiratory problems, especially if a cervical tumor is present. The patient is also evaluated for coagulation deficiencies. A history of aspirin intake is obtained and reported because the use of aspirin may impede hemostasis postoperatively. Breathing exercises are taught and demonstrated preoperatively. Postoperative pain management strategies are discussed with the patient before surgery.

### ASSESSING THE PATIENT AFTER SURGERY

The patient is monitored for deterioration in neurologic status. A sudden onset of neurologic deficit is an ominous sign and may

be due to vertebral collapse associated with spinal cord infarction. Frequent neurologic checks are carried out, with emphasis on movement, strength, and sensation of the upper and lower extremities. Assessment of sensory function involves pinching the skin of the arms, legs, and trunk to determine if there is loss of feeling and, if so, determining at what level. Vital signs are monitored at regular intervals.

### MANAGING PAIN

The prescribed pain medication should be administered in adequate amounts and at appropriate intervals to relieve pain and prevent its recurrence. Pain is the hallmark of spinal metastasis. Patients with sensory root involvement or vertebral collapse may suffer excruciating pain, which requires effective pain management.

The bed is usually kept flat initially. The nurse turns the patient as a unit, keeping shoulders and hips aligned and the back straight. The side-lying position is usually the most comfortable because this position imposes the least pressure on the surgical site. Placement of a pillow between the knees of the patient in a side-lying position helps to prevent extreme knee flexion.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

If the tumor was in the cervical area, the possibility of postoperative respiratory compromise arises. The nurse monitors the patient for asymmetric chest movement, abdominal breathing, and abnormal breath sounds. For a high cervical lesion, the endotracheal tube remains in place until adequate respiratory function is ensured. The patient is encouraged to perform deep-breathing and coughing exercises.

The area over the bladder is palpated or a bladder scan is performed to assess for urinary retention. The nurse also monitors for incontinence because urinary dysfunction usually implies significant decompensation of spinal cord function. An intake and output record is maintained. Additionally, the abdomen is auscultated for bowel sounds.

Staining of the dressing may indicate leakage of CSF from the surgical site, which may lead to serious infection or to an inflammatory reaction in the surrounding tissues that can cause severe pain in the postoperative period.

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** In preparation for discharge, patients are assessed for their ability to function independently in the home and for the availability of resources such as family members to assist in caregiving. Patients with residual sensory involvement are cautioned about the dangers of extremes in temperature. They should be alert to the dangers of heating devices (eg, hot water bottles, heating pads, and space heaters). The patient is taught to check skin integrity daily. Patients with impaired motor function related to motor weakness or paralysis may require training in activities of daily living and safe use of assistive devices, such as a cane, walker, or wheelchair.

The patient and family member are instructed about pain management strategies, bowel and bladder management, and assessment for signs and symptoms that should be reported promptly.

**Continuing Care.** Referral for inpatient or outpatient rehabilitation may be warranted to improve self-care abilities. A home care referral may be indicated and provides the home care nurse with

the opportunity to assess the patient's physical and psychological status and the patient's and family's ability to adhere to recommended management strategies. During the home visit, the nurse determines whether changes in neurologic function have occurred. The patient's respiratory and nutritional status is assessed. The adequacy of pain management is assessed, and modifications are made to ensure adequate pain relief. The need for hospice services or placement in an extended-care facility is discussed with the patient and family if warranted, and the patient is asked about preferences for end-of-life care (Chart 65-3). Additionally, social workers may be consulted to assist the patient and family members in identifying support groups and agencies that can provide help in coping with the disease process.

## Degenerative Disorders

Neurologic disorders of the central and peripheral nervous system that are degenerative in nature include Parkinson's disease, Huntington's disease, Alzheimer's disease, amyotrophic lateral sclerosis, muscular dystrophies, and degenerative disc disease. A relatively new phenomenon, post-polio syndrome, may be degenerative in nature and is also discussed. A slow onset of signs and symptoms characterizes these disorders. Patients are managed at home for as long as possible and admitted to the acute care setting for exacerbations, treatments, and surgical interventions as needed.

## PARKINSON'S DISEASE

Parkinson's disease is a slowly progressing neurologic movement disorder that eventually leads to disability. The degenerative or idiopathic form is the most common; there is also a secondary form with a known or suspected cause. Although the cause of most cases is unknown, research suggests several causative factors, including genetics, atherosclerosis, excessive accumulation of oxygen free radicals, viral infections, head trauma, chronic antipsychotic medication use, and some environmental exposures. Parkinsonian symptoms usually first appear in the fifth decade of life; however, cases have been diagnosed at the age of 30 years. It is the fourth most common **neurodegenerative** disease. Parkinson's disease affects men more frequently than women and nearly 1% of the population older than 60 years of age (Gray & Hildebrand, 2000).

### Chart 65-3 • Ethics and Related Issues

#### What Constitutes Assisted Suicide?

##### Situation

A 76-year-old man is admitted to the hospital with a metastatic spinal cord tumor. He is in respiratory distress and near death. The patient and family state they want no heroic measures and the physician writes a "do not resuscitate" order on the chart.

##### Dilemma

What is the nurse's role in caring for this patient at this time?

##### Discussion

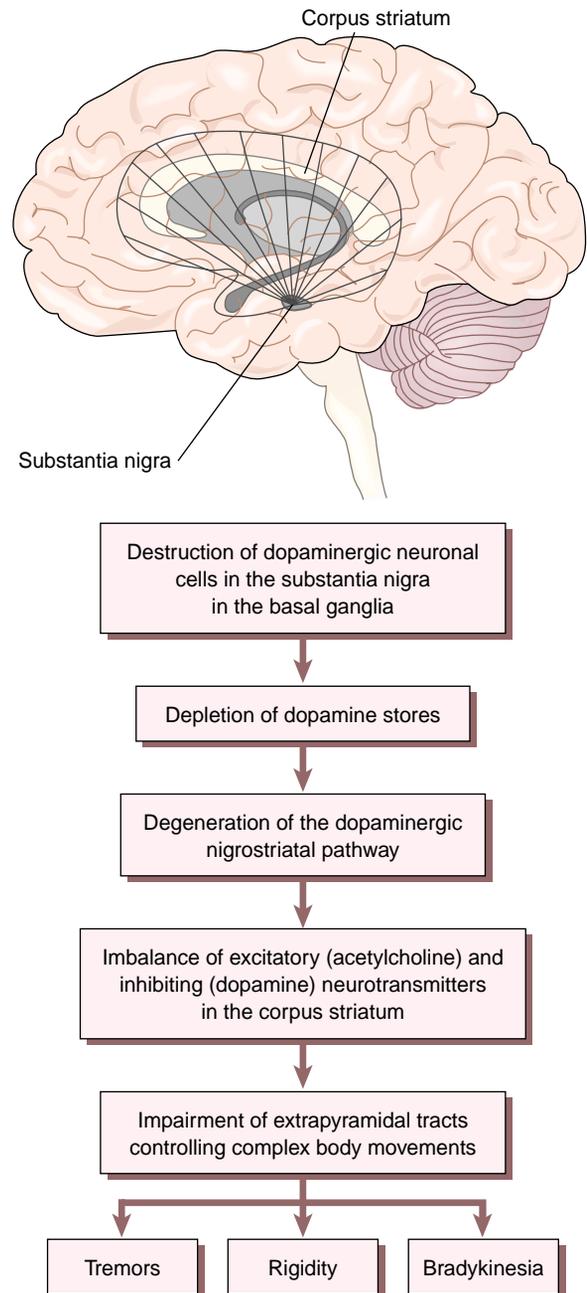

Is the "do not resuscitate" order an act of patient-assisted suicide? Is it active or passive euthanasia? What is the nurse's role in caring for the patient if this action conflicts with his/her personal beliefs? If no other nurse is available to provide care, does the nurse have the right to refuse? Is this patient abandonment?

## Pathophysiology

Parkinson's disease is associated with decreased levels of dopamine due to destruction of pigmented neuronal cells in the substantia nigra in the basal ganglia of the brain (Fig. 65-4). The nuclei of the substantia nigra project fibers or neuronal pathways to the

### Physiology/Pathophysiology

**FIGURE 65-4** Pathophysiology of Parkinson's disease. The nuclei in the substantia nigra project fibers to the corpus striatum. The nerve fibers carry dopamine to the corpus striatum. The loss of dopamine nerve cells from the brain's substantia nigra is thought to be responsible for the symptoms of parkinsonism.

corpus striatum, where neurotransmitters are key to control of complex body movements. Through the neurotransmitters acetylcholine (excitatory) and dopamine (inhibitory), striatal neurons relay messages to the higher motor centers that control and refine motor movements. The loss of dopamine stores in this area of the brain results in more excitatory neurotransmitters than inhibitory neurotransmitters, leading to an imbalance that affects voluntary movement.

Basic science research in the past two decades has revealed that more neurotransmitter pathways in the brain than just the dopaminergic system are involved. Parts of the glutamatergic, cholinergic, tryptaminergic, noradrenergic, adrenergic, serotonergic, and peptidergic pathways (responsible for cell metabolism, growth, nutrition, and so forth) show damage in Parkinson's disease (Chase, Oh & Konitsiotis, 2000; Przuntek, 2000; Rascol, 2000).

Clinical symptoms do not appear until 60% of the pigmented neurons are lost and the striatal dopamine level is decreased by 80%. Cellular degeneration impairs the extrapyramidal tracts that control semiautomatic functions and coordinated movements; motor cells of the motor cortex and the pyramidal tracts are not affected.

## Clinical Manifestations

Parkinson's disease has a gradual onset and symptoms progress slowly over a chronic, prolonged course. The three cardinal signs are tremor, rigidity, and **bradykinesia** (abnormally slow movements). Other features include hypokinesia, gait disturbances, and postural instability (Gray & Hildebrand, 2000).

### TREMOR

Although symptoms are variable, a slow, unilateral, resting tremor is present in 70% of patients at the time of diagnosis. Resting tremor characteristically disappears with purposeful movement but is evident when the extremities are motionless. The tremor may present as a rhythmic, slow turning motion (pronation–supination) of the forearm and the hand and a motion of the

thumb against the fingers as if rolling a pill (Fig. 65-5). Tremor is present while the patient is at rest; it increases when the patient is walking, concentrating, or feeling anxious.

### RIGIDITY

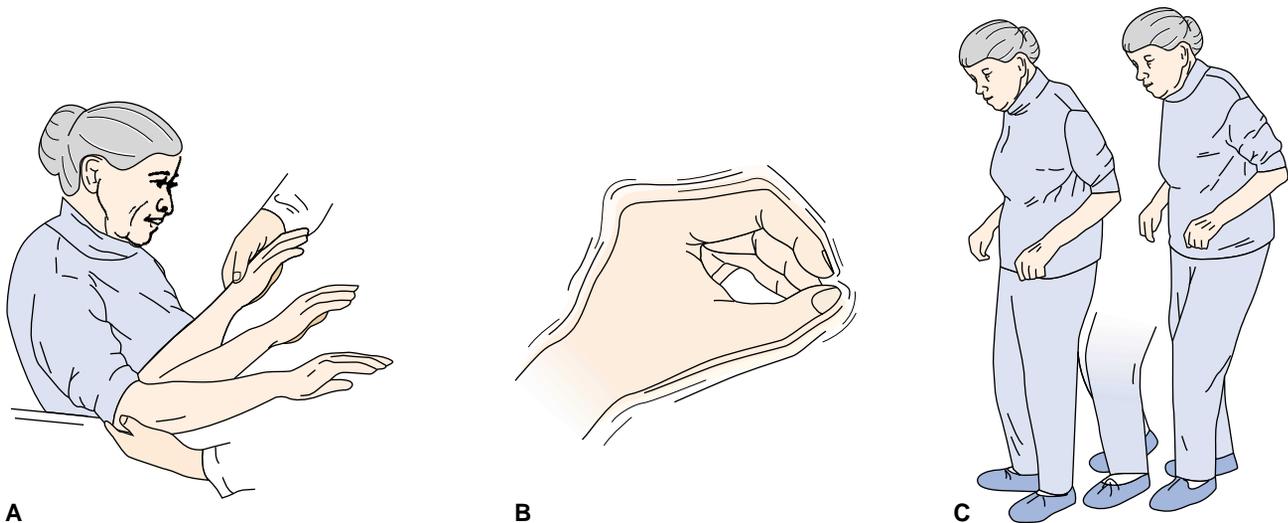

Resistance to passive limb movement characterizes muscle rigidity. Passive movement of an extremity may cause the limb to move in jerky increments referred to as cogwheeling. Rigidity of the passive extremity increases when another extremity is engaged in voluntary active movement. Stiffness of the neck, trunk, and shoulders is common. Early in the disease, the patient may complain of shoulder pain.

### BRADYKINESIA

One of the most common features of Parkinson's disease is bradykinesia. Patients take longer to complete most activities and have difficulty initiating movement, such as rising from a sitting position or turning in bed.

Hypokinesia (abnormally diminished movement) is also common and may appear after the tremor. The freezing phenomenon is a transient inability to perform active movement and is thought to be an extreme form of bradykinesia. Additionally, the patient tends to shuffle and exhibits a decreased arm swing. As dexterity declines, **micrographia** (shrinking, slow handwriting) develops. The face becomes increasingly masklike and expressionless and the frequency of blinking decreases. **Dysphonia** (soft, slurred, low-pitched, and less audible speech) may occur due to weakness and incoordination of the muscles responsible for speech. In many cases, the patient develops dysphagia, begins to drool, and is at risk for choking and aspiration.

The patient commonly develops postural and gait problems. There is a loss of postural reflexes, and the patient stands with the head bent forward and walks with a propulsive gait. The posture is caused by the forward flexion of the neck, hips, knees, and elbows. The patient may walk faster and faster, trying to move the feet forward under the body's center of gravity (shuffling gait). Difficulty in pivoting and loss of balance (either forward or backward) places the patient at risk for falls.

**FIGURE 65-5** Manifestations of Parkinson's disease: (A) "cogwheeling" accompanies passive movement of the hand and arm; (B) "pill-rolling" tremor; (C) postural instability, forward stoop, shuffling gait.

### NURSING RESEARCH PROFILE 65-1

#### Falls and Risk Factors

Gray, P., & Hildebrand, K. (2000). Fall risk factors in Parkinson's disease. *Journal of Neuroscience Nursing*, 32(4), 222–228.

#### Purpose

Patients with Parkinson's disease have frequent falls, yet there is little research on identifying risk factors specific to these patients. The purpose of this study was to identify risk factors associated with falls in a group of patients with Parkinson's disease.

#### Study Sample and Design

The sample for this descriptive, exploratory study was recruited from a hospital-based clinic in Canada. Patients who could stand, walk, and had no other medical conditions that predisposed them to falls were included. The Unified Parkinson's Disease Rating Scale established the degree of symptoms. Multiple instruments were used to assess demographic, environmental, and medical information; participants also completed fall diaries for 12 weeks. The sample consisted of 118 patients; 48 (41%) reported no falls and 70 (59%) reported one or more falls. Participants in the study included 73 (62%) males.

#### Findings

Demographic, environmental, and medical information and fall diaries were analyzed to identify factors that appeared to increase the risk for falls. A total of 237 falls were reported in the 3-month study period; 59% of the participants reported one or more falls. Males, as well as patients over age 80 years, reported higher rates of falls. Factors associated with a high risk for falls included duration and severity of parkinsonian symptoms including freezing, involuntary movements, and walking and postural difficulties. Postural hypotension and daily intake of alcohol were additional factors associated with a high risk for falls.

#### Nursing Implications

Nurses, especially home care nurses, can use the findings of this study to help identify patients with risk factors: "freezing," involuntary movements, walking and postural difficulties, postural hypotension, and daily use of alcohol. Patients with these risk factors should be targeted for intervention programs and specific patient and family education to reduce falls. Early identification of risk factors would permit nurses to provide assistance, education, support, and appropriate referrals to patients at high risk for falls.

### OTHER MANIFESTATIONS

The effect of Parkinson's disease on the basal ganglia often produces autonomic symptoms that include excessive and uncontrolled sweating, paroxysmal flushing, orthostatic hypotension, gastric and urinary retention, constipation, and sexual disturbances (Herndon et al., 2000).

Psychiatric changes are often interrelated and may be predictive of one another. They include depression, **dementia** (progressive mental deterioration), sleep disturbances, and hallucinations (Herndon et al., 2000). Depression is common; whether it is a reaction to the disorder or is related to a biochemical abnormality remains a question. Mental changes may appear in the form of cognitive, perceptual, and memory deficits, although intellect is not usually affected. A number of psychiatric manifestations (personality changes, psychosis, dementia, and acute confusion) are common among the elderly. The prevalence of dementia is about 25% and the pattern is similar to that of patients with Alzheimer's disease. Although there is no direct documented causal relationship, the rates of depression and dementia are highly correlated in these patients (Herndon et al., 2000).

Approximately 41% of women and 25% of men with Parkinson's disease experience sleep disturbances. This may be connected to depression, dementia, or medications. Auditory and visual hallucinations have been reported in approximately 37% of persons with Parkinson's and may be associated with depression, dementia, lack of sleep, or adverse effects of medications (Herndon et al., 2000).

Complications associated with Parkinson's disease are common and are typically related to disorders of movement. As the disease progresses, patients are at risk for respiratory and urinary tract infection, skin breakdown, and injury from falls. The adverse effects of medications used to treat the symptoms are associated with numerous complications.

### Assessment and Diagnostic Findings

Laboratory tests and imaging studies are not helpful in the diagnosis of Parkinson's disease, although PET scanning has been used in evaluating levodopa (precursor of dopamine) uptake and conversion to dopamine in the corpus striatum (Freed et al., 2001). Currently, the disease is diagnosed clinically from the patient's history and the presence of two of the three cardinal manifestations: tremor, muscle rigidity, and bradykinesia.

Early diagnosis can be difficult because the patient can rarely pinpoint when symptoms started. Often a family member notices a change such as stooped posture, a stiff arm, a slight limp, tremor, or slow, small handwriting. The medical history, presenting symptoms, neurologic examination, and response to pharmacologic management are carefully evaluated when making the diagnosis.

### Medical Management

Treatment is directed at controlling symptoms and maintaining functional independence because there are no medical or surgical approaches that prevent disease progression. Care is individualized for each patient based on presenting symptoms and social, occupational, and emotional needs. Pharmacologic management is the mainstay of treatment, although advances in research have led to increased interest in surgical interventions. Patients are usually cared for at home and admitted to the hospital only for complications or to initiate new treatments.

### PHARMACOLOGIC THERAPY

Antiparkinsonian medications act by 1) increasing striatal dopaminergic activity, 2) reducing the excessive influence of excitatory cholinergic neurons on the extrapyramidal tract, thereby restoring a balance between dopaminergic and cholinergic activities, or 3) acting on neurotransmitter pathways other than the dopaminergic pathway.

**Antiparkinsonian Medications.** Levodopa (Dopar, Larodopa) is the most effective agent and the mainstay of treatment (Karch, 2002; Obeso et al., 2001). Because levodopa is thought to precipitate oxidation, which further damages the substantia nigra and eventually speeds disease progression, physicians delay prescribing the medication or increasing the dosage for as long as possible (Karch, 2002). Levodopa is converted to dopamine in the basal ganglia, producing symptom relief. The beneficial effects of levodopa are most pronounced in the first few years of treatment. Benefits begin to wane and adverse effects become more severe over time. Confusion, hallucinations, depression, and sleep alterations are associated with prolonged use. Levodopa is usually given in combination with carbidopa (Sinemet), an

amino acid decarboxylase inhibitor that helps to maximize the beneficial effects of levodopa by preventing its breakdown outside the brain and reducing its adverse effects (Karch, 2002).

Within 5 to 10 years, most patients develop a response to the medication characterized by **dyskinesia** (abnormal involuntary movements), including facial grimacing, rhythmic jerking movements of the hands, head bobbing, chewing and smacking movements, and involuntary movements of the trunk and extremities. The patient may experience an on-off syndrome in which sudden periods of near immobility (“off effect”) are followed by a sudden return of effectiveness (“on effect”). Various adjunctive therapies are used to minimize dyskinesias (Przuntek, 2000; Rascol, 2000).

Budipine, available in Europe but not the United States, is a non-dopaminergic, antiparkinsonian medication that significantly reduces akinesia, rigidity, and tremor. It is non-dopaminergic because the action appears to be on neurotransmitter pathways other than the dopaminergic pathway. It may be used as monotherapy or in conjunction with other available antiparkinsonian medications (Przuntek, 2000; Przuntek et al., 2002). The usual dose of 40 to 60 mg is reached gradually. Nausea and dry mouth are the most common side effects, although 75% of patients experienced no side effects in clinical drug trials (Przuntek, 2000).

**Anticholinergic Therapy.** Anticholinergic agents (trihexyphenidyl, cycrimine, procyclidine, biperiden, and bentsropine mesylate) are effective in controlling tremor and rigidity. They may be used in combination with levodopa. They counteract the action of the neurotransmitter acetylcholine. Because the side effects include blurred vision, flushing, rash, constipation, urinary retention, and acute confusional states, these medications are often poorly tolerated in elderly patients. Intraocular pressure must be closely monitored: these medications are contraindicated in patients with narrow-angle glaucoma. Patients with prostate hyperplasia are monitored for signs of urinary retention.

**Antiviral Therapy.** Amantadine hydrochloride (Symmetrel) is an antiviral agent used in early Parkinson’s treatment to reduce rigidity, tremor, and bradykinesia. It is thought to act by releasing dopamine from neuronal storage sites. Studies suggest it may also have antiglutamatergic properties that affect the glutamatergic pathway, thus improving levodopa-induced dyskinesias (Rascol, 2000). Amantadine has a low incidence of side effects, which include psychiatric disturbances (mood changes, confusion, depression, hallucinations), lower extremity edema, nausea, epigastric distress, urinary retention, headache, and visual impairment.

**Dopamine Agonists.** Bromocriptine mesylate and pergolide (ergot derivatives) are dopamine receptor agonists and are useful in postponing the initiation of carbidopa or levodopa therapy. Dopamine agonists are often added to the medication regimen when carbidopa or levodopa loses effectiveness. Pergolide (Permax) is 10 times more potent than bromocriptine mesylate (Parlodel), although this provides no therapeutic advantage. Adverse reactions to these medications include nausea, vomiting, diarrhea, lightheadedness, hypotension, impotence, and psychiatric effects.

Two new dopamine agonists, ropinirole hydrochloride (Requip) and pramipexole (Mirapex) (nonergot derivatives), are primarily for patients in the early stages of Parkinson’s disease and are not expected to have the potentially serious adverse effects of pergolide and bromocriptine mesylate. Pramipexole (Mirapex) can

be used without levodopa for treatment of early disease and with levodopa in advanced stages. Cabergoline (Dostinex), an ergot alkaloid with a long duration of action, has been approved for use.

**Monoamine Oxidase Inhibitors (MAO Inhibitors).** Of the MAO inhibitors, selegiline (Eldepryl) is one of the most exciting and controversial developments in the pharmacotherapy of Parkinson’s disease (Herndon et al., 2000). This medication inhibits dopamine breakdown and is thought to slow the progression of the disease. Researchers believe this medication may have a neuroprotective effect in the early stages of Parkinson’s disease, but this has not been shown in clinical trials. Selegiline is currently used in combination with a dopamine agonist to delay the use of carbidopa or levodopa therapy. Adverse effects are similar to those of levodopa.

**Catechol-O-methyltransferase (COMT) Inhibitors.** Clinical trials suggest that the COMT inhibitors entacapone (Comtess) and tolcapone (Tasmar) have little effect on parkinsonian symptoms when given alone but can increase the duration of action of carbidopa or levodopa when given in combination with them. COMT inhibitors block an enzyme that metabolizes levodopa, making more levodopa available for conversion to dopamine in the brain. Entacapone and tolcapone reduce motor fluctuations in patients with advanced Parkinson’s disease.

**Antidepressants.** Tricyclic antidepressants may be prescribed to alleviate the depression that is so common in Parkinson’s disease. The usual dosage is one-third to one-half the dosage used in depressed patients without Parkinson’s disease. Amitriptyline is typically prescribed because of its anticholinergic and antidepressant effect. Serotonin reuptake inhibitors, such as fluoxetine hydrochloride (Prozac) and bupropion hydrochloride (Wellbutrin), are effective for treating depression but may aggravate parkinsonism.

**Antihistamines.** Diphenhydramine hydrochloride (Benadryl), orphenadrine citrate (Banflex), and phenindamine hydrochloride (Neo-Syneprine) have mild central anticholinergic and sedative effects and may reduce tremors.

## SURGICAL MANAGEMENT

The limitations of levodopa therapy, improvements in stereotactic surgery, and new approaches in transplantation have renewed interest in the surgical treatment of Parkinson’s disease. In patients with disabling tremor, rigidity, or severe levodopa-induced dyskinesia, surgery may be considered. Although surgery provides some relief in selected patients, it has not been shown to alter the course of the disease or produce permanent improvement.

**Stereotactic Procedures.** Thalamotomy and pallidotomy are effective in relieving many of the symptoms of Parkinson’s disease. Patients eligible for these procedures are those who have had an inadequate response to medical therapy; they must meet strict criteria to be eligible. Candidates eligible for these procedures are patients with idiopathic Parkinson’s disease who are taking maximum doses of antiparkinsonian medications. Patients with dementia and atypical Parkinson’s disease are usually not considered for stereotactic procedures. Parkinson’s disease rating scales and specific neurologic testing are used to identify eligible patients.

The intent of thalamotomy and pallidotomy is to interrupt the nerve pathways and thereby alleviate tremor or rigidity. During thalamotomy, a stereotactic electrical stimulator destroys part of the ventrolateral portion of the thalamus in an attempt to

reduce tremor; the most common complications are ataxia and hemiparesis. Pallidotomy involves destroying part of the ventral aspect of the medial globus pallidus through electrical stimulation in patients with advanced disease. The procedure is effective in reducing rigidity, bradykinesia, and dyskinesia, thus improving motor function and activities of daily living in the immediate postoperative course. In small studies, clinical improvements have been demonstrated over 3 to 4 years. The clinical benefit is greater in patients younger than 60 years (Freed et al., 2001). Complications include hemiparesis, stroke, and visual changes.

CT, x-rays, MRI, or angiography is used to localize the appropriate surgical site in the brain. Then the patient's head is positioned in a stereotactic frame (Fig. 65-6). The surgeon makes an incision in the skin and then a burr hole. Next, the surgeon passes an electrode through the burr hole to the target area in the thalamus or globus pallidum. The desired response of the patient to the electrical stimulation is the basis for the final site chosen by the neurosurgeon. Stereotactic procedures are completed on one side of the brain at a time. If rigidity or tremor is bilateral, a 6-month interval is suggested between procedures.

**Neural Transplantation.** Surgical implantation of adrenal medullary tissue into the corpus striatum is performed in an effort to reestablish normal dopamine release. Preliminary evidence has shown high morbidity and mortality rates, and the implants appear to improve parkinsonian symptoms for only 6 months. Researchers are conducting studies to determine if transplanting human fetal brain cells or genetically engineered cells into the nigrostriatal region is effective (Aminoff, 2000). Legal and ethical issues surrounding the use of fetal brain cells have limited the implementation of this procedure. Recently, fetal pig neuronal cells survived transplantation into a patient with Parkinson's disease; this may provide an alternative to human cell transplants (Aminoff, 2000).

**Deep Brain Stimulation.** Recently approved by the FDA, pacemaker-like brain implants show promising results in relieving tremors. The stimulation can be bilateral or unilateral, although bilateral stimulation of the subthalamic nucleus is thought to be of greater benefit to patients than results achieved with thalamotomy, pallidotomy, or fetal nigral transplantation (Obeso et al., 2001). In deep brain stimulation, an electrode is placed in the

thalamus and connected to a pulse generator implanted in a subcutaneous subclavicular or abdominal pouch. The battery-powered pulse generator sends high-frequency electrical impulses through a wire placed under the skin to a lead anchored to the skull (Fig. 65-7). The electrode blocks nerve pathways in the brain that cause tremors. These devices are not without complications, both from the surgical procedure needed for implantation and from complications (such as lead leakage) of the device itself (Koller et al., 2001; Obeso et al., 2001).

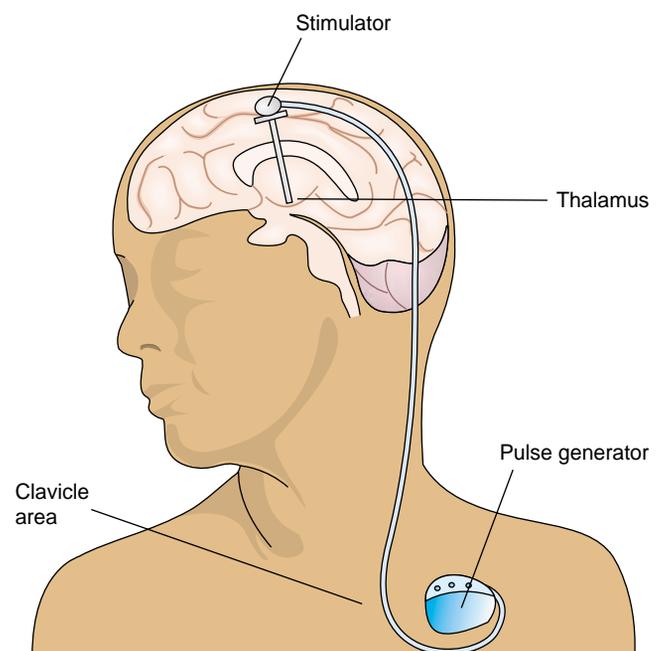

## NURSING PROCESS: THE PATIENT WITH PARKINSON'S DISEASE

### Assessment

Assessment focuses on how the disease has affected the patient's activities of daily living and functional abilities. Patients are observed for degree of disability and the functional changes that occur throughout the day, such as responses to medication. Nearly every patient with a movement disorder has some functional alteration and may have some type of behavioral dysfunction. The following questions may be useful to assess alterations:

- Do you have leg or arm stiffness?
- Have you experienced any irregular jerking of your arms or legs?
- Have you ever been "frozen" or rooted to the spot and unable to move?
- Does your mouth water excessively? Have you (or others) noticed yourself grimacing or making faces or chewing movements?
- What specific activities do you have difficulty doing?

During this assessment, the nurse observes the patient for quality of speech, loss of facial expression, swallowing deficits

**FIGURE 65-6** A stereotactic frame is applied to a patient's head in preparation for pallidotomy. The frame immobilizes the head.

**FIGURE 65-7** Deep brain stimulation is provided by a pulse generator surgically implanted in a pouch beneath the clavicle. The generator sends high-frequency electrical impulses to the thalamus, thereby blocking the nerve pathways associated with tremors in Parkinson's disease.

(drooling, poor head control, coughing), tremors, slowness of movement, weakness, forward posture, rigidity, evidence of mental slowness, and confusion. Parkinsonian symptoms, as well as side effects of medications, put these patients at high risk of falls; therefore, a fall risk assessment should be included (Gray & Hildebrand, 2000).

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Impaired physical mobility related to muscle rigidity and motor weakness
- Self-care deficits (feeding, dressing, hygiene, and toileting) related to tremor and motor disturbance
- Constipation related to medication and reduced activity
- Imbalanced nutrition, less than body requirements, related to tremor, slowness in eating, difficulty in chewing and swallowing
- Impaired verbal communication related to decreased speech volume, slowness of speech, inability to move facial muscles
- Ineffective coping related to depression and dysfunction due to disease progression

Other nursing diagnoses may include sleep pattern disturbances, deficient knowledge, risk for injury, risk for activity intolerance, disturbed thought processes, and compromised family coping.

## Planning and Goals

The goals for the patient may include improving functional mobility, maintaining independence in activities of daily living, achieving adequate bowel elimination, attaining and maintaining acceptable nutritional status, achieving effective communication, and developing positive coping mechanisms.

## Nursing Interventions

### IMPROVING MOBILITY

A progressive program of daily exercise will increase muscle strength, improve coordination and dexterity, reduce muscular rigidity, and prevent contractures that occur when muscles are not used. Walking, riding a stationary bicycle, swimming, and gardening are all exercises that help maintain joint mobility. Stretching (stretch–hold–relax) and range-of-motion exercises promote joint flexibility. Postural exercises are important to counter the tendency of the head and neck to be drawn forward and down. A physical therapist may be helpful in developing an individualized exercise program and can provide instruction to the patient and caregiver on exercising safely. Faithful adherence to an exercise and walking program helps to delay the progress of the disease. Warm baths and massage in addition to passive and active exercises help relax muscles and relieve painful muscle spasms that accompany rigidity.

Balance may be adversely affected because of the rigidity of the arms (arm swinging is necessary in normal walking). Special walking techniques must be learned to offset the shuffling gait and the tendency to lean forward. The patient is taught to concentrate on walking erect, to watch the horizon, and to use a wide-based gait (ie, walking with the feet separated). A conscious effort must be made to swing the arms, raise the feet while walking,

and to use a heel-toe placement of the feet with long strides. The patient is advised to practice walking to marching music or to the sound of a ticking metronome because this provides sensory reinforcement. Doing breathing exercises while walking helps to move the rib cage and to aerate parts of the lungs. Frequent rest periods aid in preventing frustration and fatigue.

### ENHANCING SELF-CARE ACTIVITIES

Encouraging, teaching, and supporting the patient during activities of daily living promote self-care. See Chapter 11 for rehabilitation techniques.

Environmental modifications are necessary to compensate for functional disabilities. Patients may have severe mobility problems that make normal activities impossible. Adaptive or assistive devices may be useful. A hospital bed at home with bedside rails, an overbed frame with a trapeze, or a rope tied to the foot of the bed can provide assistance in pulling up without help. An occupational therapist can evaluate the patient's needs in the home and make recommendations regarding adaptive devices and teach the patient and caregiver how to improvise.

### IMPROVING BOWEL ELIMINATION

The patient may have severe problems with constipation. Among the factors causing constipation are weakness of the muscles used in defecation, lack of exercise, inadequate fluid intake, and decreased autonomic nervous system activity. The medications used for the treatment of the disease also inhibit normal intestinal secretions. A regular bowel routine may be established by encouraging the patient to follow a regular time pattern, consciously increase fluid intake, and eat foods with a moderate fiber content. Laxatives should be avoided. Psyllium, for example, decreases constipation but carries the risk for bowel obstruction (Herndon et al., 2000). A raised toilet seat is useful because the patient has difficulty in moving from a standing to a sitting position.

### IMPROVING NUTRITION

Patients may have difficulty maintaining their weight. Eating becomes a very slow process, requiring concentration due to a dry mouth from medications and difficulty chewing and swallowing. They are at risk for aspiration because of impaired swallowing and the accumulation of saliva. They may be unaware that they are aspirating, and subsequently bronchopneumonia may develop.

Monitoring weight on a weekly basis indicates whether caloric intake is adequate. Supplemental feedings increase caloric intake. As the disease progresses, a nasogastric tube or percutaneous endoscopic gastroscopy may be necessary to maintain adequate nutrition. A dietitian can be consulted regarding nutritional needs.

### ENHANCING SWALLOWING

Swallowing disorders can be due to poor head control, tongue tremor, hesitancy in initiating swallowing, difficulty in shaping food into a bolus, and disturbances in pharyngeal motility. To offset these problems, the patient should sit in an upright position during mealtime. A semisolid diet with thick liquids is easier to swallow than solids; thin liquids should be avoided. It is helpful for patients to think through the swallowing sequence. The patient is taught to place the food on the tongue, close the lips and teeth, lift the tongue up and then back, and swallow. The patient is encouraged to chew first on one side of the mouth and then on the other. To control the buildup of saliva, the patient is reminded to hold the head upright and make a conscious effort to swallow. Massaging the facial and neck muscles before meals may be beneficial.

Chart 65-4

## Home Care Checklist • The Patient With Parkinson's Disease

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Define Parkinson's disease and discuss its long-term effects.	✓	✓
• Identify the medication regimen and name adverse effects, and precautions.	✓	✓
• Discuss the risk for injury, prevent falls; implement adaptive measures in the home.	✓	✓
• Describe nutritional needs, dietary restrictions, dysphagia management, and ways to prevent aspiration.	✓	✓
• Manage constipation: fluid intake, bowel routine.	✓	✓
• Manage urinary problems: functional incontinence, retention (Foley catheter care, suprapubic catheter care).	✓	✓
• Explain effects of immobility and define preventive care: skin breakdown (frequent turning, pressure release, skin care), pneumonia (deep breathing, movement), contractures (range-of-motion exercises).	✓	✓
• Define benefits of daily exercise program.	✓	✓
• Walk and balance safely.	✓	
• Demonstrate speech and communication skills: speech exercises, communication techniques, breathing exercises.	✓	
• Name signs and symptoms of infection (urinary and respiratory) and state when health care provider should be notified.	✓	✓
• Describe strategies to promote self-care activities and independence.	✓	✓
• Identify resources: American Parkinson's Disease Association, National Parkinson's Disease Foundation, and local support groups.	✓	✓

### ENCOURAGING THE USE OF ASSISTIVE DEVICES

An electric warming tray keeps food hot and permits the patient to rest during the prolonged time that it takes to eat. Special utensils also assist at mealtime. A plate that is stabilized, a nonspill cup, and eating utensils with built-up handles are useful self-help devices. The occupational therapist can assist in identifying appropriate adaptive devices.

### IMPROVING COMMUNICATION

Speech disorders are present in most patients with Parkinson's disease. Their low-pitched, monotonous, soft speech requires that they make a conscious effort to speak slowly, with deliberate attention to what they are saying. Patients are reminded to face the listener, exaggerate the pronunciation of words, speak in short sentences, and take a few deep breaths before speaking.

A speech therapist may be helpful in designing speech improvement exercises and assisting the family and health care personnel to develop and use a method of communication to meet the patient's needs. A small electronic amplifier is helpful if the patient has difficulty being heard.

### SUPPORTING COPING ABILITIES

Support can be given by encouraging the patient and pointing out that activities are being maintained through active participation. A combination of physiotherapy, psychotherapy, medication therapy, and support group participation may help reduce the depression that often occurs.

Patients often feel embarrassed, apathetic, inadequate, bored, and lonely. These feelings may be due, in part, to physical slowness and the great effort that even small tasks require. Patients are assisted and encouraged to set achievable goals (eg, improvement of mobility).

Because parkinsonism tends to lead to withdrawal and depression, patients must be active participants in their therapeutic program, including social and recreational events. There should be a planned program of activity throughout the day to prevent too much daytime sleeping as well as disinterest and apathy.

Every effort should be made to encourage patients to carry out the tasks involved in meeting their own daily needs and to remain independent. Doing things for the patient merely to save time is contrary to the basic goal of improving coping abilities and promoting a positive self-concept.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

Patient and family education is important in the management of Parkinson's disease. Teaching needs depend on the severity of symptoms and the stage of the disease. Care must be taken not to overwhelm the patient and family with too much information early in the disease process. The patient's and family's need for information is ongoing as adaptations become necessary. The education plan should include a clear explanation of the disease, assisting the patient to remain functionally independent as long as possible. Every effort is made to explain the nature of the disease and its management to offset disabling anxieties and fears. The patient and family must be taught about the effects and side effects of medications and about the importance of reporting side effects to the physician (Chart 65-4).

#### Continuing Care

In the early stages patients can be managed well at home. Family members often serve as caregivers, with home care or community services available to assist in meeting health care needs as the disease progresses. The family caregiver may be under considerable stress from living with and caring for a person with a significant disability. Providing information about treatment and care prevents many unnecessary problems. The caregiver is included in the plan and may be advised to learn stress reduction techniques, to include others in the caregiving process, to obtain periodic relief from responsibilities, and to have a yearly health assessment. Allowing family members to express feelings of frustration, anger, and guilt is often helpful to them.

The patient should be evaluated in the home for adaptation and safety needs and compliance with the plan of care. In the advanced stages, patients usually enter long-term care facilities when family support is absent. Periodically, admission to an acute care facility may be necessary for changes in medical management or treatment of complications. Nurses provide support, education, and monitoring of patients over the course of illness.

The nurse involved in home and continuing care needs to remind patients and family members of the need to address health promotion needs such as screening for hypertension and stroke risk assessments in this predominantly elderly population. Patients who have not been involved in these practices in the past are educated about their importance and are referred to appropriate health care providers. Informational booklets and a newsletter for patient education are published by the National Parkinson's Foundation, Inc. and the American Parkinson's Disease Association.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Strives toward improved mobility
  - a. Participates in exercise program daily
  - b. Walks with wide base of support; exaggerates arm swinging when walking
  - c. Takes medications as prescribed
2. Progresses toward self-care
  - a. Allows time for self-care activities
  - b. Uses self-help devices
3. Maintains bowel function
  - a. Consumes adequate fluid
  - b. Increases dietary intake of fiber
  - c. Reports regular pattern of bowel function
4. Attains improved nutritional status
  - a. Swallows without aspiration
  - b. Takes time while eating
5. Achieves a method of communication
  - a. Communicates needs
  - b. Practices speech exercises
6. Copes with effects of Parkinson's disease
  - a. Sets realistic goals
  - b. Demonstrates persistence in meaningful activities
  - c. Verbalizes feelings to appropriate person

## HUNTINGTON'S DISEASE

Huntington's disease is a chronic, progressive, hereditary disease of the nervous system that results in progressive involuntary choreiform movement and dementia. It affects men and women of all races. Because it is transmitted as an autosomal dominant genetic disorder, each child of a parent with Huntington's disease has a 50% risk of inheriting the illness (Bradley et al., 2000).

### Pathophysiology

The basic pathology involves premature death of cells in the striatum (caudate and putamen) of the basal ganglia, the region deep within the brain involved in the control of movement. There is also loss of cells in the cortex, the region of the brain associated with thinking, memory, perception, and judgment, and in the

### NURSING RESEARCH PROFILE 65-2

#### Coping Patterns Following Gene Testing

Williams, J. K., Schutte, D., Evers, C., & Holkup, P. A. (2000). Redefinition: Coping with normal results from predictive gene testing for neurodegenerative disorders. *Research in Nursing & Health*, 23, 260–269.

#### Purpose

Predictive testing for an inherited neurodegenerative disease is a source of intense stress for adults. The purpose of this study was to describe the psychosocial impact and coping process of normal (negative) results from predictive testing for an inherited neurodegenerative disease.

#### Study Sample and Design

The study used a qualitative, descriptive design and the constant comparative method of data analysis. Ten adults with normal results of predictive testing for Huntington's disease (HD) or the pallido-pont-nigral degeneration (PPND) gene mutation participated in semistructured interviews 1 and 6 months following gene testing. The sample included 8 females, the age range was 33 to 59 years, 80% were married, and 80% had known they were at risk for one of the diseases for more than 5 years.

#### Findings

The major descriptive theme identified was redefinition. The redefinition occurred in the following three domains: redefinition of self, relationships with family, and role in society. The process evolved from a personal level at 1 month to a more future-oriented perspective at 6 months following normal gene test results.

#### Nursing Implications

Nurses working with individuals at risk for HD and PPND should keep in mind that many people prepare for the worst results when undergoing gene testing. The coping process following negative results (ie, absence of gene for the disease) evolves from a personal focus at 1 month to a broader future perspective at 6 months after testing. These components of the redefinition process are important considerations in planning interventions to promote coping with normal gene results within at-risk families during an extremely stressful time.

cerebellum, the area that coordinates voluntary muscle activity. Researchers now believe that a building block for protein called glutamine abnormally collects in the cell nucleus, causing cell death. The reason that the protein destroys only certain brain cells is unknown. The cells' destruction results in a lack of the neurotransmitters gamma-aminobutyric acid (GABA) and acetylcholine, which inhibit nerve action (Bradley et al., 2000). Onset usually occurs between the ages of 35 and 45 years, although about 10% of patients are children. The disease progresses slowly. Despite a ravenous appetite, patients usually become emaciated and exhausted. Patients succumb in 10 to 20 years to heart failure, pneumonia, or infection, or as a result of a fall or choking.

### Clinical Manifestations

The most prominent clinical features of the disease are abnormal involuntary movements (**chorea**), intellectual decline, and, often, emotional disturbance. As the disease progresses, a constant writhing, twisting, uncontrollable movement may involve the entire body. These motions are devoid of purpose or rhythm, although patients may try to turn them into purposeful movement. All of the body musculature is involved. Facial movements

produce tics and grimaces. Speech is affected, becoming slurred, hesitant, often explosive, and eventually unintelligible. Chewing and swallowing are difficult, and there is a constant danger of choking and aspiration. Choreiform movements persist but diminish during sleep.

As with speech, the gait becomes disorganized to the point that ambulation eventually is impossible. Although independent ambulation should be encouraged for as long as possible, a wheelchair usually becomes necessary. Eventually, the patient is confined to bed when the chorea interferes with walking, sitting, and all other activities. Bladder and bowel control is lost.

Cognitive function is usually affected, with dementia usually occurring. Initially, the patient generally is aware that the disease is responsible for the myriad dysfunctions that are occurring. The mental and emotional changes that occur may be more devastating to the patient and family than the abnormal movements. Personality changes may result in nervous, irritable, or impatient behaviors. In the early stages, patients are particularly subject to uncontrollable fits of anger, profound, often suicidal depression, apathy, anxiety, psychosis, or euphoria (Hofmann, 1999). Judgment and memory are impaired, and dementia eventually ensues. Hallucinations, delusions, and paranoid thinking may precede the appearance of disjointed movements. Emotional symptoms often become less acute as the disease progresses.

## Assessment and Diagnostic Findings

The diagnosis is made based on the clinical presentation of characteristic symptoms, a positive family history, and exclusion of other causes. Imaging studies, such as CT and MRI, may show atrophy of the caudate nuclei once the disease is well established (Bradley et al., 2000).

A genetic marker for Huntington's has been identified through the use of recombinant DNA technology. As a result, researchers can now identify presymptomatic individuals who will develop this disease. Although this presymptomatic test can remove the uncertainty, it offers no hope of cure or even specific prediction of the timing of its onset. Researchers continue to study the genetic causes that lead to the death of brain cells (Bradley et al., 2000).

## Management

Although no treatment halts or reverses the underlying process, several methods of management have fairly good palliative results (Bradley et al., 2000; Sawle, 1999). Thiothixene hydrochloride (Navane) and haloperidol decanoate (Haldol), which predominantly block dopamine receptors, improve the chorea in many patients (Bradley et al., 2000). Chorea also is lessened by reserpine (depletes presynaptic dopamine) and tetrabenazine (reduces dopaminergic transmission). Motor signs must be assessed and evaluated on an ongoing basis so that optimal therapeutic drug levels can be reached. **Akathisia** (motor restlessness) in the overmedicated patient is dangerous because it may be mistaken for the restless fidgeting of the illness and consequently can be overlooked.

In certain types of the disease, hypokinetic motor impairment resembles parkinsonism. In patients who present with rigidity, some temporary benefit may be obtained from antiparkinson medication, such as levodopa.

Patients who have emotional disturbances, particularly depression, may be helped by antidepressant medications. The threat of suicide is always present. Psychotic symptoms usually

respond to antipsychotic medications. Psychotherapy aimed at allaying anxiety and reducing stress may be beneficial (Hofman, 1999). It is imperative that nurses look beyond the disease to focus on the patient's needs and capabilities (Chart 65-5). One study showed improved physical, mental, and social functioning in a small group of patients with Huntington's disease using remotivation therapy and providing a more stimulating environment (Sullivan, Bird, Alpay et al., 2001). Surgically implanted fetal neural allografts are being tested in hopes of improving the functional, motor, and cognitive function of patients (Bachoud-Levi, Remy, Nguyen et al., 2000; Diederich & Goetz, 2000).

## PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** The needs of the patient and family for education depend on the nature and severity of physical, cognitive, and psychological changes experienced by the patient. Patients and family members are taught about the medications prescribed and about signs indicating a need for change in medication or dosage. The teaching plan addresses strategies to manage symptoms such as chorea, swallowing problems, limitations in ambulation, and loss of bowel and bladder function. Consultation with a speech therapist may be indicated to assist in identifying alternative communication strategies if speech is affected.

Individuals of child-bearing age often seek information about their risk for transmitting the disease. Even though presymptomatic testing has been offered since 1986, approximately 75% of individuals at risk choose not to be tested (Hayden, 2000). For most people, the benefits of testing are unclear because of ethical and confidentiality issues. Genetic counseling is crucial following testing, and patients and their families may require long-term psychological counseling and emotional, financial, and legal support (Williams, Schutte, Evers et al., 2000).

**Continuing Care.** A program combining medical, nursing, psychological, social, occupational, speech, and physical rehabilitation services is needed to help the patient and family cope with this severely disabling illness. Huntington's exacts enormous emotional, physical, social, and financial tolls on every member of the patient's family. The family often live under a heavy burden of uncertainty, anxiety, and guilt. Regular follow-up helps to allay the fear of abandonment.

Home care assistance, day care centers, respite care, and eventually skilled long-term care can assist the patient and family in coping with the constant strain of the illness. Although the relentless progression of the disease cannot be halted, families can benefit from supportive care.

Voluntary organizations can be major aids to families and have been largely responsible for bringing the illness to national attention. The Huntington's Disease Foundation of America helps patients and families by providing information, referrals, family and public education, and support for research.

## ALZHEIMER'S DISEASE

Alzheimer's disease, or senile dementia of the Alzheimer's type, is a chronic, progressive, and degenerative brain disorder accompanied by profound effects on memory, cognition, and ability for self-care. About 10% of the population older than age 65 are affected, and the prevalence reaches 47% by age 85. Research suggests that inflammation plays a role in the pathophysiology of the

Chart  
65-5

## Care of the Patient With Huntington's Disease

**Nursing Diagnosis**

Risk for injury from falls and possible skin breakdown (pressure ulcers, abrasions), resulting from constant movement

**Nursing Interventions**

Pad the sides and head of the bed; ensure that the patient can see over the sides of bed.

Use padded heel and elbow protectors.

Keep the skin meticulously clean.

Apply emollient cleansing agent and skin lotion frequently.

Use soft sheets and bedding.

Have patient wear football padding or other forms of padding.

Encourage ambulation with assistance to maintain muscle tone.

Secure the patient (only if necessary) in bed or chair with padded protective devices, making sure that they are loosened frequently.

**Nursing Diagnosis**

Imbalanced nutrition, less than body requirements, due to inadequate intake and dehydration resulting from swallowing or chewing disorders and danger of choking or aspirating food

**Nursing Interventions**

Administer phenothiazines as prescribed before meals (appears to calm some patients).

Use a warming tray.

Talk to the patient before mealtime to promote relaxation; use mealtime for social interaction. Provide undivided attention.

Help the patient enjoy the mealtime experience.

Learn the position that is best for *this* patient. Keep patient as close to upright as possible while feeding. Stabilize patient's head gently with one hand while feeding.

Show the food and tell the patient what the foods are (eg, whether hot or cold).

Encircle the patient with one arm and get as close as possible to provide stability and support. Use pillows and wedges for additional support.

Do not interpret stiffness, turning away, or sudden turning of the head as rejection; these are uncontrollable choreiform movements.

For feeding, use a long-handled spoon (iced-tea spoon). Place spoon on middle of tongue and exert slight pressure.

Place bite-sized food between patient's teeth. Serve stews, casseroles, thick liquids; avoid too many milk drinks (produces mucus).

Disregard messiness. Treat the person with dignity.

Wait for the patient to chew and swallow before introducing another spoonful. Make sure that bite-sized food is small.

Give between-meal feedings. Constant movement expends more calories. Patients often have voracious appetites, particularly for sweets.

Use blenderized meals if patient cannot chew; do not repeatedly give the same strained baby foods; gradually introduce increased textures and consistencies to the diet.

For swallowing difficulties:

Apply gentle deep pressure around the patient's mouth.

Rub fingers in circles on the patient's cheeks.

Rub fingers simultaneously down each side of the patient's throat.

Develop skill in Heimlich maneuver (to be used in the event of choking).

**Nursing Diagnosis**

Anxiety and impaired communication from excessive grimacing and unintelligible speech

**Nursing Interventions**

Read to the patient.

Employ biofeedback and relaxation therapy to reduce stress.

Consult with speech therapist to help maintain and prolong communication abilities.

Try to devise a communication system, perhaps using cards with words or pictures of familiar objects, before verbal communication becomes too difficult. Patients can indicate correct card by hitting it with hand, grunting, or blinking the eyes.

Learn how this particular patient expresses needs and wants—particularly nonverbal messages (widening of eyes, responses).

Patients can understand even if unable to speak. Do not isolate patients by ceasing to communicate with them.

**Nursing Diagnosis**

Disturbed thought processes and impaired social interaction

**Nursing Interventions**

Have clock, calendar, and wall posters to view.

Interact with the patient in a creative manner.

Use every opportunity for one-to-one contact.

Use music for relaxation.

Reorient the patient after awakening.

Have the patient wear an identification bracelet with name, telephone number, and "memory impaired" on it.

Keep the patient in the social mainstream.

Recruit and train volunteers for social interaction. Role model appropriate interactions.

Do not abandon a patient because the disease is eventually terminal. Patients are *living* until the end.

disease and that anti-inflammatory agents such as nonsteroidal anti-inflammatory drugs (NSAIDs) may be helpful adjuncts in treatment (Neuroinflammation Working Group, 2000).

Alzheimer's is one of the most feared disorders of modern times because it has catastrophic consequences for the patient and family, who experience what has been termed an endless funeral. Chapter 12 discusses the manifestations, management, and nursing care of the patient with Alzheimer's disease.

**AMYOTROPHIC LATERAL SCLEROSIS**

Amyotrophic lateral sclerosis (ALS) is a disease of unknown cause in which there is a loss of motor neurons (nerve cells controlling muscles) in the anterior horns of the spinal cord and the motor

nuclei of the lower brain stem. As these cells die, the muscle fibers that they supply undergo atrophic changes. Neuronal degeneration may occur in both the upper and lower motor neuron systems. Several theories exist regarding the cause of ALS, including autoimmune disease and free radical damage. The leading theory held by researchers is that overexcitation of nerve cells by the neurotransmitter glutamate leads to cell injury and neuronal degeneration.

The incidence of ALS is 203 cases per 100,000 in the general population (Charles & Swash, 2001; Brown, Meininger & Swash, 2000). ALS affects more men than women, with onset occurring usually in the fifth or sixth decade. It is often referred to as Lou Gehrig's disease after the famous baseball player who suffered from it.

## Clinical Manifestations

Clinical manifestations depend on the location of the affected motor neurons, because specific neurons activate specific muscle fibers. The chief symptoms are fatigue, progressive muscle weakness, cramps, fasciculations (twitching), and incoordination (Brown, Meininger & Swash, 2000). Loss of motor neurons in the anterior horns of the spinal cord results in progressive weakness and atrophy of the muscles of the arms, trunk, or legs. Spasticity usually is present, and the deep tendon stretch reflexes become brisk and overactive. Usually, the anal and bladder sphincters are intact because the spinal nerves that control muscles of the rectum and urinary bladder are not affected.

In about 25% of patients, weakness starts in the muscles supplied by the cranial nerves, and there is difficulty talking, swallowing, and ultimately breathing. When the patient ingests liquids, soft palate and upper esophageal weakness causes the liquid to be regurgitated through the nose. Weakness of the posterior tongue and palate impairs the ability to laugh, cough, or even blow the nose. When bulbar muscles are impaired, there is progressive difficulty in speaking and swallowing, and aspiration becomes a risk. The voice assumes a nasal sound, and articulation becomes so disrupted that the speech is unintelligible. Some emotional lability may be present, but intellectual function is not impaired. Eventually, respiratory function is compromised.

The prognosis generally is based on the area of the CNS involved and the speed with which the disease progresses. Death usually occurs as a result of infection, respiratory failure, or aspiration. The average time from onset of the disease to death is about 3 years. A few patients survive for longer periods.

## Assessment and Diagnostic Findings

ALS is diagnosed on the basis of the signs and symptoms because no clinical or laboratory tests are specific for this disease. EMG studies of the affected muscles indicate reduction in the number of functioning motor units. MRI may show high signal intensity in the corticospinal tracts; this differentiates it from a multifocal motor neuropathy (Rowland & Shneider, 2001).

## Management

There is no specific therapy for ALS. The main focus of medical and nursing management is on interventions to maintain or improve function, well-being, and quality of life (Brown, Meininger & Swash, 2000). One study of 60 patients with ALS found that despite the decline in physical function, quality of life and religiosity change little over time (Robbins, Simmons, Bremer et al., 2001).

The medication riluzole (Rilutek), a glutamate antagonist, was approved by the FDA in 1995 after clinical trials found that it slows the deterioration of motor neurons. How riluzole works is not clear, but its pharmacologic properties suggest that it may have a neuroprotective effect in the early stages of ALS. Two randomized drug trials showed a dose of 100 mg riluzole per day to be modestly effective in prolonging survival time for patients with ALS (Miller, Mitchell & Moore, 2001).

Symptomatic treatment and rehabilitative measures are employed to support the patient and improve the quality of life. Baclofen (Lioresal), dantrolene sodium (Dantrium), or diazepam (Valium) may be useful for patients troubled by spasticity, which causes pain and interferes with self-care. Several neurotrophic factors that facilitate nutrition and metabolism for nerve tissue are being investigated (Rowland & Shneider, 2001).

Most patients with ALS are managed at home and in the community, with hospitalization for acute problems. The most common reasons for hospitalization are dehydration and malnutrition, pneumonia, and respiratory failure (Lechtzin, Wiener, Clawson et al., 2001). Recognizing these problems at an earlier stage in the illness will allow for the development of preventive strategies.

A patient experiencing problems with aspiration and swallowing may require enteral feeding. The American Academy of Neurology practice guidelines suggest the placement of a percutaneous endoscopic gastrostomy tube before the forced vital capacity drops below 50% of predicted (Boitano, Jordan & Benditt, 2001). This tube can be safely placed in patients who are using noninvasive positive-pressure ventilation for ventilatory support (Boitano, Jordan & Benditt, 2001).

Mechanical ventilation (using negative-pressure ventilators) is an option when alveolar hypoventilation develops. A small study of patients who used noninvasive positive-pressure ventilation at night showed that hypoventilation and sleep disturbances were at least partially improved, enhancing their cognitive function (Newsom-Davis et al., 2001). The use of noninvasive positive-pressure ventilation also postpones the decision of whether to undergo a tracheotomy for long-term mechanical ventilation (Rowland & Shneider, 2001).

Decisions about life support measures are made by the patient and family and should be based on a thorough understanding of the disease, the prognosis, and the implications of initiating such therapy. Patients are encouraged to complete an advance directive or “living will” to preserve their autonomy in decision-making.

The ALS Association has broad programs of research funding, patient and clinical services, patient information and support, and medical and public information. The *ALS Association Quarterly Newsletter* is a source of practical information.

## MUSCULAR DYSTROPHIES

The muscular dystrophies are a group of chronic muscle disorders characterized by progressive weakening and wasting of the skeletal or voluntary muscles. Most of these diseases are inherited. Duchenne muscular dystrophy is the most common and occurs in 1 of every 3,000 male births (Bach, 1999). The pathologic features include degeneration and loss of muscle fibers, variation in muscle fiber size, phagocytosis and regeneration, and replacement of muscle tissue by connective tissue. The common characteristics of these diseases include varying degrees of muscle wasting and weakness, abnormal elevation in blood muscle enzymes, and myopathic findings on EMG and muscle biopsy (Bach, 1999). The differences center on the pattern of inheritance, the muscles involved, the age of onset, and the rate of progression. The unique needs of these patients, who in the past did not live to adulthood, must be addressed as they live longer as a result of better supportive care (Carson & Hieber, 2001).

## Medical Management

Treatment of the muscular dystrophies at this time focuses on supportive care and preventing complications in the absence of a cure or specific pharmacologic interventions (Bach, 1999; Carson & Hieber, 2001). Supportive management aims to keep the patient active and functioning as normally as possible and to minimize functional deterioration. An individualized therapeutic exercise program is prescribed to prevent muscle tightness, contractures, and disuse atrophy. Night splints and stretching exercises are used

to delay contractures of the joints, especially the ankles, knees, and hips. Braces may compensate for muscle weakness.

Spinal deformity is a severe problem. Weakness of trunk muscles and spinal collapse occur almost routinely in patients with severe neuromuscular disease. In the battle against spinal deformity, the patient is fitted with an orthotic jacket to improve sitting stability and reduce trunk deformity. This measure also supports cardiovascular status. In time, spinal fusion is performed to maintain spinal stability. Other procedures may be carried out to correct deformities.

Compromised pulmonary function may be due either to progression of the disease or to deformity of the thorax secondary to severe scoliosis. Intercurrent illnesses, upper respiratory infections, and fractures from falls must be vigorously treated in a way that minimizes immobilization because joint contractures become worse when the patient's activities are more restricted than usual.

Other difficulties may be manifested in relation to the underlying disease. Dental and speech problems may result from weakness of the facial muscles, which makes it difficult to attend to dental hygiene and to speak coherently. Gastrointestinal tract problems may include gastric dilation, rectal prolapse, and fecal impaction. Finally, cardiomyopathy appears to be a common complication in all forms of muscular dystrophy.

Genetic counseling is advised for parents and siblings of the patient because of the genetic nature of this disease. The Muscular Dystrophy Association works to combat neuromuscular disease through research, programs of patient services and clinical care, and professional and public education.

## Nursing Management

The goals of the patient and the nurse are to maintain function at optimal levels and to enhance the quality of life. Therefore, the patient's physical requirements, which are considerable, are addressed without losing sight of emotional and developmental needs (Carson & Hieber, 2001). The patient and family are actively involved in decision-making, including end-of-life decisions.

During hospitalization for treatment of complications, the knowledge and expertise of the patient and family members responsible for caregiving in the home are assessed. Because the patient and family caregivers often have developed caregiving strategies that work effectively for them, these strategies need to be acknowledged and accepted, and provisions must be made to ensure that they are maintained during hospitalization (Carson & Hieber, 2001).

Families of chronically ill individuals often need assistance to shift the focus of care from pediatric to adult care. Nursing goals include assisting the person with a chronic condition to make the transition to adult values and expectations while providing age-appropriate ongoing care (Carson & Hieber, 2001). The nurse may need to help build the confidence of an older adolescent or adult patient by encouraging him or her to pursue job training to become economically independent. Other nursing interventions might include guidance in accessing adult health care and finding appropriate programs in sex education (Carson & Hieber, 2001).

## PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** The management goals are addressed in special rehabilitation programs or in the patient's home and community (Natterlund & Ahlstrom, 1999). Thus, the pa-

tient and family require information and instruction about the disorder, its anticipated course, and care and management strategies that will optimize the patient's growth and development and physical and psychological status. Members of a variety of health-related disciplines are involved in patient and family teaching; recommendations are communicated to all members of the health care team so that they may work toward common goals.

**Continuing Care.** Both the neuromuscular disease and the associated deformities may progress in adolescence and adulthood. Self-help and assistive devices can aid in maintaining maximum independence. Additional self-help devices, recommended by physical and occupational therapists, often become necessary as more muscle groups are affected.

The family is taught to monitor the patient for respiratory problems, as respiratory infection and cardiac failure are the most common causes of death (Carson & Hieber, 2001). As respiratory difficulties develop, patients and their families need information regarding respiratory support. Options currently exist that can provide ventilatory support (negative-pressure devices, positive-pressure ventilators) while allowing mobility (Bach, 1999). Patients can remain relatively independent in a wheelchair, for example, while being maintained on a ventilator at home for many years.

The patient is encouraged to continue with range-of-motion exercises to prevent contractures, which are particularly disabling. Practical adaptations must be made, however, to cope with the effects of chronic neuromuscular disability. The patient at various stages of the disease may require a manual or an electric wheelchair, gait aids, upper and lower extremity and spinal orthoses, seating systems, bathroom equipment, lifts, ramps, and additional assistive devices, all of which require a team approach (Bach, 1999). The home care nurse assesses how the patient and family are managing, makes referrals, and coordinates the activities of the physical therapist, occupational therapist, and social services.

Of great concern to the patient are the issues surrounding the threat of increasing disability and dependence on others, accompanied by a significant deterioration in health-related quality of life (Natterlund, Gunnarsson & Ahlstrom, 2000). The patient is faced with a progressive loss of function, leading eventually to death. Feelings of helplessness and powerlessness are common. Each functional loss is accompanied by grief and mourning. The patient and family are assessed for depression, anger, or denial. The patient and family are assisted to address decisions about end-of-life options before their need arises.

A psychiatric nurse clinician or other mental health professional may assist the patient to cope and adapt to the disease. By understanding and addressing the physical and psychological needs of the patient and family, the nurse provides a hopeful, supportive, and nurturing environment.

## DEGENERATIVE DISK DISEASE

Low back pain is a significant public health disorder in the United States (Bigos et al., 1994). It is a challenging disorder to quantify. Current estimates are that between 22% and 65% of individuals have an episode of back pain in any given year, and between 11% and 84% of adults have an episode within their lifetime (Walker, 2000). This results in significant economic and social costs. Acute low back pain has a duration of less than 3 months; chronic or degenerative disease has a duration of 3 months or longer. Most back problems are related to disk disease.

## Pathophysiology

The intervertebral disk is a cartilaginous plate that forms a cushion between the vertebral bodies (Fig. 65-8A). This tough, fibrous material is incorporated in a capsule. A ball-like cushion in the center of the disk is called the nucleus pulposus. In herniation of the intervertebral disk (ruptured disk), the nucleus of the disk protrudes into the annulus (the fibrous ring around the disk), with subsequent nerve compression. Protrusion or rupture of the nucleus pulposus usually is preceded by degenerative changes that occur with aging. Loss of protein polysaccharides in the disk decreases the water content of the nucleus pulposus. The development of radiating cracks in the annulus weakens resistance to nucleus herniation. After trauma (falls and repeated minor stresses such as lifting), the cartilage may be injured.

For most patients, the immediate symptoms of trauma are short-lived, and those resulting from injury to the disk do not appear for months or years. Then, with degeneration in the disk, the capsule pushes back into the spinal canal, or it may rupture and allow the nucleus pulposus to be pushed back against the dural sac or against a spinal nerve as it emerges from the spinal column (see Fig. 65-8B). This sequence produces pain due to pressure in the area of distribution of the involved nerve endings (**radiculopathy**). Continued pressure may produce degenerative changes in the involved nerve, such as changes in sensation and deep tendon reflexes.

## Clinical Manifestations

A herniated disk with accompanying pain may occur in any portion of the spine: cervical, thoracic (rare), or lumbar. The clinical manifestations depend on the location, the rate of development (acute or chronic), and the effect on the surrounding structures.

## Assessment and Diagnostic Findings

A thorough health history and physical examination are important to rule out potentially serious conditions that may present as

low back pain, including fracture, tumor, infection, or cauda equina syndrome (Bigos et al., 1994).

MRI has become the diagnostic tool of choice for localizing even small disk protrusions, particularly for lumbar spine disease. If the clinical symptoms are not consistent with the pathology seen on MRI, CT and myelography are then performed. A neurologic examination is carried out to determine if there is reflex, sensory, or motor impairment from root compression and to provide a baseline for future assessment. EMG may be used to localize the specific spinal nerve roots involved.

## Medical Management

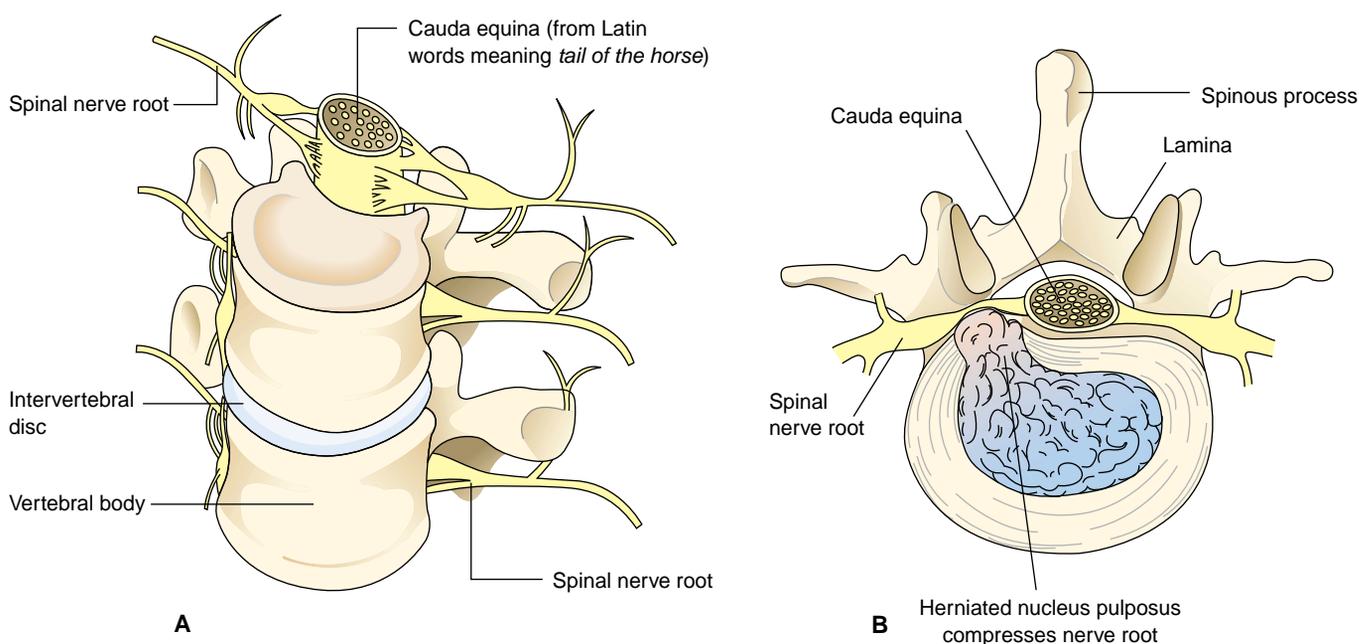

Herniations of the cervical and the lumbar disks occur most commonly and are usually managed conservatively with bed rest and medication. The specific conservative management strategies, along with surgical interventions for each form of herniation, are discussed next.

## SURGICAL MANAGEMENT

In general, surgical excision of a herniated disk is performed when there is evidence of a progressing neurologic deficit (muscle weakness and atrophy, loss of sensory and motor function, loss of sphincter control) and continuing pain and **sciatica** (leg pain resulting from sciatic nerve involvement) that are unresponsive to conservative management. The goal of surgical treatment is to reduce the pressure on the nerve root to relieve pain and reverse neurologic deficits (Hall, 1999). Microsurgical techniques are making it possible to remove only the amount of tissue that is necessary, better preserving the integrity of normal tissue and imposing less trauma on the body. During these procedures, spinal cord function can be monitored electrophysiologically.

To achieve the goal of pain relief, several surgical techniques are used, depending on the type of disk herniation, surgical morbidity, and overall results of surgery:

- Discectomy: removal of herniated or extruded fragments of intervertebral disk

**FIGURE 65-8** (A) Normal lumbar spine vertebrae, intervertebral disks, and spinal nerve root; (B) ruptured vertebral disk.

- **Laminectomy:** removal of the bone between the spinal process and facet pedicle junction to expose the neural elements in the spinal canal (Hall, 1999); allows the surgeon to inspect the spinal canal, identify and remove pathology, and relieve compression of the cord and roots
- **Hemilaminectomy:** removal of part of the lamina and part of the posterior arch of the vertebra
- **Partial laminectomy or laminotomy:** creation of a hole in the lamina of a vertebra (Hall, 1999)
- **Discectomy with fusion:** a bone graft (from iliac crest or bone bank) is used to fuse the vertebral spinous process; the object of spinal fusion is to bridge over the defective disk to stabilize the spine and reduce the rate of recurrence
- **Foraminotomy:** removal of the intervertebral foramen to increase the space for exit of a spinal nerve, resulting in reduced pain, compression, and edema

Surgical procedures for herniated cervical disk and lumbar disk are discussed in the sections that follow.

## HERNIATION OF A CERVICAL INTERVERTEBRAL DISK

The cervical spine is subjected to stresses that result from disk degeneration (from aging, occupational stresses) and **spondylosis** (degenerative changes occurring in disk and adjacent vertebral bodies). Cervical disk degeneration may lead to lesions that can cause damage to the spinal cord and its roots.

A cervical disk herniation usually occurs at the C5-6 and C6-7 interspaces. Pain and stiffness may occur in the neck, the top of the shoulders, and the region of the scapulae. Sometimes patients interpret these signs as symptoms of heart trouble or bursitis. Pain may also occur in the upper extremities and head, accompanied by **paresthesia** (tingling or a “pins and needles” sensation) and numbness of the upper extremities. Cervical MRI usually confirms the diagnosis.

### Medical Management

The goals of treatment are (1) to rest and immobilize the cervical spine to give the soft tissues time to heal and (2) to reduce inflammation in the supporting tissues and the affected nerve roots in the cervical spine. Bed rest (usually 1 to 2 days) is important because it eliminates the stress of gravity and relieves the cervical spine from the need to support the head. It also reduces inflammation and edema in soft tissues around the disk, relieving pressure on the nerve roots. Proper positioning on a firm mattress may bring dramatic relief from pain.

The cervical spine may be rested and immobilized by a cervical collar, cervical traction, or a brace. A collar allows maximal opening of the intervertebral foramina and holds the head in a neutral or slightly flexed position. The patient may have to wear the collar 24 hours a day during the acute phase. The skin under the collar is inspected for irritation. When the patient is free of pain, cervical isometric exercises are started to strengthen the neck muscles.

Cervical traction is accomplished by means of a head halter attached to a pulley and weight. It increases vertebral separation and thus relieves pressure on the nerve roots. The head of the bed is elevated to provide countertraction (see Chap. 67). If the skin becomes irritated, the halter can be padded. Experience has

shown that a male patient may suffer more skin irritation if he shaves; the beard offers a natural form of padding.

### PHARMACOLOGIC THERAPY

Analgesic agents (NSAIDs, propoxyphene [Darvon], oxycodone [Tylox], or hydrocodone [Vicodin]) are prescribed during the acute phase to relieve pain, and sedatives may be administered to control the anxiety often associated with cervical disk disease. Muscle relaxants (cyclobenzaprine [Flexeril], methocarbamol [Robaxin], metaxalone [Skelaxin]) are administered to interrupt the cycle of muscle spasm and to promote comfort. NSAIDs (aspirin, ibuprofen [Motrin, Advil], naproxen [Naprosyn, Anaprox]) or corticosteroids are prescribed to treat the inflammatory response that usually occurs in the supporting tissues and affected nerve roots. Occasionally, an injection of a corticosteroid into the epidural space may be administered for relief of radicular (spinal nerve root) pain. NSAIDs are given with food and antacids to prevent gastrointestinal irritation. Hot, moist compresses (for 10 to 20 minutes) applied to the back of the neck several times daily increase blood flow to the muscles and help relax the spastic muscles and the patient.

### SURGICAL MANAGEMENT

Surgical excision of the herniated disk may be necessary when there is a significant neurologic deficit, progression of the deficit, evidence of cord compression, or pain that either worsens or fails to improve. A cervical discectomy, with or without fusion, may be performed to alleviate symptoms. An anterior surgical approach may be used through a transverse incision to remove disk material that has herniated into the spinal canal and foramina, or a posterior approach may be used at the appropriate level of the cervical spine. Potential complications with the anterior approach include carotid or vertebral artery injury, recurrent laryngeal nerve dysfunction, esophageal perforation, and airway obstruction. Complications of the posterior approach include damage to the nerve root or the spinal cord due to retraction or contusion of either of these structures, resulting in weakness of muscles supplied by the nerve root or cord.

Microsurgery, such as endoscopic microdiscectomy, may be performed in selected patients through a small incision and using magnification techniques. The patient who undergoes microsurgery usually has less tissue trauma and pain and consequently a shorter hospital stay than after conventional surgical approaches.

## NURSING PROCESS: THE PATIENT UNDERGOING A CERVICAL DISCECTOMY

### Assessment

The patient is asked about past injuries to the neck (whiplash) because unresolved trauma may cause persistent discomfort, pain and tenderness, and symptoms of arthritis in the injured joint of the cervical spine. Assessment includes determining the onset, location, and radiation of pain, paresthesias, limited movement, and diminished function of the neck, shoulders, and upper extremities. It is important to determine whether the symptoms are bilateral because with large herniations, bilateral symptoms may be due to cord compression. The area around the cervical spine is palpated to assess muscle tone and tenderness. Range of motion in the neck and shoulders is evaluated.

The patient is asked about any health concerns that may influence the postoperative course. The nurse determines the patient's need for information about the surgical procedure and reinforces what the physician has explained. Strategies for pain management are discussed with the patient.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Acute pain related to the surgical procedure
- Impaired physical mobility related to the postoperative surgical regimen
- Deficient knowledge about the postoperative course and home care management

Other nursing diagnoses may include preoperative anxiety, postoperative constipation, urinary retention related to surgical procedure and dehydration, self-care deficits related to neck orthosis, and sleep pattern disturbance related to disruption in lifestyle.

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on all the assessment data, the potential complications may include the following:

- Hematoma at the surgical site, resulting in cord compression and neurologic deficit
- Recurrent or persistent pain after surgery

## Planning and Goals

The goals for the patient may include relief of pain, improved mobility, increased knowledge and self-care ability, and prevention of complications.

## Nursing Interventions

### RELIEVING PAIN

The patient may be kept flat in bed for 12 to 24 hours. If the patient has had a bone fusion with bone removed from the iliac crest, considerable pain may be experienced. Interventions consist of monitoring the donor site for hematoma formation, administering the prescribed postoperative analgesic agent, positioning for comfort, and reassuring the patient that the pain can be relieved. If the patient experiences a sudden reappearance or increase of pain, extrusion of the graft may have occurred, requiring reoperation and surgical repositioning of the graft. This should be promptly reported to the surgeon.

The patient may experience a sore throat, hoarseness, and dysphagia due to temporary edema. These symptoms are relieved by throat lozenges, voice rest, and humidification. A puréed diet may be given if the patient has dysphagia.

### IMPROVING MOBILITY

Postoperatively, a cervical collar (neck orthosis) is usually worn, which contributes to limited neck motion and altered mobility. Patients are instructed to turn the body instead of the neck when looking from side to side. The neck should be kept in a neutral

(midline) position. Patients are assisted during position changes, making sure that head, shoulders, and thorax are kept aligned. When assisting a patient to a sitting position, the nurse supports the patient's neck and shoulders. Patients should wear shoes when ambulating to increase stability.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

The patient is evaluated for bleeding and hematoma formation by assessing for excessive pressure in the neck or severe pain in the incision area. The dressing is inspected for serosanguineous drainage, which suggests a dural leak. In this event, meningitis is a threat. A complaint of headache requires careful evaluation. Neurologic checks are made for swallowing deficits and upper and lower extremity weakness because cord compression may produce rapid or delayed onset of paralysis. The patient who has had an anterior cervical discectomy is also assessed for a sudden return of radicular (spinal nerve root) pain, which may indicate instability of the spine.

Throughout the postoperative course, the patient is monitored frequently to detect any signs of respiratory difficulty because retractors during surgery may injure the recurrent laryngeal nerve, resulting in hoarseness and the inability to cough effectively and clear pulmonary secretions. In addition, the blood pressure and pulse are monitored to evaluate cardiovascular status.

Bleeding at the surgical site and subsequent hematoma formation may occur. Severe localized pain not relieved by analgesic agents should be reported to the surgeon. A change in neurologic status (motor or sensory function) should be reported promptly because it suggests hematoma formation that may necessitate surgery to prevent irreversible motor and sensory deficits.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

The patient's hospital stay is likely to be short; therefore, the patient and family should understand the care that is important for a smooth recovery. A cervical collar is usually worn for about 6 weeks. The patient is instructed in use and care of the cervical collar. Patients are instructed to alternate tasks in which the body does not move (eg, reading) with tasks that require greater body movement.

The patient is instructed about strategies for pain management and about signs and symptoms that may indicate complications that should be reported to the physician. The nurse assesses the patient's understanding of these management strategies, limitations, and recommendations. Additionally, the nurse assists the patient in identifying strategies to cope with activities of daily living (ie, self-care and childcare) and minimize risks to the surgical site (Chart 65-6).

A discharge teaching plan is developed collaboratively by members of the health care team to decrease the risk for recurrent disk herniation. Topics include those previously discussed as well as proper body mechanics, maintenance of optimal weight, proper exercise techniques, and modifications in activity.

#### Continuing Care

Patients are instructed to see their physician at prescribed intervals to document the disappearance of old symptoms and for assessment of range of motion of the neck. Recurrent or persistent pain may occur despite removal of the offending disk or disk

Chart 65-6

## Home Care Checklist • The Patient With Cervical Discectomy and Cervical Collar

At the completion of home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Care for the surgical incision site.		
• Keep staples or sutures clean and dry and cover with dry dressing.		✓
• Notify physician if any signs or symptoms of infection occur, such as fever, redness or irritation, drainage, increased pain.	✓	✓
• Demonstrate proper body mechanics and prescribed exercise techniques.	✓	
• Modify activity:		
• Avoid sitting or standing for more than 30 minutes.	✓	
• Avoid twisting, flexing, extending, or rotating the neck.	✓	
• Avoid long automobile rides.	✓	
• Avoid sleeping in a prone position or use of pillows, to minimize neck flexion in bed; keep head in a neutral position.	✓	
• Use adequate mattress and chair support.	✓	
• Wear low-heeled shoes.	✓	
• Follow physician's instructions regarding lifting, climbing stairs, driving a car, sexual activity, sports, exercise, and return to work.	✓	
• Practice stress reduction and relaxation techniques.	✓	
• Care of the cervical collar:		
• Wear the collar at all times until directed otherwise by the physician.	✓	
• Wash the neck twice a day with mild soap.	✓	✓
• Keep the neck still while the collar is open.	✓	
• With the assistance of a helper, wash the neck in steps:		
• Lie flat and supine.	✓	
• Open the Velcro tabs on each side of the collar and remove its front portion.		✓
• Gently wash and dry the neck.		✓
• Replace the front part of the collar and refasten the tabs.		✓
• Turn to one side with a thin pillow under the head.	✓	
• Open one tab.	✓	
• Gently wash and dry the back of the neck. Refasten the tab.		✓
• Turn to the other side and wash and dry this side. Refasten the tab.		✓
• Place a wrinkle-free silk scarf under the collar to increase comfort.	✓	✓
• <b>For men:</b> Shave without twisting or moving the neck. This may be done with help while lying flat or sitting. Remove only the front part of the collar for shaving.	✓	✓

fragments. Patients who undergo discectomy usually have consented to surgery after prolonged pain; they have often undergone repeated courses of ineffective conservative management and previous surgeries to relieve the pain. Therefore, the recurrence or persistence of symptoms postoperatively, including pain and sensory deficits, is often discouraging for the patient and family. The patient who experiences recurrence of symptoms requires emotional support and understanding. Additionally, the patient is assisted in modifying activities and in considering options for subsequent treatment.

The patient with degenerative disk disease tends to focus on obvious needs, issues, and deficits. The nurse needs to remind patients and family members of the need for participating in health promotion and health screening practices.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Reports decreasing frequency and severity of pain
2. Demonstrates improved mobility

- a. Demonstrates progressive participation in self-care activities
  - b. Identifies prescribed activity limitations and restrictions
  - c. Demonstrates proper body mechanics
3. Is knowledgeable about postoperative course, medications, and home care management.
    - a. Lists the signs and symptoms to be reported postoperatively
    - b. Identifies dose, action, and potential side effects of medications
    - c. Identifies appropriate home care management activities and any restrictions
  4. Absence of complications
    - a. Reports no increase in incision pain or sensory symptoms
    - b. Demonstrates normal findings on neurologic assessment

## HERNIATION OF A LUMBAR DISK

Most lumbar disk herniations occur at the L4-5 or the L5-S1 interspaces (Humphreys & Eck, 1999). A herniated lumbar disk produces low back pain accompanied by varying degrees of sensory and motor impairment.

## Clinical Manifestations

The patient complains of low back pain with muscle spasms, followed by radiation of the pain into one hip and down into the leg (sciatica). Pain is aggravated by actions that increase intraspinal fluid pressure (bending, lifting, straining, as in sneezing and coughing) and usually is relieved by bed rest. Usually there is some type of postural deformity, because pain causes an alteration of the normal spinal mechanics. If the patient lies on the back and attempts to raise a leg in a straight position, pain radiates into the leg because this maneuver, called the straight leg-raising test, stretches the sciatic nerve. Additional signs include muscle weakness, alterations in tendon reflexes, and sensory loss.

## Assessment and Diagnostic Findings

The diagnosis of lumbar disk disease is based on the history and physical findings and the use of imaging techniques such as MRI, CT, and myelography.

## Medical Management

The objectives of treatment are to relieve pain, slow disease progression, and increase the patient's functional ability. Bed rest for 1 to 2 days on a firm mattress (to limit spinal flexion) is encouraged to reduce the weight load and gravitational forces, thereby freeing the disk from stress (Humphrey & Eck, 1999). The patient is allowed to assume a comfortable position; usually, a semi-Fowler's position with moderate hip and knee flexion relaxes the back muscles. When the patient is in a side-lying position, a pillow is placed between the legs. To get out of bed, the patient lies on one side while pushing up to a sitting position.

Because muscle spasm is prominent during the acute phase, muscle relaxants are used. NSAIDs and systemic corticosteroids may be administered to counter the inflammation that usually occurs in the supporting tissues and the affected nerve roots. Moist heat and massage help to relax spastic muscles and have a sedative effect. Antidepressant agents appear to help in low back pain that is neuropathic in origin (Fishbain, 2000). See also Nursing Process: The Patient With Low Back Pain in Chapter 13 for nursing interventions.

## SURGICAL MANAGEMENT

In the lumbar region, surgical treatment includes lumbar disk excision through a posterolateral laminotomy and the newer techniques of microdiscectomy and percutaneous discectomy. In microdiscectomy, an operating microscope is used to visualize the offending disk and compressed nerve roots; it permits a small incision (2.5 cm [1 inch]) and minimal blood loss and takes about 30 minutes of operating time. Generally, it involves a short hospital stay, and the patient makes a rapid recovery. Percutaneous discectomy is an alternative treatment for herniated intervertebral disks of the lumbar spine at the L4-5 level. One approach in current use is through a 2.5-cm (1-inch) incision just above the iliac crest. A tube, trocar, or cannula is inserted under x-ray guidance through the retroperitoneal space to the involved disk space. Special instruments are used to remove the disk. The operating time is about 15 minutes. Blood loss and postoperative pain are minimal, and the patient is generally discharged within 2 days after surgery. The disadvantage of this procedure is the possibility of damage to structures in the surgical pathway.

**Complications of Disk Surgery.** A patient undergoing a disk procedure at one level of the vertebral column may have a degenerative process at other levels. A herniation relapse may occur at the same level or elsewhere, so that the patient may become a candidate for another disk procedure. Arachnoiditis (inflammation of the arachnoid membrane) may occur after surgery (and after myelography); it involves an insidious onset of diffuse, frequently burning pain in the lower back, radiating into the buttocks. Disk excision can leave adhesions and scarring around the spinal nerves and dura, which then produce inflammatory changes that create chronic neuritis and neurofibrosis. Disk surgery may relieve pressure on the spinal nerves, but it does not reverse the effects of neural injury and scarring and the pain that results. Failed disk syndrome (recurrence of sciatica after lumbar discectomy) remains a common cause of disability.

## Nursing Management

### PROVIDING PREOPERATIVE CARE

Most patients fear surgery on any part of the spine and therefore need explanations about the surgery and reassurance that surgery will not weaken the back. When data are being collected for the health history, any reports of pain, paresthesia, and muscle spasm are recorded to provide a baseline for comparison after surgery. Preoperative assessment also includes an evaluation of movement of the extremities as well as bladder and bowel function. To facilitate the postoperative turning procedure, the patient is taught to turn as a unit (called logrolling) as part of the preoperative preparation (Fig. 65-9). Before surgery, the patient is also encouraged to take deep breaths, cough, and perform muscle-setting exercises to maintain muscle tone.

### ASSESSING THE PATIENT AFTER SURGERY

After lumbar disk excision, vital signs are checked frequently and the wound is inspected for hemorrhage because vascular injury is a complication of disk surgery. Because postoperative neurologic deficits may occur from nerve root injury, the sensation and motor strength of the lower extremities are evaluated at specified intervals, along with the color and temperature of the legs and sensation of the toes. It is important to assess for urinary retention, another sign of neurologic deterioration.

In discectomy with fusion, the patient has an additional surgical incision if bone fragments were taken from the iliac crest or fibula to serve as wedges in the spine. The recovery period is longer than for those patients who underwent discectomy without spinal fusion because bony union must take place.

### POSITIONING THE PATIENT

To position the patient, a pillow is placed under the head and the knee rest is elevated slightly to relax the back muscles. When the patient is lying on one side, however, extreme knee flexion must be avoided. The patient is encouraged to move from side to side to relieve pressure and is reassured that no injury will result from moving. When the patient is ready to turn, the bed is placed in a flat position and a pillow is placed between the legs. The patient turns as a unit (logrolls), without twisting the back.

To get out of bed, the patient lies on one side while pushing up to a sitting position. At the same time, the nurse or family member eases the patient's legs over the side of the bed. Coming to a sitting or standing posture is accomplished in one long, smooth

**FIGURE 65-9** Before the patient undergoes laminectomy surgery, the logrolling technique that will be used for turning the patient should be demonstrated. The patient's arms will be crossed and the spine aligned. To avoid twisting the spine, the head, shoulders, knees, and hips are turned at the same time so that the patient rolls over like a log. When in a side-lying position, the patient's back, buttocks, and legs are supported with pillows.

motion. Most patients walk to the bathroom the same day as surgery. Sitting is discouraged except for defecation.

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** The patient is advised to gradually increase activity as tolerated because it takes up to 6 weeks for the ligaments to heal. Excessive activity may result in spasm of the paraspinal muscles.

Activities that produce flexion strain on the spine (eg, driving a car) should be avoided until healing has taken place. Heat may be applied to the back to relax muscle spasms. Scheduled rest periods are important, and the patient is advised to avoid heavy work for 2 to 3 months after surgery. Exercises are prescribed to strengthen the abdominal and erector spinal muscles. A back brace or corset may be necessary if back pain persists.

## POST-POLIO SYNDROME

Patients who survived the polio epidemic of the 1950s, many now elderly, are developing new symptoms of weakness, fatigue, and musculoskeletal pain. It is estimated that between 60% and 80% of the 640,000 polio survivors are experiencing the phenomenon known as post-polio syndrome. Men and women appear to be equally at risk (Chasens & Umlauf, 2000).

## Pathophysiology

The exact cause of post-polio syndrome is not known, but researchers suspect that with aging or muscle overuse the neurons not destroyed originally by the poliovirus cannot continue generating axon sprouts. These new terminal axon sprouts reinnervated the affected muscles following the initial insult but may be more vulnerable as the body ages (Chasens & Umlauf, 2000).

## Assessment and Diagnostic Findings

No specific diagnostic test exists for this syndrome. The clinical diagnosis is made on the basis of the history and physical examination and exclusion of other medical conditions that may be causing the new symptoms. Patients report a history of paralytic poliomyelitis with partial or complete recovery of function with a plateau of function for at least 10 years and then the recurrence of symptoms (Chasens & Umlauf, 2000; Chasens, Umlauf, Valappil et al., 2001).

## Management

No specific medical or surgical treatment is available for this syndrome, and therefore nursing plays a pivotal role in the team approach to assisting patients and families in dealing with the symptoms of progressive loss of muscle strength and significant fatigue. Other health care professionals who may assist in patient care include physical, occupational, speech, and respiratory therapists. Nursing interventions are aimed at slowing the loss of strength and maintaining the patient's physical, psychological, and social well-being.

Patients need to plan and coordinate activities to conserve energy and reduce fatigue. Rest periods should be planned and assistive devices used to reduce weakness and fatigue. Important activities should be planned for the morning, as fatigue often increases in the afternoon and evening (Chasens & Umlauf, 2000).

One study investigated the barriers (internal and external environmental phenomena) that created further disability in polio survivors (Harrison & Stufbergen, 2001). Disability, the inability to perform societal roles, was correlated with perceived barriers to health but not with functional limitations, comorbidity, or secondary conditions. Secondary conditions were correlated with the number of years that the patient had lived with the condition.

Pain in muscles and joints may be a problem. Nonpharmacologic techniques such as the application of heat and cold are most appropriate because these patients tend to have strong reactions to medications (Chasens & Umlauf, 2000).

Maintaining a balance between adequate nutritional intake yet avoiding excess calories that can lead to obesity in this sedentary group of patients is a challenge. Pulmonary hygiene and adequate fluid intake can help with airway management. Several interventions can improve sleep, including limiting caffeine intake before bedtime and assessing for nocturia. If nocturia is an issue, the patient needs to be evaluated for obstructive sleep apnea (Chasens et al., 2001). Supportive ventilation may be appropriate with continuous positive airway pressure if sleep apnea is a problem.

Bone density testing in patients with post-polio syndrome has demonstrated low bone mass and osteoporosis. Thus, the importance of identifying risks, preventing falls, and treating osteoporosis must be discussed with patients and families. The nurse also needs to remind patients and family members of the need for health promotion activities and health screening.

## Critical Thinking Exercises

1. A 68-year-old patient with known cerebral metastases is admitted to the hospital. He reports a new-onset right-sided weakness and headache. What immediate action should you take? What medical treatments can you anticipate? What surgical treatment (if any) would be anticipated? What teaching for the patient and the family is warranted, and why?
2. A 35-year-old woman with a diagnosis of Huntington's disease is admitted to the nursing unit with pneumonia. Her husband is wondering if he should obtain genetic testing of their two children. What would the risks and benefits of genetic testing be? What type of individual and family supports and counseling services would you anticipate the need for and make referrals to? Explain the rationale for these referrals.
3. A 42-year-old man newly diagnosed with Parkinson's disease asks what type of medication he will be given. What are the possible medications that will be used to treat his disease, and the long-term effects of each? How would your discharge teaching targeted toward medications be modified if the patient lives alone?
4. A 60-year-old patient with post-polio syndrome is having difficulty with fatigue and pain. What interventions and actions would you suggest to assist in the management of these symptoms? What strategies would you advise the patient to avoid? What is the rationale for your suggestions? State the types of health promotion activities you would recommend to this patient and the rationale for your recommendations.

# ● Assessment of Musculoskeletal Function

## **LEARNING OBJECTIVES**

*On completion of this chapter, the learner will be able to:*

1. Describe the anatomy and physiology of the musculoskeletal system.
2. Discuss the significance of the health history to the assessment of musculoskeletal health.
3. Describe the significance of physical assessment to the diagnosis of musculoskeletal dysfunction.
4. Specify the diagnostic tests used for assessment of musculoskeletal function.
5. Describe physical assessment of the musculoskeletal system.

The musculoskeletal system includes the bones, joints, muscles, tendons, ligaments, and bursae of the body. The problems associated with these structures are common and affect all age groups. Problems with the musculoskeletal system are generally not life-threatening, but they have a significant effect on the patient's normal activities and productivity. Nurses in all practice areas encounter patients with changes in musculoskeletal function.

## Anatomic and Physiologic Overview

The health and proper functioning of the musculoskeletal system is interdependent with that of the other body systems. The bony structure provides protection for vital organs, including the brain, heart, and lungs. The bony skeleton provides a sturdy framework to support body structures. The bone matrix stores calcium, phosphorus, magnesium, and fluoride. More than 98% of the total-body calcium is present in bone. In addition, the red bone marrow located within bone cavities produces red and white blood cells in a process called hematopoiesis. Joints hold the bones together and allow the body to move. The muscles attached to the skeleton contract, moving the bones and producing heat, which helps to maintain body temperature.

## STRUCTURE AND FUNCTION OF THE SKELETAL SYSTEM

There are 206 bones in the human body, divided into four categories:

- Long bones (eg, femur)
- Short bones (eg, metacarpals)
- Flat bones (eg, sternum)
- Irregular bones (eg, vertebrae)

The shape and construction of a specific bone are determined by its function and the forces exerted on it. Bones are constructed of **cancellous** (trabecular) or **cortical** (compact) bone tissue. Long bones are shaped like rods or shafts with rounded ends (Fig. 66-1). The shaft, known as the **diaphysis**, is primarily cortical bone. The ends of the long bones, called **epiphyses**, are primarily cancellous bone. The epiphyseal plate separates the epiphyses from the diaphysis and is the center for longitudinal growth in children. In the adult, it is calcified. The ends of long bones are covered at the joints by articular **cartilage**, which is a tough, elastic, avascular tissue. Long bones are designed for weight bearing and movement. Short bones consist of cancellous bone covered by a layer of compact bone. Flat bones are important sites for hematopoiesis and frequently provide vital organ protection. They are made of cancellous bone layered between compact bone. Irregular bones have unique shapes related to their functions. Generally, irregular bone structure is similar to that of flat bones.

Bone is composed of cells, protein matrix, and mineral deposits. The cells are of three basic types—**osteoblasts**, **osteocytes**, and **osteoclasts**. Osteoblasts function in bone formation by secreting bone matrix. The matrix, which consists of collagen and ground substances (glycoproteins and proteoglycans), provides a framework in which inorganic mineral salts are deposited. Osteocytes are mature bone cells involved in bone-maintenance functions; they are located in lacunae (bone matrix units). Osteoclasts, located in shallow Howship's lacunae (small pits in bones), are multinuclear cells involved in destroying, resorbing, and remodeling bone. The microscopic functioning unit of mature cortical bone is the **osteon** (Haversian system). The center of the osteon, the Haversian canal, contains a capillary. Around the capillary are circles of mineralized bone matrix called **lamellae**. Within the lamellae are lacunae containing osteocytes. These are nourished

## Glossary

**atonic:** without tone; denervated muscle that atrophies

**atrophy:** shrinkage-like decrease in the size of a muscle

**bursa:** fluid-filled sac found in connective tissue, usually in the area of joints

**callus:** cartilaginous/fibrous tissue at fracture site

**cancellous bone:** lattice-like bone structure; trabecular bone

**cartilage:** tough, elastic, avascular tissue at ends of bone

**clonus:** rhythmic contraction of muscle

**contracture:** abnormal shortening of muscle or joint, or both; fibrosis

**cortical bone:** compact bone

**crepitus:** grating or crackling sound or sensation; may occur with movement of ends of a broken bone or irregular joint surface

**diaphysis:** shaft of long bone

**effusion:** excess fluid in joint

**endosteum:** a thin, vascular membrane covering the marrow cavity of long bones and the spaces in cancellous bone

**epiphysis:** end of long bone

**fascia (epimysium):** fibrous tissue that covers, supports, and separates muscles

**fasciculation:** involuntary twitch of muscle fibers

**flaccid:** limp; without muscle tone

**hypertrophy:** enlargement; increase in size of muscle

**isometric contraction:** muscle tension increased, length unchanged, no joint motion

**isotonic contraction:** muscle tension unchanged, muscle shortened, joint moved

**joint:** area where bone ends meet; provides for motion and flexibility

**joint capsule:** fibrous tissue that encloses bone ends and other joint surfaces

**kyphosis:** increase in thoracic curvature of the spine

**lamellae:** mature compact bone structures that form concentric rings of bone matrix; lamellar bone

**ligament:** fibrous band connecting bones

**lordosis:** increase in lumbar curvature of the spine

**ossification:** process in which minerals (calcium) are deposited in bone matrix

**osteoarthritis:** degenerative joint disease characterized by destruction of the articular cartilage and overgrowth of bone

**osteoblast:** bone-forming cell

**osteoclast:** bone resorption cell

**osteocyte:** mature bone cell

**osteogenesis:** bone formation

**osteoid:** pertaining to bone matrix tissue; "pre-bone"

**osteon:** microscopic functional bone unit

**osteoporosis:** significant loss of bone mass and strength with increased risk for fracture

**paralysis:** absence of muscle movement suggesting nerve damage

**paresthesia:** abnormal sensation (eg, burning, tingling, numbness)

**periosteum:** fibrous connective tissue covering bone

**remodeling:** process of reorganizing new bone structure according to function

**resorption:** removal/destruction of tissue, such as bone

**scoliosis:** lateral curving of the spine

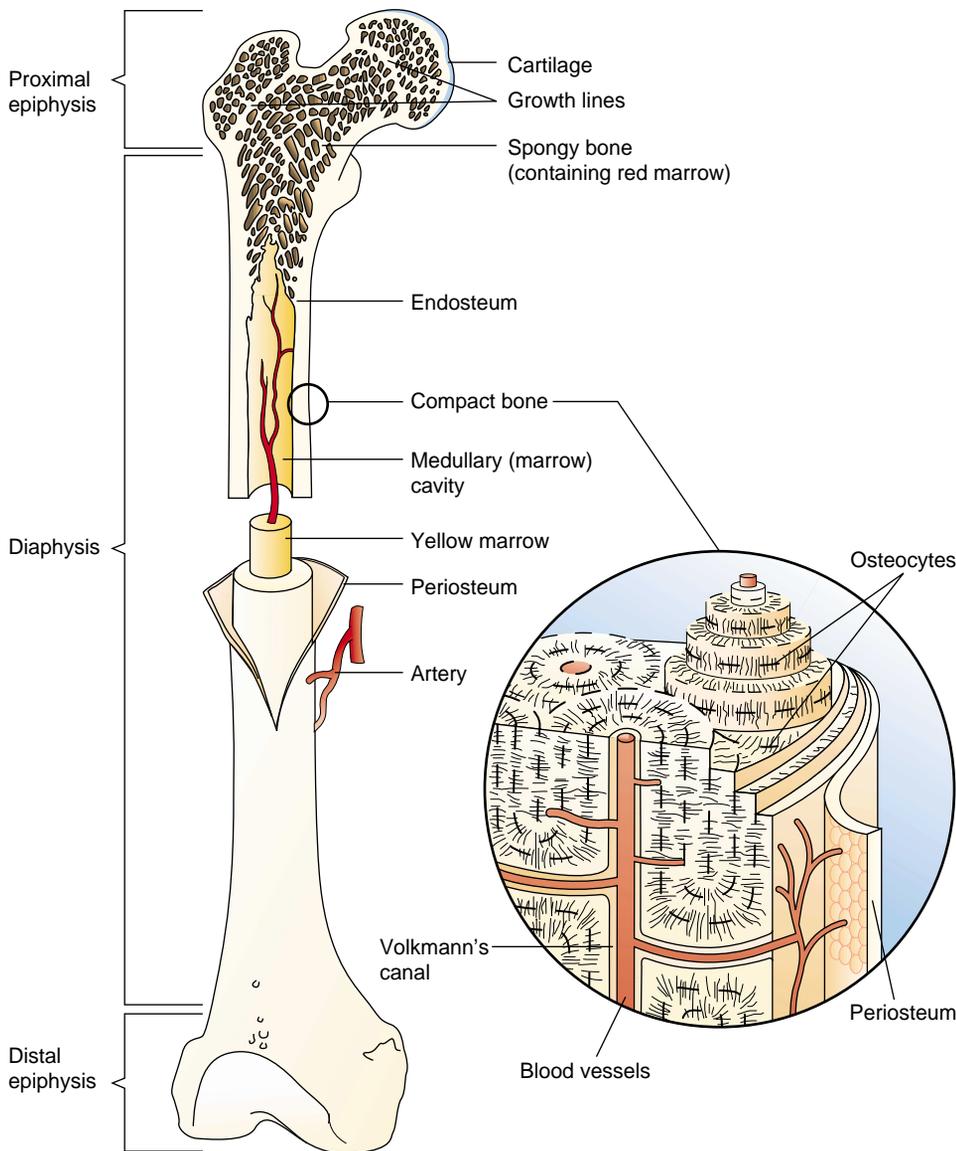

**spastic:** having greater than normal muscle tone

**synovium:** membrane in joint that secretes lubricating fluid

**tendon:** cord of fibrous tissue connecting muscle to bone

**tone (tonus):** normal tension (resistance to stretch) in resting muscle

**trabeculae:** lattice-like bone structure; cancellous bone

**FIGURE 66-1** Structure of a long bone; composition of compact bone.

through tiny structures, canaliculi (canals), that communicate with adjacent blood vessels within the Haversian system (see Fig. 66-1).

Lacunae in cancellous bone are layered in an irregular lattice network (**trabeculae**). Red bone marrow fills the lattice network. Capillaries nourish the osteocytes located in the lacunae.

Covering the bone is a dense, fibrous membrane known as the **periosteum**. The periosteum nourishes bone and allows for its growth; it also provides for the attachment of tendons and ligaments. The periosteum contains nerves, blood vessels, and lymphatics. The layer closest to the bone contains osteoblasts, which are bone-forming cells.

The **endosteum** is a thin, vascular membrane that covers the marrow cavity of long bones and the spaces in cancellous bone. Osteoclasts, which dissolve bone to maintain the marrow cavity, are located near the endosteum in Howship's lacunae.

Bone marrow is a vascular tissue located in the medullary (shaft) cavity of long bones and in flat bones. Red bone marrow, located mainly in the sternum, ilium, vertebrae, and ribs in adults, is responsible for producing red and white blood cells. In adults, the long bone is filled with fatty, yellow marrow.

Bone tissue is well vascularized. Cancellous bone receives a rich blood supply through metaphyseal and epiphyseal vessels. Periosteal vessels carry blood to compact bone through minute Volkmann's canals. In addition, nutrient arteries penetrate the periosteum and enter the medullary cavity through foramina (small openings). Nutrient arteries supply blood to the marrow and bone. The venous system may accompany arteries or may exit independently.

### Bone Formation (Osteogenesis)

Bone begins to form long before birth. **Ossification** is the process by which the bone matrix (collagen fibers and ground substance) is formed and hardening minerals (eg, calcium salts) are deposited on the collagen fibers. The collagen fibers give tensile strength to the bone, and the calcium provides compressional strength.

There are two basic processes of ossification: endochondral and intramembranous. Most bones in the body are formed by endochondral ossification, in which a cartilage-like tissue (**osteoid**) is formed, resorbed, and replaced by bone. Intramembranous ossification occurs when bone develops within membrane, as in the bones of the face and skull.

## Bone Maintenance

Bone is a dynamic tissue in a constant state of turnover—**resorption** and formation. The important regulating factors that determine the balance between bone formation and bone resorption include local stress, vitamin D, parathyroid hormone, calcitonin, and blood supply.

Local stress (weight bearing) acts to stimulate bone formation and remodeling. Weight-bearing bones are thick and strong. Without weight-bearing or stress, as in prolonged bed rest, the bone loses calcium (resorption) and becomes osteopenic and weak. The weak bone may fracture easily.

Biologically active vitamin D (calcitriol) functions to increase the amount of calcium in the blood by promoting absorption of calcium from the gastrointestinal tract. It also facilitates mineralization of osteoid tissue. A deficiency of vitamin D results in bone mineralization deficit, deformity, and fracture.

Parathyroid hormone and calcitonin are the major hormonal regulators of calcium homeostasis. Parathyroid hormone regulates the concentration of calcium in the blood, in part by promoting movement of calcium from the bone. In response to low calcium levels in the blood, increased levels of parathyroid hormone prompt the mobilization of calcium, the demineralization of bone, and the formation of bone cysts. Calcitonin, secreted by the thyroid gland in response to elevated blood calcium levels, inhibits bone resorption and increases the deposit of calcium in bone.

Blood supply to the bone also affects bone formation. With diminished blood supply or hyperemia (congestion), **osteogenesis** (bone formation) and bone density decrease. Bone necrosis occurs when the bone is deprived of blood.

## Bone Healing

Most fractures heal through a combination of intramembranous and endochondral ossification processes. When a bone is fractured, the bone fragments are not merely patched together with scar tissue. Instead, the bone regenerates itself.

Fracture healing occurs in four areas, including:

- Bone marrow, where endothelial cells rapidly undergo transformation and become osteoblastic bone-forming cells
- Bone cortex, where new osteons are formed
- Periosteum, where a hard callus/bone is formed through intramembranous ossification peripheral to the fracture, and where a cartilage model is formed through endochondral ossification adjacent to the fracture site
- External soft tissue, where a bridging **callus** (fibrous tissue) stabilizes the fracture

Buckwalter (2000) summarized the process of fracture healing into six stages stimulated by the release and activation of biologic regulators and signaling molecules:

1. *Hematoma and inflammation*: The body's response is similar to that after injury elsewhere in the body. There is bleeding into the injured tissue and formation of a fracture hematoma. The hematoma is the source of signaling molecules, such as cytokines, transforming growth factor-beta (TGF- $\beta$ ), and platelet-derived growth factor (PDGF), which initiate the fracture healing processes. The fracture fragment ends become devitalized because of the interrupted blood supply. The injured area is invaded by macrophages (large white blood cells), which debride the area. Inflammation, swelling, and pain are present. The inflammatory stage lasts several days and resolves with a decrease in pain and swelling.

2. *Angiogenesis and cartilage formation*: Under the influence of signaling molecules, cell proliferation and differentiation occur. Blood vessels and cartilage overlie the fracture.
3. *Cartilage calcification*: Chondrocytes in the cartilage callus form matrix vesicles, which regulate calcification of the cartilage. Enzymes within these matrix vesicles prepare the cartilage for calcium release and deposit.
4. *Cartilage removal*: The calcified cartilage is invaded by blood vessels and becomes resorbed by chondroblasts and osteoclasts. It is replaced by woven bone similar to that of the growth plate.
5. *Bone formation*: Minerals continue to be deposited until the bone is firmly reunited. With major adult long bone fractures, ossification takes 3 to 4 months.
6. *Remodeling*: The final stage of fracture repair consists of **remodeling** the new bone into its former structural arrangement. Remodeling may take months to years, depending on the extent of bone modification needed, the function of the bone, and the functional stresses on the bone. Cancellous bone heals and remodels more rapidly than does compact cortical bone.

Serial x-ray films are used to monitor the progress of bone healing. The type of bone fractured, the adequacy of blood supply, the surface contact of the fragments, and the general health of the person influence the rate of fracture healing. Adequate immobilization is essential until there is x-ray evidence of bone formation with ossification.

## BONE HEALING WITH FRAGMENTS FIRMLY APPROXIMATED

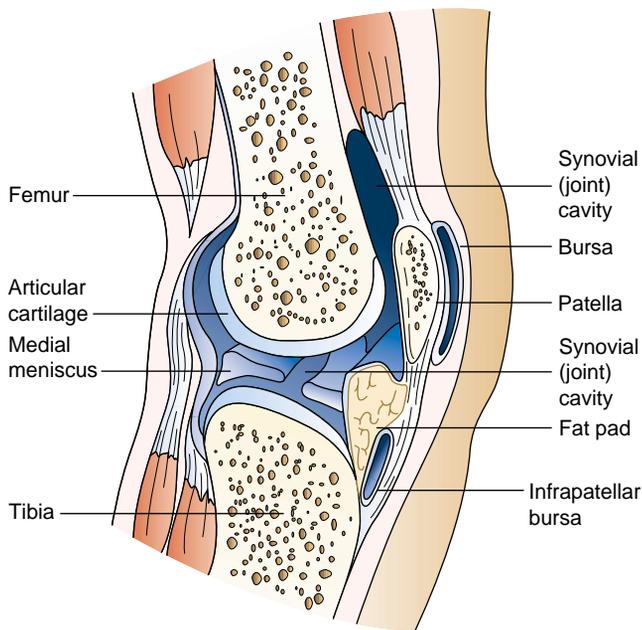

When fractures are treated with open rigid compression plate fixation techniques, the bony fragments can be placed in direct contact. Primary bone healing occurs through cortical bone (Haversian) remodeling. Little or no cartilaginous callus develops. Immature bone develops from the endosteum. There is an intensive regeneration of new osteons, which develop in the fracture line by a process similar to normal bone maintenance. Fracture strength is obtained when the new osteons have become established.

## STRUCTURE AND FUNCTION OF THE ARTICULAR SYSTEM

The junction of two or more bones is called a **joint** (articulation). There are three basic kinds of joints: synarthrosis, amphiarthrosis, and diarthrosis joints. Synarthrosis joints are immovable, as exemplified by the skull sutures. Amphiarthrosis joints, such as the vertebral joints and the symphysis pubis, allow limited motion. The bones of amphiarthrosis joints are joined by fibrous cartilage. Diarthrosis joints are freely movable joints (Fig. 66-2).

There are several types of diarthrosis joints:

- *Ball-and-socket* joints, best exemplified by the hip and the shoulder, permit full freedom of movement.
- *Hinge* joints permit bending in one direction only and are best exemplified by the elbow and the knee.
- *Saddle* joints allow movement in two planes at right angles to each other. The joint at the base of the thumb is a saddle, biaxial joint.
- *Pivot* joints are characterized by the articulation between the radius and the ulna. They permit rotation for such activities as turning a doorknob.
- *Gliding* joints allow for limited movement in all directions and are represented by the joints of the carpal bones in the wrist.

**FIGURE 66-2** Hinge joint of the knee.

The ends of the articulating bones of a typical movable joint are covered with smooth hyaline cartilage. A tough, fibrous sheath called the **joint capsule** surrounds the articulating bones. The capsule is lined with a membrane, the **synovium**, which secretes the lubricating and shock-absorbing synovial fluid into the joint capsule. Therefore, the bone surfaces are not in direct contact. In some synovial joints (eg, the knee), fibrocartilage disks (eg, medial meniscus) are located between the articular cartilage surfaces. These disks provide shock absorption.

**Ligaments** (fibrous connective tissue bands) bind the articulating bones together. Ligaments and muscle tendons, which pass over the joint, provide joint stability. In some joints, interosseous ligaments (eg, the cruciate ligaments of the knee) are found within the capsule and add stability to the joint.

A **bursa** is a sac filled with synovial fluid that cushions the movement of tendons, ligaments, and bones at a point of friction. Bursae are found at the elbow, shoulder, knee, and some other joints.

## STRUCTURE AND FUNCTION OF THE SKELETAL MUSCLE SYSTEM

Muscles are attached by **tendons** (cords of fibrous connective tissue) or aponeuroses (broad, flat sheets of connective tissue) to bones, connective tissue, other muscles, soft tissue, or skin. The muscles of the body are composed of parallel groups of muscle cells (fasciculi) encased in fibrous tissue called **fascia** or **epimysium**. The more fasciculi contained in a muscle, the more precise the movements. Muscles vary in shape and size according to the activities for which they are responsible. Skeletal (striated) muscles are involved in body movement, posture, and heat-production functions. Muscles contract to bring the two points of attachment closer together, resulting in movement.

### Skeletal Muscle Contraction

Each muscle cell (also referred to as a muscle fiber) contains myofibrils, which in turn are composed of a series of sarcomeres, the actual contractile units of skeletal muscle. Sarcomeres contain thick myosin and thin actin filaments.

Muscle fibers contract in response to electrical stimulation delivered by an effector nerve cell at the motor end plate. When stimulated, the muscle cell depolarizes and generates an action potential in a manner similar to that described for nerve cells. These action potentials propagate along the muscle cell membrane and lead to the release of calcium ions that are stored in specialized organelles called the sarcoplasmic reticulum. When there is a local increase in calcium ion concentration, the myosin and actin filaments slide across one another. Shortly after the muscle cell membrane is depolarized, it recovers its resting membrane voltage. Calcium is rapidly removed from the sarcomeres by active reaccumulation in the sarcoplasmic reticulum. When calcium concentration in the sarcomere decreases, the myosin and actin filaments cease to interact, and the sarcomere returns to its original resting length (relaxation). Actin and myosin do not interact in the absence of calcium.

Energy is consumed during muscle contraction and relaxation. The primary source of energy for the muscle cells is adenosine triphosphate (ATP), which is generated through cellular oxidative metabolism. At low levels of activity (ie, sedentary activity), the skeletal muscle synthesizes ATP from the oxidation of glucose to water and carbon dioxide. During periods of strenuous activity, when sufficient oxygen may not be available, glucose is metabolized primarily to lactic acid, an inefficient process compared with that of oxidative pathways. Stored muscle glycogen is used to supply glucose during periods of activity. Muscle fatigue is thought to be caused by depletion of glycogen and accumulation of lactic acid. As a result, the cycle of muscle contraction and relaxation cannot continue.

During muscle contraction, the energy released from ATP is not completely used. The excess energy is dissipated in the form of heat. During isometric contraction, almost all of the energy is released in the form of heat; during isotonic contraction, some of the energy is expended in mechanical work. In some situations, such as shivering because of cold, the need to generate heat is the primary stimulus for muscle contraction.

### Types of Muscle Contractions

The contraction of muscle fibers can result in either isotonic or isometric contraction of the muscle. In **isometric contraction**, the length of the muscles remains constant but the force generated by the muscles is increased; an example of this is when one pushes against an immovable wall. **Isotonic contraction**, on the other hand, is characterized by shortening of the muscle with no increase in tension within the muscle; an example of this is flexion of the forearm. In normal activities, many muscle movements are a combination of isometric and isotonic contraction. For example, during walking, isotonic contraction results in shortening of the leg, and isometric contraction causes the stiff leg to push against the floor.

The speed of the muscle contraction is variable. Myoglobin is a hemoglobin-like protein pigment present in striated muscle cells that transports oxygen. Muscles containing large quantities of myoglobin (red muscles) have been observed to contract slowly and powerfully (eg, respiratory and postural muscles). Muscles containing little myoglobin (white muscles) contract quickly (eg, extraocular eye muscles). Most muscles contain both red and white muscle fibers.

### Muscle Tone

Relaxed muscles demonstrate a state of readiness to respond to contraction stimuli. This state of readiness, known as muscle **tone (tonus)**, is produced by the maintenance of some of the

muscle fibers in a contracted state. Muscle spindles, which are sense organs in the muscles, monitor muscle tone. Muscle tone is minimal during sleep and is increased when the person is anxious. A muscle that is limp and without tone is described as **flaccid**; a muscle with greater-than-normal tone is described as **spastic**. In conditions characterized by lower motor neuron destruction (eg, polio), denervated muscle becomes **atonic** (soft and flabby) and atrophies.

## Muscle Actions

Muscles accomplish movement by contraction. Through the coordination of muscle groups, the body is able to perform a wide variety of movements (Chart 66-1). The prime mover is the muscle that causes a particular motion. The muscles assisting the prime mover are known as synergists. The muscles causing movement opposite to that of the prime mover are known as antagonists. An antagonist must relax to allow the prime mover to contract, producing motion. For example, when contraction of the biceps causes flexion of the elbow joint, the biceps is the prime mover, and the triceps is the antagonist. A person with muscle **paralysis**, which is a loss of movement possibly from nerve damage, may be able to retrain functioning muscles within the synergistic group to produce the needed movement. Muscles of the synergistic group then become the prime mover.

## Exercise, Disuse, and Repair

Muscles need to be exercised to maintain function and strength. When a muscle repeatedly develops maximum or close to maximum tension over a long time, as in regular exercise with weights, the cross-sectional area of the muscle increases. This enlargement, known as **hypertrophy**, results from an increase in the size of individual muscle fibers without an increase in the number of muscle fibers. Hypertrophy persists only if the exercise is continued. The opposite phenomenon occurs with disuse of muscle over a long period of time. Age and disuse cause loss of muscular function as fibrotic tissue replaces the contractile muscle tissue. The decrease in the size of a muscle is called **atrophy**. Bed rest and immobility cause loss of muscle mass and strength. When immobility is the result of a treatment mode (eg, casting, traction), the patient can decrease the effects of immobility by isometric exercise of the muscles of the immobilized part. Quadriceps setting exercises (tightening the muscles of the thigh) and gluteal setting exercises (tightening of the muscles of the buttocks) help maintain the larger muscle groups that are important in ambulation. Active and weight-resistance exercises of uninjured parts of the body maintain muscle strength. When muscles are injured, they need rest and immobilization until tissue repair occurs. The healed muscle then needs progressive exercise to resume its pre-injury strength and functional ability.

## Gerontologic Considerations

Multiple changes in the musculoskeletal system occur with aging (Table 66-1). Bone mass peaks at about 35 years of age, after which there is a universal gradual loss of bone. There is a loss of height due to osteoporosis (abnormal excessive bone loss), kyphosis, thinned intervertebral disks, and flexion of the knees and hips. Numerous metabolic changes, including menopausal withdrawal of estrogen and decreased activity, contribute to osteoporosis. Women lose more bone mass than men do. Additionally, bones change in shape and have reduced strength. Fractures are com-

mon. In the elderly, collagen structures are less able to absorb energy. Ligaments become weak. The articular cartilage degenerates in weight-bearing areas and heals less readily. This contributes to the development of **osteoarthritis**. Joints enlarge and range of motion decreases. Muscle mass and strength are also diminished. There is an actual loss in the size and number of muscle fibers due to myofibril atrophy with fibrous tissue replacement. Increased inactivity, diminished neuron stimulation, and nutritional deficiencies contribute to loss of muscle strength. In addition, remote musculoskeletal problems for which the patient has compensated may become new problems with age-related changes. For example, people who have had polio and who have been able to function normally by using synergistic muscle groups may discover increasing incapacity because of a reduced compensatory ability. Many of the effects of aging, however, can be slowed if the body is kept healthy and active through positive lifestyle behaviors.

## Assessment

### HEALTH HISTORY

The nursing assessment of the patient with musculoskeletal dysfunction includes an evaluation of the effects of the musculoskeletal problem on the patient. The nurse is concerned with assisting patients who have musculoskeletal problems to maintain their general health, accomplish their activities of daily living, and manage their treatment programs. The nurse ensures systemic homeostasis, encourages optimal nutrition, and prevents problems related to immobility. Through an individualized plan of nursing care, the nurse helps the patient achieve maximum health.

### Initial Interview

In the initial interview, the nurse obtains a general impression of the patient's health status, gathering subjective data from the patient concerning the onset of the problem and how it has been managed, as well as the patient's perceptions and expectations related to health. Concurrent health conditions (eg, diabetes, heart disease, chronic obstructive pulmonary disease, infection, preexisting disability) and related problems, such as familial or genetic abnormalities, also need to be considered when developing the plan of care. A history of medication use and response to pain medication aids in designing medication management regimens.

The nurse notes allergies and describes them in terms of the reactions they produce in the patient. The nurse also assesses the patient's use of tobacco, alcohol, and other drugs to evaluate how these agents may affect patient care. Information concerning the patient's learning ability, economic status, and current occupation is needed for rehabilitation and discharge planning. Additions to the initial interview data are made as the nurse interacts with the patient. Such data assist the nurse to adjust the individualized plan of care as needed.

### Assessment Data

During the interview and physical assessment, the patient may report pain, tenderness, tightness, and abnormal sensations. The nurse assesses and documents this information.

### PAIN

Most patients with diseases and traumatic conditions or disorders of muscles, bones, and joints experience pain. Bone pain is characteristically described as a dull, deep ache that is "boring" in nature,

Body Movements Produced by Muscle Contraction

- Flexion—bending at a joint (eg, elbow)
- Extension—straightening at a joint
- Abduction—moving away from midline
- Adduction—moving toward midline
- Rotation—turning around a specific axis (eg, shoulder joint)
- Circumduction—cone-like movement
- Supination—turning upward
- Pronation—turning downward
- Inversion—turning inward
- Eversion—turning outward
- Protraction—pushing forward
- Retraction—pulling backward

From Weber, J. W., & Kelley, J. (2003). *Health assessment in nursing* (2nd ed.). Philadelphia: Lippincott Williams & Wilkins.

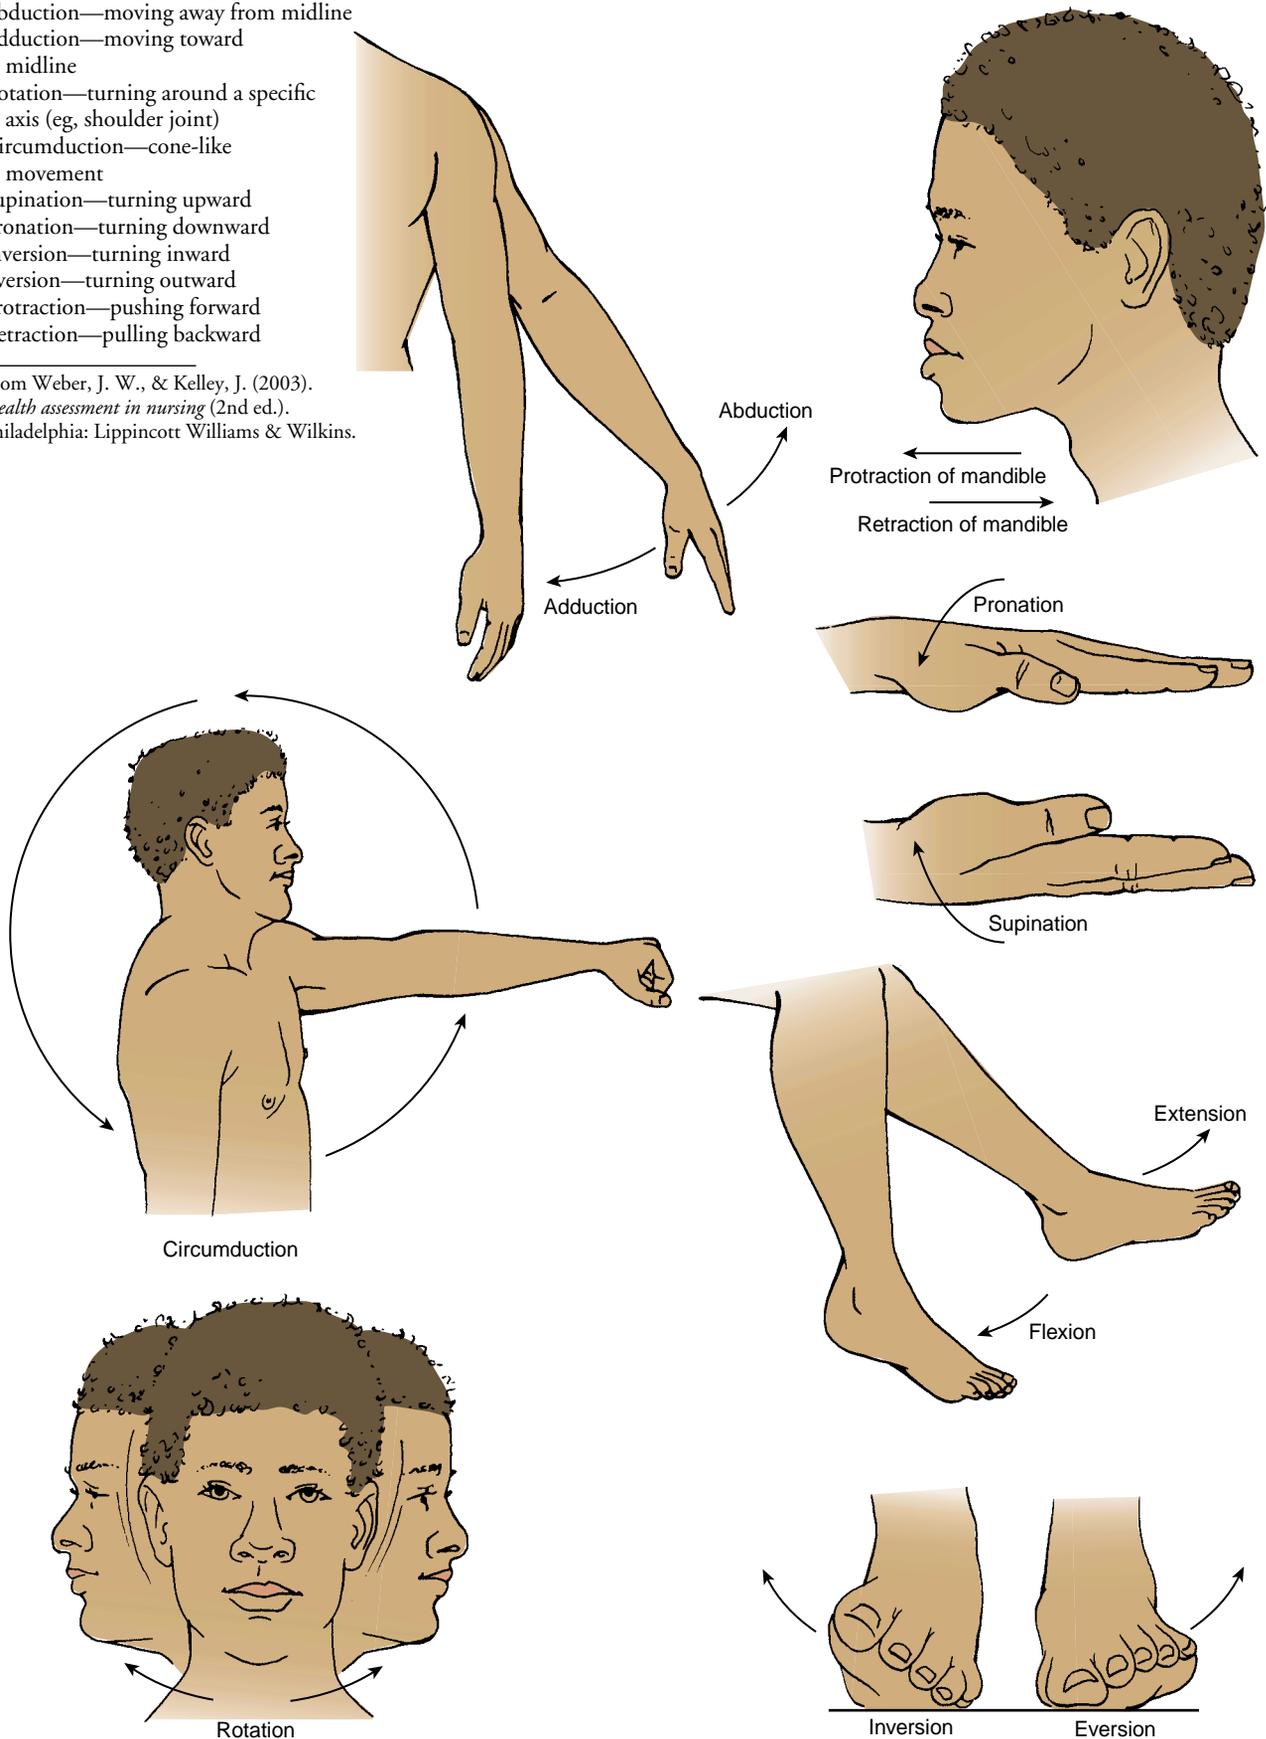

Table 66-1 • Age-Related Changes of the Musculoskeletal System

MUSCULOSKELETAL SYSTEM	STRUCTURAL CHANGES	FUNCTIONAL CHANGES	HISTORY AND PHYSICAL FINDINGS
Bones	Gradual, progressive loss of bone mass after age 35 yr Vertebrae collapse	Bones fragile and prone to fracture: vertebrae, hip, wrist	Loss of height Posture changes Kyphosis Flexion of hips and knees Back pain Osteoporosis Fracture
Muscles	Increase in collagen and resultant fibrosis Muscles diminish in size (atrophy); wasting Tendons less elastic	Loss of strength and flexibility Weakness Fatigue Stumbling Falls	Loss of strength Diminished agility Decreased endurance Prolonged response time (diminished reaction time) Diminished tone Broad base of support History of falls
Joints	Cartilage—progressive deterioration Thinning of intervertebral discs	Stiffness, reduced flexibility, and pain interfere with activities of daily living	Diminished range of motion Loss of flexibility Stiffness Loss of height
Ligaments	Lax ligaments (less than normal strength; weakness)	Postural joint abnormality Weakness	Joint pain on motion; resolves with rest Crepitus Joint swelling/enlargement Degenerative joint disease (osteoarthritis)

whereas muscular pain is described as soreness or aching and is referred to as “muscle cramps.” Fracture pain is sharp and piercing and is relieved by immobilization. Sharp pain may also result from bone infection with muscle spasm or pressure on a sensory nerve.

Rest relieves most musculoskeletal pain. Pain that increases with activity may indicate joint sprain or muscle strain, whereas steadily increasing pain points to the progression of an infectious process (osteomyelitis), a malignant tumor, or neurovascular complications. Radiating pain occurs in conditions in which pressure is exerted on a nerve root. Pain is variable, and its assessment and nursing management must be individualized.

Questions that the nurse can ask regarding pain include the following:

- How does the patient describe the pain?
- Is the pain localized?
- Does the pain radiate? If so, in which direction and to which body parts?
- Is there pain in any other part of the body?
- How intense is the pain on a scale of 0 to 10 (with 10 being the worst possible pain)?
- What is the character of the pain (sharp, dull, boring, shooting, throbbing, cramping)?
- Is it constant? Is it increasing or decreasing in intensity?
- What relieves it?
- What makes it worse?
- What was the patient doing before the pain occurred?
- What was the manner of onset?
- Is the body in proper alignment?
- Is there pressure from traction, bed linens, a cast, or other appliances?
- Is there tension on the skin at a pin site?

Does the patient experience increased discomfort when overly tired from lack of sleep, exciting stimuli, or too much activity?

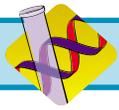

It is important that the patient’s pain and discomfort be managed successfully. Not only is pain exhausting, but, if prolonged, it can force the patient to become increasingly preoccupied and dependent (see Chapter 13).

### ALTERED SENSATIONS

Sensory disturbances are frequently associated with musculoskeletal problems. The patient may describe **paresthesias**, which are burning, tingling sensations or numbness. These sensations may be caused by pressure on nerves or by circulatory impairment. Soft tissue swelling or direct trauma to these structures can impair their function. The nurse assesses the neurovascular status of the involved musculoskeletal area.

Questions that the nurse can ask regarding altered sensations include the following:

- Is the patient experiencing any abnormal sensations or numbness?
- When did this begin? Is it getting worse?
- Does the patient also have pain?
- Can the patient move the affected part?
- What is the color of the part distal to the affected area? Is it pale? Dusky? Cyanotic?
- Does rapid capillary refill occur? (The nurse can gently squeeze a nail until it blanches, then release the pressure. The amount of time for the color under the nail to return to normal is noted. Color normally returns within 3 seconds. The return of color is evidence of capillary refill.)
- Is a pulse palpable distal to the affected area?

## GENETICS IN NURSING PRACTICE—Musculoskeletal Disorders

When assessing a patient with musculoskeletal complaints, nurses should not overlook the possibility of a genetic component to the patient's problems

### MUSCULOSKELETAL IMPAIRMENTS INFLUENCED BY GENETIC FACTORS

- Achondroplasia
- Club foot
- Congenital hip dislocation
- Ehlers-Danlos syndrome
- Marfan syndrome
- Stickler syndrome
- Osteogenesis imperfecta
- Osteoporosis
- Scoliosis

### NURSING ASSESSMENTS

#### FAMILY HISTORY

- Assess for other similarly affected family members
- Assess for the presence of other related genetic conditions (eg, hematologic, cardiac, integumentary conditions)
- Determine the age at onset (eg, fractures present at birth as in osteogenesis imperfecta, or later onset osteoporosis)

#### PHYSICAL ASSESSMENT

- Assess for other skeletal findings including pectus excavatum, scoliosis, long fingers (Marfan syndrome)
- Assess for signs of blue/gray sclerae, opalescent dentin, hearing impairment (osteogenesis imperfecta)
- Assess stature (unusually short—achondroplasia; unusually tall—Marfan syndrome)
- Assess skin for velvety texture with unusual scarring and/or thin fragile skin (Ehlers-Danlos syndrome)

- Assess for vision impairment (Stickler syndrome, Marfan syndrome)

### MANAGEMENT ISSUES SPECIFIC TO GENETICS

- Inquire whether DNA gene mutation or other genetic testing has been performed on affected family members.
- If indicated, refer patient for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, and the availability of genetic testing and gene-based interventions
- Offer appropriate genetics information and resources
- Assess patient's understanding of genetics information
- Provide support to families with newly diagnosed genetic-related digestive disorders
- Participate in management and coordination of care of patients with genetic conditions and individuals predisposed to develop or pass on a genetic condition

### GENETICS RESOURCES

Genetic Alliance—a directory of support groups for patients and families with genetic conditions; [www.geneticalliance.org](http://www.geneticalliance.org)

Gene Clinics—a listing of common genetic disorders with up-to-date clinical summaries, genetic counseling and testing information; [www.geneclinics.org](http://www.geneclinics.org)

National Organization of Rare Disorders—a directory of support groups and information for patients and families with rare genetic disorders; [www.rarediseases.org](http://www.rarediseases.org)

OMIM: Online Mendelian Inheritance in Man—a complete listing of inherited genetic conditions; <http://www.ncbi.nlm.nih.gov/omim/stats/html>

Is edema present?

Is any constrictive device or clothing causing nerve or vascular compression?

Does elevating the affected part or modifying its position affect the symptoms?

## PHYSICAL ASSESSMENT

An examination of the musculoskeletal system ranges from a basic assessment of functional capabilities to sophisticated physical examination maneuvers that facilitate diagnosis of specific bone, muscle, and joint disorders (Chart 66-2). The extent of assessment depends on the patient's physical complaints, health history, and physical clues that warrant further exploration. The nursing assessment is primarily a functional evaluation, focusing on the patient's ability to perform activities of daily living.

Techniques of inspection and palpation are used to evaluate the patient's posture, gait, bone integrity, joint function, and muscle strength and size. In addition, assessing the skin and neurovascular status is an important part of a complete musculoskeletal assessment. The nurse also should understand and be able to perform correct assessment techniques on patients with musculoskeletal trauma. When specific symptoms or physical findings of musculoskeletal dysfunction are apparent, the nurse carefully

documents the examination findings and shares the information with the physician, who may decide that more extensive examination and diagnostic workup are necessary.

### Posture

The normal curvature of the spine is convex through the thoracic portion and concave through the cervical and lumbar portions. Common deformities of the spine include **kyphosis**, an increased forward curvature of the thoracic spine; **lordosis**, or swayback, an exaggerated curvature of the lumbar spine; and **scoliosis**, a lateral curving deviation of the spine (Fig. 66-3). Kyphosis is frequently seen in elderly patients with osteoporosis and in some patients with neuromuscular diseases. Scoliosis may be congenital, idiopathic (without an identifiable cause), or the result of damage to the paraspinal muscles, as in poliomyelitis. Lordosis is frequently seen during pregnancy as the woman adjusts her posture in response to changes in her center of gravity.

During inspection of the spine, the entire back, buttocks, and legs are exposed. The examiner inspects the spinal curves and trunk symmetry from posterior and lateral views. Standing behind the patient, the examiner notes any differences in the height of the shoulders or iliac crests. The gluteal folds are normally symmetric. Shoulder and hip symmetry, as well as the line of the

## Chart 66-2 • ASSESSMENT

### Peripheral Nerve Function

Assessment of peripheral nerve function has two key elements: evaluation of sensation and evaluation of motion. The nurse may perform one or all of the following during a musculoskeletal assessment.

Nerve	Test of Sensation	Test of Movement
Peroneal nerve	Prick the skin centered between the great and second toe.	Ask the patient to dorsiflex the ankle and extend the toes.

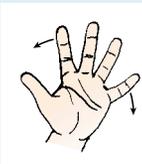

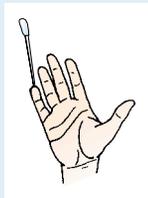

Tibial nerve	Prick the medial and lateral surface of the sole.	Ask the patient to plantarflex toes and ankle.
--------------	---	--

Radial nerve	Prick the skin centered between the thumb and second finger.	Ask the patient to stretch out the thumb, then the wrist, and then the fingers at the metacarpal joints.
--------------	--	--

Ulnar nerve	Prick the fat pad at the top of the small finger.	Ask the patient to spread all fingers.
-------------	---	--

Median nerve	Prick the top or distal surface of the index finger.	Ask the patient to touch the thumb to the little finger. Also observe whether the patient can flex the wrist.
--------------	--	---

vertebral column, are inspected with the patient erect and with the patient bending forward (flexion). (Scoliosis is evidenced by an abnormal lateral curve in the spine, shoulders that are not level, an asymmetric waistline, and a prominent scapula, accentuated by bending forward.) Older adults experience a loss in height due to loss of vertebral cartilage and osteoporosis-related vertebral fractures. Therefore, an adult's height should be measured periodically.

### Gait

Gait is assessed by having the patient walk away from the examiner for a short distance. The examiner observes the patient's gait for smoothness and rhythm. Any unsteadiness or irregular movements (frequently noted in elderly patients) are considered abnormal. When a limping motion is noted, it is most frequently caused by painful weight bearing. In such instances, the patient can usually pinpoint the area of discomfort, thus guiding further examination. If one extremity is shorter than another, a limp may also be observed as the patient's pelvis drops downward on the affected side with each step. Limited joint motion may affect gait. In addition, a variety of neurologic conditions are associated with abnormal gaits such as a spastic hemiparesis gait (stroke), steppage gait (lower motor neuron disease), and shuffling gait (Parkinson's disease).

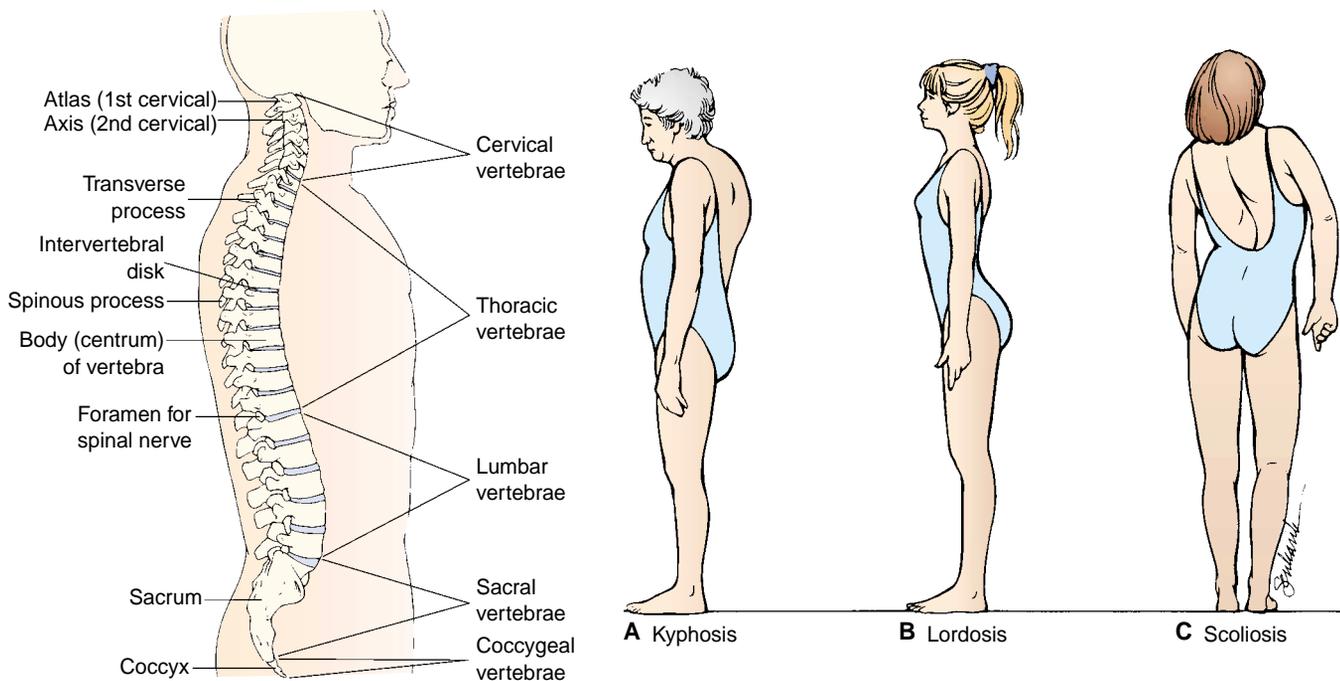

### Bone Integrity

The bony skeleton is assessed for deformities and alignment. Symmetric parts of the body are compared. Abnormal bony growths due to bone tumors may be observed. Shortened extremities, amputations, and body parts that are not in anatomic alignment are noted. Fracture findings may include abnormal angulation of long bones, motion at points other than joints, and crepitus (a grating sound) at the point of abnormal motion. Movement of fracture fragments must be minimized to avoid additional injury.

### Joint Function

The articular system is evaluated by noting range of motion, deformity, stability, and nodular formation. Range of motion is evaluated both actively (the joint is moved by the muscles surrounding the joint) and passively (the joint is moved by the examiner). The examiner is familiar with the normal range of motion of major joints (see Chapter 11). Precise measurement of range of motion can be made by a goniometer (a protractor designed for evaluating joint motion). Limited range of motion may be the result of skeletal deformity, joint pathology, or **contracture** of the surrounding muscles, tendons, and joint capsule. In elderly patients, limitations of range of motion associated with **osteoarthritis** (degenerative joint disease) may reduce their ability to perform activities of daily living.

If joint motion is compromised or the joint is painful, the joint is examined for **effusion** (excessive fluid within the capsule), swelling, and increased temperature that may reflect active inflammation. An effusion is suspected if the joint is swollen and the normal bony landmarks are obscured. The most common site for joint effusion is the knee. If a small amount of fluid is present in the joint spaces beneath the patella, it may be identified by the following maneuver. The medial and lateral aspects of the extended knee are milked firmly in a downward motion. This displaces any fluid downward. As pressure is exerted against the

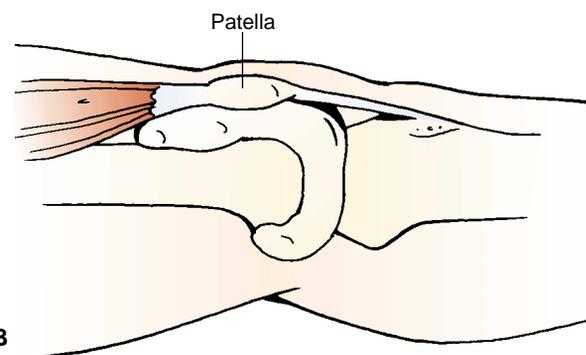

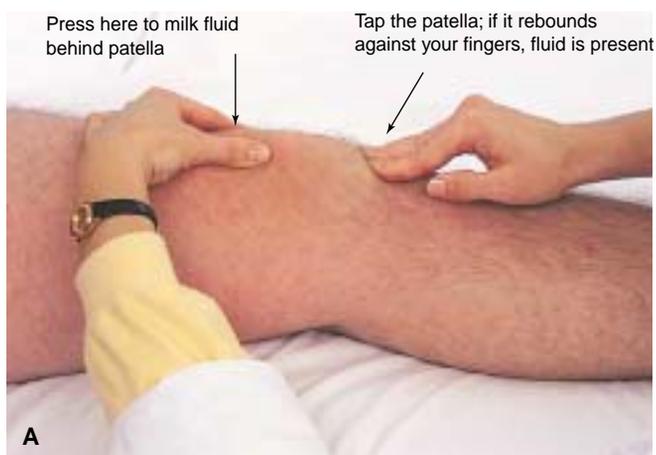

**FIGURE 66-3** A normal spine and three abnormalities. (A) Kyphosis: an increased convexity or roundness of the spine's thoracic curve. (B) Lordosis: swayback; exaggeration of the lumbar spine curve. (C) Scoliosis: a lateral curvature of the spine.

medial or lateral side, the examiner observes the opposite side for a bulge below the patella. When larger amounts of fluid are present, the patella becomes elevated from the femur during knee extension and the ballottement test is positive (Fig. 66-4). If inflammation or fluid is suspected in a joint, physician consultation is indicated.

Joint deformity may be caused by contracture (shortening of surrounding joint structures), dislocation (complete separation of joint surfaces), subluxation (partial separation of articular surfaces), or disruption of structures surrounding the joint. Weakness or disruption of joint-supporting structures may result in a weak joint that requires an external supporting appliance (eg, brace).

Palpation of the joint while it is passively moved provides information about the integrity of the joint. Normally, the joint moves smoothly. A snap or crack may indicate that a ligament is slipping over a bony prominence. Slightly roughened surfaces, as in arthritic conditions, result in **crepitus** (grating, crackling sound or sensation) as the irregular joint surfaces move across one another.

The tissues surrounding joints are examined for nodule formation. Rheumatoid arthritis, gout, and osteoarthritis produce characteristic nodules. The subcutaneous nodules of rheumatoid arthritis are soft and occur within and along tendons that provide extensor function to the joints. The nodules of gout are hard and lie within and immediately adjacent to the joint capsule itself.

**FIGURE 66-4** (A) Technique for ballottement test to detect fluid in the knee (B). Photo from Weber, J. W., & Kelley, J. (2003). *Health assessment in nursing* (2nd ed.). Philadelphia: Lippincott Williams & Wilkins.

They may rupture, exuding white uric acid crystals onto the skin surface. Osteoarthritic nodules are hard and painless and represent bony overgrowth that has resulted from destruction of the cartilaginous surface of bone within the joint capsule. They are frequently seen in older adults.

Often, the size of the joint is exaggerated by atrophy of the muscles proximal and distal to that joint. This is seen in rheumatoid arthritis of the knees, in which the quadriceps muscle may atrophy dramatically. In rheumatoid arthritis, joint involvement assumes a symmetric pattern (Fig. 66-5). (See Chapter 54 for further information about rheumatoid arthritis.)

## Muscle Strength and Size

The muscular system is assessed by noting the patient's ability to change position, muscular strength and coordination, and the size of individual muscles. Weakness of a group of muscles might indicate a variety of conditions, such as polyneuropathy, electrolyte disturbances (particularly potassium and calcium), myasthenia gravis, poliomyelitis, and muscular dystrophy. By palpating the muscle while passively moving the relaxed extremity, the nurse can determine the muscle tone. The nurse assesses muscle strength by having the patient perform certain maneuvers with and without added resistance. For example, when the biceps are tested, the patient is asked to extend the arm fully and then to flex it against resistance applied by the nurse. A simple handshake may provide an indication of grasp strength.

The nurse may elicit muscle **clonus** (rhythmic contractions of a muscle) in the ankle or wrist by sudden, forceful, sustained dorsiflexion of the foot or extension of the wrist. **Fasciculations** (involuntary twitching of muscle fiber groups) may be observed.

The nurse measures the girth of an extremity to monitor increased size due to exercise, edema, or bleeding into the muscle. Girth may decrease due to muscle atrophy. The unaffected extremity is measured and used as the reference standard. Measurements are taken at the maximum circumference of the extremity. It is important that the measurements be taken at the same location on the extremity, and with the extremity in the same position, with the muscle at rest. Distance from a specific anatomic landmark (eg, 10 cm below the medial aspect of the knee for measurement of the calf muscle) should be indicated in the patient's record so that subsequent measurements can be made at the same

point. For ease of serial assessment, the nurse may indicate the point of measurement by marking the skin. Variations in size greater than 1 cm are considered significant.

## Skin

In addition to assessing the musculoskeletal system, the nurse inspects the skin for edema, temperature, and color. Palpation of the skin can reveal whether any areas are warmer, suggesting increased perfusion or infection, or cooler, suggesting decreased perfusion, and whether edema is present. Cuts, bruises, skin color, and evidence of decreased circulation or infection can influence nursing management of musculoskeletal conditions.

## Neurovascular Status

It is important for the nurse to perform frequent neurovascular assessments of patients with musculoskeletal disorders (especially of those with fractures) because of the risk of tissue and nerve damage. One complication that the nurse needs to be alert for when assessing the patient is compartment syndrome, which is described in detail later in this unit. This major neurovascular problem is caused by pressure within a muscle compartment that increases to such an extent that microcirculation diminishes, leading to nerve and muscle anoxia and necrosis. Function can be permanently lost if the anoxic situation continues for longer than 6 hours. Assessment of neurovascular status (Chart 66-3) is frequently referred to as assessment of CMS (circulation, motion, and sensation).

## The Patient With Musculoskeletal Injury

Special precautions must be taken when assessing a trauma patient. If there is injury to an extremity, it is important to assess for soft tissue trauma, deformity, and neurovascular status. If the patient has a possible cervical spine injury and is wearing a cervical collar, the collar must not be removed until the absence of spinal cord injury is confirmed on x-ray. When the collar is removed, the cervical spine area is gently assessed for swelling, tenderness, and deformity. With pelvic trauma, abdominal organ injuries may occur. The patient is assessed for abdominal pain, tenderness, hematomas, and the presence or absence of femoral pulses. If blood is present at the urinary meatus, the nurse should suspect bladder and urethral injury, and the patient should not

**FIGURE 66-5** Rheumatoid arthritis joint deformity with ulnar deviation of fingers and “swan-neck” deformity of fingers (ie, hyperextension of proximal interphalangeal joints with flexion of distal interphalangeal joints).

be catheterized. Instead, such findings should be reported immediately to the primary health care provider.

## Diagnostic Evaluation

### IMAGING PROCEDURES

#### X-ray Studies

X-ray studies are important in evaluating patients with musculoskeletal disorders. Bone x-rays determine bone density, texture, erosion, and changes in bone relationships. Multiple x-rays are needed for full assessment of the structure being examined. X-ray study of the cortex of the bone reveals any widening, narrowing, or signs of irregularity. Joint x-rays reveal fluid, irregularity, spur formation, narrowing, and changes in the joint structure. After being positioned for the study, the patient must remain still while the x-rays are taken.

#### Computed Tomography

A computed tomography (CT) scan shows in detail a specific plane of involved bone and can reveal tumors of the soft tissue or injuries to the ligaments or tendons. It is used to identify the location and extent of fractures in areas that are difficult to evaluate (eg, acetabulum). CT studies, which may be performed with or without the use of contrast agents, last about 1 hour. The patient must remain still during the procedure.

#### Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a noninvasive imaging technique that uses magnetic fields, radio waves, and computers to demonstrate abnormalities (ie, tumors or narrowing of tissue pathways through bone) of soft tissues such as muscle, tendon, cartilage, nerve, and fat. Because an electromagnet is used, patients with any metal implants, clips, or pacemakers are not candidates for MRI.

**NURSING ALERT** Jewelry, hair clips, hearing aids, credit cards with magnetic strips, and other metal-containing objects must be removed before the MRI is done; otherwise they can become dangerous projectile objects.

To enhance visualization of anatomic structures, contrast media may be injected intravenously. During the procedure, the patient needs to lie still for 1 to 2 hours and will hear a rhythmic knocking sound. Patients who experience claustrophobia may be unable to tolerate the confinement of closed MRI equipment without sedation. Open MRI systems are available, but they use lower-intensity magnetic fields, which reduces the quality of the imaging; repeated imaging may be required. Advantages of open MRI include increased patient comfort, reduced problems with claustrophobic patients, and reduced noise.

#### Arthrography

Arthrography is useful in identifying acute or chronic tears of the joint capsule or supporting ligaments of the knee, shoulder, ankle, hip, or wrist. A radiopaque substance or air is injected into the joint cavity to outline soft tissue structures and the contour of the joint. The joint is put through its range of motion to distribute the contrast agent while a series of x-rays is obtained. If a tear is present, the contrast agent leaks out of the joint and is evident on the x-ray image.

After an arthrogram, the joint is usually rested for 12 hours, and a compression elastic bandage is applied as prescribed. In addition, the nurse provides comfort measures (mild analgesia, ice) as appropriate. The nurse should explain to the patient that it is normal to experience clicking or crackling in the joint for a day or two after the procedure, until the contrast agent or air is absorbed.

#### Nursing Interventions

Before the patient undergoes an imaging study, the nurse should assess for conditions that may require special consideration during the study or that may be contraindications to the study (eg, pregnancy; claustrophobia; inability to tolerate required positioning due to age, debility, or disability; metal implants). It is essential that the patient remove all jewelry, hair clips, hearing aids, and other metal before having an MRI. If contrast agents will be used for CT scan, MRI, or arthrography, the nurse should carefully assess the patient for possible allergy.

#### Bone Densitometry

Bone densitometry is used to estimate bone mineral density (BMD). This can be done through the use of x-rays or ultrasound. Dual-energy x-ray absorptiometry (DEXA) determines bone mineral density at the wrist, hip, or spine to estimate the extent of osteoporosis and to monitor a patient's response to treatment for osteoporosis. Bone sonometry (ultrasound) measures heel bone quantity and quality and is used to estimate BMD and the risk of fracture for people with osteoporosis. Bone density sonography is a cost-effective, readily available screening tool for diagnosing osteoporosis and predicting a person's risk for fracture.

### NUCLEAR STUDIES

#### Bone Scan

A bone scan is performed to detect metastatic and primary bone tumors, osteomyelitis, certain fractures, and aseptic necrosis. A bone-seeking radioisotope is injected intravenously. The scan is performed 2 to 3 hours after the injection. At this point, distribution and concentration of the isotope in the bone are determined. The degree of nuclide uptake is related to the metabolism of the bone. An increased uptake of isotope is seen in primary skeletal disease (osteosarcoma), metastatic bone disease, inflammatory skeletal disease (osteomyelitis), and certain types of fractures.

#### NURSING INTERVENTIONS

Before the patient undergoes a bone scan, the nurse should inquire about possible allergy to the radioisotope and should assess for any condition that would contraindicate performing the procedure (eg, pregnancy). In addition, it is important to encourage the patient to drink plenty of fluids to help distribute and eliminate the isotope. Before the scan, the nurse asks the patient to empty the bladder, because a full bladder interferes with scanning of the pelvic bones.

### ENDOSCOPIC STUDIES

#### Arthroscopy

Arthroscopy is a procedure that allows direct visualization of a joint to diagnose joint disorders. Treatment of tears, defects, and disease processes may be performed through the arthroscope. The procedure is carried out in the operating room under sterile conditions; injection of a local anesthetic into the joint or general

anesthesia is used. A large-bore needle is inserted, and the joint is distended with saline. The arthroscope is introduced, and joint structures, synovium, and articular surfaces are visualized. After the procedure, the puncture wound is closed with adhesive strips or sutures and covered with a sterile dressing. Complications are rare but may include infection, hemarthrosis, neurovascular compromise, thrombophlebitis, stiffness, effusion, adhesions, and delayed wound healing.

### NURSING INTERVENTIONS

The joint is wrapped with a compression dressing to control swelling. In addition, ice may be applied to control edema and discomfort. Frequently, the joint is kept extended and elevated to reduce swelling. It is important to monitor neurovascular function. The nurse administers prescribed analgesics to control discomfort. The nurse should explain when the patient can resume activity and what weight-bearing limits to follow, as prescribed by the orthopedic surgeon. The nurse also explains to the patient and family the symptoms (eg, swelling, numbness, cool skin) to watch for in order to determine whether complications are occurring and the importance of notifying the physician of these observations. The physician's prescription for analgesic medication is also explained.

### OTHER STUDIES

#### Arthrocentesis

Arthrocentesis (joint aspiration) is carried out to obtain synovial fluid for purposes of examination or to relieve pain due to effusion. Examination of synovial fluid is helpful in the diagnosis of septic arthritis and other inflammatory arthropathies and reveals the presence of hemarthrosis (bleeding into the joint cavity), which suggests trauma or a bleeding disorder. Normally, synovial fluid is clear, pale, straw-colored, and scanty in volume. Using aseptic technique, the physician inserts a needle into the joint and aspirates fluid. Anti-inflammatory medications may be injected into the joint. A sterile dressing is applied after aspiration. There is a risk for infection after this procedure.

#### Electromyography

Electromyography (EMG) provides information about the electrical potential of the muscles and the nerves leading to them. The test is done to evaluate muscle weakness, pain, and disability. The purpose of the procedure is to determine any abnormality of function and to differentiate muscle and nerve problems. Needle electrodes are inserted into selected muscles, and responses to electrical stimuli are recorded on an oscilloscope. Warm compresses may relieve residual discomfort after the study.

#### Biopsy

Biopsy may be performed to determine the structure and composition of bone marrow, bone, muscle, or synovium to help diagnose specific diseases. The nurse monitors the biopsy site for edema, bleeding, pain, and infection. Ice is applied as prescribed to control bleeding and edema. In addition, analgesics are administered as prescribed for comfort.

### LABORATORY STUDIES

Examination of the patient's blood and urine can provide information about a primary musculoskeletal problem (eg, Paget's disease), a developing complication (eg, infection), the baseline

for instituting therapy (eg, anticoagulant therapy), or the response to therapy. The complete blood count includes the hemoglobin level (which is frequently lower after bleeding associated with trauma and surgery) and the white blood cell count (which is elevated in acute infections, trauma, acute hemorrhage, and tissue necrosis). Before surgery, coagulation studies are performed to detect bleeding tendencies (because bone is very vascular tissue).

Blood chemistry studies provide data about a wide variety of musculoskeletal conditions. Serum calcium levels are altered in patients with osteomalacia, parathyroid function, Paget's disease, metastatic bone tumors, or prolonged immobilization. Serum phosphorus levels are inversely related to calcium levels and are diminished in osteomalacia associated with malabsorption syndrome. Acid phosphatase is elevated in Paget's disease and metastatic cancer. Alkaline phosphatase is elevated during early fracture healing and in diseases with increased osteoblastic activity (eg, metastatic bone tumors). Bone metabolism may be evaluated through thyroid studies and determination of calcitonin, parathyroid hormone, and vitamin D levels. Serum enzyme levels of creatine kinase and aspartate aminotransferase become elevated with muscle damage. Aldolase is elevated in muscle diseases (eg, muscular dystrophy, skeletal muscle necrosis). Serum osteocalcin (bone GLA protein) indicates the rate of bone turnover. Urine calcium levels increase with bone destruction (eg, parathyroid dysfunction, metastatic bone tumors, multiple myeloma).

Specific serum biochemical markers can be used to provide information about bone formation; these include bone-specific alkaline phosphatase and osteocalcin from osteoblasts, and procollagen 1 carboxyterminal propeptide and procollagen 1 aminoterminal propeptide from the bone matrix. Specific serum biochemical markers that provide information about bone resorption include tartrate-resistant acid phosphatase and bone sialoprotein from osteoclasts, and aminoterminal telopeptide of type 1 collagen and carboxyterminal telopeptide of type 1 collagen from bone matrix. Biochemical markers of bone resorption in the urine include pyridinoline and deoxypyridinoline crosslinks, aminoterminal telopeptide of type 1 collagen, and hydroxyproline from collagen degradation from bone matrix (Koopman, 2001; Woitge & Seibel, 2001).

### Nursing Implications

Determining the patient's functional status and health care needs is an integral part of the nursing assessment. Nursing diagnoses and the care plan are developed and modified according to the patient's needs.

During the period of assessment, the patient requires support and nursing care, including physical and psychological preparation for examinations and tests. Patient education before the tests (what is to be done; why it is being done; what the patient can expect to experience, including tactile, visual, and auditory sensations; and what patient participation is expected) reduces anxiety and enables the patient to be an active participant in care.

The resulting medical diagnosis and prescribed treatment regimen affect the nursing management of the patient. The nursing plan of care includes nursing measures to facilitate the resolution of the patient's health problems and promotion of health. The nursing assessment enables the nurse to identify the health problems that can be improved by nursing interventions. In collaboration with the patient, health goals and nursing strategies are formulated to resolve the identified nursing diagnoses.

## Critical Thinking Exercises

**1.** A young adult patient who experienced multiple fractures of the left tibia is to be confined to non-weight-bearing activity for about 3 months. During a clinic visit 3 weeks after the fracture occurred, he tells the nurse that his left leg is “withering away” and he is afraid that he will have no strength in this leg when he is finally permitted to walk on it. Discuss the nursing interventions to help this patient. What additional assessments and explanations could the nurse make to help this patient deal with the effects of immobility?

**2.** You are teaching a class on age-associated body changes at a senior center. Your focus is on the musculoskeletal system. The participants have experienced many of the changes you identify and ask you what they can do about them. What strategies to minimize these changes and maximize musculoskeletal health would you discuss with the participants?

**3.** An older patient with low back pain is scheduled for a bone scan. She tells the nurse that she just had a bone density study for osteoporosis a month ago and does not understand why the doctor wants her to have another one so soon. What additional assessment should the nurse perform? Discuss the differences in the two procedures.

# ● Musculoskeletal Care Modalities

## **LEARNING OBJECTIVES**

*On completion of this chapter, the learner will be able to:*

1. Describe the preventive and health teaching needs of the patient with a cast.
2. Use the nursing process as a framework for care of the patient with a cast.
3. Describe the various types of traction and the principles of effective traction.
4. Identify the preventive nursing care needs of the patient in traction.
5. Use the nursing process as a framework for care of the patient in traction.
6. Compare the nursing needs of the patient undergoing total hip replacement with those of the patient undergoing total knee replacement.
7. Use the nursing process as a framework for care of the patient undergoing orthopedic surgery.

The management of musculoskeletal problems frequently includes the use of casts, traction, artificial joint replacement, and/or surgery. Patient education is essential for optimal outcomes. The nurse prepares the patient for immobilization with casts or traction, for surgery, and for joint replacement when indicated. Nursing care is planned to maximize the effectiveness of these treatment modalities and to prevent potential complications associated with each of the interventions. The patient is taught to manage his or her care at home and how to safely resume activities.

## Managing Care of the Patient in a Cast

A **cast** is a rigid external immobilizing device that is molded to the contours of the body. The purposes of a cast are to immobilize a body part in a specific position and to apply uniform pressure on encased soft tissue.

A cast is used specifically to immobilize a reduced **fracture**, to correct a deformity, to apply uniform pressure to underlying soft tissue, or to support and stabilize weakened joints. Generally, casts permit mobilization of the patient while restricting movement of a body part.

The condition being treated influences the type and thickness of the cast applied. Generally speaking, the joints proximal and distal to the area to be immobilized are included in the cast. With some fractures, however, cast construction and molding may allow movement of a joint while immobilizing a fracture (eg, three-point fixation in a patellar tendon weight-bearing cast). Various types of casts include the following:

*Short arm cast:* Extends from below the elbow to the palmar crease, secured around the base of the thumb. If the thumb is included, it is known as a *thumb spica* or *gauntlet* cast.

*Long arm cast:* Extends from the upper level of the axillary fold to the proximal palmar crease. The elbow usually is immobilized at a right angle.

*Short leg cast:* Extends from below the knee to the base of the toes. The foot is flexed at a right angle in a neutral position.

*Long leg cast:* Extends from the junction of the upper and middle third of the thigh to the base of the toes. The knee may be slightly flexed.

*Walking cast:* A short or long leg cast reinforced for strength.

*Body cast:* Encircles the trunk.

*Shoulder spica cast:* A body jacket that encloses the trunk and the shoulder and elbow.

*Hip spica cast:* Encloses the trunk and a lower extremity. A double hip spica cast includes both legs.

Figure 67-1 illustrates the long-arm and long-leg cast and areas in which pressure problems commonly occur with these casts.

## CASTING MATERIALS

### Nonplaster

Generally referred to as fiberglass casts, these water-activated polyurethane materials have the versatility of plaster (see later discussion) but are lighter in weight, stronger, water resistant, and durable. They consist of an open-weave, nonabsorbent fabric impregnated with cool water-activated hardeners that bond and reach full rigid strength in minutes.

Nonplaster casts are porous and therefore diminish skin problems. They do not soften when wet, which allows for hydrotherapy (use of water for treatment) when appropriate. When wet, they are dried with a hair drier on a cool setting; thorough drying is important to prevent skin breakdown. They are used for nondisplaced fractures with minimal swelling and for long-term wear.

### Plaster

The traditional cast is made of plaster. Rolls of plaster bandage are wet in cool water and applied smoothly to the body. A crystallizing reaction occurs, and heat is given off (an exothermic reaction). The heat given off during this reaction can be uncomfortable, and the nurse should inform the patient about the sensation of increasing warmth so that the patient does not become alarmed. Additionally, the nurse should explain that the cast needs to be exposed to allow maximum dissipation of the heat and that most casts cool after about 15 minutes.

The crystallization process produces a rigid dressing. The speed of the reaction varies from a few minutes to 15 to 20 minutes. The orthopedist determines the plaster setting speed appropriate for the cast being applied. After the plaster sets, the cast remains wet and somewhat soft. It does not have its full strength

## Glossary

**abduction:** movement away from the center or median line of the body

**adduction:** movement toward the center or median line of the body

**arthrodesis:** surgical fusion of a joint

**arthroplasty:** surgical repair of a joint; joint replacement

**avascular necrosis:** death of tissue due to insufficient blood supply

**brace:** externally applied device to support body, control movement, and prevent injury

**cast:** rigid external immobilizing device molded to contours of body part

**cast syndrome:** psychological (claustrophobic reaction) and physiologic (superior

mesenteric artery syndrome) responses to confinement in body cast

**continuous passive motion (CPM) device:** a device that promotes range of motion, circulation, and healing

**edema:** soft tissue swelling due to fluid accumulation

**external fixator:** external metal frame attached to and stabilizing bone fragments

**fasciotomy:** surgical procedure to release constricting muscle fascia so as to relieve muscle tissue pressure

**fracture:** a break in the continuity of the bone

**heterotopic ossification:** misplaced formation of bone

**neurovascular status:** neurologic (motor and sensory components) and circulatory functioning of a body part

**open reduction with internal fixation (ORIF):** surgery to repair and stabilize a fracture

**osteomyelitis:** infection of the bone

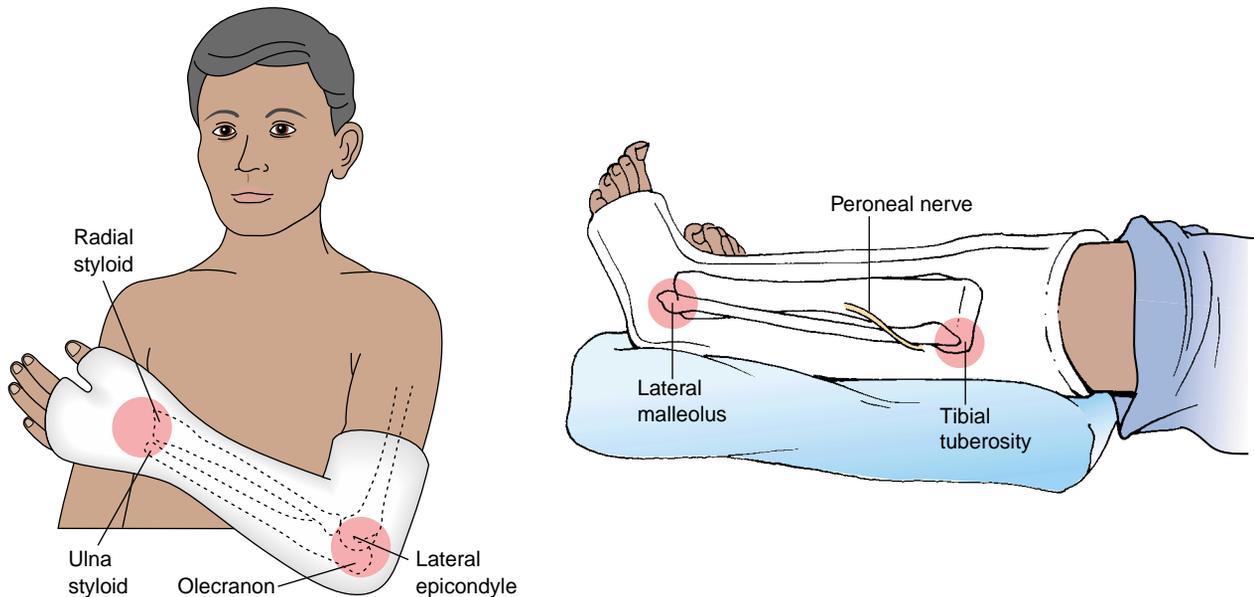

**osteotomy:** surgical cutting of bone

**sling:** bandage used to support an arm

**splint:** device designed specifically to support and immobilize body part in desired position

**traction:** application of a pulling force to a part of the body

**trapeze:** overhead patient-helping device to promote patient mobility in bed

**FIGURE 67-1** Pressure areas in common types of casts. *Left*, long arm cast; *right*, short leg cast.

until it is dry. While damp, the cast can be dented. Therefore, it must be handled with the palms of the hand and not allowed to rest on hard surfaces or sharp edges. Cast dents may press on the skin causing irritation and skin breakdown. The plaster cast requires 24 to 72 hours to dry completely, depending on its thickness and the environmental drying conditions. A freshly applied cast should be exposed to circulating air to dry and should not be covered with clothing or bed linens. A wet plaster cast appears dull and gray, sounds dull on percussion, feels damp, and smells musty. A dry plaster cast is white and shiny, resonant, odorless, and firm.

## NURSING PROCESS: THE PATIENT IN A CAST

### Assessment

Before the cast is applied, the nurse completes an assessment of the patient's general health, presenting signs and symptoms, emotional status, understanding of the need for the cast, and condition of the body part to be immobilized in the cast. Physical assessment of the part to be immobilized must include assessment of the **neurovascular status** (neurologic and circulatory functioning) of the body part, degree and location of swelling, bruising, and skin abrasions.

### Diagnosis

#### NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses for the patient with a cast may include the following:

- Deficient knowledge related to the treatment regimen
- Acute pain related to the musculoskeletal disorder
- Impaired physical mobility related to the cast
- Self-care deficit: bathing/hygiene, feeding, dressing/grooming, or toileting due to restricted mobility
- Impaired skin integrity related to lacerations and abrasions
- Risk for peripheral neurovascular dysfunction related to physiologic responses to injury and compression effect of cast

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include the following:

- Compartment syndrome
- Pressure ulcer
- Disuse syndrome

### Planning and Goals

The major goals for the patient with a cast include knowledge of the treatment regimen, relief of pain, improved physical mobility, achievement of maximum level of self-care, healing of lacerations and abrasions, maintenance of adequate neurovascular function, and absence of complications.

### Nursing Interventions

#### EXPLAINING THE TREATMENT REGIMEN

Before the cast is applied, the patient needs information concerning the pathologic problem and the purpose and expectations of the prescribed treatment regimen. This knowledge promotes the patient's active participation in and adherence to the treatment program. It is important to prepare the patient for the application of the cast by describing the anticipated sights, sounds, and sensations (eg, heat from the hardening reaction of the plaster). The patient needs to know what to expect during application and that the body part will be immobilized after casting (Chart 67-1).

#### RELIEVING PAIN

The nurse must carefully evaluate pain associated with musculoskeletal problems, asking the patient to indicate the exact site and to describe the character and intensity of the pain to help determine its cause. Most pain can be relieved by elevating the involved part, applying cold as prescribed, and administering usual dosages of analgesics.

Chart 67-1

## GUIDELINES FOR Applying a Cast

When applying a cast, the physician or nurse practitioner proceeds as follows:

PROCEDURE	RATIONALE
1. Support extremity or body part to be casted.	1. Minimizes movement; maintains reduction and alignment; increases comfort.
2. Position and maintain part to be casted in position indicated by physician during casting procedure.	2. Facilitates casting; reduces incidence of complications (eg, malunion, nonunion, contracture).
3. Drape patient.	3. Avoids undue exposure; protects other body parts from contact with casting materials.
4. Wash and dry part to be casted.	4. Reduces incidence of skin breakdown.
5. Place knitted material* (eg, stockinette) over part to be casted. <ul style="list-style-type: none"> <li>• Apply in smooth and nonconstrictive manner.</li> <li>• Allow additional material.</li> </ul>	5. Protects skin from casting materials. <ul style="list-style-type: none"> <li>• Protects skin from pressure.</li> <li>• Folds over edges of cast when finishing application; creates smooth, padded edge; protects skin from abrasion.</li> </ul>
6. Wrap soft, nonwoven roll padding* smoothly and evenly around part. <ul style="list-style-type: none"> <li>• Use additional padding around bony prominences to protect superficial nerves (eg, head of fibula, olecranon process).</li> </ul>	6. Protects skin from pressure of cast. <ul style="list-style-type: none"> <li>• Protects skin at bony prominences.</li> <li>• Protects superficial nerves.</li> </ul>
7. Apply plaster or nonplaster casting material evenly on body part. <ul style="list-style-type: none"> <li>• Choose appropriate width bandage.</li> <li>• Overlap preceding turn by half the width of the bandage.</li> <li>• Use continuous motion, maintaining constant contact with body part.</li> <li>• Use additional casting material (splints) at joints and at points of anticipated cast stress.</li> </ul>	7. Creates smooth, solid, well-contoured cast. <ul style="list-style-type: none"> <li>• Facilitates smooth application.</li> <li>• Creates smooth, solid, immobilizing cast.</li> <li>• Shapes cast properly for adequate support.</li> </ul>
8. "Finish" cast: <ul style="list-style-type: none"> <li>• Smooth edges.</li> <li>• Trim and reshape with cast knife or cutter.</li> </ul>	8. Protects skin from abrasion. <ul style="list-style-type: none"> <li>• Assures full range of motion of adjacent joints.</li> </ul>
9. Remove particles of casting materials from skin.	9. Prevents particles from loosening and sliding underneath cast.
10. Support cast during hardening. <ul style="list-style-type: none"> <li>• Handle hardening casts with palms of hands.</li> <li>• Support cast on firm smooth surface.</li> <li>• Do not rest cast on hard surfaces or on sharp edges.</li> <li>• Avoid pressure on cast.</li> </ul>	10. Casting materials harden in minutes. Maximum hardness of nonplaster cast occurs in minutes. Maximum hardness of plaster cast occurs with drying (24 to 72 hours, depending on environment and thickness of cast). <ul style="list-style-type: none"> <li>• Avoids denting of cast and development of pressure areas.</li> </ul>
11. Promote drying of cast. <ul style="list-style-type: none"> <li>• Leave cast uncovered and exposed to air.</li> <li>• Turn patient every 2 hours supporting major joints.</li> <li>• Fans may be used to increase air flow and speed drying.</li> </ul>	11. Facilitates drying.

\*Nonabsorbent materials are used with nonplaster casts.

**NURSING ALERT** A patient's unrelieved pain must be immediately reported to the physician to avoid possible paralysis and necrosis.

Pain associated with the disease process (eg, fracture) is frequently controlled by immobilization. Pain due to **edema** that is associated with trauma, surgery, or bleeding into the tissues can frequently be controlled by elevation and, if prescribed, intermittent application of cold. Ice bags (one-third to one-half full) or cold application devices are placed on each side of the cast, if prescribed, making sure not to indent the cast.

Pain may be indicative of complications. Pain associated with compartment syndrome is relentless and is not controlled by modalities such as elevation, application of cold if prescribed, and usual dosages of analgesics. Severe pain over a bony prominence warns of an impending pressure ulcer. Pain decreases when ulceration occurs. Discomfort due to pressure on the skin may be relieved by elevation that controls edema or by positioning that alters pressure. It may be necessary, however, to modify the cast or to apply a new cast.

**NURSING ALERT** The nurse must never ignore complaints of pain from the patient in a cast because of the possibility of potential problems, such as impaired tissue perfusion or pressure ulcer formation.

### IMPROVING MOBILITY

Every joint that is not immobilized should be exercised and moved through its range of motion to maintain function. If the patient has a leg cast, the nurse encourages toe exercises. If the patient has an arm cast, the nurse encourages finger exercises.

### PROMOTING HEALING OF SKIN ABRASIONS

Before the cast is applied, it is important to treat skin lacerations and abrasions to promote healing. The nurse thoroughly cleans the skin and treats it as prescribed. Sterile dressings are used to cover the injured skin. If the skin wounds are extensive, an alternative method (eg, external fixator) may be chosen to immobilize the body part. While the cast is on, the nurse observes the patient for systemic signs of infection, odors from the cast, and purulent drainage staining the cast. It is important to notify the physician if any of these occurs.

### MAINTAINING ADEQUATE NEUROVASCULAR FUNCTION

Swelling and edema are natural responses of the tissue to trauma and surgery. The patient may complain that the cast is too tight. Vascular insufficiency and nerve compression due to unrelieved swelling can result in compartment syndrome (see Chap. 69, Management of Patients With Musculoskeletal Trauma). The nurse monitors circulation, motion, and sensation of the affected extremity, assessing the fingers or toes of the casted extremity and comparing them with those of the opposite extremity. Normal findings include minimal swelling, minimal discomfort, pink color, warm to touch, rapid capillary refill response, normal sensations, and ability to exercise fingers or toes. The nurse encourages the patient to move fingers or toes hourly when awake to stimulate circulation.

It is important to perform frequent, regular assessments of neurovascular status. Early recognition of diminished circulation and nerve function is essential to prevent loss of function. Assessment data including progressive unrelieved pain, pain on passive stretch, paresthesia, motor loss, sensory loss, coolness, paleness, slow capillary refill, and sensation of tightness indicate potential compartment syndrome. The nurse adjusts the extremity so that it is no higher than heart level to enhance arterial perfusion and control edema and notifies the physician at once.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

#### Compartment Syndrome

Compartment syndrome occurs when there is increased tissue pressure within a limited space (eg, cast, muscle compartment) that compromises the circulation and the function of the tissue within the confined area. To relieve the pressure, the cast must be bivalved (cut in half longitudinally) while maintaining alignment, and the extremity must be elevated no higher than heart level (Chart 67-2). If pressure is not relieved and circulation is not restored, a **fasciotomy** may be necessary to relieve the pressure within the muscle compartment. The nurse closely monitors the patient's response to conservative and surgical management of compartment syndrome. The nurse records neurovascular responses and promptly reports changes to the physician.

#### Pressure Ulcers

Pressure of the cast on soft tissues may cause tissue anoxia and pressure ulcers. Lower extremity sites most susceptible to pressure

are the heel, malleoli, dorsum of the foot, head of the fibula, and anterior surface of the patella. The main pressure sites on the upper extremity are located at the medial epicondyle of the humerus and the ulnar styloid (see Fig. 67-1).

Usually, the patient with a pressure ulcer reports pain and tightness in the area. A warm area on the cast suggests underlying tissue erythema. The area may break down. The drainage may stain the cast and emit an odor. Even if discomfort does not occur with tissue breakdown and necrosis, there may still be extensive loss of tissue. The nurse must monitor the patient with a cast for pressure ulcer development and report findings to the physician.

To inspect the pressure area, the physician may bivalve the cast or cut an opening (window) in the cast. If the physician elects to create a window to inspect the pressure site, a portion of the cast is cut out. The affected area is inspected and possibly treated. The portion of the cast is replaced and held in place by an elastic compression dressing or tape. This prevents the underlying tissue from swelling through the window and creating pressure areas around its margins.

#### Disuse Syndrome

While in a cast, the patient needs to learn to tense or contract muscles (eg, isometric muscle contraction) without moving the part. This helps to reduce muscle atrophy and maintain muscle strength. The nurse teaches the patient with a leg cast to “push down” the knee and teaches the patient in an arm cast to “make a fist.” Muscle-setting exercises (eg, quadriceps-setting and gluteal-setting exercises) are important in maintaining muscles essential for walking (Chart 67-3). Isometric exercises should be performed hourly while the patient is awake.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching the Patient Self-Care

Self-care deficits occur when a portion of the body is immobilized. The nurse encourages the patient to participate actively in personal care and to use assistive devices safely. The nurse must assist the patient in identifying areas of self-care deficit and in developing strategies to achieve independence in activities of daily living (ADLs) (Chart 67-4). The patient's participation in

Chart 67-2

#### GUIDELINES FOR BIVALVING A CAST

When cutting a cast in half (bivalving), the physician or nurse practitioner proceeds as follows:

1. With a cast cutter, a longitudinal cut is made to divide the cast in half.
2. The underpadding is cut with scissors.
3. The cast is spread apart with cast spreaders to relieve pressure and to inspect and treat the skin without interrupting the reduction and alignment of the bone.
4. After the pressure is relieved, the anterior and posterior parts of the cast are secured together with an elastic compression bandage to maintain immobilization.
5. To control swelling and promote circulation, the extremity is elevated (but no higher than heart level, to minimize the effect of gravity on perfusion of the tissues).

Chart 67-3

#### Muscle-Setting Exercises

Isometric contractions of the muscle maintain muscle mass and strength and prevent atrophy.

##### Quadriceps-Setting Exercise

- Position patient supine with leg extended.
- Instruct patient to push knee back onto the mattress by contracting the anterior thigh muscles.
- Encourage patient to hold the position for 5 to 10 seconds.
- Let patient relax.
- Have the patient repeat the exercise 10 times each hour when awake.

##### Gluteal-Setting Exercise

- Position the patient supine with legs extended, if possible.
- Instruct the patient to contract the muscles of the buttocks.
- Encourage the patient to hold the contraction for 5 to 10 seconds.
- Let the patient relax.
- Have the patient repeat the exercise 10 times each hour when awake.

Chart 67-4

## Home Care Checklist • The Patient With a Cast

At the completion of the home care teaching program, the patient or caregiver will be able to:

	Patient	Caregiver
• Describe techniques to promote cast drying (eg, do not cover, leave exposed to circulating air; handle damp plaster cast with palms of hands and do not rest the cast on hard surfaces or sharp edges that can dent soft cast)	✓	✓
• Describe approaches to controlling swelling and pain (eg, elevate casted extremity to heart level, apply intermittent ice bag if prescribed, take analgesics as prescribed)	✓	✓
• Report pain uncontrolled by elevating the casted limb and by analgesics (may be an indicator of impaired tissue perfusion—compartment syndrome or pressure ulcer)	✓	
• Demonstrate ability to transfer (eg, from a bed to a chair)	✓	
• Use mobility aids safely	✓	
• Avoid excessive use of injured extremity; observe prescribed weight-bearing limits	✓	
• Manage minor irritations from cast (eg, for skin irritation from cast edge, pad rough edges with tape; to relieve itching, blow cool air from hair drier)	✓	✓
• Demonstrate exercises to promote circulation and minimize disuse syndrome	✓	
• State indicators of complications to report promptly to physician (eg, uncontrolled swelling and pain; cool, pale fingers or toes; paresthesia; paralysis; purulent drainage staining casts; signs of systemic infection; cast breaks)	✓	✓
• Describe care of extremity following cast removal (eg, skin care; gradual resumption of normal activities to protect limb from undue stresses; management of swelling)	✓	✓

planning and accomplishing ADLs is an important aspect of self-care, independence, maintaining control, and avoiding untoward psychological reactions, such as depression.

When the cast is dry, the nurse instructs the patient as follows:

- Move about as normally as possible, but avoid excessive use of the injured extremity and avoid walking on wet, slippery floors or sidewalks.
- Perform prescribed exercises regularly, as scheduled.
- Elevate the casted extremity to heart level frequently to prevent swelling.
- Do not attempt to scratch the skin under the cast. This may cause a break in the skin and result in the formation of a skin ulcer. Cool air from a hair dryer may alleviate an itch.
- Cushion rough edges of the cast with tape.
- Keep the cast dry but do not cover it with plastic or rubber, because this causes condensation, which dampens the cast and skin. Moisture softens a plaster cast. (A wet fiberglass cast must be dried thoroughly with a hair dryer on a cool setting to avoid skin problems.)
- Report any of the following to the physician: persistent pain, swelling that does not respond to elevation, changes in sensation, decreased ability to move exposed fingers or toes, and changes in skin color and temperature.
- Note odors around the cast, stained areas, warm spots, and pressure areas. Report them to the physician.
- Report a broken cast to the physician; do not attempt to fix it yourself.

The nurse prepares the patient for cast removal or cast changes by explaining what to expect (Chart 67-5). The cast is cut with a cast cutter, which vibrates. The patient can feel the vibration and pressure during its use. The cutter does not penetrate deeply enough to hurt the patient's skin. The cast padding is cut with scissors.

The casted body part is weak from disuse, is stiff, and may appear atrophied. There may be extreme stiffness even after only a few weeks of immobilization. Therefore, support is needed when the cast is removed. The skin, which is usually dry and scaly from accumulated dead skin, is vulnerable to injury from scratching.

The skin needs to be washed gently and lubricated with an emollient lotion.

The nurse and physical therapist teach the patient to resume activities gradually within the prescribed therapeutic regimen. Exercises that are prescribed to help the patient regain joint motion are explained and demonstrated. Because the muscles are weak from disuse, the body part that has been casted cannot withstand normal stresses immediately. In addition, the nurse teaches the patient who has noticeable swelling of the affected extremity after the cast is removed to continue to elevate the extremity to control swelling until normal muscle tone and use are reestablished.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Understands the therapeutic regimen
  - a. Elevates affected extremity
  - b. Exercises according to instructions
  - c. Keeps cast dry
  - d. Reports any problems that develop
  - e. Keeps follow-up clinic or physician appointments
2. Reports less pain
  - a. Elevates extremity that is in the cast
  - b. Repositions self
  - c. Uses occasional oral analgesic
3. Demonstrates increased mobility
  - a. Uses assistive devices safely
  - b. Exercises to increase strength
  - c. Changes position frequently
  - d. Performs range-of-motion exercises of joints not in the cast
4. Exhibits healing of abrasions and lacerations
  - a. Demonstrates no local signs of infection (ie, local discomfort, purulent drainage, cast staining, or odor from cast)
  - b. Demonstrates no systemic signs or symptoms of infection
  - c. Demonstrates intact skin when cast is removed

Chart 67-5

## GUIDELINES FOR Removing a Cast

When removing a cast, the physician or nurse practitioner proceeds as follows:

PROCEDURE	RATIONALE
1. Inform the patient about the procedure.	1. Facilitates cooperation and reduces fear about the procedure.
2. Reassure patient that the electric saw or cast cutter will not cut skin.	2. Reduces anxiety. (Explains that blade oscillates to cut cast and vibrations will be felt.)
3. Wear eye protection (patient and operator of the cast cutter).	3. Protects eyes from flying cast particles.
4. Bivalve cast using a series of alternating pressures and linear movements of blade along the line to be cut.	4. Cuts cast in halves. Avoids burning sensation from prolonged contact of oscillating blade with padding.
5. Cut padding with scissors.	5. Releases all of the casting materials.
6. Support body part as it is removed from the cast.	6. Reduces stresses on body part that has been immobilized.
7. Gently wash and dry area that has been immobilized.* Apply emollient lotion.	7. Removes dead skin that has accumulated during immobilization. Keeps skin supple.
8. Teach patient to avoid rubbing and scratching skin.	8. Prevents skin breakdown.
9. Collaborates with physical therapist to teach patient to resume active use of body part gradually within the guidelines of prescribed therapeutic regimen.	9. Protects weakened part from excessive stress. Progressive exercises reduce stiffness, restore muscle strength and function.
10. Teach patient to control swelling by elevating the extremity or using elastic bandage if prescribed.	10. Facilitates circulation (ie, venous return) and controls fluid pooling.

\*If a new cast is to be applied, follow guidelines for application of a cast and associated nursing care.

5. Maintains adequate neurovascular function of affected extremity
  - a. Exhibits normal skin color and temperature
  - b. Experiences minimal swelling
  - c. Exhibits satisfactory capillary refill on testing
  - d. Demonstrates active movement of fingers or toes if they are not casted
  - e. Reports normal sensations in casted body part
  - f. Reports that pain is controllable
6. Exhibits absence of complications
  - a. Demonstrates normal neurovascular status of casted extremity
  - b. Develops no pressure ulcers
  - c. Exhibits minimal muscle wasting
7. Participates in self-care activities
  - a. Performs hygiene and grooming activities independently or with minimal assistance
  - b. Performs ADLs independently or with minimal assistance
  - c. Adheres to prescribed exercise regimen.

A **sling** may be used when the patient ambulates. To prevent pressure on the cervical spinal nerves, the sling should distribute the supported weight over a large area and not on the back of the neck. The nurse encourages the patient to remove the arm from the sling and elevate it frequently.

Circulatory disturbances in the hand may become apparent with signs of cyanosis, swelling, and an inability to move the fingers. One serious effect of impaired circulation in the arm is Volkmann's contracture, a form of compartment syndrome. Contracture of the fingers and wrist occurs as the result of obstructed arterial blood flow to the forearm and hand. The patient is unable to extend the fingers, describes abnormal sensation (eg, unrelenting pain, pain on passive stretch), and exhibits signs of diminished circulation to the hand. Permanent damage develops within a few hours if action is not taken.

This serious complication can be prevented with nursing surveillance and proper care. The nurse makes frequent neurovascular checks (see Chap. 66). Compartment syndrome is managed in part by bivalving (cutting) the cast to release constricting cast and dressings. A fasciotomy may be necessary to improve vascular status.

## Specific Cast Management Considerations

### ARM CASTS

The patient whose arm is immobilized in a cast must readjust to many routine tasks. The unaffected arm must assume all the upper extremity activities. The nurse, in consultation with an occupational therapist, suggests devices designed to aid one-handed activities. The patient may experience fatigue due to modified activities and the weight of the cast. Frequent rest periods are necessary.

### Nursing Interventions

To control swelling, the nurse elevates the immobilized arm. When the patient is lying down, the arm is elevated so that each joint is positioned higher than the preceding proximal joint (eg, elbow higher than the shoulder, hand higher than the elbow).

### LEG CASTS

The application of a leg cast imposes a degree of immobility on the patient. The cast may be a short leg cast, extending to the knee, or a long leg cast, extending to the groin. The fresh cast must be handled in a manner that will not cause denting or disruption of the cast.

### Nursing Interventions

The nurse supports the patient's leg on pillows to heart level to control swelling and applies ice packs as prescribed over the fracture site for 1 or 2 days. The patient is taught to elevate the casted leg when seated. The patient should also assume a recumbent position several times a day with the casted leg elevated to promote venous return and control swelling.

The nurse assesses circulation by observing the color, temperature, and capillary refill of the exposed toes. Nerve function is

assessed by observing the patient's ability to move the toes and by asking about the sensations in the foot. Numbness, tingling, and burning may be caused by peroneal nerve injury from pressure at the head of the fibula.

**NURSING ALERT** Injury to the peroneal nerve as a result of pressure is a cause of footdrop (the inability to maintain the foot in a normally flexed position). Consequently, the patient drags the foot when ambulating.

When the cast is hard and dry, the nurse teaches the patient how to transfer and ambulate safely with assistive devices (eg, crutches, walker). The gait to be used depends on whether the patient is permitted to bear weight. If weight bearing is allowed, the cast is reinforced to withstand the body weight. A cast boot, worn over the casted foot, provides a broad, nonskid walking surface.

## BODY OR SPICA CASTS

Casts that encase the trunk (body cast) and portions of one or two extremities (spica cast) require special nursing strategies. Body casts are used to immobilize the spine. Hip spicas are used for some femoral fractures and after some hip joint surgeries, and shoulder spica casts are used for some humeral neck fractures.

### Nursing Interventions

Nursing responsibilities include preparing and positioning the patient, assisting with skin care and hygiene, and monitoring for **cast syndrome**. Explaining the procedure helps reduce the patient's apprehension about being encased in a large cast. The nurse reassures the patient that several people will provide care during the application, that support for the injured area will be adequate, and that care providers will be as gentle as possible. Medications for pain relief and relaxation administered before the procedure enable the patient to cooperate during application of the cast.

Cracking or denting of the cast is prevented by supporting the patient on a firm mattress and with flexible, waterproof pillows until the cast dries. The nurse positions the pillows next to each other, because spaces between pillows allow the damp cast to sag, become weak, and possibly break. A pillow is not placed under the head and shoulders of a patient in a body cast while the cast is drying, because doing so causes pressure on the chest.

The nurse turns the patient as a unit toward the uninjured side every 2 hours to relieve pressure and to allow the cast to dry. It is important to avoid twisting the patient's body within the cast. Sufficient personnel (at least three people) are needed when the patient is turned so that the fresh cast can be adequately supported with the palms of the hands at vulnerable points (ie, body joints) to prevent cracking. The nurse encourages the patient to assist in the repositioning, if not contraindicated, by use of the **trapeze** or bed rail. A stabilizing abduction bar incorporated into a spica cast should not be used as a turning device. The nurse adjusts the pillows to provide support without creating areas of pressure.

The nurse turns the patient to a prone position, twice daily if tolerated, to provide postural drainage of the bronchial tree and to relieve pressure on the back. A small pillow under the abdomen enhances comfort. The nurse can either place a pillow lengthwise under the dorsa of the feet or allow the toes to hang over the edge of the bed to prevent the toes from being forced into the mattress.

The nurse inspects the skin around the edges of the cast frequently for signs of irritation. The nurse can inspect some of the skin under the cast by pulling the skin taut and using a flashlight.

The skin can be bathed and massaged by reaching under the cast edges with the fingers.

The perineal opening must be large enough for hygienic care. To protect the cast from soiling, the nurse can insert clean dry plastic sheeting under the cast and over the cast edge before elimination by the patient. Usually, fracture bedpans are easier for patients with a hip spica cast to use than regular bedpans.

Patients immobilized in large casts may develop cast syndrome—psychological and physiologic responses to the confinement. The psychological component is similar to a claustrophobic reaction. The patient exhibits an acute anxiety reaction characterized by behavioral changes and autonomic responses (eg, increased respiratory rate, diaphoresis, dilated pupils, increased heart rate, elevated blood pressure). The nurse needs to recognize the anxiety reaction and provide an environment in which the patient feels secure.

The physiologic cast syndrome responses (superior mesenteric artery syndrome) are associated with immobility in a body cast. With decreased physical activity, gastrointestinal motility decreases, intestinal gases accumulate, intestinal pressure increases, and ileus may occur. The patient exhibits abdominal distention, abdominal discomfort, nausea, and vomiting. As with other instances of adynamic ileus, the patient is treated conservatively with decompression (nasogastric intubation connected to suction) and intravenous fluid therapy until gastrointestinal motility is restored. If the cast restricts the abdomen, the abdominal window must be enlarged. After the ileus resolves and bowel sounds resume, the patient gradually resumes an oral diet. Rarely, the distention places traction on the superior mesenteric artery, reducing the blood supply to the bowel. The bowel may become gangrenous, which requires surgical intervention. The nurse monitors the patient in a large body cast for potential cast syndrome, noting bowel sounds every 4 to 8 hours, and reports distention, nausea, and vomiting to the physician.

The patient with a body or spica cast is often cared for in the home. The nurse teaches family members how to care for the patient, which includes providing hygienic and skin care, ensuring proper positioning, preventing complications, and recognizing symptoms that should be reported to the health care provider.

## Managing the Patient With Splints and Braces

Contoured **splints** of plaster or pliable thermoplastic materials may be used for conditions that do not require rigid immobilization, for those in which swelling may be anticipated, and for those that require special skin care. The splint needs to immobilize and support the body part in a functional position. The splint must be well padded to prevent pressure, skin abrasion, and skin breakdown. The splint is overwrapped with an elastic bandage applied in a spiral fashion and with pressure uniformly distributed so that the circulation is not restricted. The nurse frequently assesses the neurovascular status and skin integrity of the splinted extremity.

Soft immobilizers may be used to support an injured body part. Usually, the extremity is wrapped with an elastic bandage and then secured in a padded, contoured, canvas immobilizer. Rigid immobilization is not achieved. The nurse provides skin care and makes adjustments for swelling.

For long-term use, **braces** (orthoses) are used to provide support, control movement, and prevent additional injury. They are custom fitted to various parts of the body. Braces may be constructed of plastic materials, canvas, leather, or metal. The orthotist adjusts the brace for fit, positioning, and motion.

The nurse helps the patient learn to apply the brace and to protect the skin from irritation and breakdown. The nurse also assesses neurovascular integrity and comfort when the patient is

wearing the brace, encourages the patient to wear the brace as prescribed, and reassures the patient that minor adjustments of the brace by the orthotist will increase comfort and minimize problems associated with its long-term use.

## Managing the Patient With an External Fixator

**External fixators** are used to manage open fractures with soft tissue damage. They provide stable support for severe comminuted (crushed or splintered) fractures while permitting active treatment of damaged soft tissues (Fig. 67-2). Complicated fractures of the humerus, forearm, femur, tibia, and pelvis are managed with external skeletal fixators. The fracture is reduced, aligned, and immobilized by a series of pins inserted in the bone. Pin position is maintained through attachment to a portable frame. The fixator facilitates patient comfort, early mobility, and active exercise of adjacent uninvolved joints. Complications related to disuse and immobility are minimized.

### Nursing Interventions

It is important to prepare the patient psychologically for application of the external fixator. The apparatus looks clumsy and foreign. Reassurance that the discomfort associated with the device

is minimal and that early mobility is anticipated promotes acceptance of the device.

After the external fixator is applied, the extremity is elevated to reduce swelling. If there are sharp points on the fixator or pins, they are covered to prevent device-induced injuries. The nurse monitors the neurovascular status of the extremity every 2 to 4 hours and assesses each pin site for redness, drainage, tenderness, pain, and loosening of the pin. Some serous drainage from the pin sites is to be expected. The nurse must be alert for potential problems caused by pressure from the device on the skin, nerves, or blood vessels and for the development of compartment syndrome (see Chap. 69). The nurse carries out pin care as prescribed to prevent pin tract infection. This typically includes cleaning each pin site separately three times a day with cotton-tipped applicators soaked in sterile saline solution. Crusts should not form at the pin site. If signs of infection are present or if the pins or clamps seem loose, the nurse notifies the physician.

**NURSING ALERT** The nurse never adjusts the clamps on the external fixator frame. It is the physician's responsibility to do so.

The nurse encourages isometric and active exercises within the limits of tissue damage. When the swelling subsides, the nurse helps the patient to become mobile within the prescribed weight-bearing limits (non-weight bearing to full weight bearing). Adherence to weight-bearing instructions minimizes the chance of loosening of the pins when stress is applied to the bone-pin interface. The fixator is removed after the soft tissue heals. The fracture may require additional stabilization by a cast or molded orthosis while healing.

The Ilizarov external fixator is a special device used to correct angulation and rotational defects, to treat nonunion (failure of bone fragments to heal), and to lengthen limbs. Tension wires are attached to fixator rings, which are joined by telescoping rods. Bone formation is stimulated by prescribed daily adjustment of the telescoping rods. It is important to teach the patient how to adjust the telescoping rods and how to perform skin care. Generally, the nurse can encourage weight bearing. After the desired correction has been achieved, no additional adjustments are made, and the fixator is left in place until the bone heals.

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching the Patient Self-Care.** The nurse teaches the patient to perform pin site care according to the prescribed protocol (clean technique can be used at home [McKenzie, 1999]) and to report promptly any signs of pin site infection: redness, tenderness, increased or purulent pin site drainage, or fever. The nurse also instructs the patient and family to monitor neurovascular status and report any changes promptly. The nurse teaches the patient or family member to check the integrity of the fixator frame daily and to report loose pins or clamps. A physical therapy referral is helpful in teaching the patient how to transfer, use ambulatory aids safely, and adjust to weight-bearing limits and altered gait patterns (Chart 67-6).

## Managing the Patient in Traction

**Traction** is the application of a pulling force to a part of the body. Traction is used to minimize muscle spasms; to reduce, align, and immobilize fractures; to reduce deformity; and to increase space between opposing surfaces. Traction must be applied in the cor-

**FIGURE 67-2** External fixation device. Pins are inserted into bone. The fracture is reduced and aligned and then stabilized by attaching the pins to a rigid portable frame. The device facilitates treatment of soft tissue damaged in complex fractures.

## Chart 67-6

## Home Care Checklist • The Patient With an External Fixator

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Demonstrate prescribed pin site care	✓	✓
• State signs of pin site infection (eg, redness, tenderness, increased or purulent pin site drainage) to be reported promptly	✓	✓
• Describe approaches to controlling swelling and pain (eg, elevate extremity to heart level, take analgesics as prescribed)	✓	✓
• Report pain uncontrolled by elevation and analgesics (may be an indicator of impaired tissue perfusion, compartment syndrome, or pin tract infection)	✓	
• Demonstrate ability to transfer	✓	
• Use mobility aids safely	✓	
• Avoid excessive use of injured extremity; observe prescribed weight-bearing limits	✓	
• State indicators of complications to report promptly to physician (eg, uncontrolled swelling and pain; cool, pale fingers or toes; paresthesia; paralysis; purulent drainage; signs of systemic infection; loose fixator pins or clamps)	✓	✓
• Describe care of extremity after fixator removal (eg, gradual resumption of normal activities to protect limb from undue stresses)	✓	✓

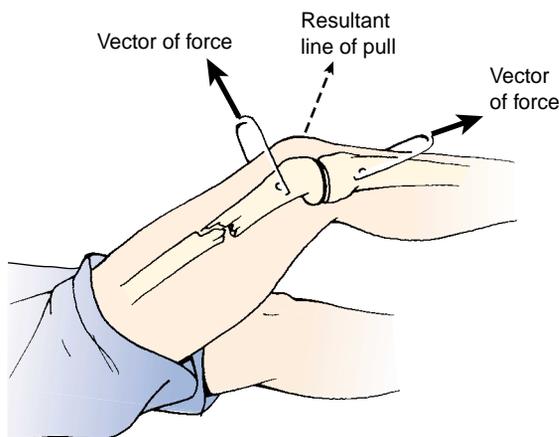

rect direction and magnitude to obtain its therapeutic effects. As muscle and soft tissues relax, the amount of weight used may be changed to obtain the desired effect.

At times, traction needs to be applied in more than one direction to achieve the desired line of pull. When this is done, one of the lines of pull counteracts the other. These lines of pull are known as the vectors of force. The actual resultant pulling force is somewhere between the two lines of pull (Fig. 67-3). The effects of traction are evaluated with x-ray studies, and adjustments are made if necessary.

Traction is used primarily as a short-term intervention until other modalities, such as external or internal fixation, are possible. This reduces the risk of disuse syndrome and minimizes the length of hospitalization, often allowing the patient to be cared for in the home setting.

## PRINCIPLES OF EFFECTIVE TRACTION

Whenever traction is applied, countertraction must be used to achieve effective traction. Countertraction is the force acting in

**FIGURE 67-3** Traction may be applied in different directions to achieve the desired therapeutic line of pull. Adjustments in applied forces may be prescribed over the course of treatment.

the opposite direction. Usually, the patient's body weight and bed position adjustments supply the needed countertraction.

**NURSING ALERT** Countertraction must be maintained for effective traction.

The following are additional principles to follow when caring for the patient in traction:

- Traction must be continuous to be effective in reducing and immobilizing fractures.
- Skeletal traction is *never* interrupted.
- Weights are not removed unless intermittent traction is prescribed.
- Any factor that might reduce the effective pull or alter its resultant line of pull must be eliminated:
  - The patient must be in good body alignment in the center of the bed when traction is applied.
  - Ropes must be unobstructed.
  - Weights must hang free and not rest on the bed or floor.
  - Knots in the rope or the footplate must not touch the pulley or the foot of the bed.

There are several types of traction. *Straight* or *running traction* applies the pulling force in a straight line with the body part resting on the bed. Buck's extension traction (Fig. 67-4) is an example of straight traction. *Balanced suspension traction* (Fig. 67-5) supports the affected extremity off the bed and allows for some patient movement without disruption of the line of pull.

Traction may be applied to the skin (*skin traction*) or directly to the bony skeleton (*skeletal traction*). The mode of application is determined by the purpose of the traction. Traction can be applied with the hands (*manual traction*). This is temporary traction that may be used when applying a cast, giving skin care under a Buck's extension foam boot, or adjusting the traction apparatus.

## SKIN TRACTION

Skin traction is used to control muscle spasms and to immobilize an area before surgery. Skin traction is accomplished by using a weight to pull on traction tape or on a foam boot attached to the skin. The amount of weight applied must not exceed the toler-

**FIGURE 67-4** Buck's extension traction. Lower extremity in unilateral Buck's extension traction is aligned in a foam boot and traction applied by the free-hanging weight.

ance of the skin. No more than 2 to 3.5 kg (4.5 to 8 lb) of traction can be used on an extremity. Pelvic traction is usually 4.5 to 9 kg (10 to 20 lb), depending on the weight of the patient.

Types of skin traction used for adults include Buck's extension traction (applied to the lower leg), the cervical head halter (occasionally used to treat neck pain), and the pelvic belt (sometimes used to treat back pain).

### Buck's Extension Traction

Buck's extension traction (unilateral or bilateral) is skin traction to the lower leg. The pull is exerted in one plane when partial or temporary immobilization is desired (see Fig. 67-4). It is used to provide immobility after fractures of the proximal femur before surgical fixation.

Before the traction is applied, the nurse inspects the skin for abrasions and circulatory disturbances. The skin and circulation must be in healthy condition to tolerate the traction. The extremity should be clean and dry before the foam boot or traction tape is applied.

To apply Buck's traction, one nurse elevates and supports the extremity under the patient's heel and knee while another nurse

places the foam boot under the leg, with the patient's heel in the heel of the boot. Next, the nurse secures Velcro straps around the leg. Traction tape overwrapped with elastic bandage in a spiral fashion may be used instead of the boot. Excessive pressure is avoided over the malleolus and proximal fibula during application to prevent pressure ulcers and nerve damage. The nurse then passes the rope affixed to the spreader or footplate over a pulley fastened to the end of the bed and attaches the weight—usually 5 to 8 pounds—to the rope.

### Potential Complications

Skin breakdown, nerve pressure, and circulatory impairment are complications that may develop as a result of skin traction. Skin breakdown results from irritation caused by contact of the skin with the tape or foam and shearing forces. Older adults are at greater risk for this complication because of their sensitive, fragile skin.

Nerve pressure results from pressure on the peripheral nerves. Footdrop may occur if pressure is applied to the peroneal nerve at the point at which it passes around the neck of the fibula just below the knee.

Circulatory impairment is manifested by cold skin temperature, decreased peripheral pulses, slow capillary refill time, and bluish skin. Deep vein thrombosis (DVT), a serious circulatory impairment, is manifested by calf tenderness, swelling, and a positive Homans' sign (see Chap. 31).

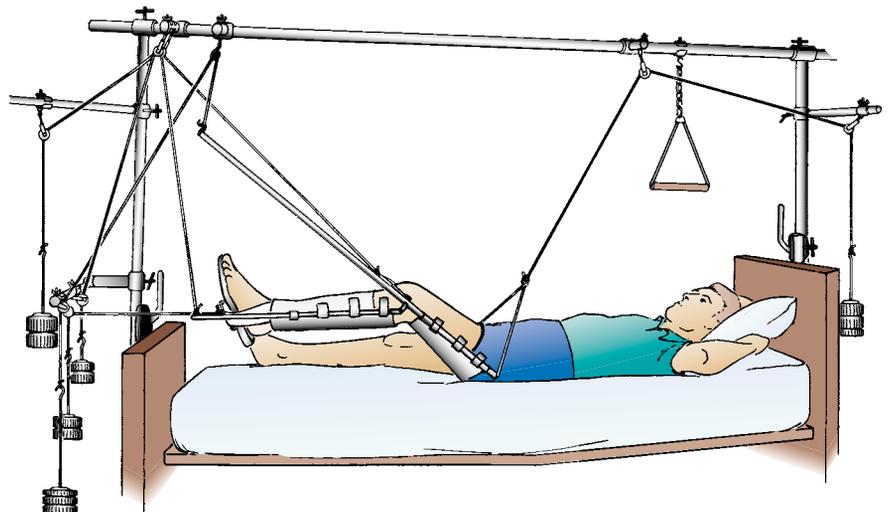

### Nursing Interventions

#### ENSURING EFFECTIVE TRACTION

To ensure effective skin traction, it is important to avoid wrinkling and slipping of the traction bandage and to maintain countertraction. Proper positioning must be maintained to keep the leg in a neutral position. To prevent bony fragments from moving against one another, the patient should not turn from side to side; however, the patient may shift position slightly with assistance.

#### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

**Skin Breakdown.** During the initial assessment, the nurse identifies sensitive, fragile skin (common in older adults). The nurse also closely monitors the reaction of the skin in contact with tape or foam to ensure that shearing forces are avoided. The nurse per-

**FIGURE 67-5** Balanced suspension skeletal traction with Thomas leg splint. The patient can move vertically as long as the resultant line of pull is maintained.

forms the following procedures to monitor and prevent skin breakdown:

- Removes the foam boots to inspect the skin, the ankle, and the Achilles tendon three times a day. A second nurse is needed to support the extremity during the inspection and skin care.
- Palpates the area of the traction tapes daily to detect underlying tenderness.
- Provides back care at least every 2 hours to prevent pressure ulcers. The patient who must remain in a supine position is at increased risk for development of a pressure ulcer.
- Uses special mattress overlays (eg, air-filled, high-density foam) to minimize the development of skin ulcers.

**Nerve Pressure.** Skin traction can place pressure on peripheral nerves. When traction is applied to the lower extremity, care must be taken to avoid pressure on the peroneal nerve at the point at which it passes around the neck of the fibula just below the knee. Pressure at this point can cause footdrop. The nurse questions the patient about sensation and asks the patient to move the toes and foot. Dorsiflexion of the foot demonstrates function of the peroneal nerve. Weakness of dorsiflexion or foot movement and inversion of the foot might indicate pressure on the common peroneal nerve. Plantar flexion demonstrates function of the tibial nerve.

The following are important points to keep in mind when caring for the patient in traction:

- Regularly assess sensation and motion.
- Immediately investigate any complaint of burning sensation under the traction bandage or boot.
- Promptly report altered sensation or motor function.

**Circulatory Impairment.** After skin traction is applied, the nurse assesses circulation of the foot or hand within 15 to 30 minutes and then every 1 to 2 hours. Circulatory assessment consists of the following:

- Peripheral pulses, color, capillary refill, and temperature of the fingers or toes
- Indicators of DVT, including calf tenderness, swelling, and a positive Homans' sign

The nurse also encourages the patient to perform active foot exercises every hour when awake.

## SKELTAL TRACTION

Skeletal traction is applied directly to the bone. This method of traction is used occasionally to treat fractures of the femur, the tibia, and the cervical spine. The traction is applied directly to the bone by use of a metal pin or wire (eg, Steinmann pin, Kirschner wire) that is inserted through the bone distal to the fracture, avoiding nerves, blood vessels, muscles, tendons, and joints. Tongs applied to the head (eg, Gardner-Wells or Vinke tongs) are fixed in the skull to apply traction that immobilizes cervical fractures.

The orthopedic surgeon applies skeletal traction, using surgical asepsis. The insertion site is prepared with a surgical scrub agent such as povidone-iodine solution. A local anesthetic is administered at the insertion site and periosteum. The surgeon makes a small skin incision and drills the sterile pin or wire through the bone. The patient feels pressure during this procedure and possibly some pain when the periosteum is penetrated.

After insertion, the pin or wire is attached to the traction bow or caliper. The ends of the wire are covered with corks or tape to prevent injury to the patient or caregivers. The weights are attached to the pin or wire bow by a rope-and-pulley system that exerts the appropriate amount and direction of pull for effective traction. Skeletal traction frequently uses 7 to 12 kg (15 to 25 lb) to achieve the therapeutic effect. The weights applied initially must overcome the shortening spasms of the affected muscles. As the muscles relax, the traction weight is reduced to prevent fracture dislocation and to promote healing.

Often, skeletal traction is balanced traction, which supports the affected extremity, allows for some patient movement, and facilitates patient independence and nursing care while maintaining effective traction. The Thomas splint with a Pearson attachment is frequently used with skeletal traction for fractures of the femur (see Fig. 67-5). Because upward traction is required, an overbed frame is used.

When skeletal traction is discontinued, the extremity is gently supported while the weights are removed. The pin is cut close to the skin and removed by the physician. Internal fixation, casts, or splints are then used to immobilize and support the healing bone.

## Nursing Interventions

### MAINTAINING EFFECTIVE TRACTION

When skeletal traction is used, the nurse checks the apparatus to see that the ropes are in the wheel grooves of the pulleys, that the ropes are not frayed, that the weights hang free, and that the knots in the rope are tied securely. The nurse also evaluates the patient's position, because slipping down in bed results in ineffective traction.

**NURSING ALERT** The nurse must never remove weights from skeletal traction unless a life-threatening situation occurs. Removal of the weights completely defeats their purpose and may result in injury to the patient.

### MAINTAINING POSITIONING

The nurse must maintain alignment of the patient's body in traction as prescribed to promote an effective line of pull. The nurse positions the patient's foot to avoid footdrop (plantar flexion), inward rotation (inversion), and outward rotation (eversion). The patient's foot may be supported in a neutral position by orthopedic devices (eg, foot supports).

### PREVENTING SKIN BREAKDOWN

The patient's elbows frequently become sore, and nerve injury may occur if the patient repositions by pushing on the elbows. In addition, patients frequently push on the heel of the unaffected leg when they raise themselves. This digging of the heel into the mattress may injure the tissues. Therefore, the nurse should protect the elbows and heels and inspect them for pressure areas. To encourage movement without using the elbows or heel, the nurse can suspend a trapeze overhead within easy reach of the patient. This apparatus helps the patient to move about in bed and to move on and off the bedpan.

Specific pressure points are assessed for redness and skin breakdown. Areas that are particularly vulnerable to pressure caused by traction apparatus applied to the lower extremity include the ischial tuberosity, popliteal space, Achilles tendon, and heel. If the patient is not permitted to turn on one side or the other, the nurse must make a special effort to provide back care and to keep

the bed dry and free of crumbs and wrinkles. The patient can assist by holding the overhead trapeze and raising the hips off the bed. If the patient cannot do this, the nurse can push down on the mattress with one hand to relieve pressure on the back and bony prominences and to provide for some shifting of weight. A pressure-relieving air-filled or high-density foam mattress overlay may reduce the risk of pressure ulcer.

For change of bed linens, the patient raises the torso while nurses on both sides of the bed roll down and replace the upper mattress sheet. Then, as the patient raises the buttocks off the mattress, the nurses slide the sheets under the buttocks. Finally, the nurses replace the lower section of the bed linens while the patient rests on the back. Sheets and blankets are placed over the patient in such a way that the traction is not disrupted.

### MONITORING NEUROVASCULAR STATUS

The nurse assesses the neurovascular status of the immobilized extremity at least every hour initially and then every 4 hours. The nurse instructs the patient to report any changes in sensation or movement immediately so that they can be promptly evaluated. DVT is a significant risk for the immobilized patient. The nurse encourages the patient to do active flexion–extension ankle exercises and isometric contraction of the calf muscles (calf-pumping exercises) 10 times an hour while awake to decrease venous stasis. In addition, elastic stockings, compression devices, and anticoagulant therapy may be prescribed to help prevent thrombus formation.

Prompt recognition of a developing neurovascular problem is essential so that corrective measures can be instituted promptly.

### PROVIDING PIN SITE CARE

The wound at the pin insertion site requires attention. The goal is to avoid infection and development of **osteomyelitis**. Initially, the site is covered with a sterile dressing. Subsequent care of the pin site is individually prescribed and performed three times a day. The nurse must keep the area clean. Slight serous oozing at the pin site is expected, but crusting should be prevented. The nurse assesses the pin site and drainage for signs of infection, such as redness, tenderness, and purulent drainage. The patient may experience discomfort at the pin site due to traction on the skin caused by an unsupported muscle.

**NURSING ALERT** The nurse must inspect the pin site at least every 8 hours for signs of inflammation and evidence of infection.

### PROMOTING EXERCISE

Patient exercises, within the therapeutic limits of the traction, assist in maintaining muscle strength and tone and in promoting circulation. Active exercises include pulling up on the trapeze, flexing and extending the feet, and range-of-motion and weight-resistance exercises for noninvolved joints. Isometric exercises of the immobilized extremity (quadriceps-setting and gluteal-setting exercises) are important for maintaining strength in major ambulatory muscles (see Chart 67-3). Without exercise, the patient will lose muscle mass and strength, and rehabilitation will be greatly prolonged.

## NURSING PROCESS: THE PATIENT IN TRACTION

### Assessment

The nurse must consider the psychological and physiologic impact of the musculoskeletal problem, traction device, and immo-

bility. Traction restricts one's mobility and independence. The equipment often looks threatening, and its application can be frightening. Confusion, disorientation, and behavioral problems may develop in patients who are confined in a limited space for an extended time. Therefore, the nurse must assess and monitor the patient's anxiety level and psychological responses to traction.

It is important to evaluate the body part to be placed in traction and its neurovascular status (ie, color, temperature, capillary refill, edema, pulses, ability to move, and sensations) and compare it to the unaffected extremity. The nurse also assesses skin integrity along with body system functioning for baseline data. Ongoing assessment is indicated for the patient in traction. Immobility-related problems may include pressure ulcers, stasis pneumonia, constipation, loss of appetite, urinary stasis, urinary tract infections, and venous stasis. Early identification of preexisting or developing problems facilitates prompt interventions to resolve them.

## Diagnosis

### NURSING DIAGNOSES

Based on the nursing assessment, the patient's major nursing diagnoses related to traction may include the following:

- Deficient knowledge related to the treatment regimen
- Anxiety related to health status and the traction device
- Acute pain related to musculoskeletal disorder
- Self-care deficit: feeding, bathing/hygiene, dressing/grooming, and/or toileting related to traction
- Impaired physical mobility related to musculoskeletal disorder and traction

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include the following:

- Pressure ulcer
- Pneumonia
- Constipation
- Anorexia
- Urinary stasis and infection
- Venous stasis with DVT

## Planning and Goals

The major goals for the patient in traction may include understanding of the treatment regimen, reduced anxiety, maximum comfort, maximum level of self-care, maximum mobility within the therapeutic limits of traction, and absence of complications.

## Nursing Interventions

### PROMOTING UNDERSTANDING OF THE TREATMENT REGIMEN

The patient must understand the problem being treated and the rationale for the traction therapy. The nurse may need to repeat and reinforce the information. With increased understanding of the therapy, the patient becomes an active participant in health care.

### REDUCING ANXIETY

Before any traction is applied, the patient needs to be informed about the procedure, its purpose, and its implications. The nurse encourages the patient to participate in decisions that affect care.

Increasing the patient's sense of control reduces feelings of helplessness, allays apprehension, and fosters coping.

After being in traction for a while, the patient may react to being confined to a limited space. Frequent visits by the nurse can reduce feelings of isolation and confinement. The nurse should encourage family and friends to visit frequently for the same reason. The nurse encourages diversional activities that can be performed within the limits of the traction.

### ACHIEVING A MAXIMUM LEVEL OF COMFORT

Because the patient is immobilized in bed, the mattress needs to be firm. Special mattresses or mattress overlays designed to minimize the development of pressure ulcers may be placed on the bed before the traction is applied. The nurse can relieve pressure on dependent body parts by turning and positioning the patient for comfort within the limits of the traction and by making sure the bed linens remain wrinkle-free and dry.

**NURSING ALERT** The nurse must promptly investigate every complaint of discomfort expressed by the patient in traction.

### ACHIEVING MAXIMUM SELF-CARE

Initially, the patient may require assistance with self-care activities. The nurse helps the patient eat, bathe, dress, and toilet. Convenient arrangement of items such as telephone, tissues, water, and assistive devices (eg, reachers, overbed trapeze) may facilitate self-care. With resumption of self-care activities, the patient feels less dependent and less frustrated and experiences improved self-esteem.

Because some assistance is required throughout the period of immobility, the nurse and the patient can creatively develop routines that maximize the patient's independence.

### ATTAINING MAXIMUM MOBILITY WITH TRACTION

During traction therapy, the nurse encourages the patient to exercise muscles and joints that are not in traction to guard against their deterioration. The physical therapist can design bed exercises that minimize loss of muscle strength. During the patient's exercise, the nurse ensures that traction forces are maintained and that the patient is properly positioned to prevent complications resulting from poor alignment.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

#### Pressure Ulcers

The nurse examines the patient's skin frequently for evidence of pressure or friction, paying special attention to bony prominences. It is helpful to reposition the patient frequently and to use protective devices (eg, elbow protectors) to relieve pressure. If the risk of skin breakdown is high, as in a patient with multiple trauma or a debilitated elderly patient, use of a specialized bed is considered to prevent skin breakdown. If a pressure ulcer develops, the nurse consults with the physician and the wound care nurse specialist.

#### Pneumonia

The nurse auscultates the patient's lungs every 4 to 8 hours to determine respiratory status and teaches the patient deep-breathing and coughing exercises to aid in fully expanding the lungs and moving pulmonary secretions. If the patient history and baseline assessment indicate that the patient is at high risk for development of respiratory complications, specific therapies (eg, in-

centive spirometer) may be indicated. If a respiratory problem develops, prompt institution of prescribed therapy is needed.

#### Constipation and Anorexia

Reduced gastrointestinal motility results in constipation and anorexia. A diet high in fiber and fluids may help to stimulate gastric motility. If constipation develops, therapeutic measures might include stool softeners, laxatives, suppositories, and enemas. To improve the patient's appetite, the nurse identifies and includes the patient's food preferences, as appropriate, within the prescribed therapeutic diet.

#### Urinary Stasis and Infection

Incomplete emptying of the bladder related to positioning in bed can result in urinary stasis and infection. In addition, the patient may find use of the bedpan uncomfortable and may limit fluids to minimize the frequency of urination. The nurse monitors the fluid intake and the character of the urine. The nurse teaches the patient to consume adequate amounts of fluid and to void every 3 to 4 hours. If the patient exhibits signs or symptoms of urinary tract infection, the nurse notifies the physician.

#### Venous Stasis and Deep Vein Thrombosis

Venous stasis occurs with immobility. The nurse teaches the patient to perform ankle and foot exercises within the limits of the traction therapy every 1 to 2 hours when awake to prevent DVT, which may result from venous stasis. The patient is encouraged to drink fluids to prevent dehydration and associated hemoconcentration, which contribute to stasis. The nurse monitors the patient for signs of DVT, including calf tenderness, warmth, redness, swelling (increased calf circumference), and a positive Homans' sign (discomfort in the calf when the foot is forcibly dorsiflexed). The nurse promptly reports findings to the physician for definitive evaluation and therapy.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Demonstrates knowledge of traction regimen
  - a. Describes purpose of traction
  - b. Participates in plan of care
2. Exhibits reduced anxiety
  - a. Appears relaxed
  - b. Uses effective coping mechanisms
  - c. Expresses concerns and feelings
  - d. Engages in diversional activities
3. States increased level of comfort
  - a. Requests occasional oral analgesia
  - b. Repositions self frequently
4. Performs self-care activities
  - a. Requires minimal assistance with feeding, bathing/hygiene, dressing/grooming, and/or toileting
  - b. Uses assistive devices safely
5. Demonstrates increased mobility
  - a. Performs prescribed exercises
  - b. Repositions self within limits of traction
6. Experiences no complications
  - a. Has intact skin
  - b. Has clear lungs
  - c. Does not report shortness of breath
  - d. Does not have a productive cough
  - e. Exhibits a regular bowel evacuation pattern

- f. Has a normal appetite
- g. Voids clear, yellow, nonconcentrated urine of adequate amount
- h. Does not exhibit signs or symptoms of venous stasis

## Managing the Patient Undergoing Orthopedic Surgery

Many patients with musculoskeletal dysfunction undergo surgery to correct the problem. Problems that may be corrected by surgery include unstabilized fracture, deformity, joint disease, necrotic or infected tissue, and tumors. Frequent surgical procedures include **open reduction with internal fixation (ORIF)** and closed reduction with internal fixation (fracture fragments are not surgically exposed) for fractures; arthroplasty, meniscectomy, and joint replacement for joint problems; amputation for severe extremity problems (eg, gangrene, massive trauma); bone graft for joint stabilization, defect-filling, or stimulation of bone healing; and tendon transfer for improving motion. The goals include improving function by restoring motion and stability and relieving pain and disability. See Chart 67-7 for descriptions of orthopedic surgeries.

Joint surgery is one of the most frequently performed orthopedic surgeries. Joint disease or deformity may necessitate surgical intervention to relieve pain, improve stability, and improve function. Surgical procedures include excision of damaged and diseased tissue, repair of damaged structures (eg, ruptured tendon), removal of loose bodies (debridement), **arthroplasty** (replacement of all or part of the joint surfaces), and **arthrodesis** (immobilizing fusion of a joint).

The procedure is based on the patient's underlying orthopedic condition, general physical health, impact of joint disability on daily activities, and age. Timing of these procedures is important to ensure maximum function. Surgery should be performed before surrounding muscles become contracted and atrophied

Chart  
67-7

### Orthopedic Surgeries

**Open reduction:** the correction and alignment of the fracture after surgical dissection and exposure of the fracture

**Internal fixation:** the stabilization of the reduced fracture by the use of metal screws, plates, nails, and pins

**Arthroplasty:** the repair of joint problems through the operating arthroscope (an instrument that allows the surgeon to operate within a joint without a large incision) or through open joint surgery

**Hemiarthroplasty:** the replacement of one of the articular surfaces (eg, in a hip hemiarthroplasty, the femoral head and neck are replaced with a femoral prosthesis—the acetabulum is not replaced)

**Joint arthroplasty or replacement:** the replacement of joint surfaces with metal or synthetic materials

**Total joint arthroplasty or replacement:** the replacement of both articular surfaces within a joint with metal or synthetic materials

**Meniscectomy:** the excision of damaged joint fibrocartilage

**Amputation:** the removal of a body part

**Bone graft:** the placement of bone tissue (autologous or homologous grafts) to promote healing, to stabilize, or to replace diseased bone

**Tendon transfer:** the movement of tendon insertion to improve function

**Fasciotomy:** the incision and diversion of the muscle fascia to relieve muscle constriction, as in compartment syndrome, or to reduce fascia contracture

and serious structural abnormalities occur. The physician carefully evaluates the patient so that the most appropriate procedure is performed.

Because these are elective procedures, many patients donate their own blood during the weeks preceding their surgery. This blood is used to replace blood lost during surgery. Autologous blood transfusions eliminate many of the risks of transfusion therapy.

Also, during surgery blood is conserved to minimize loss. A pneumatic tourniquet may be applied after exsanguination of the limb with bandages to produce a “bloodless field.” Intraoperative blood salvage with reinfusion is used when a large volume of blood loss is anticipated. Postoperative blood salvage with intermittent autotransfusion also reduces the need for blood transfusion.

## JOINT REPLACEMENT

Patients with severe joint pain and disability may undergo joint replacement. Conditions contributing to joint degeneration include osteoarthritis (degenerative joint disease), rheumatoid arthritis, trauma, and congenital deformity. Some fractures (eg, femoral neck fracture) may cause disruption of the blood supply and subsequent **avascular necrosis**; management with joint replacement may be elected over ORIF. Joints frequently replaced include the hip, knee (Fig. 67-6), and finger joints. Less fre-

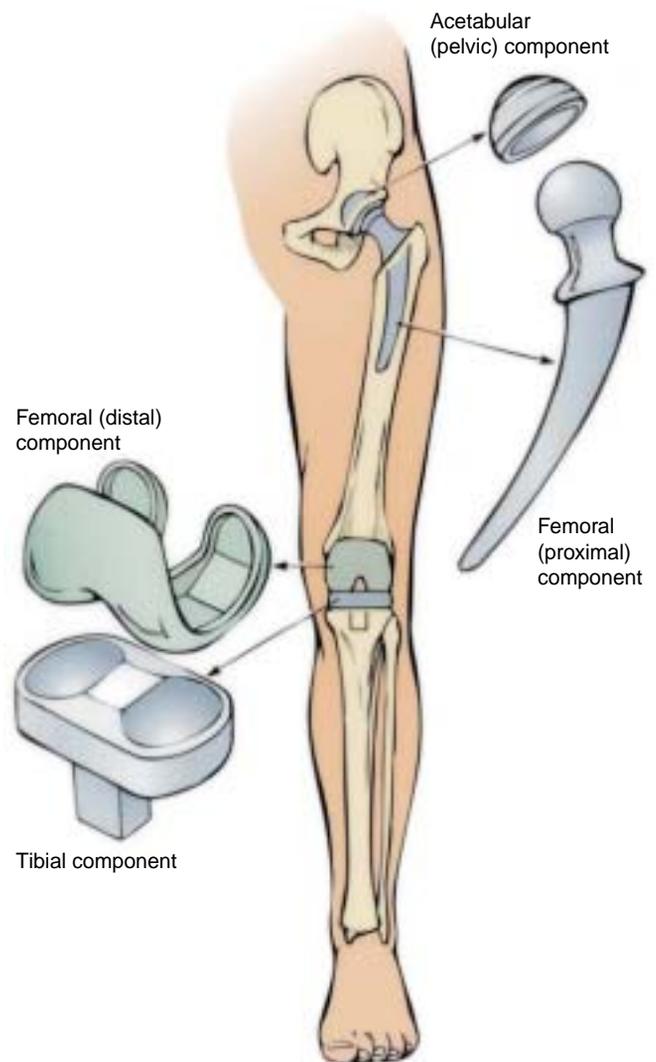

FIGURE 67-6 Examples of hip and knee replacement.

quently, more complex joints (shoulder, elbow, wrist, ankle) are replaced. The procedure is usually an elective one.

Most joint replacements consist of metal and high-density polyethylene components. Finger prostheses are usually Silastic. The joint implants may be cemented in the prepared bone with polymethyl methacrylate (PMMA), a bone-bonding agent that has properties similar to bone. Loosening of the prosthesis due to cement–bone interface failure is a common reason for prosthesis failure. Press-fit, ingrowth prostheses (porous-coated, cementless artificial joint components) that allow the patient's bone to grow into and securely fix the prosthesis in the bone are alternatives to cemented prostheses. Accurate fitting and the presence of healthy bone with adequate blood supply are important in the use of cementless components. Much progress has been made in reducing prosthesis failure rate through improved techniques, improved materials, and use of bone grafts.

With joint replacement, excellent pain relief is obtained in most patients. Return of motion and function depends on preoperative soft tissue condition, soft tissue reactions, and general muscle strength. Early failure of joint replacement is associated with excessive activity and preoperative joint and bone pathology.

## Nursing Interventions

Assessment of the patient and preoperative management are aimed at having the patient in optimal health at the time of surgery. Preoperatively, it is important to evaluate cardiovascular, respiratory, renal, and hepatic functions. Age, obesity, preoperative leg edema, history of DVT, and varicose veins increase the risk of postoperative DVT and pulmonary embolism. These are the most common causes of postoperative mortality for patients older than 60 years of age undergoing total hip replacement. Every effort is made to prevent these complications.

Preoperatively, it is important to assess the neurovascular status of the extremity undergoing joint replacement. Postoperative assessment data are compared with preoperative assessment data to identify changes and deficits. For example, an absent pulse postoperatively is of concern unless the pulse was also absent preoperatively. Nerve palsy could occur as a result of surgery.

## PREVENTING INFECTION

Preoperative assessment of the patient for infections, including urinary tract infection, is necessary because of the risk of postoperative infection. Any infection 2 to 4 weeks before planned surgery may result in postponement of surgery. Preoperative skin preparation frequently begins 1 or 2 days before the surgery. Airborne bacteria that contaminate the wound at the time of surgery cause most deep infections. Therefore, as with any surgery, there is strict adherence to aseptic principles and the operating area is controlled and made as bacteria free as possible.

Prophylactic antibiotics are administered perioperatively as a single preoperative or short perioperative course (Rosen et al., 1999). Culture of the joint during surgery, before intraoperative antibiotic therapy is begun, may be important in identifying and treating subsequent infections.

If osteomyelitis develops, it is difficult to treat. Persistent infection at the site of the prosthesis usually requires removal of the implant and joint revision, which is a complex procedure. Also, it is not always possible to achieve a functional joint when the reconstruction procedure has to be repeated.

## PROMOTING AMBULATION

Patients with total hip or total knee replacement begin ambulation with a walker or crutches within a day after surgery. The

nurse and the physical therapist assist the patient in achieving the goal of independent ambulation. At first, the patient may only be able to stand for a brief period because of orthostatic hypotension. Specific weight-bearing limits on the prosthesis are determined by the physician and are based on the patient's condition, the procedure, and the fixation method. Usually, patients with cemented prostheses can proceed to weight bearing as tolerated. If the patient has a press-fit, cementless, ingrowth prosthesis, weight bearing immediately after surgery may be limited to minimize micromotion of the prosthesis in the bone. As the patient is able to tolerate more activity, the nurse encourages transferring to a chair several times a day for short periods and walking for progressively greater distances.

## TOTAL HIP REPLACEMENT

Total hip replacement is the replacement of a severely damaged hip with an artificial joint. Indications for this surgery include arthritis (degenerative joint disease, rheumatoid arthritis), femoral neck fractures, failure of previous reconstructive surgeries (failed prosthesis, **osteotomy**), and problems resulting from congenital hip disease. A variety of total hip prostheses are available. Most consist of a metal femoral component topped by a spherical ball fitted into a plastic acetabular socket (see Fig. 67-6). The surgeon selects the prosthesis that is most suited to the individual patient, considering various factors, including skeletal structure and activity level.

The patient is usually 60 years of age or older and has unremitting pain or irreversibly damaged hip joints. With the advent of improved prosthetic materials and operative techniques, the life of the prosthesis has been extended, and today younger patients with severely damaged and painful hip joints are undergoing total hip replacement.

## Nursing Interventions

The nurse must be aware of and monitor for specific potential complications associated with total hip replacement. Complications that may occur include dislocation of the hip prosthesis, excessive wound drainage, thromboembolism, infection, and heel pressure ulcer. Other complications for which the nurse must monitor include those associated with immobility, **heterotopic ossification** (formation of bone in the periprosthetic space), avascular necrosis (bone death caused by loss of blood supply), and loosening of the prosthesis.

## PREVENTING DISLOCATION OF THE HIP PROSTHESIS

Maintenance of the femoral head component in the acetabular cup is essential. The nurse teaches the patient about positioning the leg in **abduction**, which helps to prevent dislocation of the prosthesis. The use of an abduction splint, a wedge pillow (Fig. 67-7), or two or three pillows between the legs keeps the hip in abduction. When the nurse turns the patient in bed, it is important to keep the operative hip in abduction. Depending on the surgeon's preference, some patients are not permitted to be turned onto the affected side, whereas others may be turned to either side.

The patient's hip is never flexed more than 90 degrees. To prevent hip flexion, the nurse does not elevate the head of the bed more than 60 degrees. For use of the fracture bedpan, the nurse instructs the patient to flex the unaffected hip and to use the trapeze to lift the pelvis onto the pan. The patient is also reminded not to flex the affected hip.

Limited flexion is maintained during transfers and when sitting. When the patient is initially assisted out of bed, an abduction splint or pillows are kept between the legs. The nurse

**FIGURE 67-7** An abduction pillow may be used after a total hip replacement to prevent dislocation of the prosthesis.

encourages the patient to keep the affected hip in extension, instructing the patient to pivot on the unaffected leg with assistance by the nurse, who protects the affected hip from **adduction**, flexion, internal or external rotation, and excessive weight bearing.

High-seat (orthopedic) chairs, semireclining wheelchairs, and raised toilet seats may be used to minimize hip joint flexion. When sitting, the patient's hips should be higher than the knees. The patient's affected leg should not be elevated when sitting. The patient may flex the knee.

The nurse teaches the patient protective positioning, which includes maintaining abduction and avoiding internal and external rotation, hyperextension, and acute flexion. A cradle boot may be used to prevent leg rotation and to support the heel off the bed, preventing development of a pressure ulcer. The patient should use pillows between the legs when in a supine or side-lying position and when turning. Generally, the nurse instructs the patient

not to sleep on the side on which the surgery was performed without consulting the surgeon. At no time should the patient cross his or her legs. The patient must avoid acute flexion of the hip. The patient should not bend at the waist to put on shoes and socks. Occupational therapists can provide the patient with devices to assist with dressing below the waist. Hip precautions are needed for about 4 months after surgery (Chart 67-8).

Dislocation may occur with positioning that exceeds the limits of the prosthesis. The nurse must recognize dislocation of the prosthesis. Indicators are as follows:

- Increased pain at the surgical site, swelling, and immobilization
- Acute groin pain in affected hip or increased discomfort
- Shortening of the leg
- Abnormal external or internal rotation
- Restricted ability or inability to move leg
- Reported "popping" sensation in hip

If a prosthesis becomes dislocated, the nurse (or the patient, if at home) immediately notifies the surgeon, because the hip must be reduced and stabilized promptly so that the leg does not sustain circulatory and nerve damage. After closed reduction, the hip may be stabilized with Buck's traction or a brace to prevent recurrent dislocation. As the muscles and joint capsule heal, the chance of dislocation diminishes. Stresses to the new hip joint should be avoided for the first 3 to 6 months.

#### MONITORING WOUND DRAINAGE

Fluid and blood accumulating at the surgical site are usually drained with a portable suction device. This prevents accumula-

Chart  
67-8

#### Avoiding Hip Dislocation After Replacement Surgery

Until the hip prosthesis stabilizes after hip replacement surgery, the patient needs to learn about proper positioning so that the prosthesis remains in place. Dislocation of the hip is a serious complication of surgery that causes pain and loss of function and necessitates reduction under anesthesia to correct the dislocation. Desirable positions include abduction, neutral rotation, and flexion of less than 90 degrees. When the patient is seated, the knees should be lower than the hip.

Methods for avoiding displacement include the following:

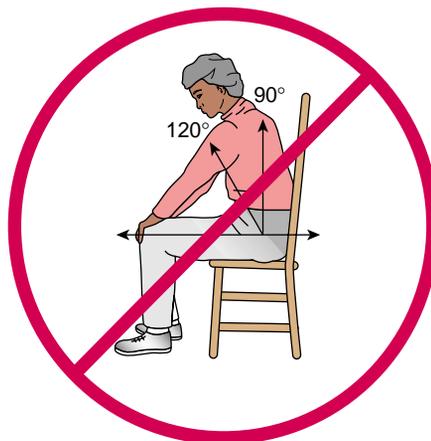

- Keep the knees apart at all times.
- Put a pillow between the legs when sleeping.

- Never cross the legs when seated.
- Avoid bending forward when seated in a chair.
- Avoid bending forward to pick up an object on the floor.
- Use a high-seated chair and a raised toilet seat.
- Do not flex the hip to put on clothing such as pants, stockings, socks or shoes.

Positions to avoid after total hip replacement are illustrated below.

Affected leg should not cross the center of the body

Hip should not bend more than 90 degrees

Affected leg should not turn inward

tion of fluid, which could contribute to discomfort and provide a site for infection. Drainage of 200 to 500 mL in the first 24 hours is expected; by 48 hours postoperatively, the total drainage in 8 hours usually decreases to 30 mL or less, and the suction device is then removed. The nurse promptly notifies the physician of any drainage volumes greater than anticipated.

If extensive blood loss is anticipated after total joint replacement surgery, an autotransfusion drainage system (in which the drained blood is filtered and reinfused into the patient during the immediate postoperative period) may be used to decrease the need for homologous blood transfusions.

### PREVENTING DEEP VEIN THROMBOSIS

The risk for thromboembolism is particularly great after reconstructive hip surgery. The incidence of DVT is 45% to 70%. The peak occurrence is 5 to 7 days after surgery. About 20% of patients with DVT develop pulmonary emboli, of which about 1% to 3% of cases are fatal. Therefore, the nurse must institute preventive measures and monitor the patient closely for the development of DVT and pulmonary emboli. Signs of DVT include calf pain, swelling, and tenderness. Measures to promote circulation and decrease venous stasis are priorities for the patient undergoing hip reconstruction. The nurse encourages the patient to consume adequate amount of fluids, to perform ankle and foot exercises hourly while awake, to use elastic stockings and sequen-

tial compression devices as prescribed, and to transfer out of bed and ambulate with assistance beginning on the first postoperative day. Low-dose heparin or enoxaparin (Lovenox) is frequently prescribed as prophylaxis for DVT after hip replacement surgery.

### PREVENTING INFECTION

Infection, a serious complication of total hip replacement, may necessitate removal of the implant. Patients who are elderly, obese, or poorly nourished and patients who have diabetes, rheumatoid arthritis, concurrent infections (eg, urinary tract infection, dental abscess), or large hematomas are at high risk for infection.

Because total joint infections are so disastrous, all efforts are undertaken to minimize their occurrence. Potential sources of infection are avoided. Prophylactic antibiotics are prescribed. If indwelling urinary catheters or portable wound suction devices are used, they are removed as soon as possible to avoid infection. Prophylactic antibiotics are prescribed if the patient needs any future surgical instrumentation, such as tooth extraction or cystoscopic examination.

Acute infections may occur within 3 months after surgery and are associated with progressive superficial infections or hematomas. Delayed surgical infections may appear 4 to 24 months after surgery and may cause return of discomfort in the hip. Infections occurring more than 2 years after surgery are attributed to the spread of infection through the bloodstream from another site in the body. If

### NURSING RESEARCH PROFILE 67-1

#### Wound Complications After Hip Surgery

Hahn, G., et al. (1999). Wound complications after surgery using a tapeless compressive support. *Orthopaedic Nursing*, 18(3), 43–49.

#### Purpose

Skin blisters (tape blisters) frequently occur after hip surgery and cause skin breakdown and patient discomfort. This study compared the incidence of blisters and wound drainage with traditional wound taping and with a tapeless compressive (stretch spica) wrap dressing (i.e., cotton stockinette or a commercial single-piece stretch spica wrap).

#### Study Sample and Design

A total of 499 hip surgeries performed by one surgeon over a 10-year period on 457 patients, whose average age was 65 years, were reviewed. Eighty-seven consecutive hip surgeries with taped dressings (control group) were compared with 368 consecutive hip surgeries with hip wrap dressings (experimental group). The patient characteristics in the two groups were similar. The surgeries were performed for osteoarthritis (60%), fracture (22%), rheumatoid arthritis (8%), and other problems (10%) including osteonecrosis, congenitally dislocated hips, Reiter's syndrome, and Legg-Perthes disease. Surgical procedures performed included hip replacement (67%), revision of hip replacement (25%), and open reduction internal fixation of hip fracture (8%).

A retrospective, descriptive study design was used to compare the incidence of wound drainage, tape blisters, infections, deep vein thrombosis, and pulmonary embolism in the two groups.

#### Findings

- Wound drainage was difficult to quantify because of the descriptive nature of charting. Twenty-eight (7%) of the spica wrap group and 13 (15%) of the tape group exhibited wound drainage. All drainage was described as slight to moderate with no drainage at the time of discharge from the hospital. The difference in incidence of drainage between groups was statistically significant ( $p < .001$ ).

- Four tape blisters (1%), two from surgical incision adhesive strips and two from taping of the dressing after the spica wrap was discontinued, occurred in the tapeless compressive wrap dressing group, compared with 13 tape blisters (15%) in the tape group. The difference in incidence of blisters between groups was statistically significant ( $p < .001$ ).
- No infections occurred in the spica wrap group, and there was one documented *Staphylococcus aureus* infection in the tape group.
- Thrombotic disease prophylaxis was used for both groups. The incidence of thrombotic disease in the spica wrap group was 12 patients (3%). Because the data recorded for the traditional tape group were insufficient to determine the incidence of thrombotic disease, no comparison with controls could be made. However, the low incidence in the experimental group suggests that the spica wrap does not contribute to an increased incidence of deep vein thrombosis.
- Patients reported that the spica wrap was comfortable and supported the incision well, so that they could move with greater confidence.
- Nurses found the spica wrap easy to apply and easy to unfasten for inspection of the wound. Also, nursing time was not required to care for tape blisters.

#### Nursing Implications

In this study, the use of a compressive spica wrap dressing, compared with taped dressings, reduced the incidence of wound complications (eg, tape blisters, drainage). Advantages included ease of application and removal for wound inspection. In addition, the hip spica dressing was comfortable for the patient.

Additional studies in other settings and with other patients comparing the use of the hip spica dressing and traditional taped dressings are recommended; randomization of patients to the spica wrap dressing group and to the tape group is also recommended.

an infection occurs, antibiotics are prescribed. Severe infections may require surgical débridement or removal of the prosthesis (Nursing Research Profile 67-1).

## PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching the Patient Self-Care.** Before the patient prepares to leave the acute care setting, the nurse provides a thorough teaching program to promote continuity of the therapeutic regimen and active participation in the rehabilitation process (Chart 67-9). The nurse advises the patient of the importance of the daily exercise program in maintaining the functional motion of the hip joint and strengthening the abductor muscles of the hip, and reminds the patient that it will take time to strengthen and retrain the muscles.

Assistive devices (crutches, walker, or cane) are used for a time. After sufficient muscle tone has developed to permit a normal gait without discomfort, these devices are not necessary. In general, by 3 months, the patient can resume routine ADLs. Stair climbing is permitted as prescribed and is kept to a minimum for 3 to 6 months. Frequent walks, swimming, and use of a high rocking chair are excellent for hip exercises. Sexual activities should be carried out with the patient in the dependent position (flat on the back) for 3 to 6 months to avoid excessive adduction and flexion of the new hip.

At no time during the first 4 months should the patient cross the legs or flex the hip more than 90 degrees. Assistance in putting on shoes and socks may be needed. The patient should avoid low chairs and sitting for longer than 45 minutes at a time. These precautions minimize hip flexion and the risks for prosthetic dislocation, hip stiffness, and flexion contracture. Traveling long distances should be avoided unless frequent position changes are possible. Other activities to avoid include tub baths, overexertion, jogging, lifting heavy loads, and excessive bending and twisting (eg, lifting, shoveling snow, forceful turning).

**Continuing Care in the Home and Community.** The nurse may make a home visit to assess for potential problems and to monitor wound healing (see Chart 67-9). The nurse, physical therapist, or occupational therapist assesses the home environment for physical barriers that may impede the patient's rehabilitation. In addition, the nurse or therapist may need to assist the patient in acquiring devices, such as reachers to help with dressing or toilet seat extenders.

After successful surgery and rehabilitation, the patient can expect a hip joint that is free or almost free of pain, has good motion, is stable, and permits normal or near-normal ambulation (see Plan of Nursing Care).

## TOTAL KNEE REPLACEMENT

Total knee replacement surgery is considered for patients who have severe pain and functional disabilities related to joint surfaces destroyed by arthritis (osteoarthritis, rheumatoid arthritis, posttraumatic arthritis) or bleeding into the joint, such as may result from hemophilia. Metal and acrylic prostheses designed to provide the patient with a functional, painless, stable joint may be used. If the patient's ligaments have weakened, a fully constrained (hinged) or semiconstrained prosthesis may be used to provide joint stability. A nonconstrained prosthesis depends on the patient's ligaments for joint stability.

## Nursing Interventions

Postoperatively, the knee is dressed with a compression bandage. Ice may be applied to control edema and bleeding. The nurse assesses the neurovascular status of the leg. It is important to encourage active flexion of the foot every hour when the patient is awake. Efforts are directed at preventing complications  
(*text continues on page 23*)

**Chart 67-9 • PATIENT EDUCATION**  
Providing Home Care After Hip Replacement

### Considerations

- Pain management
- Wound care
- Mobility
- Self-care (activities of daily living)
- Potential problems

### Nursing Interventions

Discuss with patient methods to reduce pain:

- Periodic rest
- Distraction and relaxation techniques
- Medication therapy (eg, nonsteroidal anti-inflammatory drugs, opioid analgesics): actions of medications, administration, schedule, side effects

Instruct patient in the following:

- Keeping incision clean and dry
- Taking care of the wound and changing the dressing
- Recognizing signs of wound infection (eg, pain, swelling, drainage, fever)

Explain that sutures or staples will be removed 10 to 14 days after surgery.

Teach patient about the following:

- Safe use of assistive devices
- Weight-bearing limits
- How to change positions frequently

- Limitations on hip flexion and adduction (eg, avoid acute flexion and crossing legs)
- How to stand without flexing hip acutely
- Avoidance of low-seated chairs
- Sleeping with pillow between legs to prevent adduction
- Gradual increase in activities and participation in prescribed exercise regimen

Assess home environment for physical barriers.

Instruct patient to use elevated toilet seat and to use reachers to aid in dressing.

Encourage patient to accept assistance with activities of daily living during early convalescence until mobility and strength improve. Arrange services and accommodations to address the patient's disability or illness, as appropriate.

Assess patient for development of potential problems, and instruct patient to report signs of potential problems:

- Dislocation of prosthesis (eg, increased pain, shortening of leg, inability to move leg, popping sensation in hip, abnormal rotation)
- Deep vein thrombosis (eg, calf pain, swelling)
- Wound infection (eg, swelling, purulent drainage, pain, fever)
- Pulmonary emboli (eg, sudden dyspnea, tachypnea, pleuritic chest pain)

Discuss with patient the need to continue regular health care (routine physical examinations) and screenings.

## Plan of Nursing Care

### The Patient With a Total Hip Replacement

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Pain related to total hip replacement

**Goal:** Relief of pain

1. Assess patient for pain using a standard pain intensity scale.	1. Pain is expected after a surgical procedure because of the surgical trauma and tissue response. Muscle spasms occur after total hip replacements. Immobility causes discomfort at pressure points.	<ul style="list-style-type: none"> <li>• Patient describes discomfort</li> <li>• Expresses confidence in efforts to control pain</li> <li>• States pain is reduced; pain intensity scores are decreasing</li> </ul>
2. Ask patient to describe discomfort.	2. Pain characteristics may help to determine the cause of discomfort. Pain may be due to complications (hematoma, infection, dislocation). Pain is an individual experience—it means different things to different people.	<ul style="list-style-type: none"> <li>• Appears comfortable and relaxed</li> <li>• Uses physical, psychological, and pharmacologic measures to reduce pain and discomfort</li> </ul>
3. Acknowledge existence of pain; inform patient of available analgesics or muscle relaxants.	3. The nurse can reduce the stress experienced by patient by communicating concern and availability of assistance to help the patient deal with the pain	
4. Use pain-modifying techniques. <ol style="list-style-type: none"> <li>Use analgesics.</li> <li>Change position within prescribed limits.</li> <li>Modify environment.</li> <li>Notify surgeon about persistent pain.</li> </ol>	4. <ol style="list-style-type: none"> <li>Patient will require parenteral opioids during the first 24–48 hours, and then will progress to oral analgesics.</li> <li>Use of pillows to provide adequate support and relief of pressure on bony prominences assists in minimizing pain.</li> <li>Interactions with others, distractions, and sensory overload or deprivation may affect pain experience.</li> <li>Surgical intervention may be necessary if pain is due to hematoma or excessive edema.</li> </ol>	
5. Evaluate and record discomfort and effectiveness of pain-modifying techniques.	5. Effectiveness of action is based on experience; data provide a baseline about pain experiences, management, and pain relief.	

**Nursing Diagnosis:** Impaired physical mobility related to positioning, weight-bearing, and activity restrictions after hip replacement

**Goal:** Achieves pain-free, functional, stable hip joint

1. Maintain proper positioning of hip joint (abduction, neutral rotation, limited flexion).	1. Prevents dislocation of hip prosthesis.	<ul style="list-style-type: none"> <li>• Prescribed position maintained</li> <li>• No heel pressure</li> </ul>
2. Keep pressure off heel.	2. Prevents pressure ulcer on heel.	<ul style="list-style-type: none"> <li>• Patient assists in position changes</li> <li>• Shows increased independence in transfers</li> </ul>
3. Instruct and assist in position changes and transfers.	3. Encourages patient's active participation while preventing dislocation.	<ul style="list-style-type: none"> <li>• Exercises hourly</li> <li>• Participates in progressive ambulation program</li> </ul>
4. Instruct and supervise isometric quadriceps- and gluteal-setting exercises.	4. Strengthens muscles needed for walking.	<ul style="list-style-type: none"> <li>• Actively participates in exercise regimen</li> <li>• Uses ambulatory aids correctly and safely</li> </ul>
5. In consultation with physical therapist, instruct and supervise progressive safe ambulation within limitations of weight-bearing prescription.	5. Amount of weight-bearing depends on patient's condition and prosthesis; ambulatory aids are used to assist the patient with non-weight-bearing and partial weight-bearing ambulation.	
6. Offer encouragement and support exercise regimen.	6. Reconditioning exercises can be uncomfortable and fatiguing; encouragement helps patient comply with exercise program.	
7. Instruct and supervise safe use of ambulatory aids.	7. Prevents injury from unsafe use.

Assess ability to move foot and toes.</li> <li>9. Assess pedal pulses in both feet.</li> <li>10. Notify surgeon if altered neurovascular status is noted.</li> </ol> | <ol style="list-style-type: none"> <li>1. The skin becomes pale and feels cool with decreased tissue perfusion. Venous congestion may produce cyanosis.</li> <li>2. After compression of the nail, rapid return of pink color indicates good capillary perfusion.</li> <li>3. The trauma of surgery will cause edema. Excessive swelling and hematoma formation can compromise circulation and function.</li> <li>4. Minimizes dependent edema.</li> <li>5. Surgical pain can be controlled; pain due to neurovascular compromise is not relieved by treatment.</li> <li>6. With nerve ischemia, there will be pain on passive stretch. Additionally, pain may indicate deep vein thrombosis—positive Homans' sign.</li> <li>7. Diminished pain and sensory function may indicate nerve damage. Sensation in web between great and second toe—peroneal nerve; sensation on sole of foot—tibial nerve.</li> <li>8. Dorsiflexion of ankle and extension of toes indicate function of peroneal nerve. Plantar flexion of ankle and flexion of toes indicate function of tibial nerve.</li> <li>9. Indicator of extremity circulation.</li> <li>10. Function of extremity needs to be preserved.</li> </ol> | <ul style="list-style-type: none"> <li>• Color normal</li> <li>• Extremity warm</li> <li>• Normal capillary refill</li> <li>• Moderate edema and swelling; tissue not palpably tense</li> <li>• Pain controllable</li> <li>• No pain with passive dorsiflexion</li> <li>• Normal sensations</li> <li>• No paresthesia</li> <li>• Normal motor abilities</li> <li>• No paresis or paralysis</li> <li>• Pulses strong and equal</li> </ul> |
|--|---|--|

(continued)

## Plan of Nursing Care

### The Patient With a Total Hip Replacement (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

##### Dislocation of Prosthesis

1. Position patient as prescribed.
2. Use abductor splint or pillows to maintain position and to support extremity.
3. Support leg and place pillows between legs when patient is turning and side-lying; turn to the unaffected side.
4. Avoid acute flexion of hip (head of bed at 60 degrees or less).
5. Avoid crossing legs.
6. Assess for dislocation of prosthesis (extremity shortens, internally or externally rotated, severe hip pain, patient unable to move extremity)
7. Notify surgeon of possible dislocation.

1. Hip component positioning (femoral component in acetabular component) needs to be maintained.
2. Keep hip in abduction and in a neutral rotation to prevent dislocation.
- 3–5. Prevent dislocation.
6. Findings may indicate dislocation of prosthesis.
7. Joint dislocations compromise neurovascular status and future function of extremity.

- Prosthesis not dislocated

##### Deep Vein Thrombosis

1. Use elastic compression stocking or sequential compression device as prescribed.
2. Remove stocking for 20 minutes twice a day and provide skin care.
3. Assess popliteal, dorsalis pedis, and posterior tibial pulses.
4. Assess skin temperature of legs.
5. Assess for Homans' sign every 8 hours.
6. Avoid pressure on popliteal blood vessels from equipment (eg, abductor splint straps, sequential compression stockings) or pillows.
7. Change position and increase activity as prescribed.
8. Supervise ankle exercises hourly.
9. Monitor body temperature.
10. Encourage fluids.

1. Aid in venous blood return and prevent stasis.
2. Skin care is necessary to avoid breakdown. Extended removal of stockings defeats purpose of stockings.
3. Pulses indicate arterial perfusion of extremity.
4. Local inflammation will increase local skin temperature.
5. Pain on dorsiflexion of ankle may indicate deep vein thrombosis.
6. Compression of blood vessels diminishes blood flow.
7. Activity promotes circulation and diminishes venous stasis.
8. Muscle exercise promotes circulation.
9. Body temperature increases with inflammation.
10. Dehydration increases blood viscosity

- Wears elastic stockings; uses compression device
- No skin breakdown
- Pulses equal and strong
- Skin temperature normal
- Negative Homans' sign
- Changes position with assistance and supervision
- Participates in exercise regimen
- Well hydrated
- No chest pain; lungs clear to auscultation; no evidence of pulmonary emboli

##### Infection

1. Monitor vital signs.
2. Use aseptic technique for dressing changes and emptying of portable drainage.
3. Assess wound appearance and character of drainage.
4. Assess complaints of pain.
5. Administer prophylactic antibiotics if prescribed, and observe for side effects.

1. Temperature, pulse, and respirations increase in response to infection. (Magnitude of response may be minimal in an elderly patient.)
2. Avoids introducing organisms.
3. Red, swollen, draining incision is indicative of infection.
4. Pain may be due to wound hematoma—a possible locus of infection—that needs to be surgically evacuated.
5. Infected prosthesis is avoided.

- Vital signs normal
- Well-approximated incision without drainage or excessive inflammatory response
- Minimal discomfort; no hematoma
- Patient tolerates antibiotics

(continued)

## Plan of Nursing Care

### The Patient With a Total Hip Replacement (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Risk for ineffective health maintenance related to total hip replacement

**Goal:** Cares for self at home

1. Assess home environment for discharge planning.	1. Physical barriers (especially stairs, bathrooms) may limit patient's ability to ambulate and care for self at home.	• Home is accessible for patient at time of discharge.
2. Encourage patient to express concerns about care at home; explore together possible solutions to the problem.	2. Patient may have special problems that need to be identified and resolved.	• Patient appears relaxed and develops strategies to deal with identified problems.
3. Assess availability of physical assistance for health care activities.	3. Because of limitation of mobility and limited hip range of motion, patient may require some assistance in routine health care.	• Personal assistance is available.
4. Teach caregiver home health care regimen.	4. Understanding of rehabilitative regimen is necessary for compliance.	• Patient demonstrates ability to provide necessary assistance within therapeutic prescription.
5. Instruct patient on posthospital care:	5. Lack of knowledge and poor preparation for care at home contribute to patient anxiety, insecurity, and nonadherence to therapeutic regimen.	• Patient complies with home care program.
a. Activity limitations (hip precautions, weight-bearing limits)		• Patient keeps follow-up health care appointments.
b. Exercise instructions		
c. Safe use of ambulatory aids		
d. Wound care		
e. Measures to promote healing		
f. Medications, if any		
g. Potential problems		
h. Continuing health care supervision and management		

(thromboembolism, peroneal nerve palsy, infection, limited range of motion).

A wound suction drain removes fluid accumulating in the joint. Drainage ranges from 200 to 400 mL during the first 24 hours after surgery and diminishes to less than 25 mL by 48 hours. Then the surgeon removes the drains. If extensive bleeding is anticipated, an autotransfusion drainage system may be used during the immediate postoperative period. The color, type, and amount of drainage are documented, and any excessive drainage or change in characteristics of the drainage are promptly reported to the physician.

Frequently, a **continuous passive motion (CPM) device** is used. The patient's leg is placed in this device, which increases circulation and range of motion of the knee joint. The rate and amount of extension and flexion are prescribed. Usually, 10 degrees of extension and 50 degrees of flexion are prescribed initially, increasing to 90 degrees of flexion with full extension (0 degrees) by discharge.

The nurse encourages the patient to use the device most of the time. The physical therapist supervises exercises for strength and range of motion. If satisfactory flexion is not achieved, gentle manipulation of the knee joint under general anesthesia may be necessary about 2 weeks after surgery.

The nurse assists the patient to get out of bed on the evening or the day after surgery. The knee is usually protected with a knee immobilizer (splint, cast, or brace) and is elevated when the patient sits in a chair. The physician prescribes weight-bearing limits. Progressive ambulation, using assistive devices and within the prescribed weight-bearing limits, begins on the day after the surgery.

After discharge from the hospital, the patient may continue to use the CPM device at home and may undergo physical therapy on an outpatient basis. Late complications that may occur include infection and loosening and wear of prosthetic components. Patients usually can achieve a pain-free, functional joint and participate more fully in life activities than before the surgery (Nursing Research Profile 67-2).

## NURSING PROCESS: PREOPERATIVE CARE OF THE PATIENT UNDERGOING ORTHOPEDIC SURGERY

### Assessment

Assessment of the patient is focused on hydration status, current medication history, and possible infection. Adequate hydration is an important goal for orthopedic patients. Immobilization and bed rest contribute to DVT, to urinary stasis and associated bladder infections, and to kidney stone formation. Adequate hydration decreases blood viscosity and venous stasis and ensures adequate urine flow. To determine preoperative hydration status, the nurse assesses the skin and mucous membranes, vital signs, urinary output, and laboratory values.

The medication history provides information for perioperative management. The patient with chronic illness (eg, rheumatoid arthritis, chronic pulmonary disease, multiple sclerosis, allergies) frequently has received corticosteroid medications to control symptoms. The corticosteroid should be administered preopera-

## NURSING RESEARCH PROFILE 67-2

### Information Needs of Patients and Spouses After Total Joint Arthroplasty

Showalter, A., et al. (2000). Patients' and their spouses' needs after total joint arthroplasty: A pilot study. *Orthopaedic Nursing*, 19(1), 49–57, 62.

#### Purpose

Each year almost 250,000 Americans who have arthritis-related disability choose to have total joint arthroplasty in an attempt to reduce pain and improve functional status and mobility. Health care providers need to understand the perceived needs of patients and their families during hospitalization and recovery from total joint arthroplasty so that programs can be developed or modified to meet those needs.

#### Study Sample and Design

The purposive sample consisted of 5 patients who had recently undergone total joint arthroplasty and their spouses. The mean age of patients was 68.6 years, and the mean age of spouses was 69 years. Three patients had undergone total knee replacement, and two patients had undergone total hip replacement within 4 months of data collection.

Focus group interviews were conducted and videotaped for subsequent analysis. The interviewer used an open-ended interview format to explore the perceptions of patients and spouses regarding what information that was useful before surgery, what information they wished they had received, and what else would have helped them during recovery.

#### Results

The primary need expressed by this focus group was the need for help in making transitions. The participants expressed problems in mak-

ing situational and role transitions and experienced distress over not being able to resume activities that they had previously enjoyed within an expected time frame. Spouses stated that they felt unprepared for the reality of being a care provider and often felt overwhelmed and insecure about what was expected of them.

In addition, the focus group addressed health and illness transitions and the need to know that each patient progresses toward recovery at his or her own rate. Patients commented that the patient education they received did not prepare them for problems encountered during recovery at home. Pain management was of particular concern. A home visit soon after hospital discharge was suggested as a way to help patients and spouses manage the transitions.

#### Nursing Implications

Hospital health care professionals need to be sensitive to the needs of patients and their families as they transition to care in their home. The nurse needs to include both the patient and family members in discharge teaching regarding activities and pain management. Knowledge and skills are needed by the patients and families to confidently manage problems that they encounter during recovery at home.

Further research is necessary to explore the needs of patients and families in care after hospitalization.

tively, intraoperatively, and postoperatively as prescribed to prevent the occurrence of adrenal insufficiency from suppressed adrenal function. The patient's use of other medications, such as anticoagulants, cardiovascular agents, or insulin, needs to be documented and discussed with the surgeon and anesthesiologist to ensure adequate management.

The nurse asks the patient specifically about the occurrence of colds, dental problems, urinary tract infections, and other infections within the 2 weeks before surgery. Osteomyelitis could develop through hematogenous spread. Permanent disability can result if infection occurs within a bone or joint. Preexisting infections must be resolved before elective orthopedic surgery is performed.

Other areas of preoperative assessment are similar to those for any patient undergoing surgery. Intramuscular medications are injected into an uninvolved area, because tissue absorption is better in nontraumatized tissues.

## Nursing Diagnosis

Based on the nursing assessment data, the patient's major preoperative nursing diagnoses related to orthopedic status may include the following:

- Acute pain related to fracture, orthopedic problem, swelling, or inflammation
- Risk for peripheral neurovascular dysfunction related to swelling, constricting devices, or impaired venous return
- Risk for ineffective therapeutic regimen management related to insufficient knowledge or lack of available support and resources
- Impaired physical mobility related to pain, swelling, and possible presence of an immobilization device

- Risk for situational low self-esteem: disturbed body image and/or functional impairment related to impact of musculoskeletal disorder

## Planning and Goals

The major goals for the patient before orthopedic surgery may include relief of pain, adequate neurovascular function, health promotion, improved mobility, and positive self-esteem.

## Nursing Interventions

### RELIEVING PAIN

Physical, pharmacologic, and psychological strategies to control pain are useful in the preoperative period. Specific strategies are tailored to the individual patient. Discomfort is decreased with immobilization of a fractured bone or an injured, inflamed joint. Elevation of an edematous extremity promotes venous return and reduces associated discomfort. Ice, if prescribed, relieves swelling and directly reduces discomfort by diminishing nerve stimulation. Analgesics are frequently prescribed to control the acute pain of musculoskeletal injury and associated muscle spasm. During the immediate preoperative period, the nurse needs to discuss and coordinate the administration of analgesic medications with the anesthesiologist and surgeon. Alternative methods of pain control (eg, distraction, focusing, guided imagery, quiet environment, backrubs) may be used to decrease pain perception.

### MAINTAINING ADEQUATE NEUROVASCULAR FUNCTION

Trauma, edema, or immobilization devices may interrupt tissue perfusion. The nurse must frequently assess neurovascular status (ie, color, temperature, capillary refill, pulses, edema, pain, sen-

sation, motion) of the extremity and document the findings. If circulation is compromised, the nurse institutes measures to restore adequate circulation. These include promptly notifying the physician, elevating the extremity, and releasing constricting wraps or casts as prescribed.

### PROMOTING HEALTH

The nurse assists the patient in activities that promote health during the perioperative period. The nurse assesses nutritional status and hydration. The preoperative fasting regimen is usually tolerated well. If the patient has diabetes, is elderly and frail, or is the victim of multiple trauma, special fluid and nutritional provisions may be necessary.

The nurse monitors fluid intake, urinary output, urinalysis findings, and complaints of burning on urination. At times, patients may limit their fluid intake to minimize the use of a bedpan. A small fracture pan may be more comfortable for the patient to use. An indwelling catheter should be used only when absolutely necessary to minimize the risk of urinary tract infection. Urinary tract infection must be addressed before surgery.

Coughing, deep breathing, and use of the incentive spirometer are practiced preoperatively for improved respiratory function during the postoperative period. Preoperative teaching facilitates postoperative compliance. Smoking should be stopped during the preoperative period to facilitate optimal respiratory function.

The nurse provides skin care, paying special attention to pressure points. It is important to institute the use of pressure-reducing surfaces (i.e., special mattresses) before surgery for patients at high risk for skin breakdown.

To minimize the risk for infection, the nurse meticulously and gently cleans the skin with soap and water on the day before surgery. If the surgery is elective, the orthopedic surgeon may instruct the patient to use a germicidal soap for several days before hospitalization.

The nurse discusses with the patient and the family the need for assistance with ADLs and the therapeutic regimen during convalescence so that adequate support is available when the patient is discharged. Modification of the home environment may be necessary to accommodate the altered mobility of the patient after surgery. Referral to the social worker and the case manager may be needed to ensure a smooth transition to home care.

### IMPROVING MOBILITY

Preoperatively, the patient's mobility may be impaired by pain, swelling, and immobilizing devices (eg, splints, casts, traction). The nurse should elevate and adequately support edematous extremities with pillows. It is important to control pain before an injured part is moved by administering medication in time for it to take effect and by supporting the injured part when it is moved. The nurse encourages movement within the limits of therapeutic immobility. The patient should perform active range-of-motion exercises of uninvolved joints, and, unless contraindicated, the nurse teaches gluteal-setting and quadriceps-setting isometric exercises to maintain the muscles needed for ambulation (see Chart 67-3). The patient who will be using assistive devices postoperatively may exercise to strengthen the upper extremities and shoulders. If the use of assistive devices (eg, crutches, walker, wheelchair) is anticipated, the nurse encourages the patient to practice with them preoperatively to facilitate their safe use and to promote earlier independent mobility.

### HELPING THE PATIENT MAINTAIN SELF-ESTEEM

Preoperatively, orthopedic patients may need assistance in accepting changes in body image, diminished self-esteem, or inability to

perform their roles and responsibilities. The degree of assistance required in this area varies greatly, depending on the events preceding hospitalization, the surgery and rehabilitation planned, and the temporary or permanent nature of the problems. The nurse promotes a trusting relationship for patients to express concerns and anxieties and helps them examine their feelings about changes in self-concept. The nurse clarifies any misconceptions patients may have and helps them work through modifications needed to adapt to alterations in physical capacity and to reestablish positive self-esteem.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Reports relief of pain
  - a. Uses multiple approaches to reduce pain
  - b. States that medication is effective in relieving pain
  - c. Moves with increasing comfort
2. Exhibits adequate neurovascular function
  - a. Exhibits normal skin color
  - b. Has warm skin
  - c. Has normal capillary refill response
  - d. Reports normal sensation and demonstrates joint motion
  - e. Demonstrates reduced swelling
3. Promotes health
  - a. Eats balanced diet appropriate to meet nutritional needs
  - b. Maintains adequate hydration
  - c. Abstains from smoking
  - d. Practices respiratory exercises
  - e. Repositions self to relieve skin pressure
  - f. Engages in strengthening and preventive exercises
  - g. Plans for assistance during convalescence at home
4. Maximizes mobility within the therapeutic limits
  - a. Requests assistance when moving
  - b. Elevates edematous extremity after transfer
  - c. Uses immobilizing devices and assistive devices as prescribed
5. Expresses positive self-esteem
  - a. Acknowledges temporary or permanent changes in body image
  - b. Discusses role performance changes
  - c. Participates in decisions about care

## NURSING PROCESS: POSTOPERATIVE CARE OF THE PATIENT UNDERGOING ORTHOPEDIC SURGERY

### Assessment

After orthopedic surgery, the nurse continues the preoperative care plan, modifying it to match the patient's current postoperative status. The nurse reassesses the patient's needs in relation to pain, neurovascular status, health promotion, mobility, and self-esteem. Skeletal trauma and surgery performed on bones, muscles, or joints can produce significant pain, especially during the first 1 or 2 postoperative days. Tissue perfusion must be monitored closely, because edema and bleeding into the tissues can compromise circulation and result in compartment syndrome. Inactivity contributes to venous stasis and the development of DVT. General anesthesia, analgesia, and immobility can result in altered functioning of respiratory, gastrointestinal, and urinary systems.

The nurse notes the prescribed limits on mobility and assesses the patient's understanding of the mobility restrictions. The

nurse discusses the plan of care with the patient and encourages active participation in the plan.

In addition, the nurse assesses and monitors the patient for potential problems related to the surgery. Frequent assessment of vital signs, level of consciousness, neurovascular status, wound drainage, breath sounds, bowel sounds, fluid balance, and pain provides the nurse with data that may suggest the possible development of complications. The nurse reports abnormal findings to the physician promptly.

With major orthopedic surgery, there is a risk of hypovolemic shock because of blood loss. Muscle dissection frequently produces wounds in which hemostasis is poor. Wounds that are closed under tourniquet control may bleed during the postoperative period. The nurse must be alert for signs of hypovolemic shock.

Changes in the patient's pulse rate, respiratory rate, or color may indicate pulmonary or cardiovascular complications. Atelectasis and pneumonia are common and may be related to preexisting pulmonary disease, deep anesthesia, decreased activity, analgesics, and reduced respiratory reserve due to advanced age or an underlying musculoskeletal disorder (eg, restrictive lung expansion secondary to kyphosis, rheumatoid arthritis, or osteoporosis).

Voiding in unnatural positions may contribute to urinary retention. In addition, elderly men usually have some degree of prostate enlargement and may already have difficulty voiding. Therefore, it is important to monitor urinary output.

Temperature elevations within the first 48 hours are frequently related to atelectasis or other respiratory problems. Temperature elevations during the next few days are frequently associated with urinary tract infections. Superficial wound infections take 4 to 6 days to develop. Fever from phlebitis usually occurs during the end of the first week through the second week.

Thromboembolic disease (see discussions of deep vein thrombosis in Chap. 31 and pulmonary embolism in Chap. 23) is one of the most common and most dangerous of all complications occurring in the postoperative orthopedic patient. Advanced age, venous stasis, lower extremity orthopedic surgery, and immobilization are significant risk factors. The nurse assesses the patient daily for calf swelling, tenderness, warmth, redness, and a positive Homans' sign. The nurse promptly reports abnormal findings to the physician.

In addition, fat embolus (see Chap. 69) may occur with orthopedic surgery. The nurse must be alert to changes in respiration, behavior, and level of consciousness that suggest the development of fat embolus.

## Nursing Diagnosis

Based on all assessment data, the patient's major nursing diagnoses after orthopedic surgery may include the following:

- Acute pain related to the surgical procedure, swelling, and immobilization
- Risk for peripheral neurovascular dysfunction related to swelling, constricting devices, or impaired circulation
- Risk for ineffective therapeutic regimen management related to insufficient knowledge or available support and resources
- Impaired physical mobility related to pain, edema, or the presence of an immobilizing device (eg, splint, cast, or brace)
- Risk for situational low self-esteem: disturbed body image or role performance related to impact of musculoskeletal problem

## COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications may include the following:

- Hypovolemic shock
- Atelectasis; pneumonia
- Urinary retention
- Infection
- Venous stasis and DVT

## Planning and Goals

The major goals for the patient after orthopedic surgery may include relief of pain, adequate neurovascular function, health promotion, improved mobility, positive self-esteem, and absence of complications.

## Nursing Interventions

### RELIEVING PAIN

After orthopedic surgery, pain can be intense. Edema, hematomas, and muscle spasms contribute to the pain experienced. Some patients report that the pain is less than that experienced preoperatively, and only moderate amounts of analgesics are needed. The nurse closely monitors the patient's pain level and response to therapeutic measures and makes every effort to relieve the pain and discomfort.

Multiple pharmacologic approaches to pain management exist. Patient-controlled analgesia (PCA) and epidural analgesia may be prescribed to control the pain. If intramuscular and oral analgesics are prescribed on an as-needed basis (PRN), the nurse instructs the patient to request the analgesic before the pain becomes severe. Alternatively, the nurse can offer the medication at set intervals. The nurse rotates intramuscular injection sites, avoiding the operative hip and thigh. The nurse may administer medications on a preventive basis within the prescribed intervals if the onset of pain can be predicted (eg, 30 minutes before planned activity such as transfer or exercise).

In addition to pharmacologic approaches to controlling pain, elevation of the operative extremity and application of cold, if prescribed, help to control edema and pain. Portable suction of the wound decreases fluid accumulation and hematoma formation. The nurse may find that repositioning, relaxation, distraction, and guided imagery help in reducing the patient's pain.

The nurse should report increasing and uncontrollable pain to the orthopedic surgeon for evaluation. Pain should diminish rapidly after the initial postoperative period. After 2 to 3 days, most patients require only occasional oral analgesia for residual muscle soreness and spasm.

### MAINTAINING ADEQUATE NEUROVASCULAR FUNCTION

The nurse continues the preoperative plan of care. The nurse monitors the neurovascular status of the involved body part and notifies the physician promptly of any indications of diminished tissue perfusion. The patient is reminded to perform muscle-setting, ankle, and calf-pumping exercises hourly while awake to enhance circulation.

### MAINTAINING HEALTH

The nurse continues the preoperative plan of care. It is important to encourage the patient to participate in the postoperative treatment regimen.

A well-balanced diet with adequate protein and vitamins is needed for wound healing. The patient progresses to a regular diet as soon as possible. Large amounts of milk should not be given to orthopedic patients who are on bed rest, however, because this adds to the calcium pool in the body and requires that the kidneys excrete more calcium, which increases the risk for urinary calculi.

The nurse monitors the patient for pressure ulcers, which are a threat to any patient who must spend an extended time in bed or who is elderly, malnourished, or unable to move without assistance. Turning, washing, and drying the skin and minimizing pressure over bony prominences are necessary to avoid skin breakdown.

### IMPROVING PHYSICAL MOBILITY

Patients are frequently reluctant to move after orthopedic surgery. Preoperative education about the planned postoperative treatment regimen promotes patient participation in physical activities. Patients often increase their mobility once they have been reassured that movement within therapeutic limits is beneficial, that the nurse will provide assistance, and that discomfort can be controlled.

Metal pins, screws, rods, and plates used for internal fixation are designed to maintain the position of the bone until ossification occurs. They are not designed to support the body's weight, and they can bend, loosen, or break if stressed. The estimated strength of the bone, the stability of the fracture, reduction and fixation, and the amount of bone healing are important considerations in determining weight-bearing limits. Although the incision may appear healed, the underlying bone requires more time to repair and regain normal strength. Some orthopedic procedures require weight-bearing restrictions. The orthopedic surgeon will prescribe the weight-bearing limits and the use of protective devices (orthoses), if necessary, after surgery.

The physical therapist tailors the exercise program to the individual patient's needs. The goal is the patient's return to the highest level of function in the shortest time possible. Rehabilitation involves progressive increases in the patient's activities and exercises. Assistive devices (crutches, walker) may be used for postoperative mobility. Preoperative practice with assistive devices helps the patient use them postoperatively. The nurse makes sure that the patient uses these devices safely (see discussions of crutch walking and use of a walker in Chap. 11).

### MAINTAINING SELF-ESTEEM

The nurse continues the preoperative plan of care. The nurse and the patient set realistic goals. Increased self-care activities within the limits of the therapeutic regimen and resumption of roles facilitate recognition of abilities and promote self-esteem, personal identity, and role performance. Acceptance of altered body image is facilitated by support provided by the nurse, family, and others.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

#### Hypovolemic Shock

Excessive loss of blood during or after surgery can result in shock. The nurse monitors the patient for signs and symptoms of hypovolemic shock: increased pulse rate, decreased blood pressure, urine output less than 30 mL per hour, restlessness, change in mentation, thirst, decreased hemoglobin and hematocrit. The nurse reports these findings to the orthopedic surgeon and assists

in appropriate management. (See Chap. 15 for a discussion of managing shock.)

#### Atelectasis and Pneumonia

The nurse monitors the patient's breath sounds and encourages deep breathing and coughing exercises. Full expansion of the lungs prevents the accumulation of pulmonary secretions and the development of atelectasis and pneumonia. Incentive spirometry, if prescribed, is encouraged. If signs of respiratory problems develop (eg, increased respiratory rate, productive cough, diminished or adventitious breath sounds, fever), the nurse reports the findings to the surgeon.

#### Urinary Retention

The nurse closely monitors the patient's urinary output after surgery. The nurse encourages the patient to void every 3 to 4 hours to prevent urinary retention and bladder distention. It is important to provide privacy during toileting. Because the patient may need to void in an unusual position, the nurse assists the patient with positioning. Fracture bedpans may be more comfortable than other bedpans. Voiding in the side-lying position may be helpful to the male patient. Some male patients can void only if standing, and clarification with the surgeon of the activity prescription may be needed before the patient is assisted to a standing position. If the patient is unable to void, intermittent catheterizations may be prescribed until the patient is able to void independently. Indwelling urinary catheters are to be used only when absolutely necessary and should be removed as soon as possible.

#### Infection

Infection is a risk after any surgery, but it is of particular concern for the postoperative orthopedic patient because of the high risk of osteomyelitis. Osteomyelitis often requires prolonged courses of intravenous antibiotics. At times, the infected bone and prosthesis or internal fixation device must be surgically removed. Therefore, prophylactic systemic antibiotics are usually prescribed during the perioperative and immediate postoperative period. The nurse assesses the patient's response to these antibiotics. When changing dressings and emptying wound drainage devices, aseptic technique is essential. The nurse monitors the patient's vital signs, incision, and drainage. The nurse monitors the patient for signs of urinary tract infection. Prompt assessment for and treatment of infection are essential.

#### Venous Stasis and Deep Vein Thrombosis

Prevention of DVT requires use of ankle and calf-pumping exercises, elastic compression stockings, and sequential compression devices. Adequate hydration and early mobilization are equally important. Prophylactic warfarin, adjusted-dose heparin, or low-molecular-weight heparin (eg, enoxaparin sodium) may be prescribed. Aspirin has no apparent effect in preventing DVT in the orthopedic patient. The nurse monitors the patient for signs of DVT and promptly reports findings to the physician for management.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching the Patient Self-Care

The length of stay in the hospital after orthopedic surgery is usually less than 1 week. Convalescence and rehabilitation take place at home or in a nonacute care setting. The nurse teaches the patient and the family to recognize complications that must be reported promptly to the orthopedic surgeon. The patient must

Chart 67-10

## Home Care Checklist • The Patient Who Had Orthopedic Surgery

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Describe wound care	✓	✓
• State indicators of wound infections (eg, redness, swelling, tenderness, purulent drainage, fever)	✓	✓
• Consume healthy diet to promote wound and bone healing	✓	
• Participate in prescribed exercise regimen to promote circulation and mobility	✓	
• Use mobility aids safely	✓	
• Observe prescribed weight-bearing and activity limits	✓	
• Take prescribed therapeutic and prophylactic medications (eg, antibiotics; anticoagulants, analgesics)	✓	
• State indicators of complications to report promptly to physician (eg, uncontrolled swelling and pain; cool, pale fingers or toes; paresthesia; paralysis; purulent drainage; signs of systemic infection; signs of deep vein thrombosis or pulmonary emboli)	✓	✓
• Identify modifications of home environment to promote safe environment and independence during convalescence and rehabilitation	✓	✓

understand the prescribed medication regimen. The nurse should demonstrate proper wound care. The patient gradually resumes physical activities and adheres to weight-bearing limits. The patient must be able to perform transfers and to use mobility aids safely. If the patient has a cast or other immobilizing device, family members should be instructed about how to assist the patient in a way that is safe for the patient and for the family member (eg, using proper body mechanics when lifting the patient). Specific exercises need to be taught and practiced before discharge. The nurse discusses recovery and health promotion, emphasizing a healthy lifestyle and diet.

### Continuing Care

If special equipment or home modifications are needed for safe care at home, they must be obtained before the patient is discharged home. The nurse, physical therapist, and social worker can assist the patient and family in identifying their needs and in getting ready to care for the patient at home.

Frequently, home health nursing and home physical therapy are part of the discharge plan of care. These referrals provide resources and help the patient and the family cope with the demands of care during convalescence and rehabilitation. The nurse can explore problems that the patient and family identify during the home care visit. The nurse assesses the patient's progress and monitors for possible complications. Regular medical follow-up care after discharge needs to be arranged (Chart 67-10).

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Reports decreased level of pain
  - a. Uses multiple approaches to reduce pain
  - b. Uses occasional oral medication to control discomfort
  - c. Elevates extremity to control edema and discomfort
  - d. Moves with greater comfort
2. Exhibits adequate neurovascular function
  - a. Exhibits normal color and temperature of skin
  - b. Has warm skin
  - c. Has normal capillary refill response
  - d. Demonstrates intact sensory and motor function
  - e. Demonstrates reduced swelling
3. Promotes health
  - a. Eats diet appropriate for nutritional needs
  - b. Maintains adequate hydration
  - c. Abstains from smoking
  - d. Practices respiratory exercises
  - e. Repositions self to relieve pressure on skin
  - f. Engages in strengthening and preventive exercises
4. Maximizes mobility within the therapeutic limits
  - a. Requests assistance when moving
  - b. Elevates edematous extremity after transfer
  - c. Uses immobilizing devices as prescribed
  - d. Complies with prescribed weight-bearing limitation
5. Expresses positive self-esteem
  - a. Discusses temporary or permanent changes in body image
  - b. Discusses role performances
  - c. Views self as capable of assuming responsibilities
  - d. Actively participates in planning care and in the therapeutic regimen
6. Exhibits absence of complications
  - a. Does not experience shock
  - b. Maintains normal vital signs and blood pressure
  - c. Has clear lung sounds
  - d. Demonstrates wound healing without signs of infection
  - e. Does not experience urinary retention
  - f. Voids clear urine clear
  - g. Exhibits no signs of DVT

### Critical Thinking Exercises

**1.** You are working in the emergency department of a community hospital. Early this afternoon, an elderly patient who had fallen and broken her right forearm was treated with closed reduction and casting. She was sent home and was told she could call the emergency department if she had any questions or concerns. She has been home for about 7 hours and is calling because she is experiencing extreme pain in her hand and does not know what to do. What information do you need to assess this situation? What potential problems might she be experiencing? What advice would you give? What is the rationale for this advice?

2. You are providing postoperative care to two patients who had elective hip replacements. The 67-year-old patient had a cemented prosthesis. The 52-year-old patient had a press-fit ingrowth prosthesis. Compare and contrast the plans of care for these two patients. How would they be similar? How would they be different?

3. A 48-year-old patient with multiple trauma is placed in balanced skeletal traction to treat his midshaft femoral fracture until his condition is stable for surgical management of the fracture. Discuss the principles of managing a patient in skeletal traction and how these principles can be incorporated into this patient's plan of care. What actions can you take to minimize the effects of immobilization?

4. An 84-year-old woman had an internal fixation for her fractured hip. She complains that her elastic stockings feel tight and hot and asks you to remove them. How would you respond to this request? What is the rationale for your action? Role play your explanation of the purpose of the stockings.

# ● Management of Patients With Musculoskeletal Disorders

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Use the nursing process as a framework for care of the patient with low back pain.
2. Describe the rehabilitation and health education needs of the patient with low back pain.
3. Describe conditions of the upper extremities and nursing care of the patient undergoing surgery of the hand or wrist.
4. Use the nursing process as a framework for care of the patient undergoing foot surgery.
5. Explain the pathophysiology, pathogenesis, prevention, and management of osteoporosis.
6. Identify the causes and related medical management of osteomalacia.
7. Describe the medication therapy program for the patient with Paget's disease.
8. Use the nursing process as a framework for care of the patient with osteomyelitis.
9. Use the nursing process as a framework for care of the patient with a bone tumor.

Musculoskeletal disorders, such as impairment of the back and spine, are leading health problems and causes of disability, particularly in people during their employment years. The limitations imposed on the patient are severe, and the economic cost, in terms of loss of productivity, medical expenses, and other costs that are not compensated, is in the billions of dollars.

## Common Musculoskeletal Problems

### ACUTE LOW BACK PAIN

The number of medical visits resulting from low back pain is second only to the number of visits for upper respiratory illnesses. Most low back pain is caused by one of many musculoskeletal problems, including acute lumbosacral strain, unstable lumbosacral ligaments and weak muscles, osteoarthritis of the spine, spinal stenosis, intervertebral disk problems, and unequal leg length.

Older patients may experience back pain associated with osteoporotic vertebral fractures or bone metastasis. Other causes include kidney disorders, pelvic problems, retroperitoneal tumors, abdominal aneurysms, and psychosomatic problems.

In addition, obesity, stress, and occasionally depression may contribute to low back pain. Back pain due to musculoskeletal disorders usually is aggravated by activity, whereas pain due to other conditions is not. Patients with chronic low back pain may develop a dependence on alcohol or analgesics in an attempt to cope with and self-treat the pain.

### Pathophysiology

The spinal column can be considered as an elastic rod constructed of rigid units (vertebrae) and flexible units (intervertebral disks) held together by complex facet joints, multiple ligaments, and paravertebral muscles. Its unique construction allows for flexibility while providing maximum protection for the spinal cord. The spinal curves absorb vertical shocks from running and jumping. The trunk muscles help to stabilize the spine. The abdominal and thoracic muscles are important in lifting activities. Disuse weakens these supporting structures. Obesity, postural problems, structural problems, and overstretching of the spinal supports may result in back pain.

The intervertebral disks change in character as a person ages. A young person's disks are mainly fibrocartilage with a gelatinous matrix. As a person ages, the disks become dense, irregular fibrocartilage. Disk degeneration is a common cause of back pain. The lower lumbar disks, L4–L5 and L5–S1, are subject to the greatest mechanical stress and the greatest degenerative changes. Disk protrusion (herniated nucleus pulposus) or facet joint changes can cause pressure on nerve roots as they leave the spinal canal, which results in pain that radiates along the nerve. Management of intervertebral disk disease is discussed in Chapter 65.

### Clinical Manifestations

The patient complains of either acute back pain or chronic back pain (lasting more than 3 months without improvement) and fatigue. The patient may report pain radiating down the leg, which is known as **radiculopathy** or **sciatica** and which suggests nerve root involvement. The patient's gait, spinal mobility, reflexes, leg length, leg motor strength, and sensory perception may be altered. Physical examination may disclose paravertebral muscle spasm (greatly increased muscle tone of the back postural muscles) with a loss of the normal lumbar curve and possible spinal deformity.

### Assessment and Diagnostic Findings

The Agency for Health Care Policy and Research developed guidelines for assessment and management of acute low back pain (Bigos et al., 1994). These safe, conservative, and cost-effective guidelines have reduced the use of noneffective therapeutic interventions, including prolonged bed rest.

The initial evaluation of acute low back pain includes a focused history and physical examination, including general observation of the patient, back examination, and neurologic testing (reflexes, sensory impairment, straight-leg raising, muscle strength, and muscle atrophy). The findings suggest either nonspecific back symptoms or potentially serious problems, such as sciatica, spine fracture, cancer, infection, or rapidly progressing neurologic deficit. If the initial examination does not suggest a serious condition, no additional testing is performed during the first 4 weeks of symptoms.

The diagnostic procedures described in Chart 68-1 may be indicated for the patient with potentially serious or prolonged low back pain. The nurse prepares the patient for these studies, provides the necessary support during the testing period, and monitors the patient for any adverse responses to the procedures.

### Medical Management

Most back pain is self-limited and resolves within 4 weeks with analgesics, rest, stress reduction, and relaxation. Based on initial assessment findings, the patient is reassured that the assessment indicates that the back pain is not due to a serious condition. Management focuses on relief of pain and discomfort, activity modification, and patient education.

Nonprescription analgesics (acetaminophen, ibuprofen) are usually effective in achieving pain relief. At times, a patient may require the addition of muscle relaxants or opioids. Heat or cold therapy frequently provides temporary relief of symptoms. In the absence of symptoms of disease (radiculopathy of the roots of spinal nerves), manipulation may be helpful.

Other physical modalities have no proven efficacy in treating acute low back pain. They include traction, massage, diathermy, ultrasound, cutaneous laser treatment, biofeedback, and transcutaneous electrical nerve stimulation. Likewise, acupuncture and injection procedures have no proven efficacy (Bigos et al., 1994).

## Glossary

**bursitis:** inflammation of a fluid-filled sac in a joint

**contracture:** abnormal shortening of muscle or fibrosis of joint structures

**involucrum:** new bone growth around a sequestrum

**radiculopathy:** disease of a nerve root

**sciatica:** sciatic nerve pain; pain travels down back of thigh into foot

**sequestrum:** dead bone in abscess cavity

**tendinitis:** inflammation of muscle tendons

Chart  
68-1**Diagnostic Procedures for Low Back Pain**

**X-ray of the spine**—may demonstrate a fracture, dislocation, infection, osteoarthritis, or scoliosis

**Bone scan and blood studies**—may disclose infections, tumors, and bone marrow abnormalities

**Computed tomography (CT scan)**—useful in identifying underlying problems, such as obscure soft tissue lesions adjacent to the vertebral column and problems of vertebral disks

**Magnetic resonance imaging (MRI)**—permits visualization of the nature and location of spinal pathology

**Electromyogram (EMG) and nerve conduction studies**—used to evaluate spinal nerve root disorders (radiculopathies)

Most patients need to alter their activity patterns to avoid aggravating the pain. Twisting, bending, lifting, and reaching, all of which stress the back, are avoided. The patient is taught to change position frequently. Sitting should be limited to 20 to 50 minutes based on level of comfort. Bed rest is recommended for 1 to 2 days, with a maximum of 4 days only if pain is severe. A gradual return to activities and low-stress aerobic exercise is recommended. Conditioning exercises for the trunk muscles are begun after about 2 weeks.

If there is no improvement within 1 month, additional assessments for physiologic abnormalities are performed. Management is based on findings.

## NURSING PROCESS: THE PATIENT WITH ACUTE LOW BACK PAIN

### Assessment

The nurse encourages the patient with low back pain to describe the discomfort (eg, location, severity, duration, characteristics, radiation, associated weakness in the legs). Descriptions of how the pain occurred—with a specific action (eg, opening a garage door) or with an activity in which weak muscles were overused (eg, weekend gardening)—and how the patient has dealt with the pain often suggest areas for intervention and patient teaching.

If back pain is a recurrent problem, information about previous successful pain control methods helps in planning current management. The nurse also asks how the back pain affects the patient's lifestyle. Information about work and recreational activities helps to identify areas for back health education. Because stress and anxiety can evoke muscle spasms and pain, the nurse needs insight into environmental variables, work situations, and family relationships. In addition, the nurse assesses the effect of chronic pain on the emotional well-being of the patient. Referral to a psychiatric nurse clinician for assessment and management of stressors contributing to the low back pain and related depression may be appropriate.

During the interview, the nurse observes the patient's posture, position changes, and gait. Often, the patient's movements are guarded, with the back kept as still as possible. The patient often selects a chair of standard seat height with arms for support. The patient may sit and stand in an unusual position, leaning away from the most painful side, and may ask for assistance when undressing for the physical examination.

On physical examination, the nurse assesses the spinal curve, any leg length discrepancy, and pelvic crest and shoulder symme-

try. The nurse palpates the paraspinal muscles and notes spasm and tenderness. When the patient is in a prone position, the paraspinal muscles relax, and any deformity caused by spasm subsides. The nurse asks the patient to bend forward and then laterally and notes any discomfort or limitations in movement. It is important to determine the effect of these limitations in movement on activities of daily living (ADLs). The nurse evaluates nerve involvement by assessing deep tendon reflexes, sensations (eg, paresthesia), and muscle strength. Back and leg pain on straight-leg raising (with the patient supine, the patient's leg is lifted upward with the knee extended) suggests nerve root involvement. Obesity can contribute to low back pain. If the patient is obese, the nurse completes a nutritional assessment.

### Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Acute pain related to musculoskeletal problems
- Impaired physical mobility related to pain, muscle spasms, and decreased flexibility
- Deficient knowledge related to back-conserving techniques of body mechanics
- Risk for situational low self-esteem related to impaired mobility, chronic pain, and altered role performance
- Imbalanced nutrition: more than body requirements related to obesity

### Planning and Goals

The major goals for the patient may include relief of pain, improved physical mobility, use of back-conserving techniques of body mechanics, improved self-esteem, and weight reduction (Chart 68-2).

### Nursing Interventions

#### RELIEVING PAIN

To relieve pain, the nurse encourages the patient to reduce stress on the back muscles and to change position frequently. Patients are taught to control and modify the perceived pain through behavioral therapies that reduce muscular and psychological tension. Diaphragmatic breathing and relaxation help reduce muscle tension contributing to low back pain. Diverting the patient's attention from the pain to another activity (eg, reading, conversation, watching television) may be helpful in some instances. Guided imagery, in which the relaxed patient learns to focus on a pleasant event, may be used along with other pain-relief strategies (see Chart 68-2).

If medication is prescribed, the nurse assesses the patient's response to each medication. As the acute pain subsides, medications are reduced as prescribed. Self-applied intermittent heat or cold may reduce the pain. The nurse evaluates and notes the patient's response to various pain management modalities.

#### IMPROVING PHYSICAL MOBILITY

Physical mobility is monitored through continuing assessments. The nurse assesses how the patient moves and stands. As the back pain subsides, self-care activities are resumed with minimal strain on the injured structures. Position changes should be made slowly and carried out with assistance as required. Twisting and jarring motions are avoided. The nurse encourages the patient to alter-

### Chart 68-2 • PATIENT EDUCATION Strategies for the Patient With Low Back Pain

Discuss the following strategies with the patient:

#### Pain Management

- Limit bed rest; keep knees flexed to decrease strain on back
- *Nonpharmacologic approaches:* distraction, relaxation, imagery, thermal interventions (eg, ice or heat), stress reduction
- *Pharmacologic approaches:* nonsteroidal anti-inflammatory drugs, analgesics, muscle relaxants

#### Exercise

- Stretch to enhance flexibility, do strengthening exercises
- Perform prescribed back exercises to increase function, emphasizing gradual increases in time and repetitions

#### Body Mechanics

- Practice good posture
- Avoid twisting body
- Push objects rather than pull them
- Keep load close to body when lifting
- Bend knees and tighten abdominal muscles when lifting

- Avoid overreaching
- Use wide base of support
- Use back brace to protect back

#### Work Modifications

- Adjust work area to avoid stress on back
- Adjust height of chair or work table
- Use lumbar support in chair
- Avoid prolonged standing and repetitive tasks
- Avoid bending, twisting, and lifting heavy objects
- Avoid work involving continuous vibrations

#### Stress Reduction

- Discuss with patient the interdependence of stress and anxiety on muscle tension and pain
- Explore effective coping mechanisms
- Teach stress reduction techniques
- Refer patient to back clinic

nate lying, sitting, and walking activities frequently and advises the patient to avoid sitting, standing, or walking for long periods. The patient may find that sitting in a chair with arm rests to support some of the body weight and a soft support at the small of the back provides comfort.

With severe pain, the patient limits activity for 1 to 2 days. Extended periods of inactivity are not effective and result in deconditioning. The patient rests in bed on a firm, nonsagging mattress (a bed board may be used). Lumbar flexion is increased by elevating the head and thorax 30 degrees using pillows or a foam wedge and slightly flexing the knees supported on a pillow. Alternatively, the patient assumes a lateral position with knees and hips flexed (curled position) with a pillow between the knees and legs and a pillow supporting the head (Fig. 68-1). A prone position is avoided because it accentuates lordosis. The nurse instructs the patient to get out of bed by rolling to one side and placing the legs down while pushing the torso up, keeping the back straight.

As the patient achieves comfort, activities are gradually resumed, and an exercise program is initiated. Initially, low-stress aerobic exercises, such as short walks or swimming, are suggested. After 2 weeks, conditioning exercises for the abdominal and trunk

**FIGURE 68-1** Positioning to promote lumbar flexion. © B. Proud.

muscles are started. The physical therapist designs an exercise program for the individual patient to reduce lordosis, increase flexibility, and reduce strain on the back. It may include hyperextension exercises to strengthen the paravertebral muscles, flexion exercises to increase back movement and strength, and isometric flexion exercises to strengthen trunk muscles. Each exercise period begins with relaxation. Exercise begins gradually and increases as the patient recovers.

The nurse encourages the patient to adhere to the prescribed exercise program. Erratic exercising is ineffective. For most exercise programs, it is suggested that the person exercise twice a day, increasing the number of exercises gradually. Some patients may find it difficult to adhere to a program of prescribed exercises for a long period. These patients are encouraged to improve their posture, use good body mechanics on a regular basis, and engage in regular exercise activities (eg, walking, swimming) to maintain a healthy back. Activities should not cause excessive lumbar strain, twisting, or discomfort; for example, activities such as horseback riding and weight-lifting are avoided.

#### USING PROPER BODY MECHANICS

Good body mechanics and posture are essential to avoid recurrence of back pain. The patient must be taught how to stand, sit, lie, and lift properly (Figs. 68-2 and 68-3). Providing the patient with a list of suggestions helps in making these long-term changes (Chart 68-3). The patient who wears high heels is encouraged to change to low heels. The patient who is required to stand for long periods should shift weight frequently and should rest one foot on a low stool, which decreases lumbar lordosis. The proper posture can be verified by looking in a mirror to see whether the chest is up and the abdomen is tucked in. Locking the knees when standing is avoided, as is bending forward for long periods.

When the patient is sitting, the knees and hips should be flexed, and the knees should be level with the hips or higher to minimize lordosis. The feet should be flat on the floor. The back needs to be supported. The patient should sleep on the side with knees and hips flexed, or supine with knees supported in a flexed position. Sleeping prone should be avoided.

### NURSING RESEARCH PROFILE 68-1

## Successful Interventions for Back Pain

Reavis, D. (1999). Back injury in primary care: three sides of the coin. *Nurse Practitioner Forum*, 10, 208–212.

### Purpose

Low back pain is a common job-related injury. Nurse practitioners managing industrial injuries in primary health care clinics need to design treatment protocols that are effective for the employee and contain costs for the employer.

This study compared the average number of days absent from work for patients treated with various protocols. The conservative treatment consisted of nonsteroidal anti-inflammatory drugs (NSAIDs), muscle relaxants, and rest. The active physical rehabilitation treatment consisted of NSAIDs, muscle relaxants, and referral to an exercise physiologist for muscle strength and range of motion exercise, including ice, electrical stimulation, and/or exercise therapy.

### Study Sample and Design

Two primary health care clinics located in different regions of the United States were used. One clinic used a conservative treatment protocol; the other used the active physical rehabilitation protocol. Charts of patients with the appropriate diagnostic code (ie, low-back strain) were reviewed for inclusion criteria (eg, adult age, first-time work-related injury of the back).

The convenience sample consisted of two groups of patients (18 patients in each group). The ages and gender distributions in the two groups were similar. The mean number of days off from work was cal-

culated for each of the two treatment groups and compared using the *t* test for independent groups to answer the research question: Do patients with a clinical diagnosis of low back pain differ in their responses to two sets of treatment protocols as measured by number of days absent from work?

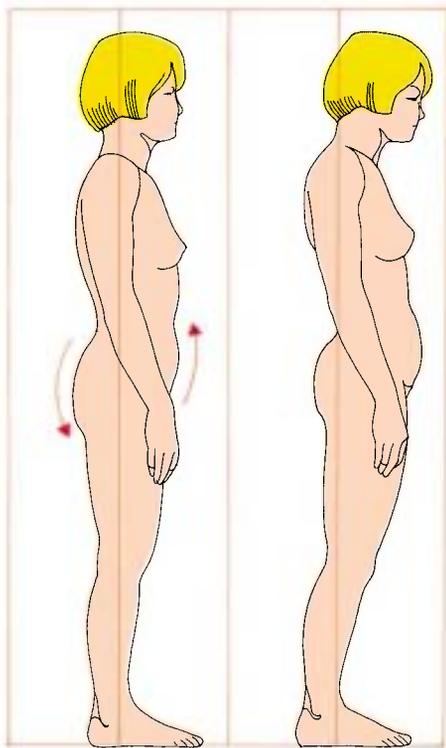

### Findings

The mean number of days absent from work was 13.3 days for the conservative treatment group and 4.5 days for the active physical rehabilitation group. This was a statistically significant difference ( $p < .01$ ), suggesting active physical rehabilitation is the superior protocol. However, employer costs, including monetary outlay for exercise therapy and loss of productivity due to number of days off from work, were not considered in this study.

### Nursing Implications

The findings suggest that active physical rehabilitation may be more effective than conservative treatment; however, additional studies are needed to replicate the findings and should include a cost-benefit analysis and random assignment of subjects.

Prevention of back injury is a primary concern of employee health nurses. Additional studies are warranted to determine effectiveness of health promotion programs before back injury occurs.

**FIGURE 68-2** Proper and improper standing postures. (Left) Abdominal muscles contracted, giving a feeling of upward pull, and gluteal muscles contracted, giving a downward pull. (Right) Slouch position, showing abdominal muscles relaxed and body out of proper alignment.

The nurse instructs the patient in the safe and correct way to lift objects—using the strong quadriceps muscles of the thighs, with minimal use of weak back muscles. With feet placed to provide a wide base of support, the patient should bend the knees, tighten the abdominal muscles, and lift the object close to the body with a smooth motion, avoiding twisting and jerking. To prevent recurrence of acute low back pain, the nurse may instruct the patient to wear a back support when repeated lifting is required and to avoid lifting more than one third of his or her weight without help.

It takes about 6 months for a person to readjust postural habits. Practicing these protective and defensive postures, positions, and body mechanics results in natural strengthening of the back and diminishes the chance that back pain will recur.

### IMPROVING SELF-ESTEEM

Because of the immobility associated with low back pain, the patient may depend on others to do various tasks. Dependency may continue beyond physiologic needs and become a way to fulfill psychosocial needs. Assisting both the patient and support people to recognize continued dependency helps the patient identify and cope with the underlying reason for the dependency.

Role-related responsibilities may have been modified with the onset of low back pain. As recovery from acute low back pain and immobility progresses, the patient may resume former role-related responsibilities.

If these activities contributed to the development of low back pain, however, it may be difficult to resume them without chronic low back pain syndrome, with associated disability and depression resulting. If the patient experiences secondary gains associ-

**FIGURE 68-3** Proper and improper lifting techniques. (*Left*) Correct position for lifting. This person is using the long and strong muscles of the arms and legs and holding the object so that the line of gravity falls within the base of support. (*Right*) Incorrect position for lifting because pull is exerted on the back muscles and leaning causes the line of gravity to fall outside the base.

ated with low back disability (eg, worker's compensation, easier lifestyle or workload, increased emotional support), a "low back neurosis" may develop. The patient may need help in coping with specific stressors and in learning how to control stressful situations. When people successfully deal with stress, they develop confidence in their abilities to manage other stressful situations. Psychotherapy or counseling may be needed to assist the person in resuming a full, productive life. Back clinics use multidisciplinary approaches to help the patient with pain and with resumption of role-related responsibilities.

### MODIFYING NUTRITION FOR WEIGHT REDUCTION

Obesity contributes to back strain by stressing the relatively weak back muscles. Exercises are less effective and more difficult to perform when the patient is overweight. Weight reduction through diet modification may prevent recurrence of back pain. Weight reduction is based on a sound nutritional plan that includes a change in eating habits to maintain desirable weight. Monitoring weight reduction, noting achievement, and providing encouragement and positive reinforcement facilitate adherence. Frequently, back problems resolve as normal weight is achieved.

#### Chart 68-3

#### Health Promotion • Activities to Promote a Healthy Back

##### Standing

- Avoid prolonged standing and walking.
- When standing for any length of time, rest one foot on a small stool or box to relieve lumbar lordosis.
- Avoid forward flexion work positions.
- Avoid high heels.

##### Sitting

- Avoid sitting for prolonged periods.
- Sit in a straight-back chair with back well supported and arm rests to support some of the body weight; use a footstool to position knees higher than hips if necessary.
- Eradicate the hollow of the back by sitting with the buttocks "tucked under."
- Maintain back support; use a soft support at the small of the back.
- Avoid knee and hip extension. When driving a car, have the seat pushed forward as far as possible for comfort.
- Guard against extension strains—reaching, pushing, sitting with legs straight out.
- Alternate periods of sitting with walking.

##### Lying

- Rest at intervals; fatigue contributes to spasm of the back muscles.

- Place a firm bed board under the mattress.
- Avoid sleeping in a prone position.
- When lying on the side, place a pillow under the head and one between the legs, with the legs flexed at the hips and knees.
- When supine, use a pillow under the knees to decrease lordosis.

##### Lifting

- When lifting, keep the back straight and hold the load as close to the body as possible.
- Lift with the large leg muscles, not the back muscles.
- Use trunk muscles to stabilize the spine.
- Squat while keeping the back straight when it is necessary to pick something off the floor.
- Avoid twisting the trunk of the body, lifting above waist level, and reaching up for any length of time.

##### Exercising

- Daily exercise is important in the prevention of back problems.
- Walking and gradually increasing the distance and pace of walking is recommended.
- Perform prescribed back exercises twice daily, increasing exercise gradually.
- Avoid jumping and jarring activities.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Experiences pain relief
  - a. Rests comfortably
  - b. Changes positions comfortably
  - c. Obtains relief through use of physical modalities, psychological techniques, and medications
  - d. Avoids drug dependency
2. Demonstrates resumption of physical mobility
  - a. Resumes activities gradually
  - b. Avoids positions that cause discomfort and muscle spasm
  - c. Plans recumbent rest periods throughout the day
3. Demonstrates back-conserving body mechanics
  - a. Improves posture
  - b. Positions self to minimize stress on the back
  - c. Demonstrates use of good body mechanics
  - d. Participates in exercise program
4. Resumes role-related responsibilities
  - a. Uses coping techniques to deal with stressful situations
  - b. Demonstrates decreased dependence on others for self-care
  - c. Resumes role responsibilities as low back pain resolves
  - d. Resumes full, productive lifestyle
5. Achieves desired weight
  - a. Identifies need to lose weight if appropriate
  - b. Sets realistic goals
  - c. Participates in development of weight-reduction plan
  - d. Complies with weight-reduction regimen

## Common Problems of the Upper Extremity

The structures in the upper extremity are frequently the sites of painful syndromes. The structures most frequently affected are the shoulder, wrist, and hand.

### BURSITIS AND TENDINITIS

**Bursitis** and **tendinitis** are inflammatory conditions that commonly occur in the shoulder. Bursae are fluid-filled sacs that prevent friction between joint structures during joint activity. When inflamed, they are painful. Similarly, muscle tendon sheaths become inflamed with repetitive stretching. The inflammation causes proliferation of synovial membrane and pannus formation, which restricts joint movement. Conservative treatment includes rest of the extremity, intermittent ice and heat to the joint, and nonsteroidal anti-inflammatory drugs (NSAIDs) to control the inflammation and pain. Arthroscopic synovectomy may be considered if shoulder pain and weakness persist.

### LOOSE BODIES

Loose bodies may occur in a joint as a result of articular cartilage wear and bone erosion. These fragments interfere with joint movement, locking the joint, and cause painful movement. Loose bodies are removed by arthroscopic surgery.

### IMPINGEMENT SYNDROME

Overuse (microtrauma) may produce an impingement syndrome in the shoulder. The supraspinatus and biceps tendons become irritated and edematous and press against the acromion process,

limiting shoulder motion. The patient experiences pain, shoulder tenderness, limited movement, muscle spasm, and atrophy. The process may progress to a rotator cuff tear. Conservative treatment includes rest, NSAIDs, joint injections, and physical therapy (Chart 68-4). Arthroscopic débridement is used for persistent pain. Gentle joint motion is begun after surgery. (See Chapter 69 for a discussion of rotator cuff injury.)

### CARPAL TUNNEL SYNDROME

Carpal tunnel syndrome is an entrapment neuropathy that occurs when the median nerve at the wrist is compressed by a thickened flexor tendon sheath, skeletal encroachment, edema, or a soft tissue mass. The syndrome is commonly caused by repetitive hand activities but may be associated with arthritis, hypothyroidism, or pregnancy. The patient experiences pain, numbness, paresthesia, and possibly weakness along the median nerve (thumb and first two fingers). Tinel's sign may be used to help identify carpal tunnel syndrome (Fig. 68-4). Night pain is common. Treatment is based on cause. Rest splints to prevent hyperextension and prolonged flexion of the wrist, avoidance of repetitive flexion of the wrist (eg, use of ergonomic changes at work to reduce wrist strain), NSAIDs, and carpal canal cortisone injections may relieve the symptoms. Specific yoga postures, relaxation, and acupuncture may provide nontraditional alternatives to relieve carpal tunnel symptoms. Traditional or endoscopic laser surgical release of the transverse carpal ligament may be necessary. The patient wears a hand splint after surgery and limits hand use during healing. The patient may need assistance with personal care and ADLs. Full recovery of motor and sensory function after nerve release surgery may take several weeks or months.

### GANGLION

A ganglion, a collection of gelatinous material near the tendon sheaths and joints, appears as a round, firm, cystic swelling, usually on the dorsum of the wrist. It most frequently occurs in women younger than 50 years of age. The ganglion is locally tender and may cause an aching pain. When a tendon sheath is in-

#### Chart 68-4 • PATIENT EDUCATION Measures to Promote Shoulder Healing

The nurse provides guidelines for general care and instructs the patient in carrying out measures that will promote shoulder healing. Patient education includes the following points:

- During the acute phase, rest the joint in a position that minimizes stress on the joint structures, to prevent further damage and the development of adhesions.
- Support the affected arm on pillows while sleeping, to keep from turning onto the shoulder.
- For the first 24 to 48 hours of the acute phase, apply cold to reduce swelling and discomfort; then, according to the treatment plan, apply heat intermittently to promote circulation and healing.
- Gradually resume motion and use of the joint. Assistance with dressing and other activities of daily living may be needed.
- Avoid working and lifting above shoulder level or pushing an object against a “locked” shoulder.
- Perform the prescribed daily range-of-motion and strengthening exercises.

**FIGURE 68-4** Tinel's sign may be elicited in patients with carpal tunnel syndrome by percussing lightly over the median nerve, located on the inner aspect of the wrist. If the patient reports tingling, numbness, and pain, the test for Tinel's sign is considered positive. From Weber, J. W., & Kelley, J. (2003). *Health assessment in nursing* (2nd ed.). Philadelphia: Lippincott Williams & Wilkins. © B. Proud

involved, weakness of the finger occurs. Treatment may include aspiration, corticosteroid injection, or surgical excision. After treatment, a compression dressing and immobilization splint are used.

## DUPUYTREN'S CONTRACTURE

Dupuytren's deformity is a slowly progressive **contracture** of the palmar fascia, which causes flexion of the fourth and fifth fingers, and frequently the middle finger. This renders the fingers more or less useless (Fig. 68-5). It is caused by an inherited autosomal dominant trait and occurs most frequently in men who are older than 50 years of age and who are of Scandinavian or Celtic origin. It is also associated with arthritis, diabetes, gout, and alcoholism. It starts as a nodule of the palmar fascia. The nodule may not change, or it may progress so that the fibrous thickening extends to involve the skin in the distal palm and produces a contracture of the fingers. The patient may experience dull aching discomfort, morning numbness, cramping, and stiffness in the affected fingers. This condition starts in one hand, but eventually both hands are affected symmetrically. Initially, finger-stretching exercises may prevent contractures. With contracture development, palmar and digital fasciectomy are performed to improve function. Finger exercises are begun on postoperative day 1 or 2.

**FIGURE 68-5** Dupuytren's contracture, a flexion deformity caused by an inherited trait, is a slowly progressive contracture of the palmar fascia, which severely impairs the function of the fourth, fifth, and sometimes, the middle fingers.

## NURSING PROCESS: THE PATIENT UNDERGOING SURGERY OF THE HAND OR WRIST

### Assessment

Surgery of the hand or wrist, unless related to major trauma, is generally an ambulatory surgery procedure. Before surgery, the nurse assesses the patient's level and type of discomfort and limitations in function caused by the ganglion, carpal tunnel syndrome, Dupuytren's contracture, or other condition of the hand.

### Nursing Diagnoses

Based on the assessment data, the nursing diagnoses for the patient undergoing surgery of the hand or wrist may include the following:

- Risk for peripheral neurovascular dysfunction related to surgical procedure
- Acute pain related to inflammation and swelling
- Self-care deficit: bathing/hygiene, dressing/grooming, feeding, and/or toileting related to bandaged hands
- Risk for infection related to surgical procedure

### Planning and Goals

The goals of the patient may include relief of pain, improved self-care, and absence of infection.

### Nursing Interventions

#### PROMOTING NEUROVASCULAR FUNCTION

Neurovascular assessment of the exposed fingers every hour for the first 24 hours is essential for monitoring function of the nerves and perfusion of the hand. The nurse compares the affected hand with the unaffected hand and the postoperative status with the documented preoperative status. The nurse asks the patient to describe the sensations in the hands and to demonstrate finger mobility. With tendon repairs and nerve, vascular, or skin grafts, motor function is tested only if prescribed. The nurse assesses the temperature of the affected hand. Dressings are to be supportive but nonconstrictive. Pain uncontrolled by analgesics suggests compromised neurovascular functioning.

#### RELIEVING PAIN

Pain may be related to surgery, edema, hematoma formation, or restrictive bandages. To control swelling that may increase the patient's pain and discomfort, the nurse elevates the hand to heart level with pillows. When higher elevation is prescribed, an elevating sling may be attached to a pole used in intravenous (IV) therapies or to an overhead frame. If the patient is ambulatory, the arm is elevated in a conventional sling with the hand at heart level.

Intermittent ice packs to the surgical area during the first 24 to 48 hours may be prescribed to control swelling. Unless contraindicated, active extension and flexion of the fingers to promote circulation are encouraged, even though movement is limited by the bulky dressing.

Generally, the pain and discomfort can be controlled by oral analgesics. The nurse evaluates the patient's response to analgesics and to other pain-control measures. Patient education concerning analgesics is important.

### IMPROVING SELF-CARE

During the first few days after surgery, the patient needs assistance with ADLs because one hand is bandaged and independent self-care is impaired. The patient may need to arrange for assistance with feeding, bathing and hygiene, dressing, grooming, and toileting. Within a few days, the patient develops skills in one-handed ADLs and is usually able to function with minimal assistance and use of assistive devices. The nurse encourages use of the involved hand, unless contraindicated, within the limits of discomfort. As rehabilitation progresses, the patient resumes use of the injured hand. Physical or occupational therapy-directed exercises may be prescribed. The nurse emphasizes adherence to the therapeutic regimen.

### PREVENTING INFECTION

As with all surgery, there is a risk for infection. The nurse teaches the patient to monitor temperature and signs and symptoms that suggest an infection. It also is important to instruct the patient to keep the dressing clean and dry and to report any drainage, foul odor, or increased pain and swelling. Patient education includes aseptic wound care as well as education related to prescribed prophylactic antibiotics.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

After the patient has undergone hand surgery, the nurse teaches the patient how to monitor neurovascular status and the signs of complications that need to be reported to the surgeon (eg, paresthesia, paralysis, uncontrolled pain, coolness of fingers, extreme swelling, excessive bleeding, purulent drainage, fever). The nurse discusses prescribed medications with the patient. In addition, the nurse teaches the patient to elevate the hand above the elbow and to apply ice (if prescribed) to control swelling. Unless contraindicated, the nurse encourages extension and flexion exercises of the fingers to promote circulation. The use of assistive devices is encouraged if they would be helpful in promoting accomplishment of ADLs. For bathing, the nurse instructs the patient to keep the dressing dry by covering it with a secured plastic bag. Generally, the wound is not redressed until the patient's follow-up visit with the surgeon (Chart 68-5).

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Maintains peripheral tissue perfusion

- a. Demonstrates normal skin temperature and capillary refill
  - b. Exhibits normal sensations
  - c. Exhibits acceptable motor function
2. Achieves pain relief
    - a. Reports increased comfort
    - b. Controls edema through elevation of the hand
    - c. Experiences no discomfort with movement
  3. Demonstrates independent self-care
    - a. Secures assistance with ADLs during first few days post-operatively
    - b. Adapts to one-handed ADLs
    - c. Uses injured hand within its functional capability
  4. Demonstrates absence of wound infection
    - a. Complies with treatment protocol and prevention strategies
    - b. Reports temperature and pulse within normal limits
    - c. Experiences no purulent wound drainage
    - d. Experiences no wound inflammation

## Common Foot Problems

Disabilities of the foot are commonly caused by poorly fitting shoes. Fashion, vanity, and eye appeal, rather than function and physiology of the foot, are the determining factors in the design of footwear. Ill-fitting shoes distort normal anatomy while inducing deformity and pain.

Several systemic diseases affect the feet. Patients with diabetes are prone to develop corns and peripheral neuropathies with diminishing sensation, leading to ulcers at pressure points of the foot. Patients with peripheral vascular disease and arteriosclerosis complain of burning and itching feet resulting in scratching and skin breakdown. Foot deformities may occur with rheumatoid arthritis. Dermatology problems commonly affect the feet in the form of fungal infections and plantar warts.

The discomforts of foot strain are treated with rest, elevation, physiotherapy, supportive strappings, and orthotic devices. The patient must inspect the foot and skin under pads and orthotic devices for pressure and skin breakdown daily. If a "window" is cut into shoes to relieve pressure over a bony deformity, the skin must be monitored daily for breakdown from pressure exerted at the "window" area. Active foot exercises promote the circulation and help strengthen the feet. Walking in properly fitting shoes is considered the ideal exercise.

Chart 68-5

#### Home Care Checklist • Hand Surgery

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Demonstrate how to assess neurovascular status.	✓	✓
• State abnormal findings (eg, unrelenting pain; paralysis; paresthesia; cool, nonblanching fingers) to report to physician promptly.	✓	✓
• Demonstrate control of edema by elevating hand above elbow and applying ice intermittently if prescribed.	✓	✓
• Identify signs and symptoms of infection (eg, elevated temperature, purulent drainage).	✓	✓
• Demonstrate finger exercises to promote circulation, unless contraindicated.	✓	
• Describe methods to prevent wound infection (eg, keeping hand dressing clean and dry during activities of daily living).	✓	✓
• Describe use of prescribed medications.	✓	✓
• Demonstrate use of assistive devices, if appropriate.	✓	

## PLANTAR FASCIITIS

Plantar fasciitis, an inflammation of the foot-supporting fascia, presents as an acute onset of heel pain experienced with the first steps in the morning. The pain is localized to the anterior medial aspect of the heel and diminishes with gentle stretching of the foot and Achilles tendon. Management includes stretching exercises, wearing shoes with support and cushioning to relieve pain, orthotic devices (eg, heel cups, arch supports), and NSAIDs. Unresolved plantar fasciitis may progress to fascial tears at the heel and eventual development of heel spurs.

## CORN

A corn is an area of hyperkeratosis (overgrowth of a horny layer of epidermis) produced by internal pressure (the underlying bone is prominent because of congenital or acquired abnormality, commonly arthritis) or external pressure (ill-fitting shoes). The fifth toe is most frequently involved, but any toe may be involved.

Corns are treated by soaking and scraping off the horny layer by a podiatrist, by application of a protective shield or pad, or by surgical modification of the underlying offending osseous structure. Soft corns are located between the toes and are kept soft by moisture. Treatment consists of drying the affected spaces and separating the affected toes with lamb's wool or gauze. A wider shoe may be helpful. Usually, a podiatrist is needed to treat the underlying cause.

## CALLUS

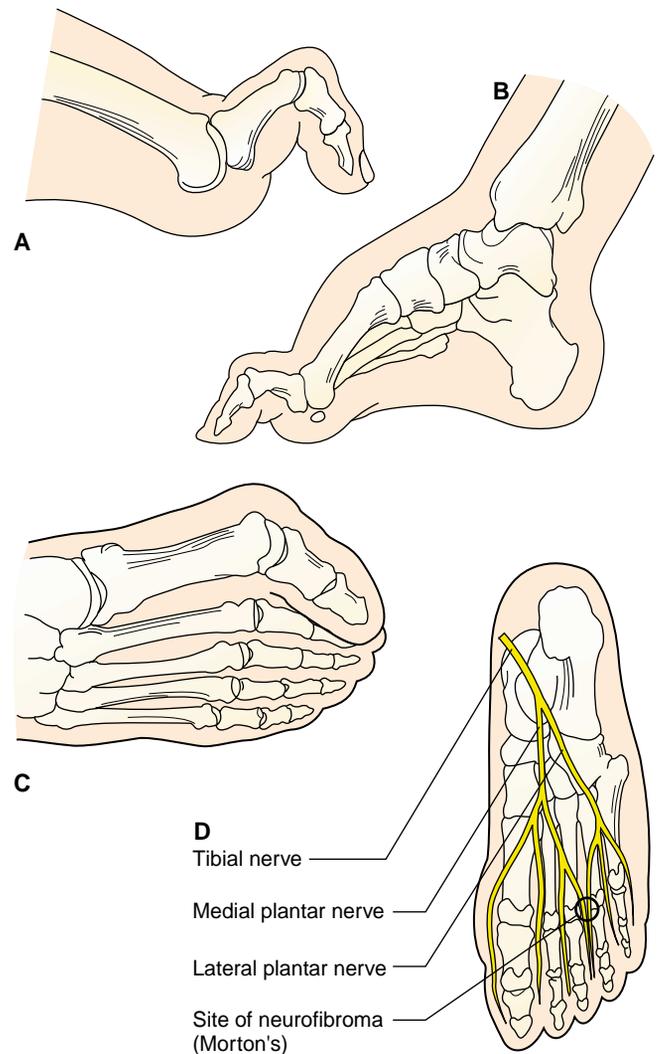

A callus is a discretely thickened area of the skin that has been exposed to persistent pressure or friction. Faulty foot mechanics usually precede the formation of a callus. Treatment consists of eliminating the underlying causes and having the callus treated by a podiatrist if it is painful. A keratolytic ointment may be applied and a thin plastic cup worn over the heel if the callus is on this area. Felt padding with adhesive backing is also used to prevent and relieve pressure. Orthotic devices can be made to remove the pressure from bony protuberances, or the protuberance may be excised.

## INGROWN TOENAIL

An ingrown toenail (onychocryptosis) is a condition in which the free edge of a nail plate penetrates the surrounding skin, either laterally or anteriorly. A secondary infection or granulation tissue may develop. This painful condition is caused by improper self-treatment, external pressure (tight shoes or stockings), internal pressure (deformed toes, growth under the nail), trauma, or infection. Trimming the nails properly (clipping them straight across and filing the corners consistent with the contour of the toe) can prevent this problem. Active treatment consists of washing the foot twice a day, followed by the application of a local antibiotic ointment, and relieving the pain by decreasing the pressure of the nail plate on the surrounding soft tissue. Warm, wet soaks help to drain an infection. A toenail may need to be excised by the podiatrist if there is severe infection.

## HAMMER TOE

Hammer toe is a flexion deformity of the interphalangeal joint, which may involve several toes (Fig. 68-6). The condition is usually an acquired deformity. Tight socks or shoes may push an

**FIGURE 68-6** Common foot deformities (A) Hammer toe, (B) Pes cavus (clawfoot), (C) Bunion (hallux valgus), (D) Site for Morton's neuroma.

overlying toe back into the line of the other toes. The toes usually are pulled upward, forcing the metatarsal joints (ball of the foot) downward. Corns develop on top of the toes, and tender calluses develop under the metatarsal area. The treatment consists of conservative measures: wearing open-toed sandals or shoes that conform to the shape of the foot, carrying out manipulative exercises, and protecting the protruding joints with pads. Surgical correction (osteotomy) is necessary for an established deformity.

## HALLUX VALGUS

Hallux valgus (commonly called a bunion) is a deformity in which the great toe deviates laterally (see Fig. 68-6). Associated with this is a marked prominence of the medial aspect of the first metatarsal-phalangeal joint. There is also osseous enlargement (exostosis) of the medial side of the first metatarsal head, over which a bursa may form (secondary to pressure and inflammation). Acute bursitis symptoms include a reddened area, edema, and tenderness.

Factors contributing to bunion formation include heredity, ill-fitting shoes, and gradual lengthening and widening of the foot associated with aging. Osteoarthritis is frequently associated

with hallux valgus. Treatment depends on the patient's age, the degree of deformity, and the severity of symptoms. If a bunion deformity is uncomplicated, wearing a shoe that conforms to the shape of the foot or that is molded to the foot to prevent pressure on the protruding portions may be all the treatment that is needed. Corticosteroid injections control acute inflammation. Surgical removal of the bunion (exostosis) and osteotomies to realign the toe may be required to improve function and appearance. Complications related to bunionectomy include limited range of motion, paresthesias, tendon injury, and recurrence of deformity.

Postoperatively, the patient may have intense throbbing pain at the operative site, requiring liberal doses of analgesic medication. The foot is elevated to the level of the heart to decrease edema and pain. The neurovascular status of the toes is assessed. The duration of immobility and initiation of ambulation depend on the procedure used. Toe flexion and extension exercises are initiated to facilitate walking. Shoes that fit the shape and size of the foot are recommended.

## PES CAVUS

Pes cavus (clawfoot) refers to a foot with an abnormally high arch and a fixed equinus deformity of the forefoot (see Fig. 68-6). The shortening of the foot and increased pressure produce calluses on the metatarsal area and on the dorsum (bottom) of the foot. Charcot-Marie-Tooth disease (a peripheral neuromuscular disease associated with a familial degenerative disorder), diabetes mellitus, and tertiary syphilis are common causes of pes cavus. Exercises are prescribed to manipulate the forefoot into dorsiflexion and relax the toes. Bracing to protect the foot may be used. In severe cases, arthrodesis (fusion) is performed to reshape and stabilize the foot.

## MORTON'S NEUROMA

Morton's neuroma (plantar digital neuroma, neurofibroma) is a swelling of the third (lateral) branch of the median plantar nerve (see Fig. 68-6). The third digital nerve, which is located in the third intermetatarsal (web) space, is most commonly involved. Microscopically, digital artery changes cause an ischemia of the nerve.

The result is a throbbing, burning pain in the foot that is usually relieved when the patient rests. Conservative treatment consists of inserting innersoles and metatarsal pads designed to spread the metatarsal heads and balance the foot posture. Local injections of hydrocortisone and a local anesthetic may provide relief. If these fail, surgical excision of the neuroma is necessary. Pain relief and loss of sensation are immediate and permanent.

## FLATFOOT

Flatfoot (pes planus) is a common disorder in which the longitudinal arch of the foot is diminished. It may be caused by congenital abnormalities or associated with bone or ligament injury, muscle and posture imbalances, excessive weight, muscle fatigue, poorly fitting shoes, or arthritis. Symptoms include a burning sensation, fatigue, clumsy gait, edema, and pain.

Exercises to strengthen the muscles and to improve posture and walking habits are helpful. A number of foot orthoses are available to give the foot additional support. Orthopedic surgeons and podiatrists treat severe flatfoot problems.

## NURSING PROCESS: THE PATIENT UNDERGOING FOOT SURGERY

### Assessment

Surgery of the foot may be necessary because of various conditions, including neuromas and foot deformities (bunion, hammer toe, clawfoot). Generally, foot surgery is performed on an outpatient basis. Before surgery, the nurse assesses the patient's ambulatory ability and balance and the neurovascular status of the foot. Additionally, the nurse considers the availability of assistance at home and the structural characteristics of the home in planning for care during the first few days after surgery. The nurse uses these data, in addition to knowledge of the usual medical management of the condition, to formulate appropriate nursing diagnoses.

### Nursing Diagnoses

Based on the assessment data, the nursing diagnoses for the patient undergoing foot surgery may include the following:

- Risk for ineffective peripheral tissue perfusion: related to swelling
- Acute pain related to surgery, inflammation, and swelling
- Impaired physical mobility related to the foot-immobilizing device
- Risk for infection related to the surgical procedure/surgical incision

### Planning and Goals

The goals for the patient may include adequate tissue perfusion, relief of pain, improved mobility, and absence of infection.

### Nursing Interventions

#### PROMOTING TISSUE PERFUSION

Neurovascular assessment of the exposed toes every 1 to 2 hours for the first 24 hours is essential to monitor the function of the nerves and the perfusion of the tissues. If the patient is discharged within several hours after the surgery, the nurse teaches the patient and family how to assess for swelling and neurovascular status (circulation, motion, sensation). Compromised neurovascular function can increase the patient's pain. See Chart 66-3 in Chapter 66.

#### RELIEVING PAIN

Pain experienced by patients who undergo foot surgery is related to inflammation and edema. Formation of a hematoma may contribute to the discomfort. To control the swelling, the foot should be elevated on several pillows when the patient is sitting or lying. Intermittent ice packs applied to the surgical area during the first 24 to 48 hours may be prescribed to control swelling and provide some pain relief. As activity increases, the patient may find that dependent positioning of the foot is uncomfortable. Simply elevating the foot often relieves the discomfort. Oral analgesics may be used to control the pain. The nurse instructs the patient and family about appropriate use of these medications.

#### IMPROVING MOBILITY

After surgery, the patient will have a bulky dressing on the foot, protected by a light cast or a special protective boot. Limits for

weight bearing on the foot will be prescribed by the surgeon. Some patients are allowed to walk on the heel and progress to weight-bearing as tolerated; other patients are restricted to non-weight-bearing activities. Assistive devices (eg, crutches, walker) may be needed. The choice of the devices depends on the patient's general condition and balance and on the weight-bearing prescription. Safe use of the assistive devices must be ensured through adequate patient education and practice before discharge. Strategies to move around the house safely while using assistive devices are discussed with the patient. As healing progresses, the patient gradually resumes ambulation within prescribed limits. The nurse emphasizes adherence to the therapeutic regimen.

### PREVENTING INFECTION

Any surgery carries a risk for infection. In addition, percutaneous pins may be used to hold bones in position, and these pins serve as potential sites for infection. Because the foot is on or near the floor, care must be taken to protect it from dirt and moisture. When bathing, the patient can secure a plastic bag over the dressing to prevent it from getting wet. Patient instruction concerning aseptic wound care and pin care may be necessary.

The nurse teaches the patient to monitor for temperature and infection. Drainage on the dressing, foul odor, or increased pain and swelling could indicate infection. The nurse instructs the patient to promptly report any of these findings to the physician. If prophylactic antibiotics are prescribed, the nurse provides instruction about their correct use.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

The nurse plans patient teaching for home care, focusing on neurovascular status, pain management, mobility, and wound care (Chart 68-6).

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Maintains peripheral tissue perfusion
  - a. Demonstrates normal skin temperature and capillary refill
  - b. Exhibits normal sensations
  - c. Exhibits acceptable motor function
2. Obtains pain relief
  - a. Elevates foot to control edema
  - b. Applies ice to foot as prescribed
  - c. Uses oral analgesics as needed and prescribed
  - d. Reports decreased pain and increased comfort
3. Demonstrates increased mobility
  - a. Uses assistive devices safely
  - b. Resumes weight-bearing gradually as prescribed
  - c. Exhibits diminished disability associated with preoperative condition
4. Develops no infection
  - a. Reports temperature and pulse within normal limits
  - b. Reports no purulent drainage or signs of wound inflammation
  - c. Maintains clean and dry dressing
  - d. Takes prophylactic antibiotics as prescribed

### Chart 68-6 • PATIENT EDUCATION Self-care After Foot Surgery

#### Neurovascular Status

Teach patient indicators of impaired circulation:

- Change in sensation
- Inability to move toes
- Toes or foot cool to touch
- Color changes

#### Pain Management

Discuss with patient methods to reduce pain:

- Elevate foot to heart level
- Apply ice as prescribed
- Use analgesics as prescribed
- Report pain that is not relieved

#### Mobility

- Instruct patient in safe use of assistive devices
- Reinforce prescribed weight-bearing limits
- Encourage patient to wear special protective shoe over wound dressing

#### Wound Care

- Instruct patient to keep dressing or cast clean and dry
- Instruct patient about signs of wound infection (eg, pain, drainage, fever)
- Discuss prescribed antibiotic regimen with patient
- Explain that the surgeon will perform the initial dressing change

## Metabolic Bone Disorders

### OSTEOPOROSIS

Osteoporosis is a disease that threatens more than 28 million Americans (National Osteoporosis Foundation, 2000). Characteristics of osteoporosis include a reduction of bone density and a change in bone structure, both of which increase susceptibility to fracture. The normal homeostatic bone turnover is altered: the rate of bone resorption is greater than the rate of bone formation, resulting in a reduced total bone mass. Suboptimal bone mass development in children and teens contributes to the development of osteoporosis. With osteoporosis, the bones become progressively porous, brittle, and fragile; they fracture easily under stresses that would not break normal bone. Osteoporosis frequently results in compression fractures (Fig. 68-7) of the thoracic and lumbar spine, fractures of the neck and intertrochanteric region of the femur, and Colles' fractures of the wrist. The probability that a 50-year-old Caucasian woman will experience a hip fracture during her lifetime is 14%; for a Caucasian man, it is 5% to 6%. The risk for African Americans is lower—6% for women and 3% for men (NIH Consensus Statement, 2000). Multiple compression fractures of the vertebrae result in skeletal deformity. Osteoporosis is a costly disorder not only in terms of health care dollars but also in terms of human suffering, pain, disability, and death.

The gradual collapse of a vertebra may be asymptomatic; it is observed as progressive kyphosis. With the development of kyphosis ("dowager's hump"), there is an associated loss of height (Fig. 68-8). Frequently, postmenopausal women lose height from vertebral collapse. The postural changes result in relaxation of the abdominal muscles and a protruding abdomen. The deformity may also produce pulmonary insufficiency. Many patients complain of fatigue.

**FIGURE 68-7** Progressive osteoporotic bone loss and compression fractures. From Rubin, E. & Farber, I. L. (1999). *Pathology* (3rd ed.). Philadelphia: Lippincott Williams & Wilkins.

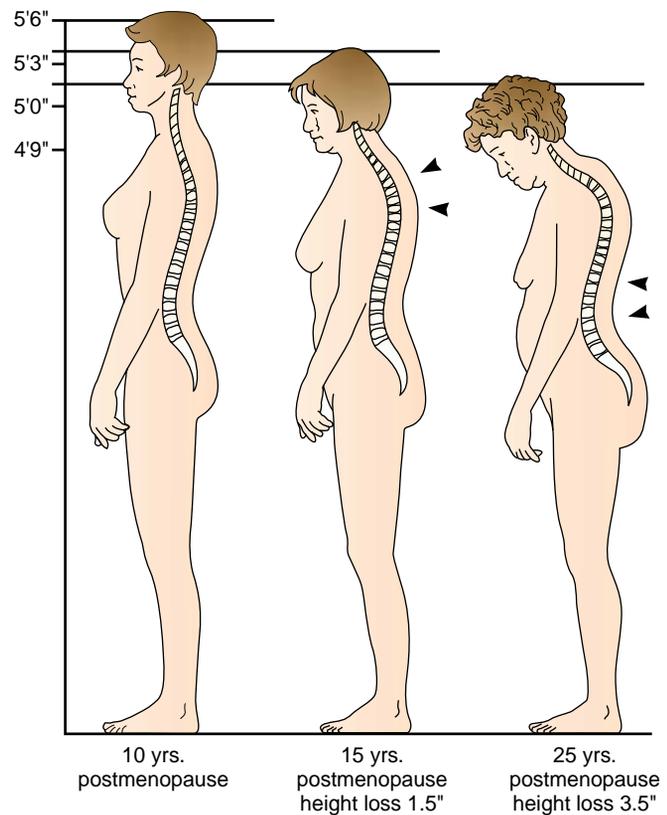

## Prevention

Primary osteoporosis occurs in women after menopause and later in life in men, but it is not merely a consequence of aging. Failure to develop optimal peak bone mass during childhood, adolescence, and young adulthood contributes to the development of osteoporosis without resultant bone loss. Early identification of at-risk teenagers and young adults, increased calcium intake, participation in regular weight-bearing exercise, and modification of lifestyle (eg, reduced use of caffeine, cigarettes, and alcohol) are interventions that decrease the risk for development of osteoporosis, fractures, and associated disability later in life. Secondary osteoporosis is the result of medications or other conditions and diseases that affect bone metabolism. Specific disease states (eg, celiac disease, hypogonadism) and medications (eg, corticosteroids, antiseizure medications) that place patients at risk need to be identified and therapies instituted to reverse the development of osteoporosis.

## Gerontologic Considerations

The prevalence of osteoporosis in women older than 80 years of age is 84% (Genant et al., 1997). The average 75-year-old woman has lost 25% of her cortical bone and 40% of her trabecular bone. With the aging of the population, the incidence of fractures (more than 1.5 million fractures per year), pain, and disability associated with osteoporosis is rising. The mortality rate 1 year after hip fracture is 20%. Two-thirds of patients with hip fracture never regain their prefracture level of functioning (NIH Consensus Statement, 2000).

Elderly people absorb dietary calcium less efficiently and excrete it more readily through their kidneys; therefore, postmenopausal women and the elderly actually need to consume liberal amounts of calcium. As much as 1500 mg daily for postmenopausal women may be prescribed. Most residents of long-term care facilities have a low bone mineral density (BMD) and are at risk for fracture. Hip protectors have been found to reduce

**FIGURE 68-8** Typical loss of height associated with osteoporosis and aging.

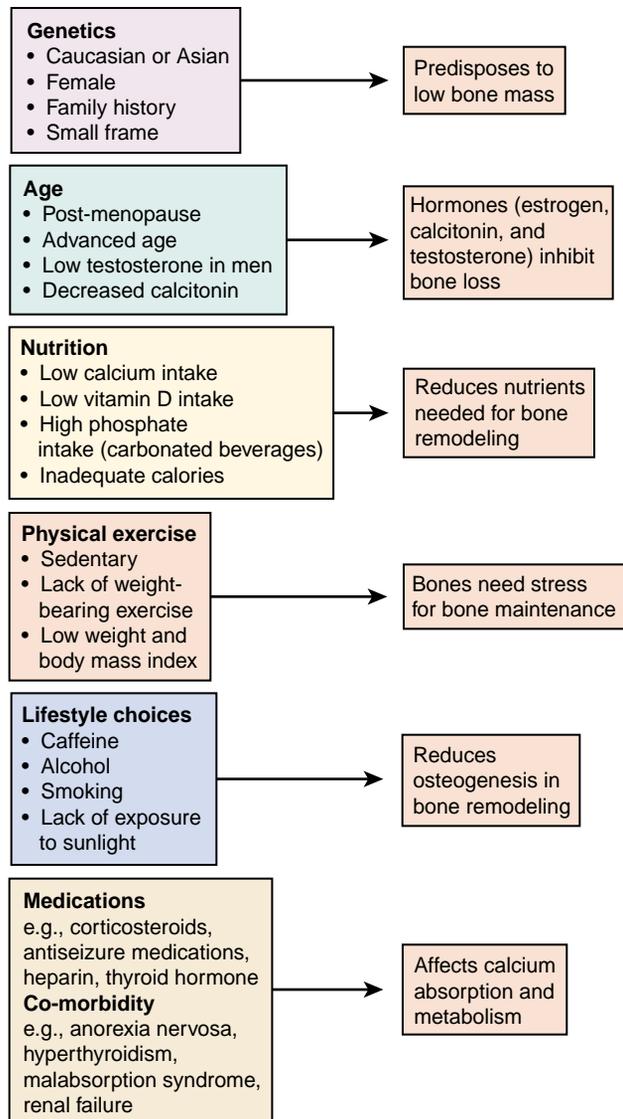

the incidence of hip fracture in the elderly; however, compliance in wearing these hip protectors is low (Kannus et al., 2000).

## Pathophysiology

Normal bone remodeling in the adult results in gradually increased bone mass until the early 30s. Gender, race, genetics, aging, low body weight and body mass index, nutrition, lifestyle choices (eg, smoking, caffeine and alcohol consumption), and physical activity influence peak bone mass and the development of osteoporosis (Fig. 68-9). Although the consequences of osteoporosis (eg, fractures) occur with aging, osteoporosis is not a disease of the elderly. Rather, its onset occurs earlier in life, when bone mass peaks and then begins to decline.

Loss of bone mass is a universal phenomenon associated with aging. Age-related loss begins soon after the peak bone mass is achieved (ie, in the fourth decade). Calcitonin, which inhibits bone resorption and promotes bone formation, is decreased. Estrogen, which inhibits bone breakdown, decreases with aging. On the other hand, parathyroid hormone (PTH) increases with aging, increasing bone turnover and resorption. The consequence of these changes is net loss of bone mass over time.

The withdrawal of estrogens at menopause or with oophorectomy causes an accelerated bone resorption that continues during the postmenopausal years. Women develop osteoporosis more frequently and more extensively than men because of lower peak bone mass and the effect of estrogen loss during menopause. More than half of all women older than 45 years of age show evidence of osteopenia. World Health Organization (WHO) diagnostic categories for osteoporosis are based on BMD scan findings (Walker-Bone et al., 2001).

**FIGURE 68-9** Pathophysiology of osteoporosis.

Secondary osteoporosis is associated with many disease states, nutritional deficiencies, and medications. Coexisting medical conditions (eg, malabsorption syndromes, lactose intolerance, alcohol abuse, renal failure, liver failure, Cushing's syndrome, hyperthyroidism, and hyperparathyroidism) contribute to bone loss and the development of osteoporosis. Medications (eg, corticosteroids, antiseizure medications, heparin, tetracycline, aluminum-containing antacids, and thyroid supplements) affect the body's use and metabolism of calcium. The degree of osteoporosis is related to the duration of medication therapy. When the therapy is discontinued or the metabolic problem is corrected, the progression of osteoporosis is halted, but restoration of lost bone mass usually does not occur.

## Risk Factors

Small-framed, nonobese Caucasian women are at greatest risk for osteoporosis. Also, Asian women of slight build are at risk for low peak BMD. African American women, who have a greater bone mass than Caucasian women, are less susceptible to osteoporosis. Men have a greater peak bone mass and do not experience sud-

den estrogen reduction. As a result, osteoporosis occurs in men at a lower rate and at an older age (about one decade later). However, it has been determined that testosterone and estrogen are important in achieving and maintaining bone mass in men.

Nutritional factors contribute to the development of osteoporosis. A balanced diet—including adequate calories and nutrients needed to maintain bone, calcium, and vitamin D—must be consumed. Vitamin D is necessary for calcium absorption and for normal bone mineralization. Dietary calcium and vitamin D must be adequate to maintain bone remodeling and body functions. The best source of calcium and vitamin D is fortified milk. A cup of milk or calcium-fortified orange juice contains about 300 mg of calcium.

The recommended adequate intake (AI) level of calcium for the age range of puberty through young adulthood (9 to 19 years of age) is 1300 mg per day. The goal of this daily level of calcium is to maximize peak bone mass. The AI level for adults 19 to 50 years of age is 1000 mg per day, and the AI level for adults 51 years and older is 1200 mg per day. The actual estimated average daily intake is 300 to 500 mg. The recommended adult vitamin D intake is 400 to 600 IU per day. Inadequate intake of calcium or vitamin D over a period of years results in decreased bone mass and the development of osteoporosis.

Bone formation is enhanced by the stress of weight and muscle activity. Resistance and impact exercises are most beneficial in developing and maintaining bone mass. Immobility contributes to the development of osteoporosis. When immobilized by casts, general inactivity, paralysis or other disability, the bone is resorbed faster than it is formed, and osteoporosis results. Risk factors for osteoporosis are summarized in Chart 68-7.

## Assessment and Diagnostic Findings

Osteoporosis may be identified on routine x-rays when there has been 25% to 40% demineralization. There is radiolucency to the bones. When the vertebrae collapse, the thoracic vertebrae become

**Chart 68-7**

### Risk Factors for Osteoporosis

#### Individual Risk Factors

- Female, Caucasian, non-Hispanic or Asian
- Increased age
- Low weight and body mass index
- Estrogen deficiency or menopause
- Family history
- Low initial bone mass
- Contributing, coexisting medical conditions (eg, celiac disease) and medications (eg, corticosteroids, antiseizure medications)

#### Lifestyle Risk Factors

- Diets low in calcium and vitamin D
- Cigarette smoking
- Use of alcohol and/or caffeine
- Lack of weight-bearing exercise
- Lack of exposure to sunshine

#### Risk-Lowering Strategies

- Increased dietary calcium and vitamin D intake
- Smoking cessation
- Alcohol and caffeine consumption in moderation
- Regular weight-bearing exercise regimen
- Walk or exercise out of doors

wedge-shaped and the lumbar vertebrae become biconcave. Osteoporosis is diagnosed by dual-energy x-ray absorptiometry (DEXA), which provides information about BMD at the spine and hip. The DEXA scan data are analyzed and reported as T-scores (the number of standard deviations [SD] above or below the average BMD value for a young, healthy Caucasian woman). A normal BMD is less than 1 SD below the young adult mean value. The WHO defines osteoporosis as being present when the T-score is at least 2.5 SD below the young adult mean value. Osteopenia is diagnosed when the BMD T-score is between 1 and 2.5 SD below the young adult mean value (Walker-Bone et al., 2001). Fracture risk increases progressively as the SD of the T-score falls below the mean value.

Quantitative ultrasound studies (QUS) of the heel also are used to diagnose osteoporosis and to predict the risk of hip and nonvertebral fracture. When standardization of sites and comparability of findings of BMD and QUS are determined, these measurements will become more clinically useful (NIH Consensus Statement, 2000).

These BMD studies are useful in identifying osteopenic and osteoporotic bone and in assessing response to therapy. Through early screening (using both assessment of risk factors and BMD scans), promotion of adequate dietary intake of calcium and vitamin D, encouragement of lifestyle changes, and early institution of preventive medications, bone loss and osteoporosis can be reduced, resulting in a reduced incidence of fracture.

Laboratory studies (eg, serum calcium, serum phosphate, serum alkaline phosphatase, urine calcium excretion, urinary hydroxyproline excretion, hematocrit, erythrocyte sedimentation rate) and x-ray studies are used to exclude other possible medical diagnoses (eg, multiple myeloma, osteomalacia, hyperparathyroidism, malignancy) that contribute to bone loss.

## Medical Management

An adequate, balanced diet rich in calcium and vitamin D throughout life, with an increased calcium intake during adolescence, young adulthood, and the middle years, protects against skeletal demineralization. Such a diet would include three glasses of skim or whole vitamin D-enriched milk or other foods high in calcium (eg, cheese and other dairy products, steamed broccoli, canned salmon with bones), daily. To ensure adequate calcium intake, a calcium supplement (eg, Caltrate, Citracal) may be prescribed and taken with meals or with a beverage high in vitamin C to promote absorption. The recommended daily dose should be split and not taken as a single dose. Common side effects of calcium supplements are abdominal distention and constipation.

Regular weight-bearing exercise promotes bone formation. From 20 to 30 minutes of aerobic exercise (eg, walking), 3 days or more a week, is recommended. Weight training stimulates an increase in BMD. In addition, exercise improves balance, reducing the incidence of falls and fractures (Chart 68-8).

## PHARMACOLOGIC THERAPY

At natural or surgical menopause, hormone replacement therapy (HRT) with estrogen and progesterone has been the mainstay of therapy to retard bone loss and prevent occurrence of fractures. Estrogen replacement decreases bone resorption and increases bone mass, reducing the incidence of osteoporotic fractures. However, recent studies have demonstrated greater risks than previously recognized (Chen, Weiss, Newcomb, Barlow & White, 2002).

Selective estrogen receptor modulators (SERMs), such as raloxifene (Evista), reduce the risk for osteoporosis by preserving bone

mineral density without estrogenic effects on the uterus. They are indicated for both prevention and treatment of osteoporosis.

Other medications that may be prescribed to treat osteoporosis include bisphosphonates (eg, alendronate [Fosamax]; risedronate [Actonel]) and calcitonin. Alendronate offers an alternative to HRT and produces increased bone mass (by inhibiting osteoclast function) and decreased bone loss. Bisphosphonates reduce spine and hip fractures associated with osteoporosis. A weekly dosage strength of alendronate is available and has been shown to be as effective as previously used daily dosing. Adequate calcium and vitamin D intake is needed for maximum effect, but these supplements should not be taken at the same time of day as bisphosphonates. Side effects of alendronate include gastrointestinal symptoms (eg, dyspepsia, nausea, flatulence, diarrhea, constipation). Alendronate and risedronate are approved for the prevention and treatment of glucocorticoid-induced osteoporosis in men and women.

Calcitonin (Miacalcin) primarily suppresses bone loss through direct action on osteoclasts and reduced bone turnover. It is effective in increasing BMD. Calcitonin is administered by nasal spray or by subcutaneous or intramuscular injection. Side effects include nasal irritation, flushing, gastrointestinal disturbances, and urinary frequency.

Recently, in clinical trials, small daily subcutaneous injections of PTH or PTH bioactive fragments (1-34; 1-38), or both, have been found to stimulate bone formation (Neer et al., 2001). U.S. Food and Drug Administration (FDA) approval of prescription of intermittent PTH is anticipated as a new anabolic approach to treatment of osteoporosis.

Natural estrogens (plant-derived phytoestrogens) have not been shown to be effective in reducing osteoporosis-related fractures (NIH Consensus Statement, 2000).

In addition, antilipid medications, such as statins (HMG-CoA reductase inhibitors), reduce the incidence of fractures in patients who take these medications to control their hyperlipidemia. The statins promote bone growth, thereby preventing the development of osteoporosis.

## FRACTURE MANAGEMENT

Fractures of the hip are managed surgically by joint replacement or by closed or open reduction with internal fixation (eg, hip pinning). Surgery, early ambulation, intensive physical therapy, and adequate nutrition result in decreased morbidity and improved outcomes. In addition, patients need to be evaluated for osteoporosis and treated, if indicated.

Osteoporotic compression fractures of the vertebra are managed conservatively. Additional vertebral fractures and progressive kyphosis are common. Pharmacologic and dietary treatment are aimed at increasing vertebral bone density. A new procedure, percutaneous vertebroplasty/kyphoplasty (injection of polymethylmethacrylate bone cement into the fractured vertebra), is reported to provide rapid acute pain relief and improved quality of life. The long-term effect of this procedure is unknown (NIH Consensus Statement, 2000).

## NURSING PROCESS: THE PATIENT WITH A SPONTANEOUS VERTEBRAL FRACTURE RELATED TO OSTEOPOROSIS

### Assessment

Health promotion, identification of people at risk for osteoporosis, and recognition of problems associated with osteoporosis form the basis for nursing assessment. The health history includes ques-

Chart 68-8

## Home Care Checklist • Osteoporosis

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
<b>Adolescents And Young Adults</b>		
• List risk factors for osteoporosis.	✓	
• Identify calcium- and vitamin D-rich foods.	✓	
• Consume diet with adequate calcium (1000–1300 mg/day) and vitamin D.	✓	
• Engage in weight-bearing exercise daily.	✓	
• Modify lifestyle choices—avoid smoking, alcohol, caffeine, and sodas.	✓	
<b>Menopausal and Postmenopausal Women</b>		
• List risk factors for osteoporosis.	✓	
• Identify calcium- and vitamin D-rich foods.	✓	
• Consume diet with adequate calcium (1200–1500 mg/day) and vitamin D.	✓	
• Discuss calcium supplements.	✓	
• Engage in weight-bearing exercise at least 3 times weekly.	✓	
• Engage in exercise that improves balance to reduce the incidence of falls.	✓	
• Demonstrate good body mechanics.	✓	
• Modify lifestyle choices—avoid smoking, and use of alcohol, caffeine, and carbonated beverages.	✓	
• Discuss pharmacologic agents to maintain and enhance bone mass.	✓	
• Review concurrent medical conditions and medications with health care provider to identify factors that contribute to bone mass loss.	✓	✓
• Assess home environment for hazards contributing to falls.	✓	✓
<b>Men</b>		
• List risk factors associated with osteoporosis in men, including medications (eg, corticosteroids, antiseizure medications, aluminum-containing antacids); chronic diseases (eg, kidney, lung, gastrointestinal); and undiagnosed low testosterone levels.	✓	
• Modify lifestyle choices to avoid smoking and excessive intake of alcohol, caffeine, and carbonated beverages.	✓	
• Engage in weight-bearing exercise daily, such as walking, weight lifting, and resistance exercise.	✓	
• Consume diet with adequate calcium (1000–1200 mg/day) and vitamin D (400 IU/day).	✓	
• Participate in screening for osteoporosis.	✓	
• Talk with health care provider about use of medications (eg, alendronate) to enhance bone mass or to correct testosterone deficiency.	✓	
• Assess home for hazards contributing to falls.	✓	

tions concerning the occurrence of osteopenia and osteoporosis and focuses on family history, previous fractures, dietary consumption of calcium, exercise patterns, onset of menopause, and use of corticosteroids as well as alcohol, smoking, and caffeine intake. Any symptoms the patient is experiencing, such as back pain, constipation, or altered body image, are explored.

Physical examination may disclose a fracture, kyphosis of the thoracic spine, or shortened stature. Problems in mobility and breathing may exist as a result of changes in posture and weakened muscles.

## Nursing Diagnoses

Based on the assessment data, the major nursing diagnoses for the patient who experiences a spontaneous vertebral fracture related to osteoporosis may include the following:

- Deficient knowledge about the osteoporotic process and treatment regimen
- Acute pain related to fracture and muscle spasm
- Risk for constipation related to immobility or development of ileus (intestinal obstruction)
- Risk for injury: additional fractures related to osteoporosis

## Planning and Goals

The major goals for the patient may include knowledge about osteoporosis and the treatment regimen, relief of pain, improved bowel elimination, and absence of additional fractures.

## Nursing Interventions

### PROMOTING UNDERSTANDING OF OSTEOPOROSIS AND THE TREATMENT REGIMEN

Patient teaching focuses on factors influencing the development of osteoporosis, interventions to arrest or slow the process, and measures to relieve symptoms. Adequate dietary or supplemental calcium and vitamin D, regular weight-bearing exercise, and modification of lifestyle, if necessary (eg, cessation of smoking, reduced use of caffeine and alcohol), help to maintain bone mass. Diet, exercise, and physical activity are the primary keys to developing high-density bones that are resistant to osteoporosis. It is emphasized that all people continue to need sufficient calcium, vitamin D, sunshine, and weight-bearing exercise to slow the progression of osteoporosis.

Patient teaching related to medication therapy is important. Because gastrointestinal symptoms and abdominal distention are

frequent side effects of calcium supplements, the nurse instructs the patient to take the calcium supplements with meals. Also, it is important to teach the patient to drink adequate fluids to reduce the risk of renal calculi. If HRT is prescribed, the nurse teaches the patient about the importance of compliance and periodic screening for breast and endometrial cancer. Alendronate requires compliance: it must be taken on an empty stomach with water, and then the patient must not consume foods or liquids or assume a reclining position for 30 to 60 minutes. Nasal calcitonin is administered daily, alternating the nares. An adequate daily intake of dietary calcium and vitamin D is needed along with these prescribed medications.

### RELIEVING PAIN

Relief of back pain resulting from compression fracture may be accomplished by resting in bed in a supine or side-lying position several times a day. The mattress should be firm and nonsagging. Knee flexion increases comfort by relaxing back muscles. Intermittent local heat and back rubs promote muscle relaxation. The nurse instructs the patient to move the trunk as a unit and to avoid twisting. The nurse encourages good posture and teaches body mechanics. When the patient is assisted out of bed, a lumbosacral corset may be worn for temporary support and immobilization, although such a device is frequently uncomfortable and is poorly tolerated by many elderly patients. The patient gradually resumes activities as pain diminishes. Vertebroplasty may be considered for some patients.

### IMPROVING BOWEL ELIMINATION

Constipation is a problem related to immobility and medications. Early institution of a high-fiber diet, increased fluids, and the use of prescribed stool softeners help to prevent or minimize constipation. If the vertebral collapse involves the T10–L2 vertebrae, the patient may develop an ileus. The nurse therefore monitors the patient's intake, bowel sounds, and bowel activity.

### PREVENTING INJURY

Physical activity is essential to strengthen muscles, improve balance, prevent disuse atrophy, and retard progressive bone demineralization. Isometric exercises can strengthen trunk muscles. The nurse encourages walking, good body mechanics, and good posture. Daily weight-bearing activity, preferably outdoors in the sunshine to enhance the body's ability to produce vitamin D, is encouraged. Sudden bending, jarring, and strenuous lifting are avoided.

### Gerontologic Considerations

Elderly people fall frequently as a result of environmental hazards, neuromuscular disorders, diminished senses and cardiovascular responses, and responses to medications. The patient and family need to be included in planning for care and preventive management regimens. For example, the home environment should be assessed for safety and elimination of potential hazards (eg, scatter rugs, cluttered rooms and stairwells, toys on the floor, pets underfoot). A safe environment can then be created (eg, well-lighted staircases with secure hand rails, grab bars in the bathroom, properly fitting footwear). Other safety devices, such as hip protectors (Fig. 68-10), have been used to diminish the impact of a fall and have reduced the hip fracture rate (Kannus et al., 2000).

**FIGURE 68-10** HipSaver Slimfit® Hip Protector is designed to prevent fall-induced hip fractures. A pad placed over each trochanter can reduce much of the force transmitted to the vulnerable hip bone when a fall is sustained. ## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Acquires knowledge about osteoporosis and the treatment regimen
  - a. States relationship of calcium and vitamin D intake and exercise to bone mass
  - b. Consumes adequate dietary calcium and vitamin D
  - c. Increases level of exercise
  - d. Takes prescribed hormonal or nonhormonal therapy
  - e. Complies with prescribed screening and monitoring procedures
2. Achieves pain relief
  - a. Experiences pain relief at rest
  - b. Experiences minimal discomfort during ADLs
  - c. Demonstrates diminished tenderness at fracture site
3. Demonstrates normal bowel elimination
  - a. Has active bowel sounds
  - b. Reports regular bowel movements
4. Experiences no new fractures
  - a. Maintains good posture
  - b. Uses good body mechanics
  - c. Consumes a diet high in calcium and vitamin D
  - d. Engages in weight-bearing exercises (walks daily)
  - e. Rests by lying down several times a day
  - f. Participates in outdoor activities
  - g. Creates a safe home environment
  - h. Accepts assistance and supervision as needed

## OSTEOMALACIA

Osteomalacia is a metabolic bone disease characterized by inadequate mineralization of bone. As a result of faulty mineralization, there is softening and weakening of the skeleton, causing pain, tenderness to touch, bowing of the bones, and pathologic fractures. On physical examination, skeletal deformities (spinal kyphosis and bowed legs) give patients an unusual appearance and a waddling or limping gait. These patients may be uncomfortable with their appearance. As a result of calcium deficiency, muscle weakness, and unsteadiness, there is an increased risk for falls and fractures.

### Pathophysiology

The primary defect in osteomalacia is a deficiency of activated vitamin D (calcitriol), which promotes calcium absorption from the gastrointestinal tract and facilitates mineralization of bone. The supply of calcium and phosphate in the extracellular fluid is low. Without adequate vitamin D, calcium and phosphate are not moved to calcification sites in bones.

Osteomalacia may result from failed calcium absorption (eg, malabsorption syndrome) or from excessive loss of calcium from the body. Gastrointestinal disorders (eg, celiac disease, chronic biliary tract obstruction, chronic pancreatitis, small bowel resection) in which fats are inadequately absorbed are likely to produce osteomalacia through loss of vitamin D (along with other fat-soluble vitamins) and calcium, the latter being excreted in the feces with fatty acids. In addition, liver and kidney diseases can produce a lack of vitamin D because these are the organs that convert vitamin D to its active form.

Severe renal insufficiency results in acidosis. The body uses available calcium to combat the acidosis, and PTH stimulates the release of skeletal calcium in an attempt to reestablish a physiologic pH. During this continual drain of skeletal calcium, bony fibrosis occurs and bony cysts form. Chronic glomerulonephritis, obstructive uropathies, and heavy-metal poisoning result in a reduced serum phosphate level and demineralization of bone.

Hyperparathyroidism leads to skeletal decalcification and thus to osteomalacia by increasing phosphate excretion in the urine. Prolonged use of antiseizure medication (eg, phenytoin, phenobarbital) poses a risk for osteomalacia, as does insufficient vitamin D (dietary, sunlight).

The malnutrition type of osteomalacia (deficiency in vitamin D often associated with poor intake of calcium) is a result of poverty, food faddism, and lack of knowledge about nutrition. It occurs most frequently in parts of the world where vitamin D is not added to food, where dietary deficiencies exist, and where sunlight is rare.

### Gerontologic Considerations

A nutritious diet is particularly important in elderly people. Adequate intake of calcium and vitamin D is promoted. Because sunlight is necessary for synthesizing vitamin D, people should be encouraged to spend some time in the sun. Prevention, identification, and management of osteomalacia in the elderly are essential to reduce the incidence of fractures. When osteomalacia is combined with osteoporosis, the incidence of fracture increases.

### Assessment and Diagnostic Findings

On x-ray, generalized demineralization of bone is evident. Studies of the vertebrae may show a compression fracture with indistinct vertebral end-plates. Laboratory studies show low serum calcium

and phosphorus levels and a moderately elevated alkaline phosphatase concentration. Urine excretion of calcium and creatinine is low. Bone biopsy demonstrates an increased amount of osteoid.

### Medical Management

The underlying cause of osteomalacia is corrected if possible. If osteomalacia is caused by malabsorption, increased doses of vitamin D, along with supplemental calcium, are usually prescribed. Exposure to sunlight for ultraviolet radiation to transform a cholesterol substance (7-dehydrocholesterol) present in the skin into vitamin D may be recommended.

If osteomalacia is dietary in origin, a diet with adequate protein and increased calcium and vitamin D is provided. The patient is instructed about dietary sources of calcium and vitamin D (eg, fortified milk and cereals, eggs, chicken livers). The safe use of supplements is reviewed. Because high doses of vitamin D are toxic and enhance the risk of hypercalcemia, the importance of monitoring serum calcium levels is stressed. Vitamin D raises the concentrations of calcium and phosphorus in the extracellular fluid and thus makes these ions available for mineralization of bone.

Physical, psychological, and pharmaceutical measures are used to reduce the patient's discomfort and pain. When assisting the patient to change positions, the nurse handles the patient gently, and pillows are used to support the body. As the patient responds to therapy, the skeletal discomforts diminish.

Frequently, skeletal problems associated with osteomalacia resolve themselves when the underlying nutritional deficiency or pathologic process is adequately treated. Long-term monitoring of the patient is appropriate to ensure stabilization or reversal of osteomalacia. Some persistent orthopedic deformities may need to be treated with braces or surgery (eg, osteotomy may be performed to correct long bone deformity).

## PAGET'S DISEASE

Paget's disease (osteitis deformans) is a disorder of localized rapid bone turnover, most commonly affecting the skull, femur, tibia, pelvic bones, and vertebrae. There is a primary proliferation of osteoclasts, which produces bone resorption. This is followed by a compensatory increase in osteoblastic activity that replaces the bone. As bone turnover continues, a classic mosaic (disorganized) pattern of bone develops. Because the diseased bone in Paget's disease is highly vascularized and structurally weak, pathologic fractures occur. Structural bowing of the legs causes malalignment of the hip, knee, and ankle joints, which contributes to the development of arthritis and back and joint pain.

Paget's disease occurs in about 2% to 3% of the population older than 50 years of age. The incidence is slightly greater in men than in women and increases with aging. A family history has been noted, with siblings developing the disease. The cause of Paget's disease is not known.

### Clinical Manifestations

Paget's disease is insidious; most patients never know they have it. Some patients do not experience symptoms but have skeletal deformity. A few patients have symptomatic deformity and pain. The condition is most frequently identified on x-ray during a routine physical examination or in the course of a workup for another problem. Sclerotic changes, skeletal deformities (eg, bowing of femur and tibia, enlargement of the skull, deformity of pelvic bones), and cortical thickening of the long bones occur.

In most patients, skeletal deformity involves the skull or long bones. The skull may thicken, and the patient may report that a hat no longer fits. In some cases of Paget's disease, the cranium, but not the face, is enlarged. This gives the face a small, triangular appearance. Most patients with skull involvement have impaired hearing from cranial nerve compression and dysfunction. Other cranial nerves may also be compressed.

The femurs and tibiae tend to bow, producing a waddling gait. The spine is bent forward and is rigid; the chin rests on the chest. The thorax is compressed and immobile on respiration. The trunk is flexed on the legs to maintain balance; the arms are bent outward and forward and appear long in relation to the shortened trunk, giving the patient an ape-like posture.

Pain, tenderness, and warmth over the bones may be noted. The pain is mild to moderate, deep, and aching; it increases with weight bearing if the lower extremities are involved. Pain and discomfort may precede skeletal deformities of Paget's disease by years and are often wrongly attributed by the patient to old age or arthritis.

The temperature of the skin overlying the affected bone increases because of increased bone vascularity. Patients with large, highly vascular lesions may develop high-output cardiac failure because of the increased vascular bed and metabolic demands.

## Assessment and Diagnostic Findings

Elevated serum alkaline phosphatase concentration and urinary hydroxyproline excretion reflect increased osteoblastic activity. Higher values suggest more active disease. Patients with Paget's disease have normal blood calcium levels. X-rays confirm the diagnosis of Paget's disease. Local areas of demineralization and bone overgrowth produce characteristic mosaic patterns and irregularities. Bone scans demonstrate the extent of the disease. Bone biopsy may aid in the differential diagnosis.

## Medical Management

Pain usually responds to administration of NSAIDs. Gait problems from bowing of the legs are managed with walking aids, shoe lifts, and physical therapy. Weight is controlled to reduce stress on weakened bones and malaligned joints. Asymptomatic patients may be managed with diets adequate in calcium and vitamin D and periodic monitoring.

Fractures, arthritis, and hearing loss are complications of Paget's disease. Fractures are managed according to location. Healing occurs if fracture reduction, immobilization, and stability are adequate. Severe degenerative arthritis may require total joint replacement. Loss of hearing is managed with hearing aids and communication techniques used with the hearing-impaired person (eg, lip reading, body language).

## PHARMACOLOGIC THERAPY

Patients with moderate to severe disease may benefit from specific antiosteoclastic therapy. Several medications reduce bone turnover, reverse the course of the disease, relieve pain, and improve mobility.

Calcitonin, a polypeptide hormone, retards bone resorption by decreasing the number and availability of osteoclasts. Calcitonin therapy facilitates remodeling of abnormal bone into normal lamellar bone, relieves bone pain, and helps alleviate neurologic and biochemical signs and symptoms. Calcitonin is administered subcutaneously or by nasal inhalation. Side effects include flushing of the face and nausea. The effect of calcitonin therapy is evident in 3 to 6 months.

Bisphosphonates, such as etidronate disodium (Didronel) and alendronate sodium (Fosamax), produce rapid reduction in bone turnover and relief of pain. They also reduce serum alkaline phosphatase and urinary hydroxyproline levels. Food inhibits absorption of these medications. Adequate daily calcium (1500 mg) and vitamin D (400 to 600 IU) are required during therapy.

Plicamycin (Mithracin), a cytotoxic antibiotic, may be used to control the disease. This medication is reserved for severely affected patients with neurologic compromise and for those whose disease is resistant to other therapy. This medication has dramatic effects on pain reduction and on serum calcium, alkaline phosphatase, and urinary hydroxyproline levels. It is administered by IV infusion and requires that hepatic, renal, and bone marrow function be monitored during therapy. Clinical remissions may continue for months after the medication is discontinued.

## Gerontologic Considerations

Careful assessment of the patient's pain and discomfort is necessary. Patient teaching helps the patient understand the treatment regimen, the need for a diet with adequate calcium and vitamin D, and how to compensate for altered musculoskeletal functioning. The home environment is assessed for safety to prevent falls and to reduce the risk for fracture. Strategies for coping with a chronic health problem and its effect on quality of life need to be developed.

## Musculoskeletal Infections

### OSTEOMYELITIS

Osteomyelitis is an infection of the bone. The bone becomes infected by one of three modes:

- Extension of soft tissue infection (eg, infected pressure or vascular ulcer, incisional infection)
- Direct bone contamination from bone surgery, open fracture, or traumatic injury (eg, gunshot wound)
- Hematogenous (bloodborne) spread from other sites of infection (eg, infected tonsils, boils, infected teeth, upper respiratory infections). Osteomyelitis resulting from hematogenous spread typically occurs in a bone area of trauma or lowered resistance, possibly from subclinical (nonapparent) trauma.

Patients who are at high risk for osteomyelitis include those who are poorly nourished, elderly, or obese. Also at risk are patients with impaired immune systems, those with chronic illness (eg, diabetes, rheumatoid arthritis), and those receiving long-term corticosteroid therapy.

Postoperative surgical wound infections occur within 30 days after surgery. They are classified as incisional (superficial, located above the deep fascia layer) or deep (involving tissue beneath the deep fascia). If an implant has been used, deep postoperative infections may occur within a year. Deep sepsis after arthroplasty may be classified as follows:

- Stage 1, acute fulminating: occurring during the first 3 months after orthopedic surgery; frequently associated with hematoma, drainage, or superficial infection
- Stage 2, delayed onset: occurring between 4 and 24 months after surgery
- Stage 3, late onset: occurring 2 or more years after surgery, usually as a result of hematogenous spread

Bone infections are more difficult to eradicate than soft tissue infections because the infected bone becomes walled off. Natural body immune responses are blocked, and there is less penetration by antibiotics. Osteomyelitis may become chronic and may affect the patient's quality of life.

## Pathophysiology

*Staphylococcus aureus* causes 70% to 80% of bone infections. Other pathogenic organisms frequently found in osteomyelitis include *Proteus* and *Pseudomonas* species and *Escherichia coli*. The incidence of penicillin-resistant, nosocomial, gram-negative, and anaerobic infections is increasing.

The initial response to infection is inflammation, increased vascularity, and edema. After 2 or 3 days, thrombosis of the blood vessels occurs in the area, resulting in ischemia with bone necrosis. The infection extends into the medullary cavity and under the periosteum and may spread into adjacent soft tissues and joints. Unless the infective process is treated promptly, a bone abscess forms. The resulting abscess cavity contains dead bone tissue (the **sequestrum**), which does not easily liquefy and drain. Therefore, the cavity cannot collapse and heal, as occurs in soft tissue abscesses. New bone growth (the **involucrum**) forms and surrounds the sequestrum. Although healing appears to take place, a chronically infected sequestrum remains and produces recurring abscesses throughout the patient's life. This is referred to as chronic osteomyelitis.

## Clinical Manifestations

When the infection is bloodborne, the onset is usually sudden, occurring often with the clinical manifestations of septicemia (eg, chills, high fever, rapid pulse, general malaise). The systemic symptoms at first may overshadow the local signs. As the infection extends through the cortex of the bone, it involves the periosteum and the soft tissues. The infected area becomes painful, swollen, and extremely tender. The patient may describe a constant, pulsating pain that intensifies with movement as a result of the pressure of the collecting pus. When osteomyelitis occurs from spread of adjacent infection or from direct contamination, there are no symptoms of septicemia. The area is swollen, warm, painful, and tender to touch.

The patient with chronic osteomyelitis presents with a continuously draining sinus or experiences recurrent periods of pain, inflammation, swelling, and drainage. The low-grade infection thrives in scar tissue, because it has a reduced blood supply.

## Assessment and Diagnostic Findings

In acute osteomyelitis, early x-ray findings demonstrate soft tissue swelling. In about 2 weeks, areas of irregular decalcification, bone necrosis, periosteal elevation, and new bone formation are evident. Radioisotope bone scans, particularly the isotope-labeled white blood cell (WBC) scan, and magnetic resonance imaging (MRI) help with early definitive diagnosis. Blood studies reveal elevated leukocyte levels and an elevated sedimentation rate. Wound and blood culture studies are performed to identify appropriate antibiotic therapy.

With chronic osteomyelitis, large, irregular cavities, raised periosteum, sequestra, or dense bone formations are seen on x-ray. Bone scans may be performed to identify areas of infection. The sedimentation rate and the WBC count are usually normal. Anemia, associated with chronic infection, may be evident. The

abscess is cultured to determine the infective organism and appropriate antibiotic therapy.

## Prevention

Prevention of osteomyelitis is the goal. Elective orthopedic surgery should be postponed if the patient has a current infection (eg, urinary tract infection, sore throat) or a recent history of infection. During orthopedic surgery, careful attention is paid to the surgical environment and to techniques to decrease direct bone contamination. Prophylactic antibiotics, administered to achieve adequate tissue levels at the time of surgery and for 24 hours after surgery, are helpful. Urinary catheters and drains are removed as soon as possible to decrease the incidence of hematogenous spread of infection.

Treatment of focal infections diminishes hematogenous spread. Aseptic postoperative wound care reduces the incidence of superficial infections and osteomyelitis. Prompt management of soft tissue infections reduces extension of infection to the bone. When patients who have had joint replacement surgery undergo dental procedures or other invasive procedures (eg, cystoscopy), prophylactic antibiotics are frequently recommended.

## Medical Management

The initial goal of therapy is to control and halt the infective process. Antibiotic therapy depends on the results of blood and wound cultures. Frequently, the infection is caused by more than one pathogen. General supportive measures (eg, hydration, diet high in vitamins and protein, correction of anemia) should be instituted. The area affected with osteomyelitis is immobilized to decrease discomfort and to prevent pathologic fracture of the weakened bone. Warm wet soaks for 20 minutes several times a day may be prescribed to increase circulation.

## PHARMACOLOGIC THERAPY

As soon as the culture specimens are obtained, IV antibiotic therapy begins, based on the assumption that infection results from a staphylococcal organism that is sensitive to a semisynthetic penicillin or cephalosporin. The aim is to control the infection before the blood supply to the area diminishes as a result of thrombosis. Around-the-clock dosing is necessary to achieve a sustained high therapeutic blood level of the antibiotic. An antibiotic to which the causative organism is sensitive is prescribed after results of the culture and sensitivity studies are known. IV antibiotic therapy continues for 3 to 6 weeks. After the infection appears to be controlled, the antibiotic may be administered orally for up to 3 months. To enhance absorption of the orally administered medication, antibiotics should not be administered with food.

## SURGICAL MANAGEMENT

If the patient does not respond to antibiotic therapy, the infected bone is surgically exposed, the purulent and necrotic material is removed, and the area is irrigated with sterile saline solution. Antibiotic-impregnated beads may be placed in the wound for direct application of antibiotics for 2 to 4 weeks. IV antibiotic therapy is continued.

In chronic osteomyelitis, antibiotics are adjunctive therapy to surgical débridement. A sequestrectomy (removal of enough involucrum to enable the surgeon to remove the sequestrum) is performed. In many cases, sufficient bone is removed to convert a deep cavity into a shallow saucer (saucerization). All dead, infected

bone and cartilage must be removed before permanent healing can occur. A closed suction irrigation system may be used to remove debris. Wound irrigation using sterile physiologic saline solution may be performed for 7 to 8 days.

The wound is either closed tightly to obliterate the dead space or packed and closed later by granulation or possibly by grafting. The débrided cavity may be packed with cancellous bone graft to stimulate healing. With a large defect, the cavity may be filled with a vascularized bone transfer or muscle flap (in which a muscle is moved from an adjacent area with blood supply intact). These microsurgery techniques enhance the blood supply. The improved blood supply facilitates bone healing and eradication of the infection. These surgical procedures may be staged over time to ensure healing. Because surgical débridement weakens the bone, internal fixation or external supportive devices may be needed to stabilize or support the bone to prevent pathologic fracture.

## NURSING PROCESS: THE PATIENT WITH OSTEOMYELITIS

### Assessment

The patient reports an acute onset of signs and symptoms (eg, localized pain, swelling, erythema, fever) or recurrent drainage of an infected sinus with associated pain, swelling, and low-grade fever. The nurse assesses the patient for risk factors (eg, older age, diabetes, long-term corticosteroid therapy) and for a history of previous injury, infection, or orthopedic surgery. The patient avoids pressure on the area and guards movement. In acute hematogenous osteomyelitis, the patient exhibits generalized weakness due to the systemic reaction to the infection.

Physical examination reveals an inflamed, markedly swollen, warm area that is tender. Purulent drainage may be noted. The patient has an elevated temperature. With chronic osteomyelitis, the temperature elevation may be minimal, occurring in the afternoon or evening.

### Nursing Diagnoses

Based on the nursing assessment data, nursing diagnoses for the patient with osteomyelitis may include the following:

- Acute pain related to inflammation and swelling
- Impaired physical mobility related to pain, use of immobilization devices, and weight-bearing limitations
- Risk for extension of infection: bone abscess formation
- Deficient knowledge related to the treatment regimen

### Planning and Goals

The patient's goals may include relief of pain, improved physical mobility within therapeutic limitations, control and eradication of infection, and knowledge of treatment regimen.

### Nursing Interventions

#### RELIEVING PAIN

The affected part may be immobilized with a splint to decrease pain and muscle spasm. The nurse monitors the neurovascular status of the affected extremity. The wounds are frequently very painful, and the extremity must be handled with great care and gentleness. Elevation reduces swelling and associated discomfort.

Pain is controlled with prescribed analgesics and other pain-reducing techniques.

#### IMPROVING PHYSICAL MOBILITY

Treatment regimens restrict activity. The bone is weakened by the infective process and must be protected by immobilization devices and by avoidance of stress on the bone. The patient must understand the rationale for the activity restrictions. The joints above and below the affected part should be gently placed through their range of motion. The nurse encourages full participation in ADLs within the physical limitations to promote general well-being.

#### CONTROLLING THE INFECTIOUS PROCESS

The nurse monitors the patient's response to antibiotic therapy and observes the IV access site for evidence of phlebitis, infection, or infiltration. With long-term, intensive antibiotic therapy, the nurse monitors the patient for signs of superinfection (eg, oral or vaginal candidiasis, loose or foul-smelling stools).

If surgery was necessary, the nurse takes measures to ensure adequate circulation (wound suction to prevent fluid accumulation, elevation of the area to promote venous drainage, avoidance of pressure on grafted area), to maintain needed immobility, and to comply with weight-bearing restrictions. The nurse changes dressings using aseptic technique to promote healing and to prevent cross-contamination.

The nurse continues to monitor the general health and nutrition of the patient. A diet high in protein and vitamin C ensures a positive nitrogen balance and promotes healing. The nurse encourages adequate hydration as well.

#### PROMOTING HOME AND COMMUNITY-BASED CARE

##### Teaching Patients Self-Care

The patient and family must learn and recognize the importance of strictly adhering to the therapeutic regimen of antibiotics and preventing falls or other injuries that could result in bone fracture. The patient needs to know how to maintain and manage the IV access and IV administration equipment in the home. Medication education includes medication name, dosage, frequency, administration rate, safe storage and handling, adverse reactions, and necessary laboratory monitoring. In addition, aseptic dressing and warm compress techniques are taught.

The nurse carefully monitors the patient for the development of additional painful areas or sudden increases in body temperature. The nurse instructs the patient and family to observe and report elevated temperature, drainage, odor, increased inflammation, adverse reactions, and signs of superinfection.

##### Continuing Care

Management of osteomyelitis, including wound care and IV antibiotic therapy, is usually performed at home. The patient must be medically stable, physically able, and motivated to adhere strictly to the therapeutic regimen of antibiotic therapy. The home care environment needs to be conducive to promotion of health and to the requirements of the therapeutic regimen.

If warranted, the nurse completes a home assessment to determine the patient's and family's abilities regarding continuation of the therapeutic regimen. If the patient's support system is questionable or if the patient lives alone, a home care nurse may be needed to assist with intravenous administration of the antibiotics. The nurse monitors the patient for response to the treatment, signs and symptoms of superinfections, and adverse drug

## Chart 68-9

## Home Care Checklist • Osteomyelitis

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Describe osteomyelitis.	✓	✓
• Relieve pain with pharmacologic and nonpharmacologic interventions.	✓	
• State weight-bearing and activity restrictions.	✓	✓
• Demonstrate safe use of ambulatory aids and assistive devices.	✓	
• Describe use of prescribed medications.	✓	✓
• Comply with antibiotic regimen.	✓	
• Promote healing through aseptic dressing changes.	✓	✓
• Demonstrate proper wound care.	✓	✓
• Report signs and symptoms of continuing infection or superinfection.	✓	✓

reactions. The nurse stresses the importance of follow-up health care appointments (Chart 68-9).

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Experiences pain relief
  - a. Reports decreased pain
  - b. Experiences no tenderness at site of previous infection
  - c. Experiences no discomfort with movement
2. Increases physical mobility
  - a. Participates in self-care activities
  - b. Maintains full function of unimpaired extremities
  - c. Demonstrates safe use of immobilizing and assistive devices
  - d. Modifies environment to promote safety and to avoid falls
3. Shows absence of infection
  - a. Takes antibiotic as prescribed
  - b. Reports normal temperature
  - c. Exhibits no swelling
  - d. Reports absence of drainage
  - e. Laboratory results indicate normal white blood cell count and sedimentation rate
  - f. Wound cultures are negative
4. Complies with therapeutic plan
  - a. Takes medications as prescribed
  - b. Protects weakened bones
  - c. Demonstrates proper wound care
  - d. Reports signs and symptoms of complications promptly
  - e. Eats a diet that is high in protein and vitamin C
  - f. Keeps follow-up health appointments
  - g. Reports increased strength
  - h. Reports no elevation of temperature or recurrence of pain, swelling, or other symptoms at the site

## SEPTIC (INFECTIOUS) ARTHRITIS

Joints can become infected through spread of infection from other parts of the body (hematogenous spread) or directly through trauma or surgical instrumentation. Previous trauma to joints, joint replacement, coexisting arthritis, and diminished host resistance contribute to the development of an infected joint. *S. aureus* causes most adult joint infections, followed by streptococci and

gram-negative organisms. Prompt recognition and treatment of an infected joint are important because accumulating pus results in chondrolysis (destruction of hyaline cartilage).

## Clinical Manifestations

The patient with acute septic arthritis usually presents with a warm, painful, swollen joint with decreased range of motion. Systemic chills, fever, and leukocytosis are present. Risk factors include advanced age, diabetes mellitus, rheumatoid arthritis, and preexisting joint disease or joint replacement.

### Gerontologic Considerations

Elderly patients and patients taking corticosteroids or immunosuppressive medications may not exhibit typical clinical manifestations of infection. Therefore, they require ongoing assessment to detect infection as early as possible in the infectious process.

## Assessment and Diagnostic Findings

An assessment for the source and cause of infection is performed. Diagnostic studies include aspiration, examination, and culture of the synovial fluid. Computed tomography and MRI may disclose damage to the joint lining. Radioisotope scanning may be useful in localizing the infectious process.

## Management

Prompt treatment is essential and may save a joint prosthesis for patients who have one. Broad-spectrum IV antibiotics are started promptly and then changed to organism-specific antibiotics after culture results are available. The IV antibiotics are continued until symptoms disappear. The synovial fluid is monitored for sterility and decrease in WBCs.

In addition to prescribing antibiotics, the physician may aspirate the joint with a needle to remove excessive joint fluid, exudate, and debris. This promotes comfort and decreases joint destruction caused by the action of proteolytic enzymes in the purulent fluid. Occasionally, arthrotomy or arthroscopy is used to drain the joint and remove dead tissue.

The inflamed joint is supported and immobilized in a functional position by a splint that increases the patient's comfort. Analgesics, such as codeine, may be prescribed to control pain. After the infection has responded to antibiotic therapy, NSAIDs may be prescribed to limit joint damage. The patient's nutrition

and fluid status is monitored. Progressive range-of-motion exercises are prescribed after the infection subsides.

If septic joints are treated promptly, recovery of normal function is expected. The patient is assessed periodically for recurrence. If the articular cartilage was damaged during the inflammatory reaction, joint fibrosis and diminished function may result.

The nurse describes the septic arthritis process to the patient and teaches the patient how to relieve pain using pharmacologic and nonpharmacologic interventions. The nurse also explains the importance of supporting the affected joint, adhering to the prescribed antibiotic regimen, and observing weight-bearing and activity restrictions. Additionally, the nurse demonstrates and encourages the patient to practice safe use of ambulatory aids and assistive devices.

The nurse teaches the patient strategies to promote healing through aseptic dressing changes and proper wound care. The patient is then encouraged to perform range-of-motion exercises after the infection subsides.

## Bone Tumors

Neoplasms of the musculoskeletal system are of various types, including osteogenic, chondrogenic, fibrogenic, muscle (rhabdomyogenic), and marrow (reticulum) cell tumors as well as nerve, vascular, and fatty cell tumors. They may be primary tumors or metastatic tumors from primary cancers elsewhere in the body (eg, breast, lung, prostate, kidney). Metastatic bone tumors are more common than primary bone tumors.

### BENIGN BONE TUMORS

Benign tumors of the bone and soft tissue are more common than malignant primary bone tumors. Benign bone tumors generally are slow growing and well circumscribed, present few symptoms, and are not a cause of death.

Benign primary neoplasms of the musculoskeletal system include osteochondroma, enchondroma, bone cyst (eg, aneurysmal bone cyst), osteoid osteoma, rhabdomyoma, and fibroma. Some benign tumors, such as giant cell tumors, have the potential to become malignant.

Osteochondroma is the most common benign bone tumor. It usually occurs as a large projection of bone at the end of long bones (at the knee or shoulder). It develops during growth and then becomes a static bony mass. In fewer than 1% of patients, the cartilage cap of the osteochondroma may undergo malignant transformation after trauma, and a chondrosarcoma or osteosarcoma may develop.

Enchondroma is a common tumor of the hyaline cartilage that develops in the hand, femur, tibia, or humerus. Usually, the only symptom is a mild ache. Pathologic fractures may occur.

Bone cysts are expanding lesions within the bone. Aneurysmal (widening) bone cysts are seen in young adults, who present with a painful, palpable mass of the long bones, vertebrae, or flat bone. Unicameral (single cavity) bone cysts occur in children and cause mild discomfort and possible pathologic fractures of the upper humerus and femur, which may heal spontaneously.

A painful tumor that occurs in children and young adults is the osteoid osteoma. The neoplastic tissue is surrounded by reactive bone formation that assists in its identification by x-ray.

Giant cell tumors (osteoclastomas) are benign for long periods but may invade local tissue and cause destruction. They occur in

young adults and are soft and hemorrhagic. Eventually, giant cell tumors may undergo malignant transformation and metastasize.

### MALIGNANT BONE TUMORS

Primary malignant musculoskeletal tumors are relatively rare and arise from connective and supportive tissue cells (sarcomas) or bone marrow elements (multiple myeloma; see Chap. 33). Malignant primary musculoskeletal tumors include osteosarcoma, chondrosarcoma, Ewing's sarcoma, and fibrosarcoma. Soft tissue sarcomas include liposarcoma, fibrosarcoma of soft tissue, and rhabdomyosarcoma. Bone tumor metastasis to the lungs is common.

Osteogenic sarcoma (osteosarcoma) is the most common and most often fatal primary malignant bone tumor. Prognosis depends on whether the tumor has metastasized to the lungs at the time the patient seeks health care. Osteogenic sarcoma appears most frequently in males between the ages of 10 and 25 years (in bones that grow rapidly), in older people with Paget's disease, and as a result of radiation exposure. Clinical manifestations include pain, swelling, limited motion, and weight loss (which is considered an ominous finding). The bony mass may be palpable, tender, and fixed, with an increase in skin temperature over the mass and venous distention. The primary lesion may involve any bone, but the most common sites are the distal femur, the proximal tibia, and the proximal humerus.

Malignant tumors of the hyaline cartilage are called chondrosarcomas. These tumors are the second most common primary malignant bone tumor. They are large, bulky, slow-growing tumors that affect adults. The usual tumor sites include the pelvis, femur, humerus, spine, scapula, and tibia. Metastasis to the lungs occurs in fewer than half of patients. When these tumors are well differentiated, large bloc excision or amputation of the affected extremity results in increased survival rates. These tumors may recur.

### METASTATIC BONE DISEASE

Metastatic bone disease (secondary bone tumor) is more common than any primary bone tumor. Tumors arising from tissues elsewhere in the body may invade the bone and produce localized bone destruction (lytic lesions) or bone overgrowth (blastic lesions). The most common primary sites of tumors that metastasize to bone are the kidney, prostate, lung, breast, ovary, and thyroid. Metastatic tumors most frequently attack the skull, spine, pelvis, femur, and humerus and involve more than one bone (polyostotic).

### Pathophysiology

A tumor in the bone causes the normal bone tissue to react by osteolytic response (bone destruction) or osteoblastic response (bone formation). Primary tumors cause bone destruction, which weakens the bone, resulting in bone fractures. Adjacent normal bone responds to the tumor by altering its normal pattern of remodeling. The bone's surface changes, and the contours enlarge in the tumor area.

Malignant bone tumors invade and destroy adjacent bone tissue. Benign bone tumors, in contrast, have a symmetric, controlled growth pattern and place pressure on adjacent bone tissue. Malignant invading bone tumors weaken the structure of the bone until it can no longer withstand the stress of ordinary use; pathologic fracture commonly results.

## Clinical Manifestations

Patients with metastatic bone tumor may have a wide range of associated clinical manifestations. They may be symptom free or have pain (mild and occasional to constant and severe), varying degrees of disability and, at times, obvious bone growth. Weight loss, malaise, and fever may be present. The tumor may be diagnosed only after pathologic fracture has occurred.

With spinal metastasis, spinal cord compression may occur. It can progress rapidly or slowly. Neurologic deficits (eg, progressive pain, weakness, gait abnormality, paresthesia, paraplegia, urinary retention, loss of bowel or bladder control) must be identified early and treated with decompressive laminectomy to prevent permanent spinal cord injury.

## Assessment and Diagnostic Findings

The differential diagnosis is based on the history, physical examination, and diagnostic studies, including computed tomography, bone scans, myelography, arteriography, MRI, biopsy, and biochemical assays of the blood and urine. Serum alkaline phosphatase levels are frequently elevated with osteogenic sarcoma. With metastatic carcinoma of the prostate, serum acid phosphatase levels are elevated. Hypercalcemia is present with breast, lung, or kidney cancer bone metastases. Symptoms of hypercalcemia include muscle weakness, fatigue, anorexia, nausea, vomiting, polyuria, cardiac dysrhythmias, seizures, and coma. Hypercalcemia must be identified and treated promptly. Surgical biopsy is performed for histologic identification. Extreme care is taken during biopsy to prevent seeding and resultant recurrence after excision of the tumor.

Chest x-rays are performed to determine the presence of lung metastasis. Surgical staging of musculoskeletal tumors is based on tumor grade and site (intracompartmental or extracompartmental), as well as on metastasis. Staging is used for planning treatment.

During the diagnostic period, the nurse explains the diagnostic tests and provides psychological and emotional support to the patient and family. The nurse assesses coping behaviors and encourages use of support systems.

## Medical Management

### PRIMARY BONE TUMORS

The goal of primary bone tumor treatment is to destroy or remove the tumor. This may be accomplished by surgical excision (ranging from local excision to amputation and disarticulation), radiation therapy if the tumor is radiosensitive, and chemotherapy (preoperative, intraoperative [neoadjuvant], postoperative, and adjunctive for possible micrometastases). Major gains are being made in the use of wide bloc excision with restorative grafting technique. Survival and quality of life are important considerations in procedures that attempt to save the involved extremity.

Limb-sparing (salvage) procedures are used to remove the tumor and adjacent tissue. A customized prosthesis, total joint arthroplasty, or bone tissue from the patient (autograft) or from a cadaver donor (allograft) replaces the resected tissue. Soft tissue and blood vessels may need grafting because of the extent of the excision. Complications may include infection, loosening or dislocation of the prosthesis, allograft nonunion, fracture, devitalization of the skin and soft tissues, joint fibrosis, and recurrence of the tumor. Function and rehabilitation after limb

salvage depend on positive encouragement and reducing the risk for complications.

Surgical removal of the tumor may require amputation of the affected extremity, with the amputation extending well above the tumor to achieve local control of the primary lesion (see Nursing Process: The Patient Undergoing an Amputation in Chapter 69.)

Because of the danger of metastasis with malignant bone tumors, combined chemotherapy is started before and continued after surgery in an effort to eradicate micrometastatic lesions. The goal of combined chemotherapy is greater therapeutic effect at a lower toxicity rate with reduced resistance to the medications. There is an improved long-term survival rate when a localized osteosarcoma is removed and chemotherapy is initiated. Soft tissue sarcomas are treated with radiation, limb-sparing excision, and adjuvant chemotherapy (see Chap. 33).

### METASTATIC BONE DISEASE

The treatment of metastatic bone cancer is palliative. The therapeutic goal is to relieve the patient's pain and discomfort while promoting quality of life.

If metastatic disease weakens the bone, structural support and stabilization are needed to prevent pathologic fracture. At times, large bones with metastatic lesions are strengthened by prophylactic internal fixation. Internal fixation of pathologic fractures, arthroplasty, or methylmethacrylate (bone cement) reconstruction minimizes associated disability and pain. Patients with metastatic disease are at higher risk for pulmonary congestion, hypoxemia, deep vein thrombosis, and hemorrhage than are other patients after orthopedic surgery.

Hypercalcemia results from breakdown of bone. It needs to be recognized promptly. Treatment includes hydration with IV administration of normal saline solution, diuresis, mobilization, and medications such as bisphosphonates, pamidronate, and calcitonin. Because inactivity leads to loss of bone mass and increased calcium in the blood, the nurse assists the patient to increase activity and ambulation.

Hematopoiesis is frequently disrupted by tumor invasion of the bone marrow or by treatment (chemotherapy or radiation). Blood product transfusions restore hematologic factors. Pain can result from multiple factors, including the osseous metastasis, surgery, chemotherapy or radiation side effects, and arthritis. Pain must be assessed accurately and managed with adequate and appropriate opioid, nonopioid, and nonpharmaceutical interventions. External beam radiation to involved metastasis sites may be used. Patients with multiple bony metastases may achieve pain control with systemically administered "bone-seeking" isotopes (eg, strontium 89). See Chapter 13 for more information about pain management.

Additional therapies are used to treat the original cancer. Radiation and hormonal therapy may be effective in promoting healing of osteolytic lesions. Chemotherapy is used to control the primary disease (see Chap. 33).

## NURSING PROCESS: THE PATIENT WITH A BONE TUMOR

### Assessment

The nurse asks the patient about the onset and course of symptoms. During the interview, the nurse notes the patient's understanding of the disease process, how the patient and the family

## NURSING RESEARCH PROFILE 68-2

### Patients' Perceptions of Bone Pain and Pain Control

Coward, D., and Wilkie, D. (2000). Metastatic bone pain: Meanings associated with self-report and self-management decision making. *Cancer Nursing*, 23, 101–108.

#### Purpose

Patients with cancer and bone metastases experience severe pain, especially when moving. Cancer pain is conceptualized as multidimensional: physiologic, sensory, affective, behavioral, and cognitive. This descriptive study examined the meanings of pain experiences as well as self-disclosure and self-management of pain in both men and women. The study goals were (1) to identify thoughts, feelings, and perceptions reported by patients experiencing metastatic bone pain, (2) to identify methods patients used to tell others about the pain, (3) to describe the process patients used to decide whether to take analgesics, and (4) to describe possible gender-related differences in pain experiences.

#### Study Sample and Design

A convenience sample consisted of 10 women and 10 men who had pain and objective evidence of bone metastasis. Most of the patients had metastases to the spine and had undergone surgery, chemotherapy, or radiation as cancer treatments before participating in the study.

Data were collected during audiotaped interviews. Interview questions were used to identify the patient's pain-related beliefs, feelings, and actions. The study participants also completed a McGill Pain Questionnaire, a visual analog scale of pain intensity, and a demographic form.

Transcribed tapes were analyzed for themes, and the narrative data were organized into descriptions of the participants' thoughts and feelings about their pain, the impact of pain on their lives, how they disclosed their pain to others, and how they decided to take analgesics.

#### Results

Participants' reported thoughts and feelings about pain included possible injury, recurrence of cancer, progression of cancer, ineffectiveness of cancer treatments, fright and uncertainty about whether the cancer could be controlled, and the need to work harder to fight the cancer.

Pain interfered with participants' activities, including activities of daily living, work/housework, and pleasure activities. Also, pain interfered with family relationships, causing the participants to be irritable with family members or to isolate themselves from the family.

Most of the participants (7 women and 5 men) preferred not to tell others about their pain because they did not want to disappoint or worry others. Women sought normalcy. Men did not want to complain or saw no purpose in telling others. Those who disclosed their pain (3 women and 5 men) wanted to be honest with their friends and thought it would help health professionals to manage their pain. Only 3 women and 6 men took analgesics on the recommended schedule. Many delayed taking analgesics because the pain reminded them to protect the hurting part and kept them from overexertion. Side effects (eg, gastrointestinal distress, feeling out of control) were a concern for some of the participants (4 women and 5 men). Another reason given for not taking analgesics was to see whether the cancer treatment was working. The sample was too small to draw any conclusions about gender-related differences in pain experiences.

#### Nursing Implications

Pain means different things to different patients. Nurses need to engage patients with cancer in discussion of their pain and pain management. Disclosure of the characteristics of pain experiences would facilitate development of individualized, effective pain management strategies. If pain is associated with movement, pain management interventions need to be used to encourage movement and participation in activities of daily living and socialization. Alternative activities that bring the patient pleasure can be devised when pain or fear of fracture causes the patient to give up previously pleasurable activities.

For various reasons, a patient may not take analgesics on the recommended schedule; these reasons should be explored by the nurse. If side effects of analgesics are reported, they can be minimized. The nurse needs to discuss with the patient the physiologic benefits of controlling pain.

have been coping, and how the patient has managed the pain. On physical examination, the nurse gently palpates the mass and notes its size and associated soft tissue swelling, pain, and tenderness. Assessment of the neurovascular status and range of motion of the extremity provides baseline data for future comparisons. The nurse evaluates the patient's mobility and ability to perform ADLs.

## Diagnosis

### NURSING DIAGNOSES

Based on the nursing assessment data, the major nursing diagnoses for the patient with a bone tumor may include the following:

- Deficient knowledge related to the disease process and the therapeutic regimen
- Acute and chronic pain related to pathologic process and surgery
- Risk for injury: pathologic fracture related to tumor and metastasis
- Ineffective coping related to fear of the unknown, perception of disease process, and inadequate support system
- Risk for situational low self-esteem related to loss of body part or alteration in role performance

## COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Potential complications may include the following:

- Delayed wound healing
- Nutritional deficiency
- Infection
- Hypercalcemia

## Planning and Goals

The major goals for the patient include knowledge of the disease process and treatment regimen, control of pain, absence of pathologic fractures, effective patterns of coping, improved self-esteem, and absence of complications.

## Nursing Interventions

The nursing care of a patient who has undergone excision of a bone tumor is similar in many respects to that of other patients who have had skeletal surgery. Vital signs are monitored; blood loss is assessed; and observations are made to assess for the development of complications such as deep vein thrombosis, pulmonary emboli, infection, contracture, and disuse atrophy. The

affected part is elevated to control swelling, and the neurovascular status of the extremity is assessed.

### PROMOTING UNDERSTANDING OF THE DISEASE PROCESS AND TREATMENT REGIMEN

Patient and family teaching about the disease process and diagnostic and management regimens is essential. Explanation of diagnostic tests, treatments (eg, wound care), and expected results (eg, decreased range of motion, numbness, change of body contours) helps the patient deal with the procedures and changes. Cooperation and adherence to the therapeutic regimen are enhanced through understanding. The nurse can most effectively reinforce and clarify information provided by the physician by being present during these discussions.

### RELIEVING PAIN

Accurate pain assessment is the foundation for pain management. Pharmacologic and nonpharmacologic pain management techniques are used to relieve pain and increase the patient's comfort level. The nurse works with the patient in designing the most effective pain management regimen, thereby increasing the patient's control over the pain. The nurse prepares the patient and gives support during painful procedures. Prescribed IV or epidural analgesics are used during the early postoperative period. Later, oral or transdermal opioid or nonopioid analgesics are usually adequate to relieve pain. In addition, external radiation or systemic radioisotopes may be used to control pain (see Chapter 13 for further discussion of pain management).

### PREVENTING PATHOLOGIC FRACTURE

Bone tumors weaken the bone to a point at which normal activities or even position changes can result in fracture. During nursing care, the affected extremities must be supported and handled gently. External supports (eg, splints) may be used for additional protection. At times, the patient may elect to have surgery (eg, open reduction with internal fixation, joint replacement) in an attempt to prevent pathologic fracture. Prescribed weight-bearing restrictions must be followed. The nurse teaches the patient how to use assistive devices safely and how to strengthen unaffected extremities.

### PROMOTING COPING SKILLS

The nurse encourages the patient and family to verbalize their fears, concerns, and feelings. They need to be supported as they deal with the impact of the malignant bone tumor. Feelings of shock, despair, and grief are expected. Referral to a psychiatric nurse liaison, psychologist, counselor, or spiritual advisor may be indicated for specific psychological help and emotional support.

### PROMOTING SELF-ESTEEM

Independence versus dependence is an issue for the patient who has a malignancy. Lifestyle is dramatically changed, at least temporarily. It is important to support the family in working through the adjustments that must be made. The nurse assists the patient in dealing with changes in body image due to surgery and possible amputation. It is helpful to provide realistic reassurance about the future and resumption of role-related activities and to encourage self-care and socialization. The patient participates in planning daily activities. The nurse encourages the patient to be as independent as possible. Involvement of the patient and family throughout treatment encourages confidence, restoration of self-concept, and a sense of being in control of one's life.

## MONITORING AND MANAGING POTENTIAL COMPLICATIONS

### Delayed Wound Healing

Wound healing may be delayed because of tissue trauma from surgery, previous radiation therapy, inadequate nutrition, or infection. The nurse minimizes pressure on the wound site to promote circulation to the tissues. An aseptic, nontraumatic wound dressing promotes healing. Monitoring and reporting of laboratory findings facilitate initiation of interventions to promote homeostasis and wound healing.

Repositioning the patient at frequent intervals reduces the incidence of skin breakdown due to pressure. Special therapeutic beds may be needed to prevent skin breakdown and to promote wound healing after extensive surgical reconstruction and skin grafting.

### Inadequate Nutrition

Because loss of appetite, nausea, and vomiting are frequent side effects of chemotherapy and radiation therapy, it is necessary to provide adequate nutrition for healing and health promotion. Antiemetics and relaxation techniques reduce the gastrointestinal reaction. Stomatitis is controlled with anesthetic or antifungal mouthwash (see Chap. 33). Adequate hydration is essential. Nutritional supplements or total parenteral nutrition may be prescribed to achieve adequate nutrition.

### Osteomyelitis and Wound Infections

Prophylactic antibiotics and strict aseptic dressing techniques are used to diminish the occurrence of osteomyelitis and wound infections. During healing, other infections (eg, upper respiratory infections) need to be prevented so that hematogenous spread does not result in osteomyelitis. If the patient is receiving chemotherapy, it is important to monitor the white blood cell count and to instruct the patient to avoid contact with people who have colds or other infections.

### Hypercalcemia

Hypercalcemia is a dangerous complication of bone cancer. The symptoms must be recognized and treatment initiated promptly. Symptoms include muscular weakness, incoordination, anorexia, nausea and vomiting, constipation, electrocardiographic changes (eg, shortened QT interval and ST segment, bradycardia, heart blocks), and altered mental states (eg, confusion, lethargy, psychotic behavior). See Chapter 14 for a full discussion of hypercalcemia and its management.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

Preparation for and coordination of continuing health care are begun early as a multidisciplinary effort. Patient teaching addresses medication, dressing, treatment regimens, and the importance of physical and occupational therapy programs. The nurse teaches weight-bearing limitations and special handling to prevent pathologic fractures. It is important that the patient and family know the signs and symptoms of possible complications as well as resources available for continuing care (Chart 68-10).

### Continuing Care

Frequently, arrangements are made with a home health care agency for home care supervision and follow-up. The home care nurse assesses the patient's and family's abilities to meet the patient's needs and determines whether the services of other agencies are needed.

Chart 68-10

## Home Care Checklist • Bone Tumor

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Describe tumor process.	✓	✓
• Control pain with pharmacologic and nonpharmacologic interventions.	✓	✓
• Support affected musculoskeletal area.	✓	
• Describe use of prescribed medications.	✓	✓
• Comply with medication regimen.	✓	
• Consume diet to promote healing and health.	✓	
• State weight-bearing and activity restrictions.	✓	✓
• Demonstrate safe use of ambulatory aids and assistive devices.	✓	✓
• Protect affected bone from pathologic fracture.	✓	✓
• Identify complications of tumor and therapy.	✓	✓
• Report signs and symptoms of complications promptly.	✓	✓
• Use effective coping strategies.	✓	
• Maintain role performance.	✓	✓

The nurse advises the patient to have readily available the telephone numbers of people to contact in case concerns arise.

The nurse emphasizes the need for long-term health supervision to ensure cure or to detect tumor recurrence or metastasis. If the patient has metastatic disease, end-of-life issues may need to be explored. Referral for hospice care is made if appropriate.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Describes disease process and treatment regimen
  - a. Describes pathologic condition
  - b. States goals of the therapeutic regimen
  - c. Seeks clarification of information
2. Achieves control of pain
  - a. Uses multiple pain control techniques, including prescribed medications
  - b. Experiences no pain or decreased pain at rest, during ADLs, or at surgical sites
3. Experiences no pathologic fracture
  - a. Avoids stress to weakened bones
  - b. Uses assistive devices safely and appropriately
  - c. Strengthens uninvolved extremities with exercise
4. Demonstrates effective coping patterns
  - a. Verbalizes feelings
  - b. Identifies strengths and abilities
  - c. Makes decisions
  - d. Requests assistance as needed
5. Demonstrates positive self-concept
  - a. Identifies home and family responsibilities that can be accomplished
  - b. Exhibits confidence in own abilities
  - c. Demonstrates acceptance of altered body image
  - d. Demonstrates independence in ADLs
6. Exhibits absence of complications
  - a. Demonstrates wound healing
  - b. Experiences no skin breakdown
  - c. Maintains or increases body weight

- d. Experiences no infections
  - e. Does not experience hypercalcemia
  - f. Manages side effects of therapies
  - g. Reports symptoms of medication toxicity or complications
7. Participates in continuing health care at home
    - a. Complies with prescribed regimen (ie, takes prescribed medications, continues physical and occupational therapy programs)
    - b. Acknowledges need for long-term health supervision
    - c. Keeps follow-up health care appointments
    - d. Reports occurrence of symptoms or complications

## Critical Thinking Exercises

1. A neighbor, who is a preschool teacher, tells you that she is experiencing low back pain and finds that she is having difficulty working. She asks you for your advice. Describe how you would assess this situation. What information are you seeking? Explain why you need this specific information. How would your critical thinking be redirected if the woman was also pregnant or overweight and postmenopausal? What initial advice would you give her?
2. You are a nurse in an orthopedic clinic. A patient, who is a data entry clerk, will be having same-day carpal tunnel release surgery. What information regarding postoperative care will you include in your preoperative patient education? The patient asks you about returning to work and asks how she can prevent this problem from recurring. What information would you share with her? What is the rationale for this information?
3. Your 18-year-old niece is visiting you for several weeks prior to entering college. Your mother, her grandmother, is suffering from spinal fractures and has experienced a Colles' fracture. You observe your niece's life-style and nutritional

habits. What factors would alert you to behaviors which put your niece at risk for the development of osteoporosis? What suggestions would you make to her to optimize her bone density and prevent osteoporosis?

4. A friend has breast cancer. She shares with you that she is experiencing pain in her hips and that the doctors have determined that she has bone metastasis. She asks you if this means that she has a new type of cancer. What additional assessment data would you gather before responding? She asks you how this bony metastasis will affect her. What factors would you consider before responding? What strategies would you discuss with her to (1) control pain, (2) prevent pathologic fracture, (3) promote coping, and (4) promote self-esteem?

# ● Management of Patients With Musculoskeletal Trauma

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Differentiate between contusions, strains, sprains, and dislocations.
2. Describe selected sports injuries and their nursing management.
3. Specify the clinical manifestations of a fracture and the emergency management of the patient with a fracture.
4. Describe the principles and methods of fracture reduction, fracture immobilization, and management of open fractures.
5. Use the nursing process as a framework for care of the patient with a simple fracture.
6. Describe the prevention and management of immediate and delayed complications of fractures.
7. Describe the rehabilitative needs of patients with fractures of the clavicle, upper and lower extremities, pelvis, hips, ribs, and thoracolumbar spine.
8. Use the nursing process as a framework for care of the elderly patient with fracture of the hip.
9. Describe the rehabilitative and health education needs of the patient who has had an amputation.
10. Use the nursing process as a framework for care of the patient with an amputation.

**I**njury to one part of the musculoskeletal system usually results in injury or dysfunction of adjacent structures and of structures enclosed or supported by them. If the bone is broken, the muscles cannot function, and blood vessels and nerves in the vicinity of the fracture may be injured. If the nerves do not send impulses to the muscles, as in paralysis, the bones cannot move. If the joint surfaces do not articulate normally, neither the bones nor the muscles can function properly.

Treatment of injury of the musculoskeletal system involves providing support to the injured part until healing is complete. Support may be provided by externally applied bandages, adhesive strapping, splints, or casts. Alternatively, support may be applied directly to the bone in the form of pins or plates. At times, traction must be applied to correct deformity or shortening.

After the immediate and the painful effects of the injury have passed, treatment efforts are focused on preventing fibrosis and stiffness in the injured muscles and joint structures. Proper exercise guards against this disability. In some cases, the support applied permits early activity. Various forms of physical and occupational therapy may hasten the healing process and recovery of function.

## Contusions, Strains, and Sprains

A **contusion** is a soft tissue injury produced by blunt force, such as a blow, kick, or fall. Many small blood vessels rupture and bleed into soft tissues (ecchymosis, or bruising). A hematoma develops when the bleeding is sufficient to cause an appreciable collection of blood. Local symptoms (pain, swelling, and discoloration) are controlled with intermittent application of cold. Most contusions resolve in 1 to 2 weeks.

A **strain** is a “muscle pull” caused by overuse, overstretching, or excessive stress. Strains are microscopic, incomplete muscle tears with some bleeding into the tissue. The patient experiences soreness or sudden pain, with local tenderness on muscle use and isometric contraction.

A **sprain** is an injury to the ligaments surrounding a joint that is caused by a wrenching or twisting motion. The function of a ligament is to maintain stability while permitting mobility. A torn ligament loses its stabilizing ability. Blood vessels rupture and edema occurs; the joint is tender, and movement of the joint becomes painful. The degree of disability and pain increases during the first 2 to 3 hours after the injury because of the associated swelling and bleeding. An x-ray should be obtained to rule out bone injury. Avulsion fracture (in which a bone fragment is

pulled away by a ligament or tendon) may be associated with a sprain.

## Management

Treatment of contusions, strains, and sprains consists of resting and elevating the affected part, applying cold, and using a compression bandage. (The acronym **RICE**—Rest, Ice, Compression, Elevation—is helpful for remembering treatment interventions.) Rest prevents additional injury and promotes healing. Moist or dry cold applied intermittently for 20 to 30 minutes during the first 24 to 48 hours after injury produces vasoconstriction, which decreases bleeding, edema, and discomfort. Care must be taken to avoid skin and tissue damage from excessive cold. An elastic compression bandage controls bleeding, reduces edema, and provides support for the injured tissues. Elevation controls the swelling. If the sprain is severe (torn muscle fibers and disrupted ligaments), surgical repair or cast immobilization may be necessary so that the joint will not lose its stability. The neurovascular status (circulation, motion, sensation) of the injured extremity is monitored frequently.

After the acute inflammatory stage (eg, 24 to 48 hours after injury), heat may be applied intermittently (for 15 to 30 minutes, four times a day) to relieve muscle spasm and to promote vasodilation, absorption, and repair. Depending on the severity of injury, progressive passive and active exercises may begin in 2 to 5 days. Severe sprains may require 1 to 3 weeks of immobilization before protected exercises are initiated. Excessive exercise early in the course of treatment delays recovery. Strains and sprains take weeks or months to heal. Splinting may be used to prevent reinjury.

## Joint Dislocations

A dislocation of a joint is a condition in which the articular surfaces of the bones forming the joint are no longer in anatomic contact. The bones are literally “out of joint.” A **subluxation** is a partial dislocation of the articulating surfaces. Traumatic dislocations are orthopedic emergencies because the associated joint structures, blood supply, and nerves are distorted and severely stressed. If the dislocation is not treated promptly, *avascular necrosis* (tissue death due to anoxia and diminished blood supply) and nerve palsy may occur.

Dislocations may be congenital, or present at birth (most often the hip); spontaneous or pathologic, caused by disease of the

## Glossary

**allograft:** tissue harvested from a donor for use in another person  
**amputation:** removal of a body part, usually a limb or part of a limb  
**arthroscope:** surgical instrument used to examine internal joint structures  
**autograft:** tissue harvested from one area of the body and used for transplantation to another area of the body  
**débridement:** surgical removal of contaminated and devitalized tissues and foreign material  
**dislocation:** separation of joint surfaces

**fracture:** a break in the continuity of a bone  
**fracture reduction:** restoration of fracture fragments into anatomic alignment and rotation  
**malunion:** healing of a fractured bone in a malaligned position  
**meniscus:** crescent-shaped fibrocartilage found in certain joints, such as the knee joint  
**nonunion:** failure of fragments of a fractured bone to heal together  
**phantom limb pain:** pain perceived as being in the amputated limb

**RICE:** acronym for Rest, Ice, Compression, Elevation  
**rotator cuff:** shoulder muscles (supraspinatus, subscapularis, infraspinatus, and teres minor) and their tendons  
**sprain:** an injury to ligaments and other soft tissues at a joint  
**strain:** a muscle pull or tear  
**subluxation:** partial separation or dislocation of joint surfaces  
**tendinitis:** inflammation of a tendon

articular or periarticular structures; or traumatic, resulting from injury in which the joint is disrupted by force.

Signs and symptoms of a traumatic dislocation are pain, change in contour of the joint, change in the length of the extremity, loss of normal mobility, and change in the axis of the dislocated bones. X-rays confirm the diagnosis and demonstrate any associated fracture.

## Medical Management

The affected joint needs to be immobilized while the patient is transported to the hospital. The dislocation is promptly reduced (ie, displaced parts are brought into normal position) to preserve joint function. Analgesia, muscle relaxants, and possibly anesthesia are used to facilitate closed reduction. The joint is immobilized by bandages, splints, casts, or traction and is maintained in a stable position. Neurovascular status is monitored. After reduction, if the joint is stable, gentle, progressive, active and passive movement is begun to preserve range of motion (ROM) and restore strength. The joint is supported between exercise sessions.

## Nursing Management

Nursing care is directed at providing comfort, evaluating the patient's neurovascular status, and protecting the joint during healing. The nurse teaches the patient how to manage the immobilizing devices and how to protect the joint from reinjury.

## Sports-Related Injuries

Many people participate in recreational sports. These recreational athletes may push themselves beyond the level of their physical conditioning and incur injuries. Injuries to the musculoskeletal system may be acute (eg, sprains, strains, dislocations, fractures), or they may be gradual, resulting from overuse (eg, chondromalacia patella, tendinitis, stress fractures). Professional athletes are also susceptible to injury, even though their training is supervised closely to minimize the occurrence of injury.

- Contusions result from direct falls or blows. The initial dull pain becomes greater, with edema and stiffness occurring by the next day.
- Sprains commonly occur in fingers, ankles, and knees. If the ligament damage is major, the joint becomes unstable, and surgical repair may be required. In addition, an avulsion fracture may exist.

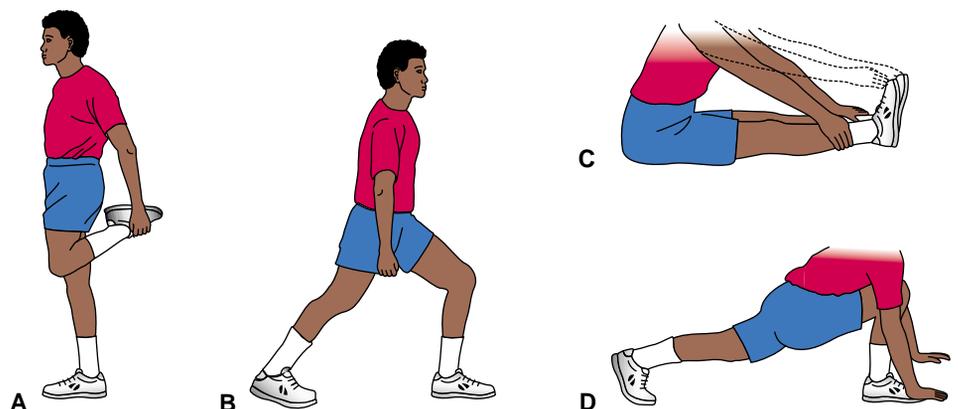

- Strains manifest with a sharp, stabbing pain caused by bleeding and immediate protective muscle contraction. Tennis players often suffer calf muscle strains; soccer players often experience quadriceps strains; and swimmers, weight lifters, and tennis players often suffer shoulder strains.
- **Tendinitis** (inflammation of a tendon) is caused by overuse and is seen in tennis players (epicondylar tendinitis, or “tennis elbow”), in runners and gymnasts (Achilles tendinitis), and in basketball players (infrapatellar tendinitis).
- Meniscal injuries of the knee occur with excessive rotational stress.
- Dislocations are seen with sports that involve throwing or lifting.
- Fractures occur with falls. Skaters and bikers frequently suffer Colles' fractures of the wrist when they fall on outstretched arms; ballet dancers and track and field athletes may experience metatarsal fractures. Stress fractures occur with repeated bone trauma from activities such as jogging, gymnastics, basketball, and aerobics. The tibias, fibulas, and metatarsals are most vulnerable.

Patients who have experienced a sports-related injury are often highly motivated to return to their previous level of activity. Compliance with restriction of activities and gradual resumption of activities may be a significant problem for these patients. They need to be taught how to avoid further injury or new injury. With recurrence of symptoms, they need to diminish their level and intensity of activity to a comfortable level and to treat the symptoms with RICE. The time required to recover from a sports-related injury can be as short as a few days or longer than 6 weeks.

## Prevention

Sports-related injuries can be prevented by the use of proper equipment (eg, running shoes for joggers, wrist guards for skaters) and by effectively training and conditioning of the body. Specific training needs to be tailored to the person and the sport. Warm-up routines generally include walking or slow jogging for about 5 minutes, followed by slow, gradual stretching. The athlete holds the stretch for 10 seconds before relaxing and repeating the stretch (Fig. 69-1). Preparing the body for sport activities increases the person's flexibility and decreases the incidence of strains and sprains.

After exercise, the body needs to cool off to prevent cardiovascular problems such as hypotension, syncope, and dysrhythmias. Changes in activities and stresses should occur gradually. In addition, the athlete needs to be taught to “tune in” to body symptoms

**FIGURE 69-1** Stretching exercises. Slow, gradual stretching (after walking to warm the muscles) increases flexibility and decreases the incidence of sprains and strains. Lower extremity stretches include (A) quadriceps stretch; (B) heel cord stretch; (C) hamstring stretch; and (D) hamstring and quadriceps stretch.

that indicate stress and to modify activities to minimize injury and to promote healing.

## ROTATOR CUFF TEARS

**Rotator cuff** tears may result from an acute injury or from chronic joint stresses. Patients complain of pain, limited ROM, and some joint dysfunction, including muscle weakness. In many cases, the patient with a rotator cuff tear experiences night pain and is unable to sleep on the involved side. The patient is unable to perform over-the-head activities. The acromioclavicular joint is tender. X-rays are helpful in evaluating the joint. Arthrography and magnetic resonance imaging (MRI) are used to determine soft tissue pathology and the extent of the rotator cuff tear.

### Medical Management

Initial conservative management includes use of nonsteroidal anti-inflammatory drugs (NSAIDs) including cyclooxygenase-2 (COX-2) inhibitors, rest with modification of activities, injection of a corticosteroid into the shoulder joint, and progressive stretching, ROM, and strengthening exercises. Some rotator cuff tears require arthroscopic **débridement** (removal of devitalized tissue) or arthroscopic or open acromioplasty with tendon repair. Postoperatively, the shoulder is immobilized for several days to 4 weeks. Physical therapy with shoulder exercises is begun as prescribed, and the patient is instructed in how to perform the exercises at home. Full recovery is expected in 6 to 12 months.

## EPICONDYLITIS (TENNIS ELBOW)

Epicondylitis is a chronic, painful condition that is caused by excessive, repetitive extension, flexion, pronation, and supination activities of the forearm. These excessive, repetitious activities result in inflammation (tendinitis) and minor tears in the tendons at the origin of the muscles on the medial or lateral epicondyles. Activities contributing to the development of epicondylitis include tennis, racket sports, pitching, gymnastics, and repetitive use of a screwdriver. The pain characteristically radiates down the extensor (dorsal) surface of the forearm. The patient may have a weakened grasp. Most often, relief is obtained by rest and avoidance of the aggravating activity.

## Medical Management

Application of ice after the activity and administration of NSAIDs, including COX-2 inhibitors, usually relieve the pain. In some instances, the arm is immobilized in a molded splint or cast. Because of its degenerative effects on tendons, local injection of a corticosteroid is reserved for patients with severe pain who do not respond to NSAIDs and immobilization. After pain subsides, rehabilitation exercises include gentle and gradually increased stretching of the tendons. A tennis elbow counterforce strap to limit extension of the elbow may be prescribed when activity is resumed. Occasionally, surgery may be needed to release strictures or to débride the joint.

## LATERAL AND MEDIAL COLLATERAL LIGAMENT INJURY

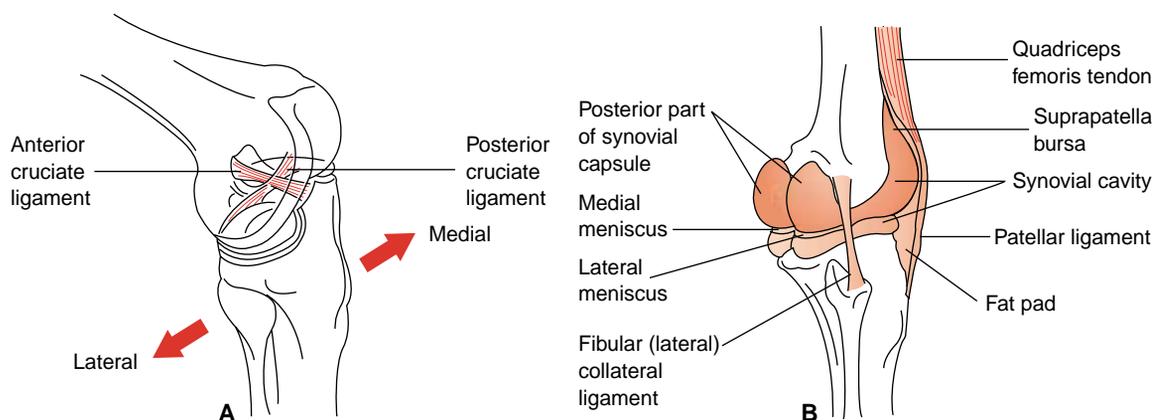

Lateral and medial collateral ligaments of the knee (Fig. 69-2) provide stability at the sides of the knee. Injury to these ligaments occurs when the foot is firmly planted and the knee is struck—either medially, causing stretching and tearing injury to the lateral collateral ligament, or laterally, causing stretching and tearing injury to the medial collateral ligament. The patient experiences pain, joint instability, and inability to walk without assistance.

### Medical Management

Emergency management includes RICE. The joint is evaluated for fracture. Hemarthrosis (bleeding into the joint) may develop, contributing to the pain. The joint fluid is aspirated to relieve pressure.

The treatment depends on the severity of the sprain. Conservative management includes limited weight bearing and use of protective elastic bandaging or a brace. As pain subsides, ROM exercise is encouraged. The patient's return to full activities, including sports, depends on return of motion, functional stability of the joint, and muscle strength.

If needed, surgical reconstruction may be performed immediately or delayed. Generally, the leg is immobilized, and weight bearing is restricted for 6 to 8 weeks. A progressive rehabilitation program helps to restore the function and strength of the knee. Rehabilitation requires many months, and the patient may need to wear a derotational brace while engaging in sports.

**FIGURE 69-2** Knee ligaments. (A) Anterolateral view. (B) Posterolateral view.

## Nursing Management

The nurse provides patient teaching about proper use of ambulatory devices, the healing process, and activity limitation to promote healing. The nurse teaches the surgical patient about pain management, medications (analgesics, antibiotics), brace use, wound care, possible complications (eg, altered neurovascular status, infection, skin breakdown), and self-care.

## ANTERIOR AND POSTERIOR CRUCIATE LIGAMENT INJURY

The anterior cruciate ligament (ACL) and the posterior cruciate ligament (PCL) of the knee stabilize forward and backward motion of the femur and tibia (see Fig. 69-2). These ligaments cross in the center of the knee. Injury occurs when the foot is firmly planted, the knee is hyperextended, and the person twists the torso and femur. The patient reports a pop or tearing sensation with this twisting injury. Usually, the ACL is torn. The patient experiences pain, joint instability, and pain with ambulation.

## Medical Management

Emergency management includes RICE. The joint is evaluated for fracture. Joint effusion and hemarthrosis require joint aspiration and wrapping with a compression elastic dressing.

Treatment depends on the severity of the injury and the effect of the injury on daily activities. Conservative treatment involves application of a brace, physical therapy, and avoidance of jumping activities. Surgical ACL reconstruction includes tendon repair with grafting and is performed as ambulatory arthroscopic surgery. After surgery, the patient is taught to control pain with oral opioid analgesics, NSAIDs, COX-2 inhibitors, and cryotherapy (a cooling pad incorporated in a dressing). The patient is taught about monitoring neurovascular status of the leg, wound care, and signs of complications that need to be reported promptly to the surgeon. Exercises (ankle pumps, quadriceps sets, and hamstring sets) are encouraged during the early postoperative period. The nurse reinforces instruction about weight-bearing limits, exercise restrictions, and the use of a knee brace or immobilizer. The patient must protect the graft by complying with exercise restrictions. The physical therapist supervises progressive ROM and weight bearing (as the patient is permitted). Continuous passive motion may be helpful in restoring full ROM. Rehabilitation after surgery typically takes 6 to 12 months.

## MENISCAL INJURIES

In the knee, there are two crescent-shaped (semilunar) cartilages, called menisci, attached to the edge of the shallow articulating surface of the head of the tibia (see Fig. 69-2). Each **meniscus** moves slightly backward and forward to accommodate the condyles of the femur when the leg is flexed or extended. Normally, little twisting movement is permitted in the knee joint. In sports or accidents, twisting of the knee or repetitive squatting and impact may result in either tearing or detachment of the cartilage from its attachment to the head of the tibia.

These injuries leave loose cartilage in the knee joint that may slip between the femur and the tibia, preventing full extension of the leg. If this happens during walking or running, patients often describe their leg as “giving way” under them. Patients may hear or feel a click in the knee when they walk, especially when they extend the leg that is bearing weight, as in going upstairs. When

the cartilage is attached to the front and back of the knee but torn loose laterally (bucket-handle tear), it may slide between the bones to lie between the condyles and prevent full flexion or extension. As a result, the knee “locks.” Meniscal injuries produce pain and disability because the patient never knows when the knee will malfunction. Also, the torn cartilage is an irritant in the joint, causing inflammation, chronic synovitis, and effusion.

## Medical Management

Initial conservative treatment includes immobilization of the knee, use of crutches, antiinflammatory agents, analgesics, and modification of activities to avoid those causing the symptoms. If symptoms persist, the damaged cartilage is surgically removed (meniscectomy) through a procedure in which the surgeon uses an **arthroscope** to visualize and repair the damage. After surgery, a pressure dressing is applied, and a knee-immobilizing splint may be required. The most common complication is an effusion into the knee joint, which produces marked pain. The physician may need to aspirate the joint to remove fluid and relieve the pressure. These patients are taught quadriceps-setting and ROM exercises. Additional exercises help to restore full function, stability, and strength. After arthroscopic meniscectomy, most patients resume activities in a day or two, and sports can be resumed in several weeks, as prescribed by the physician.

## RUPTURE OF THE ACHILLES TENDON

Traumatic rupture of the Achilles tendon, generally within the tendon sheath, occurs during activities when there is a sudden contraction of the calf muscle with the foot fixed firmly to the floor or ground. The patient experiences sharp pain and is unable to plantar flex the foot. Immediate surgical repair of complete Achilles tendon ruptures is usually recommended to obtain satisfactory results. After surgery, a cast or brace is used to immobilize the joint. In some situations, conservative management with a plantar-flexed cast for 6 to 8 weeks may be used. After immobilization, a heel lift is worn and progressive physical therapy to promote ankle ROM and strength is begun.

## Fractures

A **fracture** is a break in the continuity of bone and is defined according to its type and extent. Fractures occur when the bone is subjected to stress greater than it can absorb. Fractures are caused by direct blows, crushing forces, sudden twisting motions, and even extreme muscle contractions. When the bone is broken, adjacent structures are also affected, resulting in soft tissue edema, hemorrhage into the muscles and joints, joint dislocations, ruptured tendons, severed nerves, and damaged blood vessels. Body organs may be injured by the force that caused the fracture or by the fracture fragments.

## Types of Fractures

A *complete fracture* involves a break across the entire cross-section of the bone and is frequently displaced (removed from normal position). In an *incomplete fracture* (eg, greenstick fracture), the break occurs through only part of the cross-section of the bone. A *comminuted fracture* is one that produces several bone fragments. A *closed fracture* (simple fracture) is one that does not cause a break in the skin. An *open fracture* (compound, or complex,

fracture) is one in which the skin or mucous membrane wound extends to the fractured bone. Open fractures are graded according to the following criteria:

- Grade I is a clean wound less than 1 cm long.
- Grade II is a larger wound without extensive soft tissue damage.
- Grade III is highly contaminated, has extensive soft tissue damage, and is the most severe.

Fractures may also be described according to the anatomic placement of fragments, particularly if they are displaced or nondisplaced. Specific types of fractures are highlighted in Chart 69-1.

## Clinical Manifestations

The clinical manifestations of a fracture are pain, loss of function, deformity, shortening of the extremity, crepitus, and local swelling and discoloration. Not all of these clinical manifestations are present in every fracture. For example, many are not present with linear or fissure fractures or with impacted fractures. The diagnosis of a fracture is based on the patient's symptoms, the physical signs, and the x-ray findings. Usually, the patient reports having sustained an injury to the area.

### PAIN

The pain is continuous and increases in severity until the bone fragments are immobilized. The muscle spasm that accompanies fracture is a type of natural splinting designed to minimize further movement of the fracture fragments.

### LOSS OF FUNCTION

After a fracture, the extremity cannot function properly, because normal function of the muscles depends on the integrity of the bones to which they are attached. Pain contributes to the loss of function. In addition, abnormal movement (false motion) may be present.

### DEFORMITY

Displacement, angulation, or rotation of the fragments in a fracture of the arm or leg causes a deformity (either visible or palpable) that is detectable when the limb is compared with the uninjured extremity. Deformity also results from soft tissue swelling.

### SHORTENING

In fractures of long bones, there is actual shortening of the extremity because of the contraction of the muscles that are attached above and below the site of the fracture. The fragments often overlap by as much as 2.5 to 5 cm (1 to 2 inches).

### CREPITUS

When the extremity is examined with the hands, a grating sensation, called *crepitus*, can be felt. It is caused by the rubbing of the bone fragments against each other.

**NURSING ALERT** Testing for crepitus can produce further tissue damage and should be avoided.

### SWELLING AND DISCOLORATION

Localized swelling and discoloration of the skin (ecchymosis) occurs after a fracture as a result of trauma and bleeding into the tissues. These signs may not develop for several hours after the injury.

## Emergency Management of Fractures

Immediately after injury, whenever a fracture is suspected, it is important to immobilize the body part before the patient is moved. If an injured patient must be removed from a vehicle before splints can be applied, the extremity is supported above and below the fracture site to prevent rotation as well as angular motion.

Adequate splinting, including joints adjacent to the fracture, is essential. Movement of fracture fragments causes additional pain, soft tissue damage, and bleeding. Temporary, well-padded splints, firmly bandaged over clothing, serve to immobilize the fracture. Immobilization of the long bones of the lower extremities may be accomplished by bandaging the legs together, with the unaffected extremity serving as a splint for the injured one. In an upper extremity injury, the arm may be bandaged to the chest, or an injured forearm may be placed in a sling. The neurovascular status distal to the injury should be assessed to determine adequacy of peripheral tissue perfusion and nerve function.

With an *open fracture*, the wound is covered with a clean (sterile) dressing to prevent contamination of deeper tissues. No attempt is made to reduce the fracture, even if one of the bone fragments is protruding through the wound. Splints are applied for immobilization.

In the emergency department, the patient is evaluated completely. The clothes are gently removed, first from the uninjured side of the body and then from the injured side. The patient's clothing may be cut away. The fractured extremity is moved as little as possible to avoid more damage.

## Medical Management of Fractures

The principles of fracture treatment include reduction, immobilization, and regaining of normal function and strength through rehabilitation.

### REDUCTION

Reduction of a fracture ("setting" the bone) refers to restoration of the fracture fragments to anatomic alignment and rotation. Either closed reduction or open reduction may be used to reduce a fracture. The specific method selected depends on the nature of the fracture; however, the underlying principles are the same. Usually, the physician reduces a fracture as soon as possible to prevent loss of elasticity from the tissues through infiltration by edema or hemorrhage. In most cases, **fracture reduction** becomes more difficult as the injury begins healing.

Before fracture reduction and immobilization, the patient is prepared for the procedure; permission for the procedure is obtained, and an analgesic is administered as prescribed. Anesthesia may be administered. The injured extremity must be handled gently to avoid additional damage.

**Closed Reduction.** In most instances, closed reduction is accomplished by bringing the bone fragments into apposition (ie, placing the ends in contact) through manipulation and manual traction. The extremity is held in the desired position while the physician applies a cast, splint, or other device. Reduction under anesthesia with percutaneous pinning may be used. The immobilizing device maintains the reduction and stabilizes the extremity for bone healing. X-rays are obtained to verify that the bone fragments are correctly aligned.

Traction (skin or skeletal) may be used to effect fracture reduction and immobilization. Traction may be used until the patient is physiologically stable and able to withstand surgical fixation. Use of traction and the nursing management of a patient in traction are discussed more fully in Chapter 67.

Chart  
69-1

## Specific Types of Fractures

**Avulsion:** a fracture in which a fragment of bone has been pulled away by a ligament or tendon and its attachment

**Comminuted:** a fracture in which bone has splintered into several fragments

**Compound:** a fracture in which damage also involves the skin or mucous membranes; also called an open fracture

**Compression:** a fracture in which bone has been compressed (seen in vertebral fractures)

**Depressed:** a fracture in which fragments are driven inward (seen frequently in fractures of skull and facial bones)

**Epiphyseal:** a fracture through the epiphysis

**Greenstick:** a fracture in which one side of a bone is broken and the other side is bent

**Impacted:** a fracture in which a bone fragment is driven into another bone fragment

**Oblique:** a fracture occurring at an angle across the bone (less stable than a transverse fracture)

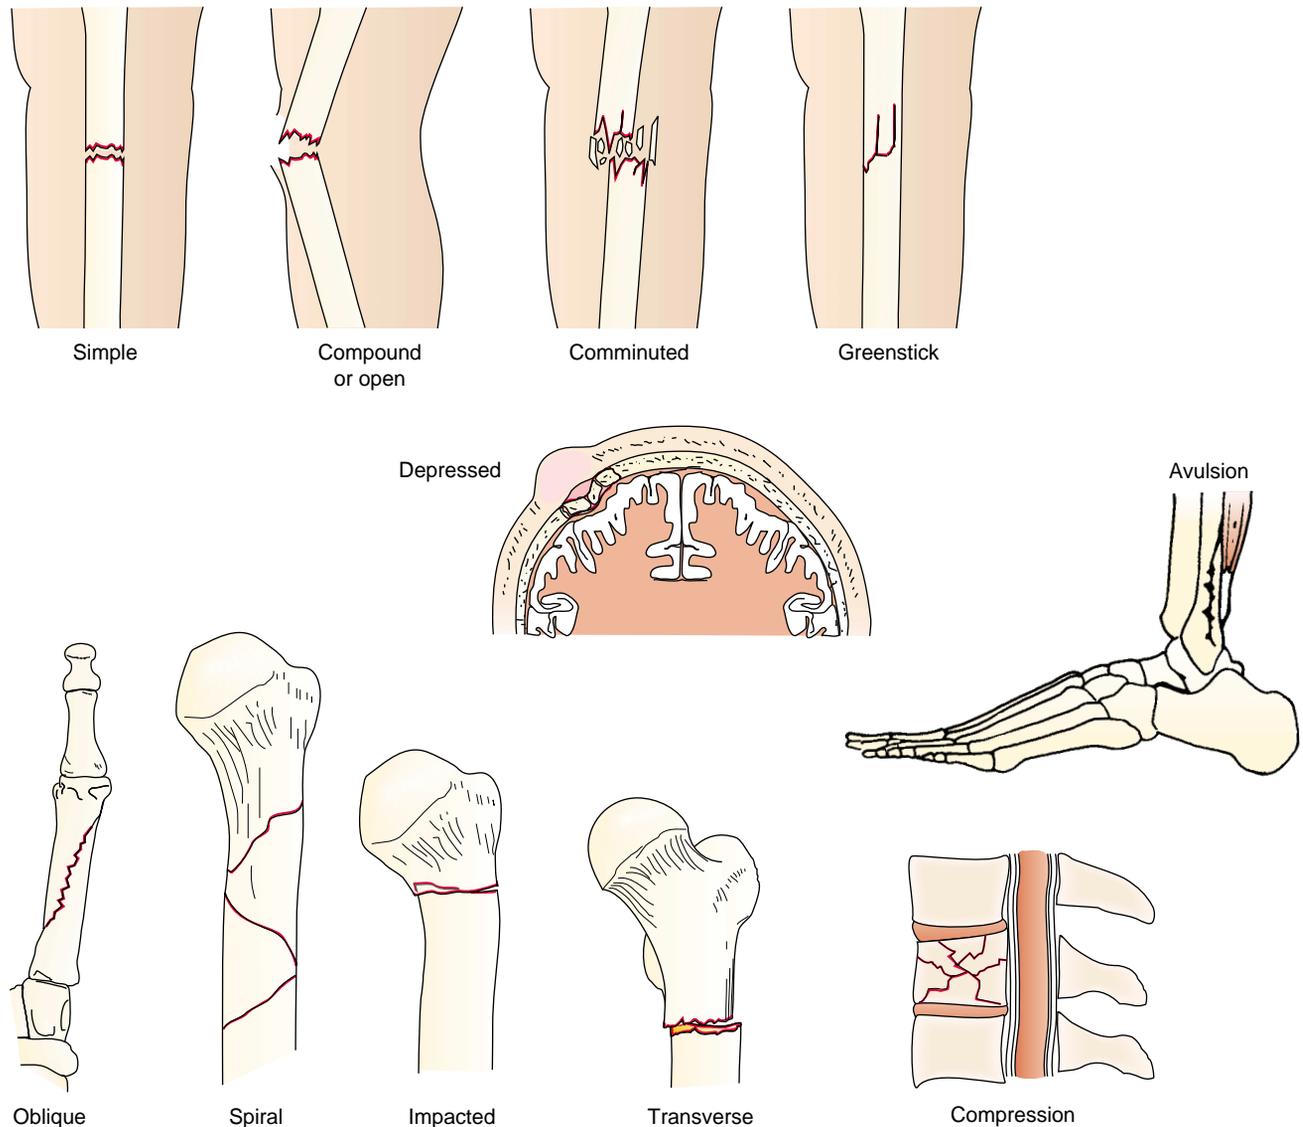

**Pathologic:** a fracture that occurs through an area of diseased bone (eg, osteoporosis, bone cyst, Paget's disease, bony metastasis, tumor); can occur without trauma or a fall

**Simple:** a fracture that remains contained; does not break the skin

**Spiral:** a fracture that twists around the shaft of the bone

**Stress:** a fracture that results from repeated loading without bone and muscle recovery

**Transverse:** a fracture that is straight across the bone

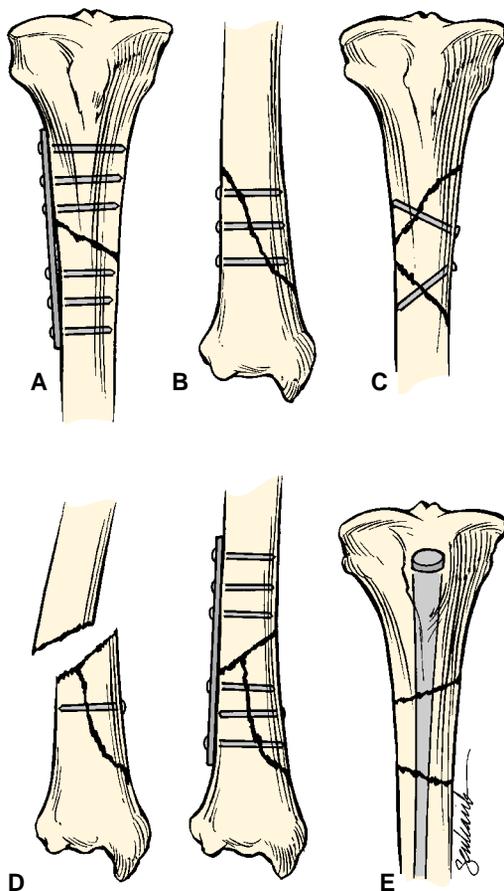

**Open Reduction.** Some fractures require open reduction. Through a surgical approach, the fracture fragments are reduced. Internal fixation devices (metallic pins, wires, screws, plates, nails, or rods) may be used to hold the bone fragments in position until solid bone healing occurs. These devices may be attached to the sides of bone, or they may be inserted through the bony fragments or directly into

the medullary cavity of the bone (Fig. 63-3). Internal fixation devices ensure firm approximation and fixation of the bony fragments.

**IMMOBILIZATION**

After the fracture has been reduced, the bone fragments must be immobilized, or held in correct position and alignment, until

**FIGURE 69-3** Techniques of internal fixation. (A) Plate and six screws for a transverse or short oblique fracture. (B) Screws for a long oblique or spiral fracture. (C) Screws for a long butterfly fragment. (D) Plate and six screws for a short butterfly fragment. (E) Medullary nail for a segmental fracture.

union occurs. Immobilization may be accomplished by external or internal fixation. Methods of external fixation include bandages, casts, splints, continuous traction, and external fixators. Metal implants used for internal fixation serve as internal splints to immobilize the fracture.

### MAINTAINING AND RESTORING FUNCTION

Reduction and immobilization are maintained as prescribed to promote bone and soft tissue healing. Swelling is controlled by elevating the injured extremity and applying ice as prescribed. Neurovascular status (circulation, movement, sensation) is monitored, and the orthopedic surgeon is notified immediately if signs of neurovascular compromise are identified. Restlessness, anxiety, and discomfort are controlled with a variety of approaches, such as reassurance, position changes, and pain relief strategies, including use of analgesics. Isometric and muscle-setting exercises are encouraged to minimize disuse atrophy and to promote circulation. Participation in activities of daily living (ADLs) is encouraged to promote independent functioning and self-esteem. Gradual resumption of activities is promoted within the therapeutic prescription. With internal fixation, the surgeon determines the amount of movement and weight-bearing stress the extremity can withstand and prescribes the level of activity. (See Nursing Process sections in Chapter 67 for more information about caring for patients who have a cast, are in traction, or are undergoing orthopedic surgery.)

### Nursing Management

#### PATIENTS WITH CLOSED FRACTURES

The nurse encourages patients with closed (simple) fractures to return to their usual activities as rapidly as possible. The nurse teaches patients how to control swelling and pain associated with the fracture and with soft tissue trauma and encourages them to be active within the limits of the fracture immobilization (Chart 69-2). It is important to teach exercises to maintain the health of unaffected

#### Chart 69-2

#### Home Care Checklist • Closed Fracture

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Describe approaches to controlling swelling and pain (eg, elevate extremity to heart level; take analgesics as prescribed).	✓	✓
• Report pain uncontrolled by elevation and analgesics (may be an indicator of impaired tissue perfusion or compartment syndrome).	✓	✓
• Describe management of immobilizing device or care of incision.	✓	
• Consume diet to promote bone healing.	✓	
• Demonstrate ability to transfer.	✓	
• Use mobility aids safely.	✓	
• Avoid excessive use of injured extremity; observe prescribed weight-bearing limits.	✓	
• State indicators of complications to report promptly to physician (eg, uncontrolled swelling and pain; cool, pale fingers or toes; paresthesia; paralysis; signs of local and systemic infection; signs of thromboembolism; problems with immobilization device).	✓	✓
• State possible delayed complications of fractures (ie, delayed union; nonunion; avascular necrosis; reaction to internal fixation device; complex regional pain syndrome (CRPS), formally called reflex sympathetic dystrophy syndrome; heterotrophic ossification).	✓	
• Describe gradual resumption of normal activities when medically cleared, and discuss how to protect fracture site from undue stresses.	✓	✓

muscles and to increase the strength of muscles needed for transferring and for using assistive devices (eg, crutches, walker, special utensils). The nurse and physical therapist teach patients how to use assistive devices safely. Plans are made to help patients modify their home environment as needed and to secure personal assistance if necessary. Patient teaching includes self-care, medication information, monitoring for potential complications, and the need for continuing health care supervision. Fracture healing and restoration of full strength and mobility may take months.

### PATIENTS WITH OPEN FRACTURES

In an open fracture, there is risk of osteomyelitis, tetanus, and gas gangrene. The objectives of management are to prevent infection of the wound, soft tissue, and bone and to promote healing of soft tissue and bone. The nurse administers tetanus prophylaxis if indicated. Serial irrigation and débridement are used to remove anaerobic organisms. Intravenous antibiotics are prescribed to prevent or treat infection.

Prompt, thorough wound irrigation and débridement in the operating room are necessary. The wound is cultured. Devitalized bone fragments are removed. The fracture is carefully reduced and stabilized by external fixation (see Chapter 67) or intramedullary nails. Any damage to blood vessels, soft tissue, muscles, nerves, and tendons is treated.

With open fractures, primary wound closure is usually delayed. Heavily contaminated wounds are left unsutured and dressed with sterile gauze to permit swelling and wound drainage. Wound irrigation and débridement may be repeated, removing infected and devitalized tissue and increasing vascularity in the region. After it has been determined that infection is not present, the wound is closed in 5 to 7 days, and all dead space is obliterated by grafting of autogenous skin or a flap.

The nurse elevates the extremity to minimize edema. It is important to assess neurovascular status frequently. The nurse measures the patient's temperature at regular intervals and monitors the patient for signs of infection. In 4 to 8 weeks, bone grafting may be necessary to bridge bone defects and to stimulate bone healing.

## Fracture Healing and Complications (Early and Delayed)

Weeks to months are required for most fractures to heal. Many factors influence the speed with which fractures heal (Chart 69-3). The reduction of fracture fragments must be accurate and maintained to ensure healing. The affected bone must have an adequate blood supply. The type of fracture also affects healing time. In general, fractures of flat bones (pelvis, scapula) heal rapidly. Fractures at the ends of long bones, where the bone is more vascular and cancellous, heal more quickly than do fractures in areas where the bone is dense and less vascular (midshaft). Weight bearing stimulates healing of stabilized fractures of the long bones in the lower extremities.

If fracture healing is disrupted, bone union may be delayed or stopped completely. Factors that can impair fracture healing include inadequate fracture immobilization, inadequate blood supply to the fracture site or adjacent tissue, extensive space between bone fragments, interposition of soft tissue between bone ends, infection, and metabolic problems.

Complications of fractures fall into two categories—early and delayed. Early complications include shock, fat embolism, compartment syndrome, deep vein thrombosis, thromboembolism

Chart  
69-3

### Factors That Affect Fracture Healing

#### Factors That Enhance Fracture Healing

- Immobilization of fracture fragments
- Maximum bone fragment contact
- Sufficient blood supply
- Proper nutrition
- Exercise: weight bearing for long bones
- Hormones: growth hormone, thyroid, calcitonin, vitamin D, anabolic steroids
- Electric potential across fracture

#### Factors That Inhibit Fracture Healing

- Extensive local trauma
- Bone loss
- Inadequate immobilization
- Space or tissue between bone fragments
- Infection
- Local malignancy
- Metabolic bone disease (eg, Paget's disease)
- Irradiated bone (radiation necrosis)
- Avascular necrosis
- Intra-articular fracture (synovial fluid contains fibrolyns, which lyse the initial clot and retard clot formation)
- Age (elderly persons heal more slowly)
- Corticosteroids (inhibit the repair rate)

(pulmonary embolism), disseminated intravascular coagulopathy, and infection. Delayed complications include delayed union and nonunion, avascular necrosis of bone, reaction to internal fixation devices, complex regional pain syndrome (formerly called reflex sympathetic dystrophy), and heterotrophic ossification.

### SHOCK (EARLY)

Hypovolemic or traumatic shock resulting from hemorrhage (both visible and nonvisible blood loss) and from loss of extracellular fluid into damaged tissues may occur in fractures of the extremities, thorax, pelvis, or spine. Because the bone is very vascular, large quantities of blood may be lost as a result of trauma, especially in fractures of the femur and pelvis. Treatment of shock consists of restoring blood volume and circulation, relieving the patient's pain, providing adequate splinting, and protecting the patient from further injury and other complications. (See Chapter 15 for a discussion of shock.)

### FAT EMBOLISM SYNDROME (EARLY)

After fracture of long bones or pelvis, multiple fractures, or crush injuries, fat emboli may develop. Fat embolism syndrome occurs most frequently in young adults (typically those 20 to 30 years of age) and elderly adults who experience fractures of the proximal femur. At the time of fracture, fat globules may move into the blood because the marrow pressure is greater than the capillary pressure or because catecholamines elevated by the patient's stress reaction mobilize fatty acids and promote the development of fat globules in the bloodstream. The fat globules (emboli) occlude the small blood vessels that supply the lungs, brain, kidneys, and other organs. The onset of symptoms is rapid, usually occurring within 24 to 72 hours, but may occur up to a week after injury.

## Clinical Manifestations

Presenting features include hypoxia, tachypnea, tachycardia, and pyrexia. The respiratory distress response includes tachypnea, dyspnea, crackles, wheezes, precordial chest pain, cough, large amounts of thick white sputum, and tachycardia. Occlusion of a large number of small vessels causes the pulmonary pressure to rise. Edema and hemorrhages in the alveoli impair oxygen transport, leading to hypoxia. Arterial blood gas values show the partial pressure of oxygen (PaO<sub>2</sub>) to be less than 60 mm Hg, with an early respiratory alkalosis and later respiratory acidosis. The chest x-ray shows a typical “snowstorm” infiltrate. Eventually, acute pulmonary edema, acute respiratory distress syndrome, and heart failure develop.

Cerebral disturbances (due to hypoxia and the lodging of fat emboli in the brain) are manifested by mental status changes varying from headache, mild agitation, and confusion to delirium and coma.

**NURSING ALERT** Subtle personality changes, restlessness, irritability, or confusion in a patient who has sustained a fracture are indications for immediate arterial blood gas studies.

With systemic embolization, the patient appears pale. Petechiae, possibly due to a transient thrombocytopenia, are noted in the buccal membranes and conjunctival sacs, on the hard palate, and over the chest and anterior axillary folds. The patient develops a temperature of more than 39.5°C (about 103°F). Free fat may be found in the urine if emboli reach the kidneys. Kidney failure may develop.

## Prevention and Management

Immediate immobilization of fractures (including early surgical fixation), minimal fracture manipulation, adequate support for fractured bones during turning and positioning, and maintenance of fluid and electrolyte balance are measures that may reduce the incidence of fat emboli. The nurse monitors high-risk patients (adults between 20 and 30 years of age with long bone, pelvic, or multiple fractures or crush injuries, and elderly patients with femur fractures) to identify this problem. Prompt initiation of respiratory support is essential.

The objectives of management are to support the respiratory system, to prevent respiratory and metabolic acidosis, and to correct homeostatic disturbances. Respiratory failure is the most common cause of death. Respiratory support is provided with oxygen given in high concentrations. Controlled-volume ventilation with positive end-expiratory pressure may be used to prevent or treat pulmonary edema. Corticosteroids may be administered to treat the inflammatory lung reaction and to control cerebral edema. Vasoactive medications to support cardiovascular function are administered to prevent hypotension, shock, and interstitial pulmonary edema. Accurate fluid intake and output records facilitate adequate fluid replacement therapy. Morphine may be prescribed for pain and anxiety for the patient who is on a ventilator. In addition, the nurse provides calm reassurance to allay apprehension. The patient's response to therapy is closely monitored.

Because fat emboli are a major cause of death for patients with fractures, the nurse must recognize early indications of fat embolism syndrome and report them promptly to the physician. Respiratory support must be instituted early.

## COMPARTMENT SYNDROME (EARLY)

Compartment syndrome is a complication that develops when tissue perfusion in the muscles is less than that required for tissue viability. The patient complains of deep, throbbing, unrelenting pain, which is not controlled by opioids. This pain can be caused by (1) a reduction in the size of the muscle compartment because the enclosing muscle fascia is too tight or a cast or dressing is constrictive, or (2) an increase in muscle compartment contents because of edema or hemorrhage associated with a variety of problems (eg, fractures, crush injuries). The forearm and leg muscle compartments are involved most frequently. The pressure within a muscle compartment may increase to such an extent as to decrease microcirculation, causing nerve and muscle anoxia and necrosis. Permanent function can be lost if the anoxic situation continues for longer than 6 hours.

## Assessment and Diagnostic Findings

Frequent assessment of neurovascular function after fracture is essential. Sensory deficits include paresthesia, unrelenting pain, and hypoesthesia. *Paresthesia* (burning or tingling sensation) and numbness along the involved nerve are early signs of nerve involvement. Motion is evaluated by asking the patient to move fingers or toes distal to the potential problem. Motor weakness may occur as a late sign of nerve ischemia. No movement (*paralysis*) suggests nerve damage.

Peripheral circulation is evaluated by assessing color, temperature, capillary refill time, swelling, and pulses. Swelling (edema) reduces tissue perfusion. Cyanotic (blue-tinged) nail beds suggest venous congestion. Pale or dusky and cold fingers or toes and prolonged capillary refill time suggest diminished arterial perfusion. Edema may obscure the presence of arterial pulsation, and Doppler ultrasonography may be used to verify a pulse. Pulselessness is a sign of arterial occlusion, not of compartment syndrome, because the tissue pressure would need to be above the systolic blood pressure for major artery occlusion to occur.

As intracompartment pressure increases, the patient complains of deep, throbbing, unrelenting pain, which is greater than expected and not controlled by opioids. Passive stretching of the muscle causes acute pain. With continued nerve ischemia and edema, the patient experiences sensations of hypoesthesia (diminished sensitivity to stimulation) and then absence of feeling. Palpation of the muscle, if possible, reveals it to be swollen and hard. The actual tissue pressure can be measured by inserting a tissue pressure-measuring device into the muscle compartment. (Normal pressure is 8 mm Hg or less.) Nerve and muscle tissues deteriorate as compartment pressure increases. Prolonged pressure of more than 30 mm Hg can result in compromised microcirculation. Nerve tissue is more sensitive than muscle to elevated tissue pressures. Paresthesia generally occurs before paralysis.

## Medical Management

Prompt management of acute compartment syndrome is essential. The physician needs to be notified immediately if neurovascular compromise is suspected. Delay may result in permanent nerve and muscle damage or even necrosis.

Compartment syndrome is managed by elevation of the extremity to the heart level, release of restrictive devices (dressings or cast), or both. If conservative measures do not restore tissue perfusion and relieve pain within 1 hour, a fasciotomy (surgical decompression with excision of the fibrous membrane that covers and separates muscles) may be needed to relieve the constrictive mus-

cle fascia. After fasciotomy, the wound is not sutured but instead is left open to permit the muscle tissues to expand; it is covered with moist, sterile saline dressings. The limb is splinted in a functional position and elevated, and prescribed passive ROM exercises are usually performed every 4 to 6 hours. In 3 to 5 days, when the swelling has resolved and tissue perfusion has been restored, the wound is débrided and closed (possibly with skin grafts).

## OTHER EARLY COMPLICATIONS

Deep vein thrombosis (DVT), thromboembolism, and pulmonary embolus (PE) are associated with reduced skeletal muscle contractions and bed rest. Patients with fractures of the lower extremities and pelvis are at high risk for thromboembolism. Pulmonary emboli may cause death several days to weeks after injury. (See Chapter 31 for a discussion of DVT; Chapter 30 for discussion of thromboembolism, and Chapter 23 for discussion of PE).

Disseminated intravascular coagulopathy (DIC) includes a group of bleeding disorders with diverse causes, including massive tissue trauma. Manifestations of DIC include ecchymoses, unexpected bleeding after surgery, and bleeding from the mucous membranes, venipuncture sites, and gastrointestinal and urinary tracts. The treatment of DIC is discussed in Chapter 33.

All open fractures are considered contaminated. Surgical internal fixation of fractures carries a risk for infection. The nurse must monitor for and teach the patient to monitor for signs of infection, including tenderness, pain, redness, swelling, local warmth, elevated temperature, and purulent drainage. Infections must be treated promptly. Antibiotic therapy must be appropriate and adequate for prevention and treatment of infection.

## DELAYED UNION AND NONUNION (DELAYED)

Delayed union occurs when healing does not occur at a normal rate for the location and type of fracture. Delayed union may be associated with distraction (pulling apart) of bone fragments, systemic or local infection, poor nutrition, or comorbidity (eg, diabetes mellitus; autoimmune disease). Eventually, the fracture heals.

**Nonunion** results from failure of the ends of a fractured bone to unite. The patient complains of persistent discomfort and abnormal movement at the fracture site. Factors contributing to union problems include infection at the fracture site, interposition of tissue between the bone ends, inadequate immobilization or manipulation that disrupts callus formation, excessive space between bone fragments (bone gap), limited bone contact, and impaired blood supply resulting in avascular necrosis.

In nonunion, fibrocartilage or fibrous tissue exists between the bone fragments; no bone salts have been deposited. A false joint (pseudarthrosis) often develops at the site of the fracture. Nonunion most commonly occurs with fractures of the middle third of the humerus, the lower third of the tibia, and, in elderly people, the neck of the femur.

## Medical Management

The physician treats nonunion with internal fixation, bone grafting, electrical bone stimulation, or a combination of these therapies. Internal fixation stabilizes the bone fragments and ensures bone contact.

Bone grafts provide for osteogenesis, osteoconduction, or osteoinduction. *Osteogenesis* (bone formation) occurs after transplantation of bone containing osteoblasts. *Osteoconduction* is provision by

the graft of the structural matrix for ingrowth of blood vessels and osteoblasts. *Osteoinduction* is the stimulation of host stem cells to differentiate into osteoblasts by several growth factors, including bone morphogenic proteins. Bone transplants undergo creeping substitution, a reconstructive process in which the bone transplant is gradually replaced by new bone.

During surgery the bone fragments are trimmed, infection (if present) is removed, and a bone graft is placed in the bony defect. The bone graft may be an **autograft** (tissue harvested from the donor for the donor, frequently from the iliac crest) or an **allograft** (tissue harvested from a donor other than the person who will receive it). The bone graft fills the bone gap, provides a lattice structure for invasion by bone cells, and actively promotes bone growth. The type of bone selected for grafting depends on function: cortical bone for structural strength, cancellous bone for osteogenesis, and corticocancellous bone for strength and rapid incorporation. Bone grafts may be chips, wedges, blocks, bone segments, or demineralized bone matrix. At times, autograft bone, allograft bone, and demineralized cortical matrix are combined to optimize graft incorporation and bone healing. Free vascularized bone autografts are grafted with their own blood supply, allowing for primary fracture healing.

After grafting, immobilization and non-weight bearing are required while the bone graft becomes incorporated and the fracture or defect heals. Depending on the type of bone grafted, healing may take from 6 to 12 months or longer. Bone grafting problems include wound or graft infection, fracture of the graft, and nonunion. Specific autograft problems include a limited quantity of bone available for harvest, increased surgery and anesthesia time, increased blood loss, and donor site pain, hematoma, and infection. Infrequent specific allograft problems include partial acceptance (lack of host and donor histocompatibility, which retards graft incorporation), graft rejection (rapid and complete resorption of the graft), and transmission of disease (rare).

Osteogenesis in nonunion may be stimulated by electrical impulses; the effectiveness is similar to that of bone grafting. Use of electrical impulses is not effective with large bone gaps or synovial pseudarthrosis. The electrical stimulation modifies the tissue environment, making it electronegative, which enhances mineral deposition and bone formation.

In some situations, pins that act as cathodes are inserted percutaneously, directly into the fracture site, and electrical impulses are directed to the fracture continuously. Direct current methods cannot be used when infection is present.

Another method for stimulating osteogenesis is noninvasive inductive coupling. Pulsing electromagnetic fields are delivered to the fracture for approximately 10 hours each day by an electromagnetic coil over the nonunion site (Fig. 69-4). During the electrical stimulation treatment period, which takes 3 to 6 months or longer, rigid fracture fixation with adequate support is needed.

## Nursing Management

The patient with a nonunion has experienced an extended time in fracture treatment and frequently becomes frustrated with prolonged therapy. The nurse provides emotional support and encouragement to the patient and encourages compliance with the treatment regimen. The orthopedic surgeon evaluates the progression of bone healing with periodic x-rays.

Nursing care for the patient with a bone graft include pain management, monitoring the patient for signs of infection at the donor and recipient sites, and patient education. The nurse needs to reinforce information concerning the objectives of the bone graft, immobilization, non-weight bearing, wound care, signs of infection, and follow-up care with the orthopedic surgeon.

**FIGURE 69-4** Bone healing stimulator applied to the arm. (Courtesy of EBI Medical Systems, Parsippany, NJ)

Nursing care for the patient with electrical bone stimulation focus on patient education that addresses immobilization, weight bearing restrictions, and correct daily use of the stimulator as prescribed.

## AVASCULAR NECROSIS OF BONE (DELAYED)

Avascular necrosis occurs when the bone loses its blood supply and dies. It may occur after a fracture with disruption of the blood supply (especially of the femoral neck). It is also seen with dislocations, bone transplantation, prolonged high-dosage corticosteroid therapy, chronic renal disease, sickle cell anemia, and other diseases. The devitalized bone may collapse or reabsorb. The patient develops pain and experiences limited movement. X-rays reveal calcium loss and structural collapse. Treatment generally consists of attempts to revitalize the bone with bone grafts, prosthetic replacement, or arthrodesis (joint fusion).

## REACTION TO INTERNAL FIXATION DEVICES (DELAYED)

Internal fixation devices may be removed after bony union has taken place. In most patients, however, the device is not removed unless it produces symptoms. Pain and decreased function are the prime indications that a problem has developed. Problems may include mechanical failure (inadequate insertion

and stabilization); material failure (faulty or damaged device); corrosion of the device, causing local inflammation; allergic response to the metallic alloy used; and osteoporotic remodeling adjacent to the fixation device (in which stress needed for bone strength is transferred to the device, causing a disuse osteoporosis). If the device is removed, the bone needs to be protected from refracture related to osteoporosis, altered bone structure, and trauma. Bone remodeling reestablishes the bone's structural strength.

## COMPLEX REGIONAL PAIN SYNDROME (DELAYED)

Complex regional pain syndrome (CRPS), formerly called reflex sympathetic dystrophy (RSD), is a painful sympathetic nervous system problem. It occurs infrequently. When it does occur, it is most often in an upper extremity after trauma and is seen more often in women. Clinical manifestations of CRPS include severe burning pain, local edema, hyperesthesia, stiffness, discoloration, vasomotor skin changes (ie, fluctuating warm, red, dry and cold, sweaty, cyanotic), and trophic changes (ie, glossy, shiny skin; increased hair and nail growth). This syndrome is frequently chronic, with extension of symptoms to adjacent areas of the body. Disuse muscle atrophy and bone deossification (osteoporosis) occur with persistence of CRPS. Patients may exhibit ineffective individual coping related to the chronic pain.

## Management

Prevention may include elevation of the extremity after injury or surgery and selection of an immobilization device (eg, external fixator) that allows for the greatest ROM and functional use of the rest of the extremity. Early effective pain relief is the focus of management. Pain may need to be controlled with analgesics, anesthetic nerve blocks, or intravenous bisphosphonate pamidronate. NSAIDs, corticosteroids, muscle relaxants, and antidepressants are also used. With pain relief, the patient can participate in ROM exercises and functional use of the affected area. The nurse needs to help the patient cope with CRPS manifestations and explore multiple ways to control pain (see Chapter 13). The nurse avoids using the involved extremity for blood pressure measurements and venipunctures.

## HETEROTROPHIC OSSIFICATION (DELAYED)

Heterotrophic ossification (myositis ossificans) is the abnormal formation of bone, near bones or in muscle, in response to soft tissue trauma after blunt trauma, fracture, or total joint replacement. The muscle is painful, and normal muscular contraction and movement are limited. Early mobilization has been recommended. Indomethacin (Indocin) may be used prophylactically if deep muscle contusion has occurred. Usually, the bone lesion resorbs over time, but the abnormal bone eventually may need to be excised if symptoms persist.

## Fractures of Specific Sites

Injuries to the skeletal structure may vary from a simple linear fracture to a severe crushing injury. The type and location of the fracture and the extent of damage to surrounding structures determine the therapeutic management. Maximum functional recovery is the goal of management.

## CLAVICLE

Fracture of the clavicle (collar bone) is a common injury that results from a direct blow to the shoulder or a fall. Head or cervical spine injuries may occur with these fractures. The clavicle helps to hold the shoulder upward, outward, and backward from the thorax. Therefore, when the clavicle is fractured, the patient assumes a protective position, slumping the shoulders and immobilizing the arm to prevent shoulder movements. The treatment goal is to align the shoulder in its normal position by means of closed reduction and immobilization.

More than 80% of these fractures occur in the middle third of the clavicle. A clavicular strap, also called a *figure-of-eight bandage* (Fig. 69-5), may be used to pull the shoulders back, reducing and immobilizing the fracture. When a clavicular strap is used, the axillae are well padded to prevent a compression injury to the brachial plexus and the axillary artery. The nurse monitors the circulation and nerve function of both arms. A sling may be used to support the arm and to relieve pain. The patient may be permitted to use the arm for light activities within the range of comfort.

Fracture of the distal third of the clavicle, without displacement and ligament disruption, is treated with a sling and restricted motion of the arm. When a fracture in the distal third is accompanied by a disruption of the coracoclavicular ligament, there is displacement, which may be treated by open reduction and internal fixation.

Complications of clavicular fractures include trauma to the nerves of the brachial plexus, injury to the subclavian vein or artery

from a bony fragment, and **malunion** (poorly aligned healing of the fractured bone). Malunion may be a cosmetic problem (eg, when low-neckline clothing is worn).

## Nursing Management

The nurse cautions the patient not to elevate the arm above shoulder level until the ends of the bone have united (about 6 weeks) but encourages the patient to exercise the elbow, wrist, and fingers as soon as possible. When prescribed, shoulder exercises (Fig. 69-6) are performed to obtain full shoulder motion. Vigorous activity is limited for 3 months.

## HUMERAL NECK

Fractures of the proximal humerus may occur through either the anatomic or the surgical neck of the humerus. The anatomic neck is located just below the humeral head. The surgical neck is the region below the tubercles. Impacted fractures of the surgical neck of the humerus are seen most frequently in older women after a fall on an outstretched arm. These are essentially non-displaced fractures. Active middle-aged patients who are injured in a fall may suffer severely displaced humeral neck fractures with associated rotator cuff damage.

The patient presents with the affected arm hanging limp at the side and supported by the uninjured hand. Neurovascular assessment of the extremity is essential to evaluate fully the extent of injury and the possible involvement of the neurovascular bundle (nerves and blood vessels) of the arm.

## Medical Management

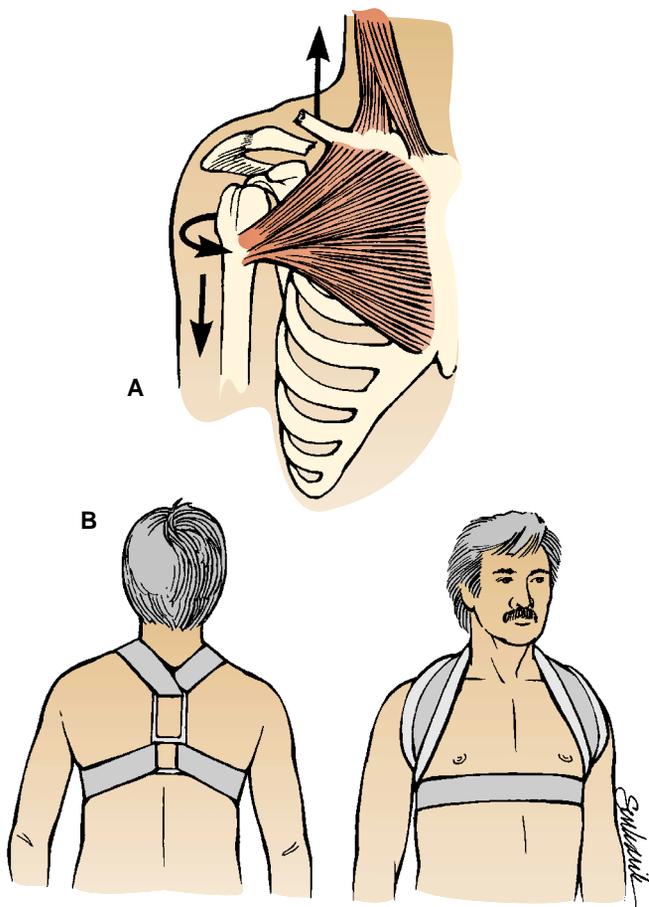

Many impacted fractures of the surgical neck of the humerus are not displaced and do not require reduction. The arm is supported and immobilized by a sling and swathe that secure the supported arm to the trunk (Fig. 69-7). A soft pad is placed in the axilla to absorb moisture and avoid skin breakdown. Limitation of motion and stiffness of the shoulder occur with disuse. Therefore, pendulum exercises are begun as soon as tolerated by the patient. (In pendulum or circumduction exercises, the nurse or physical therapist instructs the patient to lean forward and allow the affected arm to abduct and rotate [see Fig. 69-6].) Early motion of the joint does not displace the fragments if motion is carried out within the limits imposed by pain.

These fractures require 6 to 10 weeks to heal, and the patient should avoid vigorous activity (eg, tennis) for an additional 4 weeks. Residual stiffness, aching, and some limitation of ROM may persist for 6 months or longer.

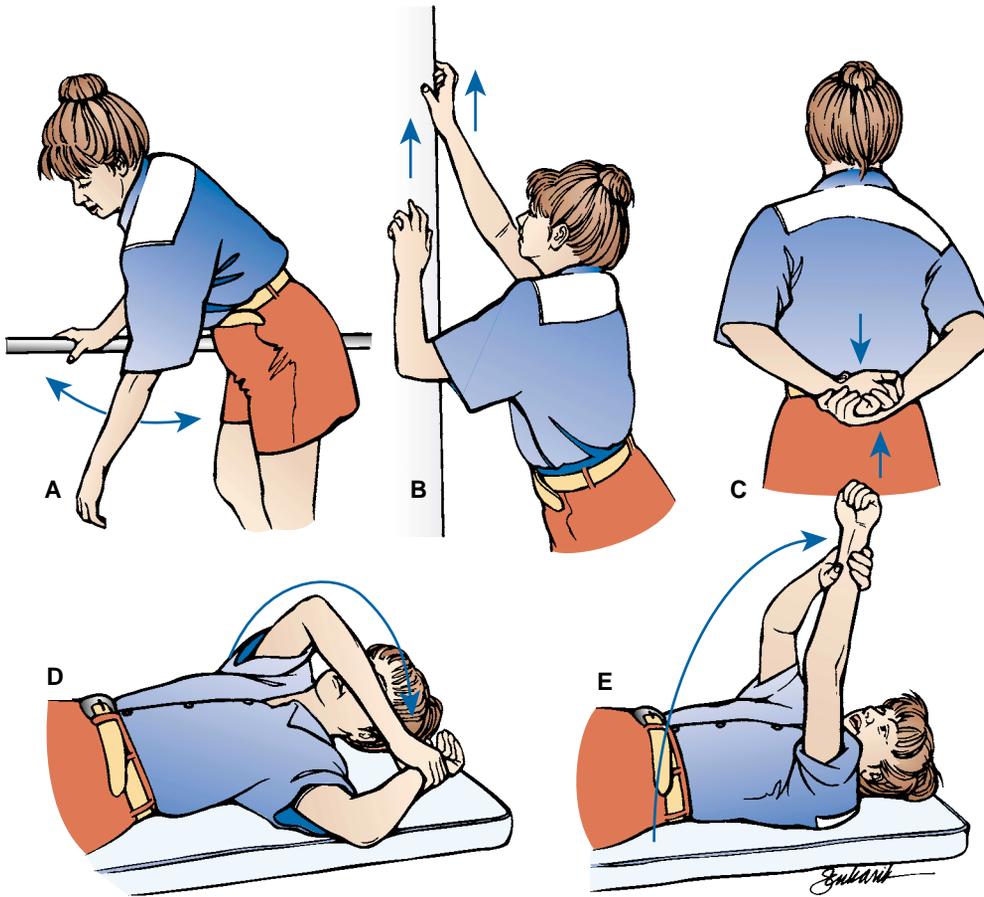

When a humeral neck fracture is displaced, treatment consists of closed reduction, open reduction with internal fixation, or replacement of the humeral head with a prosthesis. In this type of fracture, exercises are started only after a prescribed period of immobilization.

## HUMERAL SHAFT

Fractures of the shaft of the humerus are most frequently caused by (1) direct trauma that results in a transverse, oblique, or comminuted fracture, or (2) an indirect twisting force that results in a spiral fracture. The nerves and brachial blood vessels may be injured with these fractures. Wrist drop is indicative of radial nerve injury. Initial neurovascular assessment is essential to identify nerve or blood vessel injury, which requires immediate attention.

**FIGURE 69-5** Fracture of the clavicle. (A) Anteroposterior view shows typical displacement in midclavicular fracture. (B) Immobilization is accomplished with a clavicular strap.

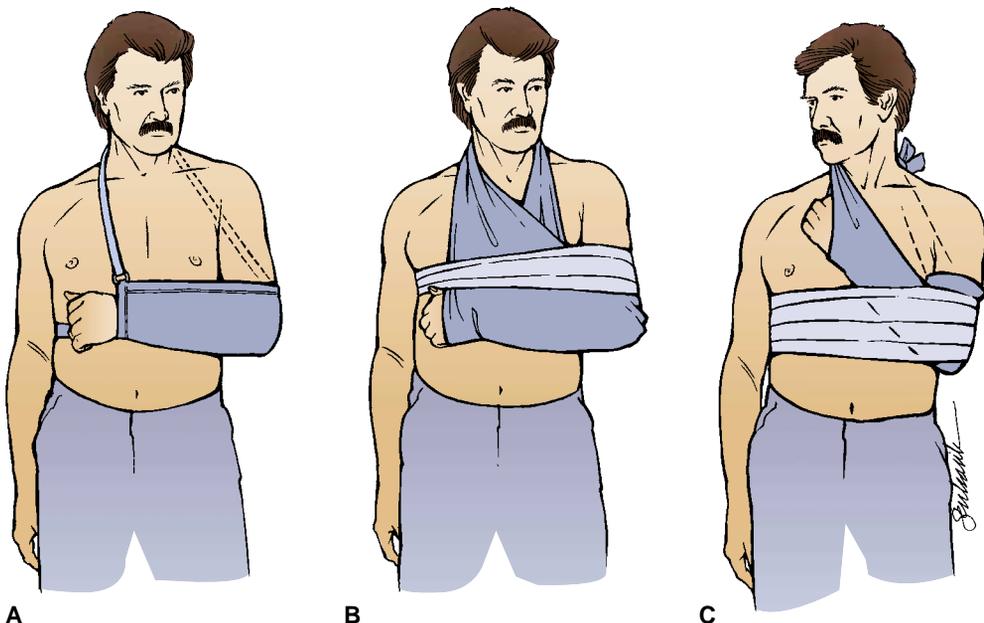

**FIGURE 69-6** Exercises that promote shoulder range of motion include (A) pendulum exercise and (B) wall climbing. The unaffected arm is used to assist with (C) internal rotation, (D) external rotation, and (E) elevation. In C, D, and E, the unaffected arm is used for power.

## Medical Management

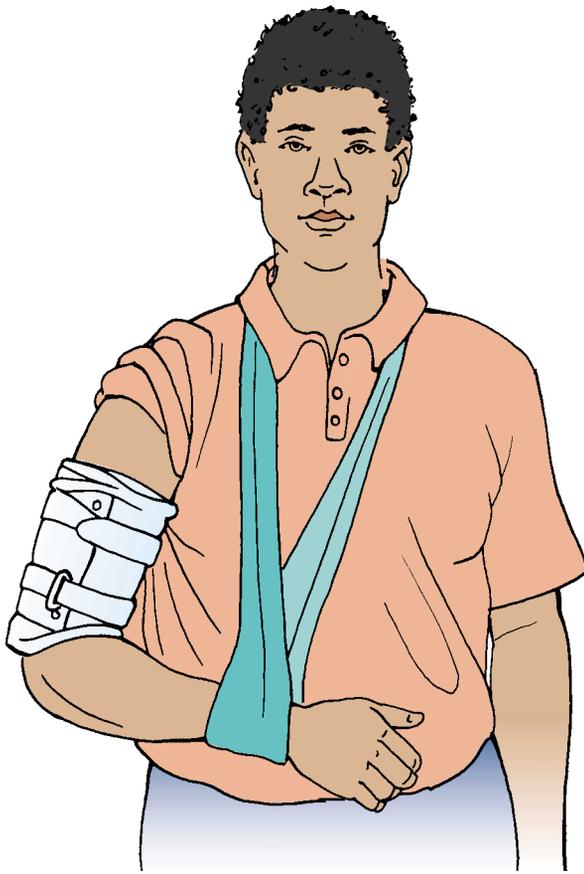

Initially, well-padded splints, overwrapped with an elastic bandage, are used to immobilize the upper arm and to support the arm in 90 degrees of flexion at the elbow. A sling or collar and cuff support the forearm. The weight of the hanging arm and splints reduce the

fracture. External fixators are used to treat open fractures of the humeral shaft (see Chapter 67). Open reduction with internal fixation of a fracture of the humerus is necessary with nerve palsy, blood vessel damage, comminuted fracture, or pathologic fracture.

Functional bracing is another form of treatment used for these fractures. A contoured thermoplastic sleeve is secured in

**FIGURE 69-7** Immobilizers for proximal humeral fractures. (A) Commercial sling with immobilizing strap permits easy removal for hygiene and is comfortable on the neck. (B) Conventional sling and swathe. (C) Stockinette Velpeau and swathe are used when there is an unstable surgical neck component. This position relaxes the pectoralis major.

**FIGURE 69-8** Functional humeral brace with collar and cuff sling.

place with interlocking fabric (Velcro) closures around the upper arm, immobilizing the reduced fracture. As swelling decreases, the sleeve is tightened, and uniform pressure and stability are applied to the fracture. The forearm is supported with a collar and cuff sling (Fig. 69-8). Functional bracing allows active use of muscles, shoulder and elbow motion, and good approximation of fracture fragments. Pendulum shoulder exercises are performed as prescribed to provide active movement of the shoulder, thereby preventing adhesions of the shoulder joint capsule. Isometric exercises may be prescribed to prevent muscle atrophy. The callus that develops is substantial, and the sleeve can be discontinued in about 8 weeks. Complications that are seen with humeral shaft fractures include delayed union and nonunion.

## ELBOW

Fractures of the distal humerus result from motor vehicle crashes, falls on the elbow (in the extended or flexed position), or a direct blow. These fractures may result in injury to the median, radial, or ulnar nerves.

The patient is evaluated for paresthesia and signs of compromised circulation in the forearm and hand. The most serious complication of a supracondylar fracture of the humerus is Volkmann's ischemic contracture (a compartment syndrome), which results from antecubital swelling or damage to the brachial artery (Chart 69-4). The nurse needs to monitor the patient regularly for compromised neurovascular status and signs of compartment syndrome.

### Chart 69-4

## Volkmann's Contracture

- Observe the distal extremity for swelling, skin color, nail bed capillary refill, and temperature. Compare affected and unaffected hands.
- Assess radial pulse.
- Assess for paresthesia (tingling and burning sensations) in the hand, which may indicate nerve injury or impending ischemia.
- Evaluate the patient's ability to move the fingers.
- Explore the intensity and character of the pain.
- Directly measure tissue pressure as prescribed.
- Report indications of diminished nerve function or diminished circulatory perfusion promptly before irreparable damage occurs; fasciotomy may become necessary.

Other potential complications are damage to the joint articular surfaces and hemarthrosis (blood in the joint). If hemarthrosis is present, the physician may aspirate the joint to remove the blood, thereby relieving the pressure and pain.

## Management

The goal of therapy is prompt reduction and stabilization of the distal humerus fracture, followed by controlled active motion after swelling has subsided and healing has begun. If the fracture is not displaced, the arm is immobilized in a cast or posterior splint with the elbow at 45 to 90 degrees of flexion and in a sling for 4 to 6 weeks. Then a thermoplastic splint is used to support the fracture and rehabilitation exercises are begun.

Usually, a displaced fracture is treated with open reduction and internal fixation. Excision of bone fragments may be necessary. Additional external support with a splint is then applied. Active finger exercises are encouraged. Gentle ROM exercise of the injured joint is begun about 1 week after internal fixation. Motion promotes healing of injured joints by producing movement of synovial fluid into the articular cartilage. Active exercise of the elbow is performed as prescribed to prevent residual limitation of motion.

## RADIAL HEAD

Radial head fractures are common and are usually produced by a fall on the outstretched hand with the elbow extended.

## Management

If blood has collected in the elbow joint (hemarthrosis), it is aspirated to relieve pain and to allow early active elbow and forearm ROM. Immobilization for these undisplaced fractures is accomplished with a splint. The patient is instructed not to lift with the arm for approximately 4 weeks. If the fracture is displaced, surgery is required, with excision of the radial head when necessary. Postoperatively, the arm is immobilized in a posterior plaster splint and sling. The patient is encouraged to carry out a program of active motion of the elbow and forearm when prescribed.

## RADIAL AND ULNAR SHAFTS

Fractures of the shaft of the bones of the forearm occur most frequently in children. The radius or the ulna may be fractured at any level. Frequently, displacement occurs when both bones

are broken. The forearm's unique functions of pronation and supination must be preserved with good anatomic position and alignment.

## Management

If the fragments are not displaced, the fracture is treated by closed reduction with a long arm cast applied from the upper arm to the proximal palmar crease. A loop may be incorporated in the cast near the elbow and a sling pulled through it to prevent the cast from sagging against the forearm.

The circulation, motion, and sensation of the hand are assessed after the cast is applied. The arm is elevated to control edema. Frequent finger flexion and extension are encouraged to reduce edema. Active motion of the involved shoulder is essential. The reduction and alignment are monitored closely by x-rays to ensure adequate immobilization. The fracture is immobilized for about 12 weeks; during the last 6 weeks, the arm may be in a functional forearm brace that allows exercise of the wrist and elbow. Lifting and twisting are avoided.

Displaced fractures are managed by open reduction with internal fixation, using a compression plate with screws, intramedullary nails, or rods. The arm is usually immobilized in a plaster splint or cast. Open fractures may be managed with external fixation devices. The arm is elevated to control swelling. Neurovascular status is monitored. Elbow, wrist, and hand exercises are begun as permitted by the immobilization device.

### NURSING RESEARCH PROFILE 69-1

#### Self-Reported Impact of Wrist Fracture

Morris, N. (2000). Distal radius fracture in adults: Self-reported physical functioning, role functioning, and meaning of injury. *Orthopaedic Nursing*, 19(4), 37–48.

#### Purpose

Distal radius fracture commonly affects women and their activities of daily living, work productivity, and overall functioning. Having a better understanding of the impact of this injury will enable the nurse to more effectively provide direct care and respond to specific needs of the patient and family.

This study explored (1) differences in physical function, role function, and meaning of injury during the first 3 months of recovery from distal radius fracture; (2) the relationships of age, gender, hand dominance, education, preinjury physical health, and treatment modality to differences in physical function, role function, and meaning of injury; and (3) differences in the patterns of change over time.

#### Study Sample and Design

A descriptive, prospective, repeated measures design was used to study adults who had sustained fractures of the distal radius. A convenience sample of 60 adults with distal radius fracture completed the study. Seventy-two percent of the subjects were women, and 28% were men. Forty-eight percent were young adults (18 to 44 years of age), 27% were middle-age adults (45 to 64 years), and 25% were older adults (65 to 87 years). Forty-five percent of the subjects were college graduates. Treatment modalities were a surgical approach (53%) and a non-surgical approach (47%).

Data were collected at the first office visit after fracture, at removal of the immobilizing device, and at the next office visit after device removal.

Several instruments were used to measure the dependent variables of physical function, role function, and meaning of illness/injury (MOI). The relationships of gender, age, education, hand dominance, preinjury physical health, and treatment modality to these dependent variables were analyzed.

Descriptive and inferential statistics were used to analyze the data.

## WRIST

Fractures of the distal radius (Colles' fracture) are common and are usually the result of a fall on an open, dorsiflexed hand. This fracture is frequently seen in elderly women with osteoporotic bones and weak soft tissues that do not dissipate the energy of the fall. The patient presents with a deformed wrist, radial deviation, pain, swelling, weakness, limited finger ROM, and numbness.

## Management

Treatment usually consists of closed reduction and immobilization with a short arm cast. For fractures with extensive comminution or impaction, open reduction and internal fixation, arthroscopic percutaneous pinning, or external fixation is used to achieve and maintain reduction and to allow for early functional rehabilitation. The wrist and forearm are elevated for 48 hours after reduction to control swelling.

Active motion of the fingers and shoulder should begin promptly. The patient is taught to do the following exercises to reduce swelling and prevent stiffness:

- Hold the hand at the level of the heart.
- Move the fingers from full extension to flexion. Hold and release. (Repeat at least 10 times every hour when awake.)
- Use the hand in functional activities.
- Actively exercise the shoulder and elbow, including complete ROM exercises of both joints.

#### Results

- Over time, there was an improvement in physical function and role function for all subjects. Dependency on others for help with daily activities and injury interference with work and social activities decreased over time.
- Physical function and role function were found to be significantly better among the younger adults ( $p < .001$ ). Middle-age adults experienced greater emotional problems that interfered with work and other daily activities until the immobilizing device was removed. The lower role function observed in middle-age adults may be explained by the multiple demands placed on this age group. The younger and older adults may have had fewer demands on their time. A greater ability to work was observed among those subjects with a higher-level education; they may have had more resources, greater problem-solving abilities, and occupations in which they could work to some extent while their arm was immobilized. Overall, physical function and role function were not affected by gender, hand dominance, education, preinjury physical health, or treatment modality.
- There was a significant change in the MOI score with removal of the immobilization device. This finding suggested that patients were able to acknowledge the disruption and reframe their current situation. There was no significant change in MOI score after this time point.

#### Nursing Implications

The nurse needs to assess the patient's need for assistance for 6 to 8 weeks while the arm is immobilized. Older adults need greater assistance in meeting self-care needs. Younger adults need less help to perform daily activities while the wrist is immobilized. Middle-age adults may have greater problems in dealing with their usual multiple demands.

The fingers may swell due to diminished venous and lymphatic return. The nurse assesses the sensory function of the median nerve by pricking the distal aspect of the index finger. The motor function is assessed by the patient's ability to touch the thumb to the little finger. Diminished circulation and nerve function must be treated promptly by release of constricting bandages.

## HAND

Trauma to the hand often requires extensive reconstructive surgery. The objective of treatment is always to regain maximum function of the hand.

## Management

For an undisplaced fracture of the phalanx (finger bone), the finger is splinted for 3 to 4 weeks to relieve pain and to protect the finger from further trauma. Displaced fractures and open fractures may require open reduction with internal fixation, using wires or pins.

The neurovascular status of the injured hand is evaluated. Swelling is controlled by elevation of the hand. Functional use of the uninvolved portion of the hand is encouraged.

## PELVIS

The sacrum, ilium, pubis, and ischium bones form the pelvic bone, a fused, stable, bony ring in adults (Fig. 69-9). Falls, motor vehicle crashes, and crush injuries can cause pelvic fractures. Pelvic fractures are serious because at least two thirds of affected patients have significant and multiple injuries. Management of severe, life-threatening pelvic fractures is coordinated with the trauma team. Hemorrhage and thoracic, intra-abdominal, and cranial injuries have priority over treatment of fractures. There is a high mortality rate associated with pelvic fractures, related to hemorrhage, pulmonary complications, fat emboli, intravascular coagulation, thromboembolic complications, and infection.

Pelvic fracture symptoms include ecchymosis; tenderness over the symphysis pubis, anterior iliac spines, iliac crest, sacrum, or coccyx; local swelling; numbness or tingling of pubis, genitals, and proximal thighs; and inability to bear weight without discomfort. Computed tomography of the pelvis helps to determine

the extent of injury by demonstrating sacroiliac joint disruption, soft tissue trauma, pelvic hematoma, and fractures. Neurovascular assessment of the lower extremities is completed to detect injury to pelvic blood vessels and nerves.

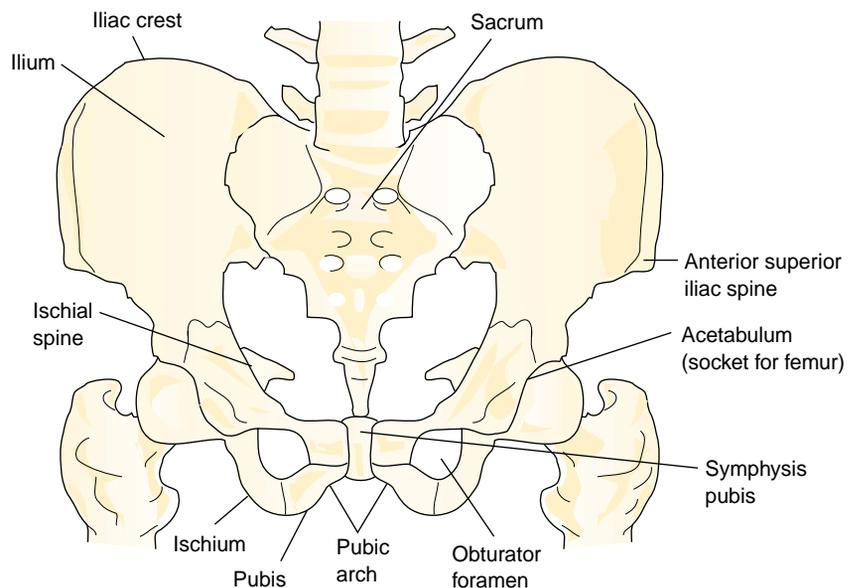

Hemorrhage and shock are two of the most serious consequences that may occur. Bleeding arises from the cancellous surfaces of the fracture fragments, from laceration of veins and arteries by bone fragments, and possibly from a torn iliac artery. The peripheral pulses of both lower extremities are palpated; absence of pulses may indicate a torn iliac artery or one of its branches. Peritoneal lavage may be performed to detect intra-abdominal hemorrhage. The patient is handled gently to minimize further bleeding and shock.

The nurse assesses for injuries to the bladder, rectum, intestines, other abdominal organs, and pelvic vessels and nerves. To assess for urinary tract injury, the patient's urine is examined for blood. A voiding cystourethrogram and an intravenous urogram may be performed. Laceration of the urethra is suspected in males with anterior fracture of the pelvis and blood at the urethral meatus. (Females rarely experience a lacerated urethra.) A catheter should not be inserted until the status of the urethra is known. Abdominal pain and signs of peritonitis suggest injury to the intestines or abdominal bleeding. Paralytic ileus may accompany pelvic fractures.

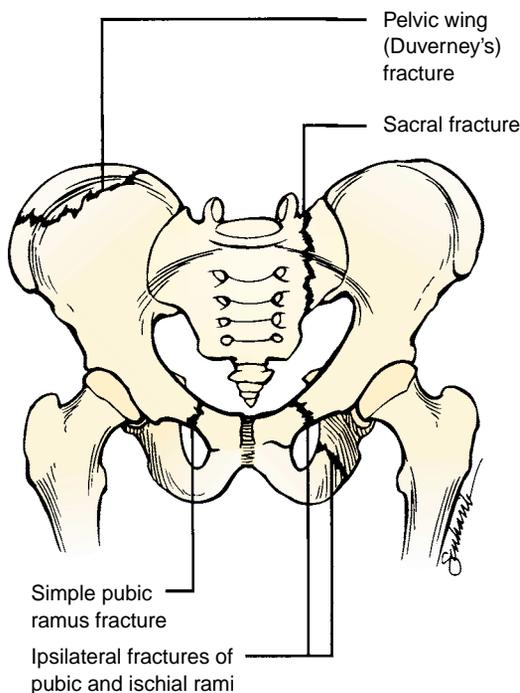

Numerous classification systems have been used to describe pelvic fractures in relation to anatomy, stability, and mechanism of injury. Some fractures of the pelvis do not disrupt the pelvic ring; others disrupt the ring, which may be rotationally or vertically unstable. The severity of pelvic fractures varies. Long-term complications of pelvic fractures include malunion, nonunion, residual gait disturbances, and back pain from ligament injury.

## Stable Pelvic Fractures

Stable fractures of the pelvis (Fig. 69-10) include fracture of a single pubic or ischial ramus, fracture of ipsilateral pubic and ischial rami, fracture of the pelvic wing of ilium (ie, Duverney's fracture), and fracture of the sacrum or coccyx. Also, if injury results in only a slight widening of the pubic symphysis or the anterior sacroiliac joint and the pelvic ligaments are intact, the disrupted pubic symphysis is likely to heal spontaneously with conservative management. Most fractures of the pelvis heal rapidly because the pelvic bones are mostly cancellous bone, which has a rich blood supply.

**FIGURE 69-9** Pelvic bones.

**FIGURE 69-10** Stable pelvic fractures.

Stable pelvic fractures are treated with a few days of bed rest and symptom management until the pain and discomfort are controlled. The patient on bed rest is at risk for complications from immobility, including constipation, venous stasis, and pulmonary complications. Fluids, dietary fiber, ankle and leg exercises, elastic compression stockings to aid venous return, log rolling, coughing and deep breathing, and skin care reduce the risk for complications and increase the patient's comfort. The patient with a fractured sacrum is at risk for paralytic ileus, and bowel sounds should be monitored.

The patient with fracture of the coccyx experiences pain on sitting and with defecation. Sitz baths may be prescribed to relieve pain, and stool softeners may be given to prevent the need to strain on defecation. As pain resolves, activity is gradually re-

sumed with the use of ambulatory aids (eg, crutches, walker) for protected weight bearing. Early mobilization reduces problems related to immobility.

### Unstable Pelvic Fractures

Unstable fractures of the pelvis (Fig. 69-11) may result in rotational instability (eg, the open book type, in which a separation occurs at the symphysis pubis with some sacral ligament disruption), vertical instability (eg, the vertical shear type, with superior–inferior displacement), or a combination of both. Lateral or anterior–posterior compression of the pelvis produces rotationally unstable pelvic fractures. Vertically unstable pelvic fractures occur when force is exerted on the pelvis vertically, as when the person falls from a height onto extended legs or is struck from above by a falling object. Vertical shear pelvic fractures involve the anterior and posterior pelvic ring with vertical displacement, usually through the sacroiliac joint. There is generally complete disruption of the posterior sacroiliac, sacrospinous, and sacrotuberous ligaments. Vertical displacement of the hemipelvis is usually evident.

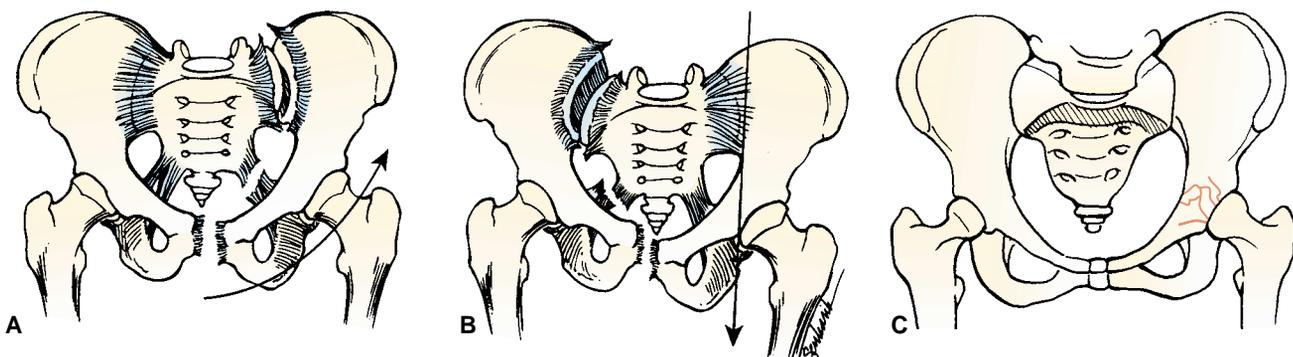

Treatment of unstable pelvic fractures generally involves external fixation or open reduction and internal fixation. This promotes hemostasis, hemodynamic stability, comfort, and early mobilization.

### Acetabulum

Fractures of the acetabulum are seen after motor vehicle crashes in which the femur is jammed into the dashboard. Treatment depends on the pattern of fracture. Stable, nondisplaced fractures and fractures that involve minimal articular weight bearing may be managed with traction and protective (toe touch) weight bearing. Displaced and unstable acetabular fractures are treated with open reduction, joint débridement, and internal fixation or arthroplasty. Internal fixation permits early non–weight-bearing ambulation and ROM exercise. Complications seen with acetabular fractures include nerve palsy, heterotopic ossification, and posttraumatic arthritis.

### FEMUR

There is a high incidence of hip fracture among elderly people, who have brittle bones from osteoporosis (particularly women) and who tend to fall frequently. Weak quadriceps muscles, gen-

**FIGURE 69-11** Unstable pelvic fracture. (A) Rotationally unstable fracture: The symphysis pubis is separated and the anterior sacroiliac, sacrotuberous, and sacrospinous ligaments are disrupted. (B) Vertically unstable fracture: The hemipelvis is displaced anteriorly and posteriorly through the symphysis pubis, and the sacroiliac joint ligaments is disrupted. (C) Undisplaced fracture of the acetabulum.

eral frailty due to age, and conditions that produce decreased cerebral arterial perfusion (transient ischemic attacks, anemia, emboli, cardiovascular disease, effects of medications) contribute to the incidence of falls. The patient who has sustained a hip fracture frequently has a comorbidity (eg, cardiovascular, pulmonary, renal, endocrine). Often, a fractured hip is a catastrophic event that will have a negative impact on the patient's lifestyle and quality of life.

There are two major types of hip fracture. *Intracapsular fractures* are fractures of the neck of the femur. *Extracapsular fractures* are fractures of the trochanteric region (between the base of the neck and the lesser trochanter of the femur) and of the subtrochanteric region (Fig. 69-12). Fractures of the neck of the femur may damage the vascular system that supplies blood to the head and the neck of the femur, and the bone may die. For this reason, nonunion or aseptic necrosis is common in patients with femoral neck fractures.

Extracapsular intertrochanteric fractures have an excellent blood supply and heal readily. However, extensive soft tissue damage

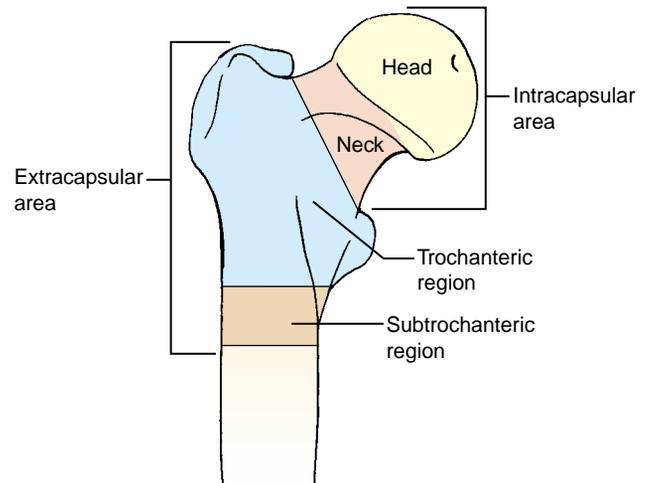

FIGURE 69-12 Regions of the proximal femur.

### NURSING RESEARCH PROFILE 69-2

#### Hip Surgery, Postoperative Pain, and Recovery

Feldt, K., & Oh, H. (2000). Pain and hip fracture outcomes for older adults. *Orthopaedic Nursing, 19*(6), 35–44.

#### Purpose

Many older adults experience hip fracture. Several factors (eg, age, prefracture functioning, mental status) have been identified as having an effect on functional outcome after surgery. This study focused on postoperative pain as a possible predictor of functional outcome at 2 months after surgery.

#### Study Sample and Design

A convenience sample of 85 patients, age 65 years or older, who were hospitalized for hip fracture and treated surgically with reduction achieved by screws or pins or with a joint prosthesis, was studied. All patients were able to walk independently (with or without ambulatory aid) before fracture. Almost all of the patients were female (90.6%); most were admitted from home (76.5%) and had used no ambulatory aid (60%).

This descriptive, comparative study included a patient interview on postoperative day 2 or 3 and a second interview at 2 months after surgery to determine functional outcomes.

Variables included demographics, mental status, pain assessment and report, use of analgesics, illness severity (ie, comorbidities, complications), and functional status/dependency as measured by the Functional Status Index.

#### Results

- Almost half of the patients were identified as cognitively impaired based on the Mini Mental State Examination. These patients were older and had a higher illness severity score.
- Almost two thirds of the patients reported that they had pain. However, significantly more of the cognitively intact patients, compared with cognitively impaired patients (71.1% versus 48.6%, respectively;  $p < .05$ ) responded “Yes” to the question, “Do you have pain?” This finding may suggest that cognitively impaired patients do not remember intermittent pain experienced with movement. When patients were asked to describe their pain, many subjects noted hip pain as well as pain from other sources (eg, osteoarthritis). Comparison of pain at rest and pain with movement was statistically significant

( $p < .0001$ ) for both cognitively intact and cognitively impaired patients.

- There was no difference between cognitively intact and cognitively impaired groups regarding prescribed analgesics and administered analgesics. However, nurses administered less than 25% of the prescribed prn medications to both groups. The study also identified that the mean amount of acetaminophen prescribed was well above the recommended guidelines. Patients were prescribed prn opioid/acetaminophen combination medications as well as prn acetaminophen.
- Functional status declined for patients after hip fracture. Preoperatively, 64% of the cognitively intact patients and 54% of the cognitively impaired patients could walk without any assistive devices; postoperatively, only 29% and 5%, respectively, were able to ambulate without assistive devices. At 2 months after surgery, functional status scores were lower for the cognitively impaired group.
- Stepwise regression analysis showed that age, mental status, illness severity, and report of pain with movement explained 51% of the variance in functional score. Pain with movement accounted for 8% of this variance.

#### Nursing Implications

Postoperative pain with movement affects functional outcomes for patients with hip fracture. Better management of postoperative pain is required for better functional outcomes.

Pain reported by patients with hip fracture may be intermittent and may be caused by problems other than the hip fracture and surgery (eg, osteoarthritis). Most pain assessments are performed with the patient at rest; however, pain is more intense with movement. Managing pain associated with movement and administering pain medication before moving and before physical therapy sessions may help to improve the outcome.

In addition, the nurse should be aware of the amount of acetaminophen in combination medications and should monitor patients, especially those with liver dysfunction, for intake of acetaminophen that exceeds the recommended maximum daily dose.

may have occurred at the time of injury. It is not uncommon for the fracture to be comminuted and unstable. There is a fairly high mortality rate after intertrochanteric hip fractures, mainly because the patients are usually elderly (70 to 85 years of age) and are poor surgical candidates.

## Clinical Manifestations

With fractures of the femoral neck, the leg is shortened, adducted, and externally rotated. The patient complains of pain in the hip and groin or in the medial side of the knee. With most fractures of the femoral neck, the patient is unable to move the leg without a significant increase in pain. The patient is most comfortable with the leg slightly flexed in external rotation. Impacted intracapsular femoral neck fractures cause moderate discomfort (even with movement), may allow the patient to bear weight, and may not demonstrate obvious shortening or rotational changes. With extracapsular femoral fractures of the trochanteric or subtrochanteric regions, the extremity is significantly shortened, externally rotated to a greater degree than intracapsular fractures, exhibits muscle spasm that resists positioning of the extremity in a neutral position, and has an associated large hematoma or area of ecchymosis. The diagnosis of fractured hip is confirmed with x-ray.

## Gerontologic Considerations

Hip fractures are a frequent contributor to death after the age of 75 years. Stress and immobility related to the trauma predispose the older adult to pneumonia, sepsis, and reduced ability to cope with other health problems.

Many elderly people hospitalized with hip fracture are confused as a result of the stress of the trauma, unfamiliar surroundings, sleep deprivation, medications, and systemic illness. Preoperative predictors of postoperative delirium include age older than 70 years, alcohol abuse, impaired cognitive status, poor functional status, and markedly abnormal serum sodium, potassium, or glucose concentrations. In addition, confusion that develops in some elderly patients may be caused by mild cerebral ischemia. Other factors associated with confusion include responses to medications and anesthesia, malnutrition, dehydration, infectious processes, mood disturbances, and blood loss.

To prevent complications, the nurse must assess the elderly patient for chronic conditions that require close monitoring. Examination of the legs may reveal edema due to heart failure or peripheral pulselessness from arteriosclerotic vascular disease. Similarly, chronic respiratory problems may be present and may contribute to the possible development of inadequate pulmonary ventilation. Coughing and deep-breathing exercises are encouraged. Frequently, elderly people are taking cardiac, antihypertensive, or respiratory medications that need to be continued. The patient's responses to these medications should be monitored.

Dehydration and poor nutrition may be present. At times, elderly people who live alone are unable to summon help at the time of injury. A day or two may pass before assistance is provided, and as a result, dehydration occurs. Dehydration contributes to hemoconcentration and predisposes to thromboembolism. Therefore, the patient needs to be encouraged to consume adequate fluids and a healthy diet.

Muscle weakness and wasting may have contributed to the fall and fracture in the first place. Bed rest and immobility will cause an additional loss of muscle strength unless the nurse encourages

the patient to move all joints except the involved hip and knee. Patients are encouraged to use their arms and the overhead trapeze to reposition themselves. This strengthens the arms and shoulders, which facilitates walking with assistive devices.

## Medical Management

Temporary skin traction, Buck's extension, may be applied to reduce muscle spasm, to immobilize the extremity, and to relieve pain. The findings of a recent study (Jerre et al., 2000) suggested that there is no benefit to the routine use of preoperative skin traction for patients with hip fractures and that the use of skin traction should be based on evaluation of the individual patient.

The goal of surgical treatment of hip fractures is to obtain a satisfactory fixation so that the patient can be mobilized quickly and avoid secondary medical complications. Surgical treatment consists of (1) open or closed reduction of the fracture and internal fixation, (2) replacement of the femoral head with a prosthesis (hemiarthroplasty), or (3) closed reduction with percutaneous stabilization for an intracapsular fracture. Surgical intervention is carried out as soon as possible after injury. The preoperative objective is to ensure that the patient is in as favorable a condition as possible for the surgery. Displaced femoral neck fractures may be treated as emergencies, with reduction and internal fixation performed within 12 to 24 hours after fracture. This minimizes the effects of diminished blood supply and reduces the risk for avascular necrosis.

After general or spinal anesthesia, the hip fracture is reduced under x-ray visualization using an image intensifier. A stable fracture is usually fixed with nails, a nail-and-plate combination, multiple pins, or compression screw devices (Fig. 69-13). The orthopedic surgeon determines the specific fixation device based on the fracture site or sites. Adequate reduction is important for fracture healing (the better the reduction, the better the healing).

Hemiarthroplasty (replacement of the head of the femur with a prosthesis) is usually reserved for fractures that cannot be satisfactorily reduced or securely nailed or to avoid complications of nonunion and avascular necrosis of the head of the femur. Total hip replacement (see Chap. 67) may be used in selected patients with acetabular defects.

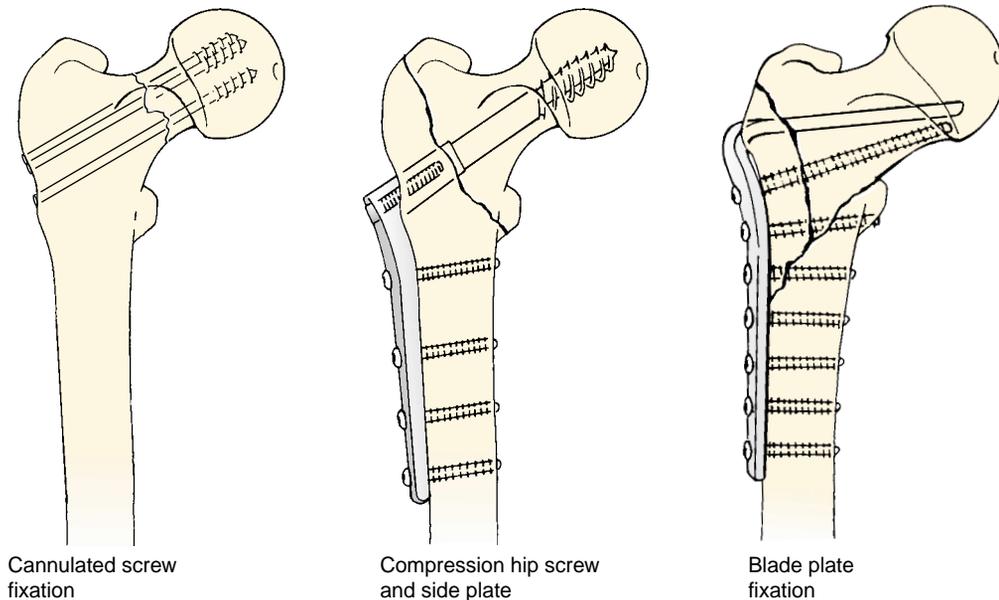

## Postoperative Nursing Management

The immediate postoperative care for a patient with a hip fracture is similar to that for other patients undergoing major surgery (see Care of the Patient Undergoing Orthopedic Surgery in Chap. 20 and Chap. 67). Attention is given to pain management, prevention of secondary medical problems, and early mobilization of the patient so that independent functioning can be restored.

During the first 24 to 48 hours, relief of pain and prevention of complications are priorities. The nurse encourages deep breathing, coughing, and foot flexion exercises every 1 to 2 hours. High-high elastic compression stockings and pneumatic compression devices are used to prevent venous stasis. The nurse administers prescribed intravenous prophylactic antibiotics and monitors the patient's hydration, nutritional status, and urine output. A pillow is placed between the legs to maintain abduction and alignment and to provide needed support when turning the patient.

## REPOSITIONING THE PATIENT

The nurse may turn the patient onto the affected or unaffected extremity as prescribed by the physician. The standard method involves placing a pillow between the patient's legs to keep the affected leg in an abducted position. The patient is then turned

**FIGURE 69-13** Examples of internal fixation for hip fractures. Internal fixation is achieved through the use of screws and plates specifically designed for stability and fixation.

onto the side while proper alignment and supported abduction are maintained.

### PROMOTING STRENGTHENING EXERCISE

The patient is encouraged to exercise as much as possible by means of the overbed trapeze. This device helps strengthen the arms and shoulders in preparation for protected ambulation (eg, toe touch, partial weight bearing). On the first postoperative day, the patient transfers to a chair with assistance and begins assisted ambulation. The amount of weight bearing that can be permitted depends on the stability of the fracture reduction. The physician prescribes the degree of weight bearing and the rate at which the patient can progress to full weight bearing. Physical therapists work with the patient on transfers, ambulation, and the safe use of a walker and crutches.

The patient who has experienced a fractured hip can anticipate discharge to home or to an extended care facility with the use of an ambulatory aid. Some modifications in the home may be needed to permit safe use of walkers and crutches and for the patient's continuing care.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Elderly people with hip fractures are particularly prone to complications that may require more vigorous treatment than the fracture. In some instances, shock proves fatal. Achievement of homeostasis after injury and after surgery is accomplished through careful monitoring and collaborative management, including adjustment of therapeutic interventions as indicated.

*Neurovascular complications* may occur from direct injury to nerves and blood vessels or from increased tissue pressure. With hip fracture, bleeding into the tissues is expected. Excessive swelling may be observed. Therefore, the nurse must monitor the neurovascular status of the affected leg.

*Deep vein thrombosis* is the most common complication. To prevent DVT, the nurse encourages intake of fluids and ankle and

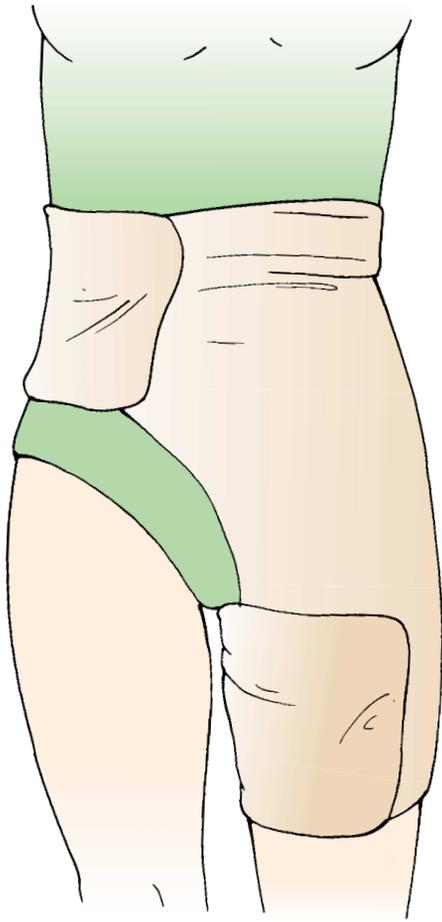

foot exercises. Elastic compression stockings, sequential compression devices, and prophylactic anticoagulant therapy may be prescribed. The nurse assesses the patient's legs at least every 4 hours for signs of DVT.

*Pulmonary complications* are a threat to elderly patients undergoing hip surgery. Deep-breathing exercises, a change of position at least every 2 hours, and the use of an incentive spirometer help to prevent respiratory complications. The nurse assesses breath sounds at least every 4 to 8 hours to detect adventitious or diminished sounds.

*Skin breakdown* is often seen in elderly patients with hip fracture. Blisters caused by tape are related to the tension of soft tissue edema under the nonelastic tape. An elastic hip spica wrap dressing (Fig. 69-14) or elastic tape applied in a vertical fashion may reduce the incidence of tape blisters. In addition, patients with hip fractures tend to remain in one position and may develop *pressure ulcers*. Proper skin care, especially on the heels, back, sacrum, and shoulders, helps to relieve pressure. High-density foam, static air, or another type of special mattress may provide protection by distributing pressure more evenly.

*Loss of bladder control* (incontinence) may occur. In general, the routine use of an indwelling catheter is avoided because of the high risk for urinary tract infection. If a catheter is inserted at the time of surgery, it usually is removed on the morning of the first postoperative day. Because urinary retention is common after surgery, the nurse must assess the patient's voiding patterns. To ensure proper urinary tract function, the nurse encourages liberal fluid intake within the cardiovascular tolerance of the patient.

*Delayed complications* of hip fractures include infection, nonunion, avascular necrosis of the femoral head (particularly with femoral neck fractures), and fixation device problems (eg, protrusion of the fixation device through the acetabulum, loosening of hardware). Infection is suspected if the patient complains of persistent, moderate discomfort in the hip and has a mildly elevated sedimentation rate. The nursing management of the elderly patient with a hip fracture is summarized in the Plan of Nursing Care.

**FIGURE 69-14** Patient using commercial single-piece stretch spica wrap.

### HEALTH PROMOTION

Osteoporosis screening of patients who have experienced hip fracture is important for prevention of future fractures. With dual-energy x-ray absorptiometry (DEXA) scan screening, the actual risk for additional fracture can be determined. Specific patient education regarding dietary requirements, lifestyle changes, and exercise to promote bone health is needed. Specific therapeutic interventions need to be initiated to retard additional bone loss and to build bone mineral density. Studies have shown that health care providers caring for patients with hip fractures fail to diagnose or treat these patients for osteoporosis despite the high probability that hip fractures are secondary to osteoporosis (Kamel, et al., 2000). Fall prevention is also important and may be achieved through exercises to improve muscle tone and balance and through the elimination of environmental hazards. In addition, the use of hip protectors that absorb or shunt impact forces may help to prevent an additional hip fracture if the patient were to fall.

### FEMORAL SHAFT

Considerable force is required to break the shaft of the femur in adults. Most femoral fractures are seen in young adults who have been involved in a motor vehicle crash or who have fallen from a high place. Frequently, these patients have associated multiple traumas.

The patient presents with an enlarged, deformed, painful thigh and cannot move the hip or the knee. The fracture may be transverse, oblique, spiral, or comminuted. Frequently, the patient de-

velops shock, because the loss of 2 to 3 units of blood into the tissues is common with these fractures. An expanding diameter of the thigh may indicate continued bleeding. Refer to Figure 69-15A for the types of femoral fractures.

### Assessment and Diagnostic Findings

Assessment includes checking the neurovascular status of the extremity, especially circulatory perfusion of the lower leg and foot (popliteal, posterior tibial, and pedal pulses and toe capillary re-fill time). A Doppler ultrasound monitoring device may be needed to assess blood flow. Dislocation of the hip and knee may accompany these fractures. Knee effusion suggests ligament damage and possible instability of the knee joint.

### Medical Management

Continued neurovascular monitoring is needed. The fracture is immobilized so that additional soft tissue damage does not occur. Generally, skeletal traction (Fig. 69-15 B and C) or splinting is used to immobilize fracture fragments until the patient is physiologically stable and ready for open reduction and internal fixation procedures.

Internal fixation usually is carried out within a few days after injury. Intramedullary locking nail devices are used for midshaft (diaphyseal) fractures. Depending on the supracondylar fracture pattern, intramedullary nailing or screw plate fixation may be used. Internal fixation permits early mobilization. A thigh cuff orthosis may be used for external support. To preserve muscle strength, the patient is instructed to exercise the lower leg, foot, toes, and hip on a regular basis. Active muscle movement enhances healing by increasing blood supply and electrical potentials at the fracture site. Prescribed weight-bearing limits are based on the fracture pattern. Physical therapy includes ROM and strengthening exercises, safe use of ambulatory aids, and gait training. Functional ambulation stimulates fracture healing. Healing time is 4 to 6 months.

Compression plates and intramedullary nails may need to be removed after 12 to 18 months due to reaction or loosening. After plates are being removed, a thigh cuff orthosis is used for several months to provide support while bone remodeling occurs.

Infrequently, because of patient risks associated with anesthesia and surgery, middle shaft and distal (supracondylar) fractures may be managed with skeletal traction. Between 2 and 4 weeks after injury, when pain and swelling have subsided, the patient is removed from skeletal traction and placed in a cast brace. The cast brace is a total contact device (ie, encircles the limb) and holds the reduced fracture. The muscle, through hydrodynamic compression, stabilizes the bone and stimulates healing. Minimal partial weight bearing is begun and is progressed to full weight bearing as tolerated. The cast brace is worn for 12 to 14 weeks.

An external fixator may be used if the patient has experienced an open fracture, has extensive soft tissue trauma, has lost bone, has an infection, or has hip and tibial fractures.

A common complication after fracture of the femoral shaft is restriction of knee motion. Active and passive knee exercises begin as soon as possible, depending on the management approach and the stability of the fracture and knee ligaments. Other complications include malunion, delayed union or nonunion, pudendal nerve palsy, and infection.

*(text continues on page 2102)*

## Plan of Nursing Care

### Care of the Elderly Patient With a Fractured Hip

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Acute pain related to fracture, soft tissue damage, muscle spasm, and surgery

**Goal:** Relief of pain

1. Assess type and location of patient's pain.	1. Pain is expected after fracture; soft tissue damage and muscle spasm contribute to discomfort; pain is subjective and is evaluated through description of characteristics and location, which are important for determining cause of discomfort and for proposing interventions. Continuing pain may indicate development of neurovascular problems.	<ul style="list-style-type: none"> <li>• Patient describes discomfort</li> <li>• Expresses confidence in efforts to control pain</li> <li>• Expresses little discomfort with position changes</li> <li>• Expresses comfort when leg is positioned and immobilized</li> <li>• Minimizes movement of extremity before reduction and fixation</li> </ul>
2. Acknowledge existence of pain; inform patient of available analgesics; record patient's baseline discomfort.	2. Reduces stress experienced by the patient by communicating concern and availability of help in dealing with pain. Documentation provides baseline data.	<ul style="list-style-type: none"> <li>• Uses physical, psychological, and pharmacologic measures to reduce discomfort</li> <li>• Describes a decrease in pain in 24–48 hours after surgery</li> </ul>
3. Handle the affected extremity gently, supporting it with hands or pillow.	3. Movement of bone fragments is painful; muscle spasms occur with movement; adequate support diminishes soft tissue tension.	<ul style="list-style-type: none"> <li>• Requests pain medications and uses pain relief measures early in pain cycle</li> <li>• States that positioning provides comfort</li> </ul>
4. Apply Buck's traction as prescribed. Use trochanter roll.	4. Immobilizes fracture to decrease pain, muscle spasm, and external rotation of hip.	<ul style="list-style-type: none"> <li>• Appears comfortable and relaxed</li> <li>• Moves with increasing comfort as healing progresses</li> </ul>
5. Use pain-modifying strategies. <ol style="list-style-type: none"> <li>a. Modify the environment.</li> <li>b. Administer prescribed analgesics as needed.</li> <li>c. Encourage patient to use pain relief measures before pain is "unbearable."</li> <li>d. Evaluate patient's response to medications and other pain-reduction techniques.</li> <li>e. Consult with physician if relief of pain is not obtained.</li> </ol>	5. Pain perception can be diminished by distraction and refocusing of attention. <ol style="list-style-type: none"> <li>a. Interaction with others, distraction, and environmental stimuli may modify pain experiences.</li> <li>b. Analgesics reduce the pain; muscle relaxants may be prescribed to decrease discomfort associated with muscle spasm.</li> <li>c. Mild pain is easier to control than severe pain.</li> <li>d. Assessment of effectiveness of measures provides basis for future management interventions; early identification of adverse reactions is necessary for corrective measures and care plan modifications.</li> <li>e. Change in treatment plan may be necessary.</li> </ol>	
6. Position for comfort and function.	6. Alignment of body facilitates comfort; positioning for function diminishes stress on musculoskeletal system.	
7. Assist with frequent changes in position.	7. Change of position relieves pressure and associated discomfort.	

**Nursing Diagnosis:** Impaired physical mobility related to fractured hip

**Goal:** Achieves pain-free, functional, stable hip

1. Maintain neutral positioning of hip.	1. Prevents stress on fixation.	• Patient engages in therapeutic positioning
2. Use trochanter roll.	2. Minimizes external rotation.	• Uses pillow between legs when turning
3. Place pillow between legs when turning.	3. Supports leg; prevents adduction.	• Assists in position changes; shows increased independence in transfers
4. Instruct and assist in position changes and transfers.	4. Encourages patient's active participation while preventing stress on hip fixation.	• Exercises every 2 hours while awake
5. Instruct in and supervise isometric, quadriceps-setting, and gluteal-setting exercises.	5. Strengthens muscles needed for walking.	• Uses trapeze
		• Participates in progressive ambulation program

(continued)

## Plan of Nursing Care

### Care of the Elderly Patient With a Fractured Hip (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> <li>6. Encourage use of trapeze.</li> <li>7. In consultation with physical therapist, instruct in and supervise progressive safe ambulation within limitations of weight-bearing prescription.</li> <li>8. Offer encouragement and support exercise regimen.</li> <li>9. Instruct in and supervise safe use of ambulatory aids.</li> </ol>	<ol style="list-style-type: none"> <li>6. Strengthens shoulder and arm muscles necessary for use of ambulatory aids.</li> <li>7. Amount of weight-bearing depends on the patient's condition, fracture stability, and fixation device; ambulatory aids are used to assist the patient with non-weight-bearing and partial-weight-bearing ambulation.</li> <li>8. Reconditioning exercises can be uncomfortable and fatiguing; encouragement helps patient comply with the program.</li> <li>9. Prevents injury from unsafe use.</li> </ol>	<ul style="list-style-type: none"> <li>• Actively participates in exercise regimen</li> <li>• Uses ambulatory aids correctly and safely</li> </ul>

#### Nursing Diagnosis: Impaired skin integrity related to surgical incision

**Goal:** Achieves wound healing

<ol style="list-style-type: none"> <li>1. Monitor vital signs.</li> <li>2. Perform aseptic dressing changes.</li> <li>3. Assess wound appearance and character of drainage.</li> <li>4. Assess report of pain.</li> <li>5. Administer prophylactic antibiotic if prescribed, and observe for side effects.</li> </ol>	<ol style="list-style-type: none"> <li>1. Temperature, pulse, and respiration increase in response to infection. (Magnitude of response may be minimal in elderly patients.)</li> <li>2. Avoids introducing infectious organisms.</li> <li>3. Red, swollen, draining incision is indicative of infection.</li> <li>4. Pain may be due to wound hematoma, a possible locus of infection, which needs to be surgically evacuated.</li> <li>5. Antibiotics reduce the risk for infection.</li> </ol>	<ul style="list-style-type: none"> <li>• Patient maintains vital signs within normal range</li> <li>• Exhibits well-approximated incision without drainage or excessive inflammatory response</li> <li>• Relates minimal discomfort; demonstrates no hematoma</li> <li>• Tolerates antibiotics; exhibits no evidence of osteomyelitis</li> </ul>
---	---	--

#### Nursing Diagnosis: Risk for impaired urinary elimination related to immobility

**Goal:** Maintains normal urinary elimination patterns

<ol style="list-style-type: none"> <li>1. Monitor intake and output.</li> <li>2. Avoid/minimize use of indwelling catheter.</li> <li>3. Perform intermittent catheterization for urinary retention</li> </ol>	<ol style="list-style-type: none"> <li>1. Adequate fluid intake ensures hydration; adequate urinary output minimizes urinary stasis.</li> <li>2. Source of bladder infection.</li> <li>3. Empties bladder; reduces urinary tract infections</li> </ol>	<ul style="list-style-type: none"> <li>• Intake and output are adequate; patient exhibits normal voiding patterns</li> <li>• Demonstrates no evidence of urinary tract infection</li> </ul>
---	--	---

#### Nursing Diagnosis: Risk for ineffective coping related to injury, anticipated surgery, and dependence

**Goal:** Uses effective coping mechanisms to modify stress

<ol style="list-style-type: none"> <li>1. Encourage patient to express concerns and to discuss the possible impact of fractured hip.</li> <li>2. Support use of coping mechanisms. Involve significant others and support services as needed.</li> <li>3. Contact social services, if needed.</li> <li>4. Explain anticipated treatment regimen and routines to facilitate positive attitude in relation to rehabilitation.</li> <li>5. Encourage patient to participate in planning.</li> </ol>	<ol style="list-style-type: none"> <li>1. Verbalization helps patient deal with problems and feelings. Clarification of thoughts and feelings promotes problem-solving.</li> <li>2. ## Plan of Nursing Care

### Care of the Elderly Patient With a Fractured Hip (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Risk for disturbed thought process related to age, stress of trauma, unfamiliar surroundings, and medication therapy

**Goal:** Remains oriented and participates in decision making

1. Assess orientation status.	1. Evaluate presenting orientation of patient; confusion may result from stress of fracture, unfamiliar surroundings, coexisting systemic disease, cerebral ischemia, or other factors. Baseline data are important for determining change.	<ul style="list-style-type: none"> <li>• Patient establishes effective communication</li> <li>• Demonstrates orientation to time, place, and person</li> <li>• Participates in self-care activities</li> <li>• Remains mentally alert</li> <li>• Avoids episodes of confusion</li> </ul>
2. Interview family regarding patient's orientation and cognitive abilities before injury.	2. Provides data for evaluation of current findings.	
3. Assess patient for auditory and visual deficits.	3. Diminished vision and auditory acuity frequently occur with aging; glasses and hearing aid may increase patient's ability to interact with environment.	
a. Assist patient with use of sensory aids (eg, glasses, hearing aid)	a. Aids must be in good working order and available for use.	
b. Control environmental distractors	b. Facilitates communication.	
4. Orient to and stabilize environment	4.	
a. Use orientation activities and aids (eg, clock, calendar, pictures, introduction of self).	a. Short-term memory may be faulty in the elderly; frequent reorientation helps.	
b. Minimize number of staff working with patient.	b. Consistency of caregivers promotes trust.	
5. Give simple explanations of procedures and plan of care.	5. Promotes understanding and active participation.	
6. Encourage participation in hygiene and nutritional activities.	6. Participation in routine activities promotes orientation, increases awareness of self.	
7. Provide for safety.	7. Side rails decrease chance for additional injury from falls; mechanism for securing assistance is available to patient; independent activities based on faulty judgment may result in injury.	
a. Keep side rails up when patient is in bed.		
b. Keep light on at night.		
c. Have call bell available.		
d. Provide prompt response to requests for assistance.		
8. Assess mental responses to medications, especially sedatives and analgesics.	8. Elderly people tend to be more sensitive to medications; abnormal responses (eg, hallucinations, depression) may occur.	

**Collaborative Problems:** Hemorrhage; peripheral neurovascular dysfunction; deep vein thrombosis; pulmonary complications; pressure ulcers related to surgery and immobility

**Goal:** Patient experiences an absence of complications

#### Hemorrhage

1. Monitor vital signs, observing for shock.	1. Changes in pulse, blood pressure, and respirations may indicate development of shock; blood loss and stress may contribute to development of shock.	<ul style="list-style-type: none"> <li>• Vital signs are stabilized within normal limits</li> <li>• Experiences no excessive or bright red drainage</li> <li>• Exhibits hemoglobin and hematocrit values within normal limits</li> </ul>
2. Consider preinjury blood pressure values and management of coexisting hypertension, if present.	2. Necessary for interpretation of current blood pressure determinations.	
3. Note character and amount of drainage.	3. Excessive drainage and bright red drainage may indicate active bleeding.	
4. Notify surgeon if patient develops shock or excessive bleeding.	4. Corrective measures need to be instituted.	
5. Note hemoglobin and hematocrit values, and report decreases in values.	5. Anemia due to blood loss may develop; bleeding into tissues after hip fracture may be extensive; blood replacement may be needed.	

(continued)

## Plan of Nursing Care

### Care of the Elderly Patient With a Fractured Hip (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

##### Pulmonary Complications

1. Assess respiratory status: respiratory rate, depth, and duration, breath sounds, sputum. Monitor temperature.
2. Report adventitious and diminished breath sounds and elevated temperature.
3. Supervise deep breathing and coughing exercises. Encourage use of incentive spirometer if prescribed.
4. Administer oxygen as prescribed.
5. Turn and reposition patient at least every 2 hours. Mobilize patient (assist patient out of bed) as soon as possible.
6. Ensure adequate hydration.

1. Anesthesia and bed rest diminish respiratory effort and cause pooling of respiratory secretions. Adventitious breath sounds, pain on respiration, shortness of breath, blood tinged sputum, cough, etc., indicate pulmonary problems.
2. Elevated temperature in the early post-operative period may be due to a respiratory problem.
3. Promote optimal ventilation. Coexisting respiratory conditions diminish lung expansion.
4. Reduced ventilatory efforts may diminish PaO<sub>2</sub> when patient is on room air.
5. Promotes optimal ventilation. Diminishes pooling of respiratory secretions.
6. Liquefies respiratory secretions. Facilitates expectoration.

- Patient has clear breath sounds
- Breath sounds present in all fields
- Exhibits no shortness of breath, chest pain, or elevated temperature
- PaO<sub>2</sub> on room air within normal limits
- Performs respiratory exercises; uses incentive spirometer as instructed
- Changes position frequently
- Consumes adequate fluids

##### Peripheral Neurovascular Dysfunction

1. Assess affected extremity for color and temperature.
2. Assess toes for capillary refill response.
3. Assess affected extremity for edema and swelling.
4. Elevate affected extremity.
5. Assess for deep, throbbing, unrelenting pain.
6. Assess for pain on passive flexion of foot.
7. Assess for sensations and numbness.
8. Assess ability to move foot and toes.
9. Assess pedal pulses in both feet.
10. Notify surgeon if diminished neurovascular status occurs.

1. The skin becomes pale and feels cool with decreased tissue perfusion. Venous congestion may cause cyanosis.
2. After compression of the nail, rapid return of pink color indicates good capillary perfusion.
3. The trauma of surgery will cause swelling; excessive swelling and hematoma formation can compromise circulation and function; edema may be due to coexisting cardiovascular disease.
4. Minimizes dependent edema.
5. Surgical pain can be controlled; pain due to neurovascular compromise is refractory to treatment with analgesics.
6. With nerve ischemia, there will be pain on passive stretch.
7. Diminished pain and paresthesia may indicate nerve damage. Sensation in web between great and second toe—peroneal nerve; sensation on sole of foot—tibial nerve.
8. Dorsiflexion of ankle and extension of toes indicate function of peroneal nerve. Plantar flexion of ankle and flexion of toes indicate functioning of tibial nerve.
9. Indicates circulatory status of extremities.
10. Function of extremity needs to be preserved.

- Patient has normal color and the extremity is warm
- Demonstrates normal capillary refill response
- Exhibits moderate swelling; tissue not palpably tense
- States pain is controllable
- Reports no pain with passive dorsiflexion
- Reports normal sensations and no paresthesia
- Demonstrates normal motor abilities and no paresis or paralysis
- Has strong and equal pulses

##### Deep Vein Thrombosis

1. Apply thigh-high elastic compression stockings and/or sequential compression device as prescribed.
2. Remove stockings for 20 minutes twice a day, and provide skin care.
3. Assess popliteal, dorsalis pedis, and posterior tibial pulses.

1. Compression aids venous blood return and prevents stasis.
2. Skin care is necessary to avoid skin breakdown. Extended removal of stocking or device defeats purpose.
3. Pulses indicate arterial perfusion of extremity. With coexisting arteriosclerotic

- Wears thigh-high elastic compression stockings
- Uses sequential compression device
- Experiences no skin breakdown
- Experiences no more warmth than usual in skin areas
- Exhibits no increase in calf circumference
- Demonstrates a negative Homans' sign

(continued)

## Plan of Nursing Care

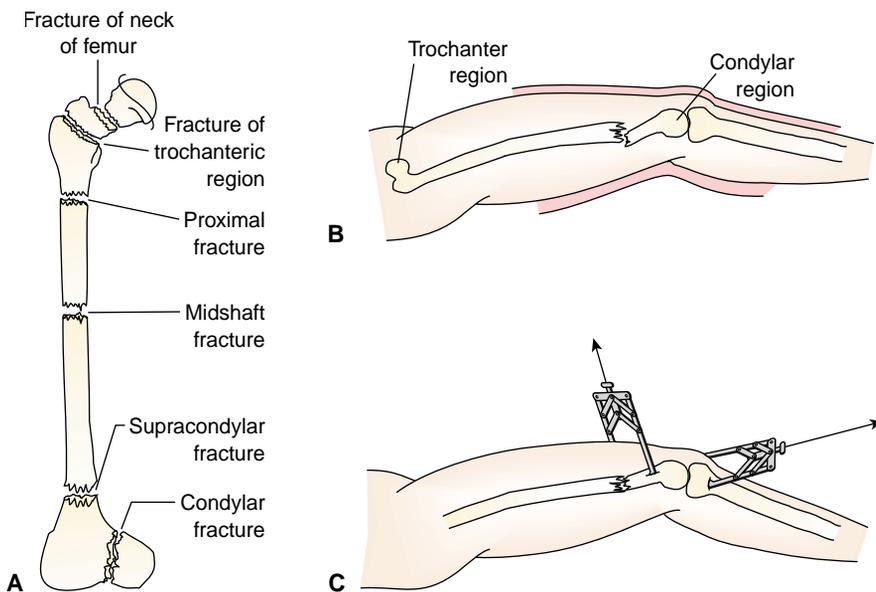

### Care of the Elderly Patient With a Fractured Hip (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> <li>4. Assess skin temperature of legs.</li> <li>5. Assess for Homans' sign every 4 hours.</li> <li>6. Measure calf circumference twice daily.</li> <li>7. Avoid pressure on popliteal blood vessels from appliances or pillows.</li> <li>8. Change patient's position and increase activity as prescribed.</li> <li>9. Supervise ankle exercises hourly while patient is awake.</li> <li>10. Ensure adequate hydration.</li> <li>11. Monitor body temperature.</li> </ol>	<p>vascular disease, pulses may be diminished or absent.</p> <ol style="list-style-type: none"> <li>4. Local inflammation increases local skin temperature.</li> <li>5. Pain in calf on dorsiflexion of ankle may indicate deep vein thrombosis.</li> <li>6. Increased calf circumference indicates edema or altered perfusion.</li> <li>7. Compression of blood vessels diminishes blood flow.</li> <li>8. Activity promotes circulation and diminishes venous stasis.</li> <li>9. Muscle exercise promotes circulation.</li> <li>10. Elderly people may become dehydrated because of low fluid intake, resulting in hemoconcentration.</li> <li>11. Body temperature increases with inflammation (magnitude of response minimal in elderly people).</li> </ol>	<ul style="list-style-type: none"> <li>• Changes position with assistance and supervision</li> <li>• Participates in exercise regimen</li> <li>• Experiences no chest pain; has lungs clear to auscultation; presents no evidence of pulmonary emboli</li> <li>• Exhibits no signs of dehydration; has normal hematocrit</li> <li>• Maintains normal body temperature</li> </ul>
<p><b>Pressure Ulcers</b></p> <ol style="list-style-type: none"> <li>1. Monitor condition of skin at pressure points (eg, heels, sacrum, shoulders); inspect heels at least twice a day.</li> <li>2. Reposition patient at least every 2 hours. Avoid skin shearing.</li> <li>3. Administer skin care, especially to pressure points.</li> <li>4. Use special care mattress and other protective devices (eg, heel protectors); support heel off the mattress.</li> <li>5. Institute care according to protocol at first indication of potential skin breakdown.</li> </ol>	<ol style="list-style-type: none"> <li>1. Elderly patients are subject to skin breakdown at points of pressure because of diminished subcutaneous tissue.</li> <li>2. Avoids prolonged pressure and trauma to the skin.</li> <li>3. Immobility causes pressure at bony prominences; position changes relieve pressure.</li> <li>4. Devices minimize pressure on skin at bony prominences.</li> <li>5. Early interventions prevent tissue destruction and prolonged rehabilitation.</li> </ol>	<ul style="list-style-type: none"> <li>• Patient exhibits no signs of skin breakdown</li> <li>• Skin remains intact</li> <li>• Repositions self frequently</li> <li>• Uses protective devices</li> </ul>

**Nursing Diagnosis:** Risk for ineffective health maintenance related to fractured hip and impaired mobility

**Goal:** Exhibits health maintenance/promotion behaviors

<ol style="list-style-type: none"> <li>1. Assess home environment for discharge planning.</li> <li>2. Encourage patient to express concerns about care at home; explore with patient possible solutions to problems.</li> <li>3. Assess availability of physical assistance for ADLs and health care activities.</li> <li>4. Teach caregiver the home health care regimen.</li> <li>5. Instruct patient in posthospital care:               <ol style="list-style-type: none"> <li>a. Activity limitations</li> <li>b. Reinforce exercise instructions</li> <li>c. Safe use of ambulatory aids</li> <li>d. Wound care</li> <li>e. Measures to promote healing (nutrition, wound care)</li> <li>f. Medications, if any</li> <li>g. Potential problems</li> <li>h. Continuing health care supervision</li> </ol> </li> </ol>	<ol style="list-style-type: none"> <li>1. Physical barriers (especially stairs, bathrooms) may limit patient's ability to ambulate and care for self at home.</li> <li>2. Patient may have special problems that need to be identified and dealt with.</li> <li>3. Because of limitation of mobility, patient requires some assistance in ADLs and routine health care.</li> <li>4. Understanding of rehabilitative regimen is necessary for compliance.</li> <li>5. Lack of knowledge and poor preparation for care at home contribute to patient anxiety, insecurity, and nonadherence to therapeutic regimen.</li> </ol>	<ul style="list-style-type: none"> <li>• Home is accessible for patient at time of discharge</li> <li>• Patient appears relaxed and develops strategies to deal with identified problems</li> <li>• Has personal assistance available</li> <li>• Demonstrates ability to use necessary assistance within therapeutic prescription</li> <li>• Complies with home care program; keeps follow-up health care appointments</li> </ul>
--	---	---

**FIGURE 69-15** (A) Types of femoral fractures. One method of correction for a fracture of the femur in the distal third is two-wire skeletal traction. (B) Example of deformity on admission to hospital. (C) Adequate reduction is achieved when additional wire is inserted in the lower femoral fragment, and vertical lift is secured.

## TIBIA AND FIBULA

The most common fracture below the knee is one of the tibia (and fibula) that results from a direct blow, falls with the foot in a flexed position, or a violent twisting motion. Fractures of the tibia and fibula often occur in association with each other. The patient presents with pain, deformity, obvious hematoma, and considerable edema. Frequently, these fractures are open and involve severe soft tissue damage because there is little subcutaneous tissue in the area.

### Assessment and Diagnostic Findings

Peroneal nerve damage is assessed. If nerve function is impaired, the patient is unable to dorsiflex the great toe and has diminished sensation in the first web space. Tibial artery damage is assessed by evaluating pulses, skin temperature, and color and by testing the capillary refill response. Hemiarthrosis or ligament damage may occur with fracture near the joint.

The patient is monitored for an anterior compartment syndrome. Symptoms include pain unrelieved by medications and increasing with plantar flexion, tense and tender muscle lateral to tibial crest, and paresthesia.

### Medical Management

Most closed tibial fractures are treated with closed reduction and initial immobilization in a long leg walking cast or a patellar tendon-bearing cast. Reduction must be relatively accurate in relation to angulation and rotation. As with other lower extremity fractures, the leg should be elevated to control edema. Partial weight bearing is usually prescribed after 7 to 10 days. Activity decreases edema and increases circulation. The cast is changed to a short leg cast or brace in 3 to 4 weeks, which allows for knee motion. Fracture healing takes 6 to 10 weeks. At times it is difficult to maintain reduction, and percutaneous pins may be placed in the bone and held in position by an external fixator.

Comminuted fractures may be treated with skeletal traction, internal fixation with intramedullary nails or plates and screws,

or external fixation. External support may be used with internal fixation. Hip, foot, and knee exercises are encouraged within the limits of the immobilizing device. Partial weight bearing is begun when prescribed and is progressed as the fracture heals in 4 to 8 weeks.

Open fractures are treated with external fixation. Distal fractures with extensive soft tissue damage heal slowly and may require bone grafting.

Continued neurovascular evaluation is needed. The development of compartment syndrome requires prompt recognition and resolution to prevent permanent functional deficit. Other complications include delayed union, infection, impaired wound edge healing due to limited soft tissue, and loosening of the internal fixation hardware.

## RIB

Uncomplicated fractures of the ribs occur frequently in adults and usually result in no impairment of function. Because these fractures produce painful respiration, the patient tends to decrease respiratory excursions and refrains from coughing. As a result, tracheobronchial secretions are not mobilized, aeration of the lung is diminished, and a predisposition to *pneumonia* and *atelectasis* results. To help the patient cough and take deep breaths, the nurse may splint the chest with her hands. Occasionally, the physician administers intercostal nerve blocks to relieve pain and to permit productive coughing.

Chest strapping to immobilize the rib fracture is *not* used, because decreased chest expansion may result in pneumonia and atelectasis. The pain associated with rib fracture diminishes significantly in 3 or 4 days, and the fracture heals within 6 weeks. In addition to pneumonia and atelectasis, complications may include a *flail chest*, *pneumothorax*, and *hemothorax*. The management of patients with these conditions is discussed in Chapter 23.

## THORACOLUMBAR SPINE

Fractures of the thoracolumbar spine may involve (1) the vertebral body, (2) the laminae and articulating processes, and (3) the spinous processes or transverse processes. The T12 to L2 area of

the spine is most vulnerable to fracture. Fractures generally result from indirect trauma caused by excessive loading, sudden muscle contraction, or excessive motion beyond physiologic limits. Osteoporosis contributes to vertebral body collapse (compression fracture).

Stable spinal fractures are caused by flexion, extension, lateral bending, or vertical loading. The anterior structural column (vertebral bodies and disks) or the posterior structural column (neural arch, articular processes, ligaments) has been disrupted. Unstable fractures occur with fracture-dislocations and exhibit disruption of both anterior and posterior structural columns. The potential for neural damage exists.

The patient with a spinal fracture presents with acute tenderness, swelling, paravertebral muscle spasm, and change in the normal curves or in the gap between spinous processes. Pain is greater with moving, coughing, or weight bearing. Immobilization is essential until initial assessments have determined whether there is any spinal cord injury and whether the fracture is stable or unstable. Few spinal fractures are associated with neurologic deficits. If spinal cord injury with neurologic deficit does occur, it usually requires immediate surgery (laminectomy with spinal fusion) to decompress the spinal cord.

## Medical Management

Stable spinal fractures are treated conservatively with limited bed rest. The head of the bed is elevated less than 30 degrees until the acute pain subsides (several days). Analgesics are prescribed for pain relief. The patient is monitored for a transient *paralytic ileus* caused by associated retroperitoneal hemorrhage. Sitting is avoided until the pain subsides. A spinal brace or plastic thoracolumbar orthosis may be applied for support during progressive ambulation and resumption of activities.

The patient with an unstable fracture is treated with bed rest, possibly with the use of a special turning device (eg, Stryker frame) to maintain spinal alignment. Neurologic status is monitored closely during the preoperative and postoperative periods. Within 24 hours after fracture, open reduction, decompression, and fixation with spinal fusion and instrument stabilization are usually accomplished. Postoperatively, the patient may be cared for on the turning device or in a bed with a firm mattress. Progressive ambulation is begun a few days after surgery, with the patient using a body brace orthosis. Patient teaching emphasizes good posture, good body mechanics, and, after healing is sufficient, back-strengthening exercises. (Spinal cord injury is discussed in Chapter 63.)

## Amputation

**Amputation** is the removal of a body part, usually an extremity. Amputation of a lower extremity is often made necessary by progressive peripheral vascular disease (often a sequela of diabetes mellitus), fulminating gas gangrene, trauma (crushing injuries, burns, frostbite, electrical burns), congenital deformities, chronic osteomyelitis, or malignant tumor. Of all these causes, peripheral vascular disease accounts for most amputations of lower extremities. (See Chapter 31 for more information.)

Amputation is used to relieve symptoms, improve function, and save or improve the patient's quality of life. If the health care team communicates a positive attitude, the patient adjusts to the amputation more readily and actively participates in the rehabilitative plan, learning how to modify activities and how to use assistive devices for ADLs and mobility.

## Levels of Amputation

Amputation is performed at the most distal point that will heal successfully. The site of amputation is determined by two factors: circulation in the part, and functional usefulness (ie, meets the requirements for the use of the prosthesis).

The circulatory status of the extremity is evaluated through physical examination and specific studies. Muscle and skin perfusion is important for healing. Doppler flowmetry, segmental blood pressure determinations, and transcutaneous partial pressure of oxygen (PaO<sub>2</sub>) are valuable diagnostic aids. Angiography is performed if revascularization is considered an option.

The objective of surgery is to conserve as much extremity length as possible. Preservation of knee and elbow joints is desired. Figure 69-16 shows the levels at which an extremity may be amputated. Almost any level of amputation can be fitted with a prosthesis.

The amputation of toes and portions of the foot causes minor changes in gait and balance. A Syme amputation (modified ankle disarticulation amputation) is performed most frequently for extensive foot trauma and produces a painless, durable extremity end that can withstand full weight-bearing. Below-knee amputations are preferred to above-knee amputations because of the importance of the knee joint and the energy requirements for walking. Knee disarticulations are most successful with young, active patients who are able to develop precise control of the prosthesis. When above-knee amputations are performed, all possible length is preserved, muscles are stabilized and shaped, and hip contractures are prevented for maximum ambulatory potential. Most people who have a hip disarticulation amputation must rely on a wheelchair for mobility.

Upper extremity amputations are performed to preserve the maximum functional length. The prosthesis is fitted early for maximum function.

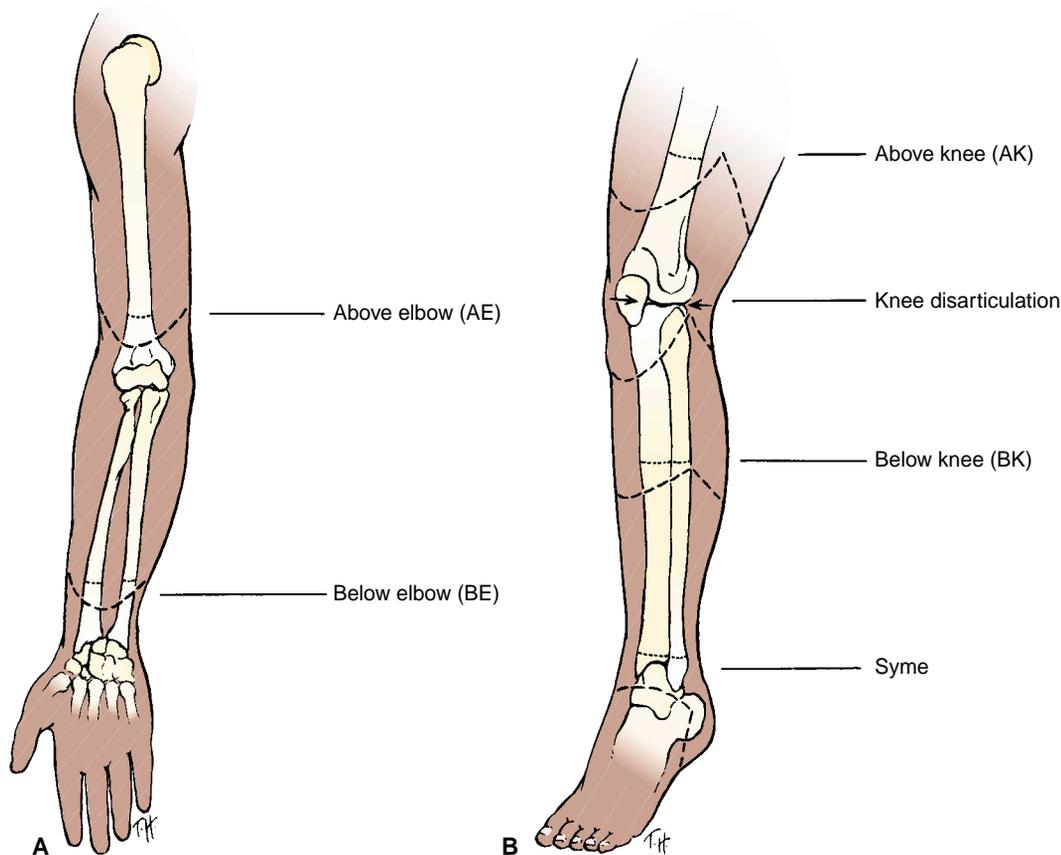

A *staged amputation* may be used when gangrene and infection exist. Initially, a guillotine amputation is performed to remove the necrotic and infected tissue. The wound is débrided and allowed to drain. Sepsis is treated with systemic antibiotics. In a few days, after the infection has been controlled and the patient's condition has stabilized, a definitive amputation with skin closure is performed.

## Complications

Complications that may occur with amputation include *hemorrhage, infection, skin breakdown, phantom limb pain, and joint contracture*. Because major blood vessels have been severed, massive bleeding may occur. Infection is a risk with all surgical procedures. The risk for infection increases with contaminated wounds after traumatic amputation. Skin irritation caused by the prosthesis may result in skin breakdown. **Phantom limb pain** is caused by the severing of peripheral nerves. Joint contracture is caused by positioning and a protective flexion withdrawal pattern associated with pain and muscle imbalance.

## Medical Management

The objective of treatment is to achieve healing of the amputation wound, the result being a nontender residual limb (stump) with healthy skin for prosthesis use. Healing is enhanced by gentle handling of the residual limb, control of residual limb edema through rigid or soft compression dressings, and use of aseptic technique in wound care to avoid infection.

**FIGURE 69-16** Levels of amputation are determined by circulatory adequacy, type of prosthesis, function of the part, and muscle balance. (A) Levels of amputation of upper extremity. (B) Levels of amputation of lower extremity.

A *closed rigid cast dressing* is frequently used to provide uniform compression, to support soft tissues, to control pain, and to prevent joint contractures. Immediately after surgery, a sterilized residual limb sock is applied to the residual limb. Felt pads are placed over pressure-sensitive areas. The residual limb is wrapped with elastic plaster-of-paris bandages while firm, even pressure is maintained. Care is taken not to constrict circulation.

For the patient with a lower extremity amputation, the plaster cast may be equipped to attach a temporary prosthetic extension (pylon) and an artificial foot. This rigid dressing technique is used as a means of creating a socket for immediate postoperative prosthetic fitting. The length of the prosthesis is tailored to the individual patient. Early minimal weight bearing on the residual limb with a rigid cast dressing and a pylon attached produces little discomfort. The cast is changed in about 10 to 14 days. Elevated body temperature, severe pain, or a loose-fitting cast may necessitate earlier replacement.

A *removable rigid dressing* may be placed over a soft dressing to control edema, to prevent joint flexion contracture, and to protect the residual limb from unintentional trauma during transfer activities. This rigid dressing is removed several days after surgery for wound inspection and is then replaced to control edema. The dressing facilitates residual limb shaping.

A *soft dressing* with or without compression may be used if there is significant wound drainage and frequent inspection of the residual limb (stump) is desired. An immobilizing splint may be incor-

porated in the dressing. Stump (wound) hematomas are controlled with wound drainage devices to minimize infection.

## Rehabilitation

Patients who require amputation because of severe trauma are usually, but not always, young and healthy, heal rapidly, and participate in a vigorous rehabilitation program. Because the amputation is the result of an injury, the patient needs psychological support in accepting the sudden change in body image and in dealing with the stresses of hospitalization, long-term rehabilitation, and modification of lifestyle. Patients who undergo amputation need support as they grieve the loss, and they need time to work through their feelings about their permanent loss and change in body image. Their reactions are unpredictable and can include anger, bitterness, and hostility.

The multidisciplinary rehabilitation team (patient, nurse, physician, social worker, psychologist, prosthetist, vocational rehabilitation worker) helps the patient achieve the highest possible level of function and participation in life activities (Fig. 69-17). Prosthetic clinics and amputee support groups facilitate this rehabilitation process. Vocational counseling and job retraining may be necessary to help patients return to work.

Psychological problems (eg, denial, withdrawal) may be influenced by the type of support the patient receives from the rehabilitation team and by how quickly ADLs and use of the

**FIGURE 69-17** Many amputees receive prostheses soon after surgery and begin learning how to use them with the help and support of the rehabilitation team, which includes nurses, physicians, physical therapists, and others.

prosthesis are learned. Knowing the full options and capabilities available with the various prosthetic devices can give the patient a sense of control over the disability.

## NURSING PROCESS: THE PATIENT UNDERGOING AN AMPUTATION

### Assessment

Before surgery, the nurse must evaluate the neurovascular and functional status of the extremity through history and physical assessment. If the patient has experienced a traumatic amputation, the nurse assesses the function and condition of the residual limb. The nurse also assesses the circulatory status and function of the unaffected extremity. If infection or gangrene develops, the patient may have associated enlarged lymph nodes, fever, and purulent drainage. A culture is taken to determine the appropriate antibiotic therapy.

The nurse evaluates the patient's nutritional status and creates a plan for nutritional care, if indicated. For wound healing, a balanced diet with adequate protein and vitamins is essential.

Any concurrent health problems (eg, dehydration, anemia, cardiac insufficiency, chronic respiratory problems, diabetes mellitus) need to be identified and treated so that the patient is in the best possible condition to withstand the trauma of surgery. The use of corticosteroids, anticoagulants, vasoconstrictors, or vasodilators may influence management and wound healing.

The nurse assesses the patient's psychological status. Determination of the patient's emotional reaction to amputation is essential for nursing care. Grief response to a permanent alteration in body image is normal. An adequate support system and professional counseling can help the patient cope in the aftermath of amputation surgery.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Acute pain related to amputation
- Risk for disturbed sensory perception: phantom limb pain related to amputation
- Impaired skin integrity related to surgical amputation
- Disturbed body image related to amputation of body part
- Ineffective coping, related to failure to accept loss of body part
- Risk for anticipatory and/or dysfunctional grieving related to loss of body part
- Self-care deficit: feeding, bathing/hygiene, dressing/grooming, or toileting, related to loss of extremity
- Impaired physical mobility related to loss of extremity

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include the following:

- Postoperative hemorrhage
- Infection
- Skin breakdown

## Planning and Goals

The major goals of the patient may include relief of pain, absence of altered sensory perceptions, wound healing, acceptance of altered body image, resolution of the grieving process, independence in self-care, restoration of physical mobility, and absence of complications.

## Nursing Interventions

### RELIEVING PAIN

Surgical pain can be effectively controlled with opioid analgesics, nonpharmaceutical interventions, or evacuation of the hematoma or accumulated fluid. Pain may be incisional or may be caused by inflammation, infection, pressure on a bony prominence, or hematoma. Muscle spasms may add to the patient's discomfort. Changing the patient's position or placing a light sandbag on the residual limb to counteract the muscle spasm may improve the patient's level of comfort. Evaluation of the patient's pain and responses to interventions is an important part of the nurse's role in pain management. The pain may be an expression of grief and alteration of body image.

### MINIMIZING ALTERED SENSORY PERCEPTIONS

Amputees may experience phantom limb pain soon after surgery or 2 to 3 months after amputation. It occurs more frequently in above-knee amputations. The patient describes pain or unusual sensations, such as numbness, tingling, or muscle cramps, as well as a feeling that the extremity is present, crushed, cramped, or twisted in an abnormal position. When a patient describes phantom pains or sensations, the nurse acknowledges these feelings and helps the patient modify these perceptions.

Phantom sensations diminish over time. The pathogenesis of the phantom limb phenomenon is unknown. Keeping the patient active helps decrease the occurrence of phantom limb pain. Early

intensive rehabilitation and stump desensitization with kneading massage brings relief. Distraction techniques and activity are helpful. Transcutaneous electrical nerve stimulation (TENS), ultrasound, or local anesthetics may provide relief for some patients. In addition, beta-blockers may relieve dull, burning discomfort; anti-seizure medications control stabbing and cramping pain; and tricyclic antidepressants are used to improve mood and coping ability.

### PROMOTING WOUND HEALING

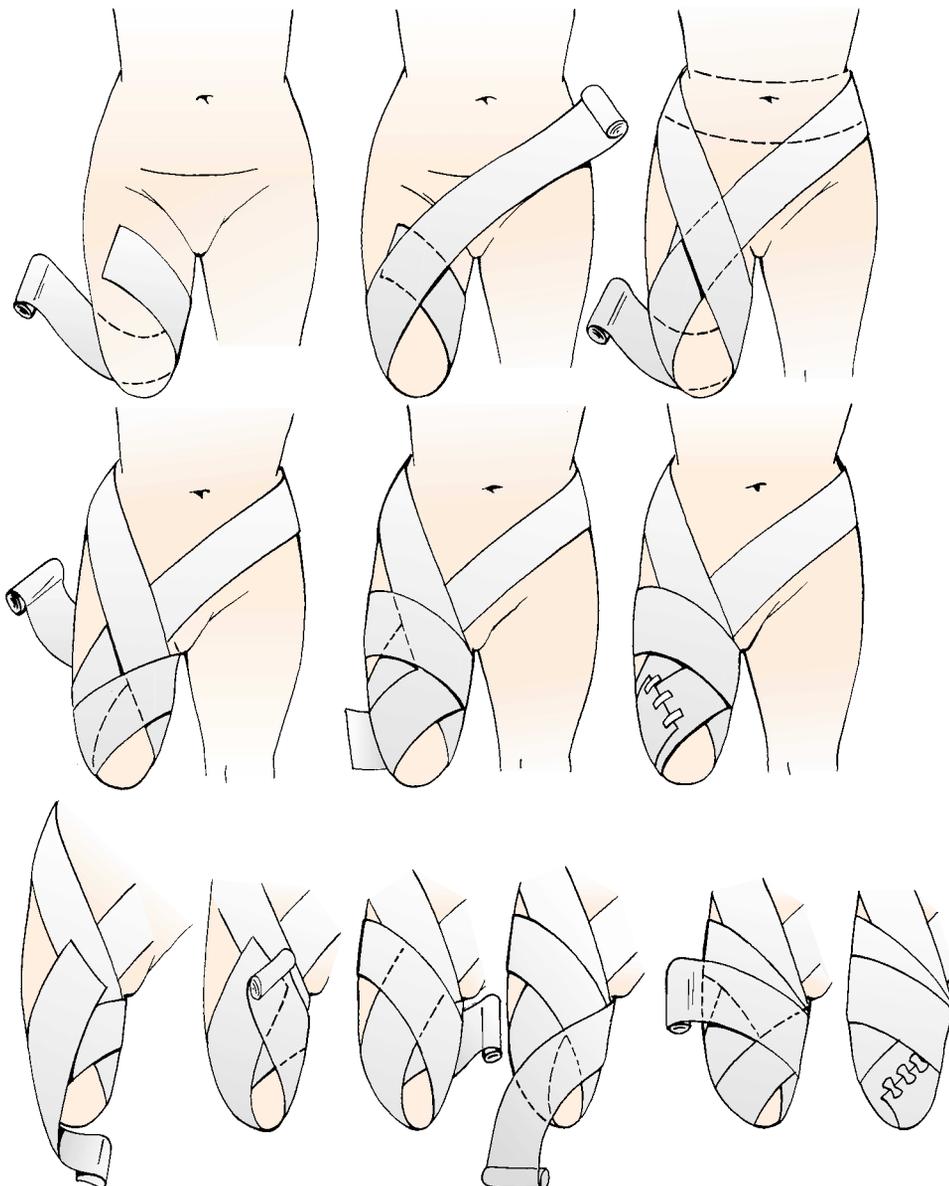

The residual limb must be handled gently. Whenever the dressing is changed, aseptic technique is required to prevent wound infection and possible osteomyelitis.

**NURSING ALERT** If the cast or elastic dressing inadvertently comes off, the nurse must immediately wrap the residual limb with an elastic compression bandage. If this is not done, excessive edema will develop in a short time, resulting in a delay in rehabilitation. The nurse notifies the surgeon if a cast dressing comes off, so that another cast can be applied.

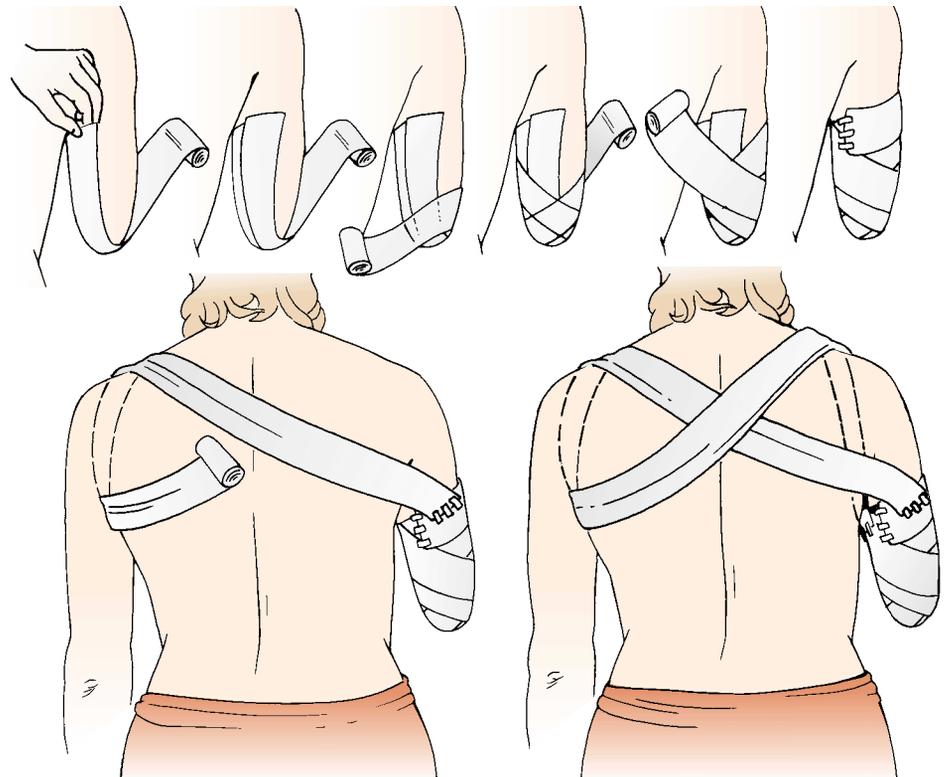

Residual limb shaping is important for prosthesis fitting. The nurse instructs the patient and family in wrapping the residual limb with elastic dressings (Figs. 69-18 and 69-19). After the incision is healed, the nurse teaches the patient to care for the residual limb.

### ENHANCING BODY IMAGE

Amputation is a reconstructive procedure that alters the patient's body image. The nurse who has established a trusting relationship with the patient is better able to communicate acceptance of the patient who has experienced an amputation. The nurse encourages the patient to look at, feel, and then care for the residual limb. It is important to identify the patient's strength and resources to facilitate rehabilitation. The nurse assists the patient to regain the previous level of independent functioning. The patient who is accepted as a whole person is more readily able to resume responsibility for self-care; self-concept improves, and body-image changes are accepted. Even with highly motivated patients, this process may take months.

**FIGURE 69-18** Wrapping the residual leg after an above-knee amputation. Elastic bandaging minimizes edema and shapes the stump in a firm conical form to fit a prosthesis.

**FIGURE 69-19** Wrapping the residual arm after an above-elbow amputation. Passing the bandage wrap across the back and shoulders may augment security.

### HELPING THE PATIENT TO RESOLVE GRIEVING

The loss of an extremity (or part of one) may come as a shock even if the patient was prepared preoperatively. The patient's behavior (eg, crying, withdrawal, apathy, anger) and expressed feelings (eg, depression, fear, helplessness) will reveal how the patient is coping with the loss and working through the grieving process. The nurse acknowledges the loss by listening and providing support.

The nurse creates an accepting and supportive atmosphere in which the patient and family are encouraged to express and share their feelings and work through the grief process. The support from family and friends promotes the patient's acceptance of the loss. The nurse helps the patient deal with immediate needs and become oriented to realistic rehabilitation goals and future independent functioning. Mental health and support group referrals may be appropriate.

### PROMOTING INDEPENDENT SELF-CARE

Amputation of an extremity affects the patient's ability to provide adequate self-care. The patient is encouraged to be an active participant in self-care. The patient needs time to accomplish these tasks and must not be rushed. Practicing an activity with consistent, supportive supervision in a relaxed environment enables the patient to learn self-care skills. The patient and the nurse need to maintain positive attitudes and to minimize fatigue and frustration during the learning process.

Independence in dressing, toileting, and bathing (shower or tub) depends on balance, transfer abilities, and physiologic tolerance of the activities. The nurse works with the physical therapist and occupational therapist to teach and supervise the patient in these self-care activities.

The patient with an upper extremity amputation has self-care deficits in feeding, bathing, and dressing. Assistance is provided only as needed; the nurse encourages the patient to learn to do

these tasks, using feeding and dressing aids when needed. The nurse, therapists, and prosthetist work with the patient to achieve maximum independence.

### HELPING THE PATIENT TO ACHIEVE PHYSICAL MOBILITY

Positioning assists in preventing the development of hip or knee joint contracture in the patient with a lower extremity amputation. Abduction, external rotation, and flexion of the lower extremity are avoided. Depending on the surgeon's preference, the residual limb may be placed in an extended position or elevated for a brief period after surgery. The foot of the bed is raised to elevate the residual limb.

**NURSING ALERT** The residual limb should not be placed on a pillow, because a flexion contracture of the hip may result.

The nurse encourages the patient to turn from side to side and to assume a prone position, if possible, to stretch the flexor muscles and to prevent flexion contracture of the hip. The nurse discourages sitting for prolonged periods, to prevent flexion contracture. The legs should remain close together to prevent an abduction deformity.

Postoperative ROM exercises are started early, because contracture deformities develop rapidly. ROM exercises include hip and knee exercises for below-knee amputations and hip exercises for above-knee amputations. It is important that the patient understand the importance of exercising the residual limb.

The upper extremities, trunk, and abdominal muscles are exercised and strengthened. The extensor muscles in the arm and the depressor muscles in the shoulder play an important part in crutch walking. The patient uses an overhead trapeze to change position and strengthen the biceps. The patient may flex and

extend the arms while holding weights. Doing push-ups while seated strengthens the triceps muscles. Exercises, such as hyperextension of the residual limb, conducted under the supervision of the physical therapist or occupational therapist, also aid in strengthening muscles as well as increasing circulation, reducing edema, and preventing atrophy.

Because an upper extremity amputee uses both shoulders to operate the prosthesis, the muscles of both shoulders are exercised. A patient with an above-the-elbow amputation or shoulder disarticulation is likely to develop a postural abnormality caused by loss of the weight of the amputated extremity. Postural exercises are helpful.

Strength and endurance are assessed, and activities are increased gradually to prevent fatigue. As the patient progresses to independent use of the wheelchair, use of ambulatory aids, or ambulation with a prosthesis, the nurse emphasizes safety considerations. Environmental barriers (eg, steps, inclines, doors, wet surfaces) are identified, and methods of managing them are practiced. It is important to anticipate, identify and manage problems associated with the use of the mobility aids (eg, pressure on the axillae from crutches, skin irritation of the hands from wheelchair use, residual limb irritation from a prosthesis).

Amputation of the leg changes the center of gravity; therefore, the patient may need to practice position changes (eg, standing from sitting, standing on one foot). The patient is taught transfer techniques early and is reminded to maintain good posture when getting out of bed. A well-fitting shoe with a nonskid sole should be worn. During position changes, the patient should be guarded and stabilized with a transfer belt at the waist to prevent falling.

As soon as possible, the patient with a lower extremity amputation is assisted to stand between parallel bars to allow extension of the temporary prosthesis to the floor with minimal weight bearing. How soon after surgery the patient is allowed to touch down the artificial foot depends on the patient's physical status and wound healing. As endurance increases and balance is achieved, ambulation is started with the use of parallel bars or crutches. The patient learns to use a normal gait, with the residual limb moving back and forth while the patient is walking with the crutches. To prevent a permanent flexion deformity from occurring, the residual limb should *not* be held up in a flexed position.

The patient with an upper extremity amputation is taught how to carry out the ADLs with one arm. The patient is started on one-handed self-care activities as soon as possible. The use of a temporary prosthesis is encouraged. The patient who learns to use the prosthesis soon after the amputation is less dependent on one-handed self-care activities.

A patient with an upper extremity amputation may wear a cotton T-shirt to prevent contact between the skin and shoulder harness and to promote absorption of perspiration. The prosthetist advises about cleaning the washable portions of the harness. Periodically, the prosthesis is inspected for potential problems.

The residual limb must be conditioned and shaped into a conical form to permit accurate fit, maximum comfort, and function of the prosthetic device. Elastic bandages, an elastic residual limb shrinker, or an air splint is used to condition and shape the residual limb. The nurse teaches the patient or a member of the family the correct method of bandaging.

Bandaging supports the soft tissue and minimizes the formation of edema while the residual limb is in a dependent position. The bandage is applied in such a manner that the remaining muscles required to operate the prosthesis are as firm as possible, whereas those muscles that are no longer useful atrophy. An im-

properly applied elastic bandage contributes to circulatory problems and a poorly shaped residual limb.

Effective preprosthetic care is important to ensure proper fitting of the prosthesis. The major problems that can delay prosthetic fitting during this period are (1) flexion deformities, (2) nonshrinkage of the residual limb, and (3) abduction deformities of the hip.

The physician usually prescribes activities to condition or "toughen" the residual limb in preparation for a prosthesis. The patient begins by pushing the residual limb into a soft pillow, then into a firmer pillow, and finally against a hard surface. The patient is taught to massage the residual limb to mobilize the surgical incision site, decrease tenderness, and improve vascularity. Massage is usually started once healing has occurred and is first done by the physical therapist. Skin inspection and preventive care are taught.

The prosthesis socket is custom molded to the residual limb by the prosthetist. Prostheses are designed for specific activity levels and patient abilities. Types of prostheses include hydraulic, pneumatic, biofeedback-controlled, myoelectrically controlled, and synchronized prostheses.

Adjustments of the prosthetic socket are made by the prosthetist to accommodate the residual limb changes that occur during the first 6 months to 1 year after surgery. A light plaster cast, an elastic bandage, or a shrinking sock is used to limit edema during periods when the patient is not wearing the permanent prosthesis.

Some patients are not candidates for a prosthesis and are thus *nonambulatory amputees*. If use of a prosthesis is not possible, the patient is instructed in the use of a wheelchair to achieve independence. A special wheelchair designed for patients who have had amputations is recommended. Because of the decreased weight in the front, a regular wheelchair may tip backward when the patient sits in it. In an amputee wheelchair, the rear axle is set back about 5 cm (2 inches) to compensate for the change in weight distribution.

## MONITORING AND MANAGING POTENTIAL COMPLICATIONS

After any surgery, efforts are made to reestablish homeostasis and to prevent problems related to surgery, anesthesia, and immobility. The nurse assesses body systems (eg, respiratory, gastrointestinal, genitourinary) for problems associated with immobility (eg, pneumonia, anorexia, constipation, urinary stasis) and institutes corrective management. Avoiding problems associated with immobility and restoring physical activity are necessary for maintenance of health.

Massive *hemorrhage* due to a loosened suture is the most threatening problem. The nurse monitors the patient for any signs or symptoms of bleeding. It is also important to monitor the patient's vital signs and to observe the suction drainage.

**NURSING ALERT** Immediate postoperative bleeding may develop slowly or may take the form of a massive hemorrhage resulting from a loosened suture. A large tourniquet should be in plain sight at the patient's bedside so that, if severe bleeding occurs, it can be applied to the residual limb to control the hemorrhage. The nurse immediately notifies the surgeon in the event of excessive bleeding.

*Infection* is a frequent complication of amputation. Patients who have undergone traumatic amputation have a contaminated wound. The nurse administers antibiotics as prescribed. It is important to monitor the incision, dressing, and drainage for indications of infection (eg, change in color, odor, or consistency of drainage; increasing discomfort). The nurse also monitors for

systemic indicators of infection (eg, elevated temperature) and promptly reports indications of infection to the surgeon.

*Skin breakdown* may result from immobilization or from pressure from various sources. The prosthesis may cause pressure areas to develop. The nurse and the patient assess for breaks in the skin. Careful skin hygiene is essential to prevent skin irritation, infection, and breakdown. The healed residual limb is washed and dried (gently) at least twice daily. The skin is inspected for pressure areas, dermatitis, and blisters. If they are present, they must be treated before further skin breakdown occurs. Usually, a residual limb sock is worn to absorb perspiration and to prevent direct contact between the skin and the prosthetic socket. The sock is changed daily and must fit smoothly to prevent irritation caused by wrinkles. The socket of the prosthesis is washed with a mild detergent, rinsed, and dried thoroughly with a clean cloth. The nurse advises the patient that the socket must be thoroughly dry before the prosthesis is applied.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching the Patient to Manage Self-Care

Before discharge to the home or to a rehabilitation facility, the nurse encourages the patient and family to become active participants in care. They participate, as appropriate, in skin care and residual limb care and in the management of the prosthesis. The patient receives ongoing instructions and practice sessions in learning how to transfer and how to use mobility aids and other assistive devices safely. The nurse explains the signs and symptoms of complications that must be reported to the physician (Chart 69-5).

### Continuing Care in the Home and Community

After the patient has achieved physiologic homeostasis and has demonstrated achievement of major health care goals, rehabilitation continues either in a rehabilitation facility or at home. Continued support and supervision by the home care nurse are essential.

Before the patient's discharge to the home, the nurse should assess the home environment. Modifications are made to ensure the

patient's continuing care, safety, and mobility. An overnight or weekend experience at home may be tried to identify problems that were not identified on the assessment visit. Physical therapy and occupational therapy may continue in the home or on an outpatient basis. Transportation to continuing health care appointments must be arranged. The social service department of the hospital or the community agency managing continued health care may be of great assistance in securing personal assistance and transportation services.

During follow-up health visits, the nurse evaluates the patient's physical and psychosocial adjustment. Periodic preventive health assessments are necessary. Frequently, an elderly spouse is unable to provide the assistance required, and additional help at home is needed. Modifications in the plan of care are made on the basis of such findings. Often, the patient and family find involvement in an amputee support group to be of value; here, they are able to share problems, solutions, and resources. Talking with those who have successfully dealt with a similar problem may help the patient develop a satisfactory solution.

Because patients and their family members and health care providers tend to focus on the most obvious needs and issues, the nurse reminds the patient and family about the importance of continuing health promotion and screening practices, such as regular physical examinations and diagnostic screening tests. Those patients who have not been involved in these practices in the past are instructed in their importance and are referred to appropriate health care providers.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Experiences absence of pain
  - a. Appears relaxed
  - b. Verbalizes comfort
  - c. Uses measures to increase comfort
  - d. Participates in self-care and rehabilitative activities

Chart 69-5

### Home Care Checklist • Amputation

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Describe approaches to controlling pain (eg, take analgesics as prescribed; use nonpharmacologic interventions).	✓	✓
• Report pain that is uncontrolled by analgesics and other pain management techniques.	✓	
• Describe care of residual limb and conditioning for prosthesis.	✓	✓
• Consume healthy diet to promote wound healing.	✓	
• Demonstrate ability to transfer.	✓	
• Use mobility and activity aids safely.	✓	
• Participate in rehabilitation program to regain functional independence.	✓	✓
• State indicators of complication to report promptly to physician (eg, uncontrolled pain; signs of local or systemic infection; residual limb skin breakdown).	✓	✓
• Identify professionals and community agencies to help with transition to home.	✓	✓
• Identify support group to facilitate rehabilitation.	✓	
• Describe effects of amputation on self-image.	✓	
• Acknowledge grieving as part of coping process.	✓	
• Identify modifications of home environment to promote safe environment and independence during rehabilitation.	✓	✓

2. Experiences absence of phantom limb pain
  - a. Reports diminished phantom sensations
  - b. Uses distraction techniques
  - c. Performs stump desensitization massage
3. Achieves wound healing
  - a. Controls residual limb edema
  - b. Achieves healed, nontender, nonadherent scar
  - c. Demonstrates residual limb care
4. Demonstrates improved body image and effective coping
  - a. Acknowledges change in body image
  - b. Participates in self-care activities
  - c. Demonstrates increasing independence
  - d. Projects self as a whole person
  - e. Resumes role-related responsibilities
  - f. Reestablishes social contacts
  - g. Demonstrates confidence in abilities
5. Exhibits resolution of grieving
  - a. Expresses grief
  - b. Works through feelings with family and friends
  - c. Focuses on future functioning
  - d. Participates in support group
6. Achieves independent self-care
  - a. Asks for assistance when needed
  - b. Uses aids and assistive devices to facilitate self-care
  - c. Verbalizes satisfaction with abilities to perform ADLs
7. Achieves maximum independent mobility
  - a. Avoids positions contributing to contracture development
  - b. Demonstrates full active ROM
  - c. Maintains balance when sitting and transferring
  - d. Increases strength and endurance
  - e. Demonstrates safe transferring technique
  - f. Achieves functional use of prosthesis
  - g. Overcomes environmental barriers to mobility
  - h. Uses community services and resources as needed
8. Exhibits absence of complications of hemorrhage, infection, skin breakdown
  - a. Does not experience excessive bleeding
  - b. Maintains normal blood values
  - c. Is free of local or systemic signs of infection
  - d. Repositions self frequently
  - e. Is free of pressure-related problems
  - f. Reports any skin discomfort and irritations promptly

discussion of the need for surgery and external fixation? Describe the anticipated postoperative care, monitoring to prevent complications, and activity restrictions.

**3.** A middle-aged patient who had been hospitalized for 3 days with a fractured pelvis is making plans for discharge. His wife approaches you and expresses concern that he has become very irritable and that he “just doesn’t seem to be himself.” Analyze this information and identify the possible causes for this behavior. Describe additional data that you would seek to further assess the situation.

**4.** You make a home health care visit to a middle-aged patient with type 2 diabetes who had a partial foot amputation 4 days ago because of peripheral vascular disease and gangrene. What is the rationale for the assessment data you gather to assist you in determining the patient’s progress? What findings might suggest that the patient is developing a problem? Describe your plan of action for each of these potential problems. What home environment factors would you include in your assessment of the home care situation?

## Critical Thinking Exercises

**1.** Your church is participating in a women’s soccer league and asks you to help out with first aid on the field. Common injuries you would expect include sprains, strains, and, possibly, dislocations and fractures. What specific assessment would you make to differentiate these problems? Discuss the emergency management for each of these problems. Explain your rationale for these emergency interventions.

**2.** A 46-year-old man experiences an open fracture of his right ankle while skiing. The orthopedic surgeon recommends surgery and external fixation. The patient asks why surgery is needed—a lot of his friends have broken their ankles, have not had surgery, and have just had a cast put on for a couple of weeks. What would you include in your

- generation bisphosphonate pamidronate. *Clinical Rheumatology*, 16(1), 51–56.

# Management of Patients With Infectious Diseases

## LEARNING OBJECTIVES

*On completion of this chapter, the learner will be able to:*

1. Differentiate between colonization, infection, and disease.
2. Use information obtained from the microbiology report to interpret infectious disease evidence.
3. Identify federal and local resources available to the nurse seeking information about infectious diseases.
4. Identify the merit of vaccines recommended for health care workers.
5. Identify the reasons for Standard and Transmission-Based Precautions and discuss recommended behaviors.
6. Describe the concept of emerging infectious diseases and factors that lead to the development of these diseases.
7. List potential biological warfare agents and describe recommended precautions.
8. Use the nursing process as a framework for care of patients with sexually transmitted disease.
9. Describe home health care measures that reduce the risk for infection.
10. Use the nursing process as a framework for care of patients with infectious diseases.

An infectious disease is any disease caused by the growth of pathogenic microbes in the body. It may or may not be communicable (ie, contagious). Modern science has controlled, eradicated, or decreased the incidence of many infectious diseases. However, increases in other infections, such as those caused by antibiotic-resistant organisms and emerging infectious diseases, are of great concern. Examples of these types of infectious diseases are highlighted in this chapter. Other infectious diseases are discussed in the appropriate chapters, such as the information on tuberculosis (TB) found in Chapter 23.

It is important to understand infectious causes and treatment for contagious, serious, and common infections. Table 70-1 presents an overview of many infectious diseases, their causative organisms, mode of transmission, and usual **incubation periods** (ie, time between contact and development of the first signs and symptoms).

The nurse has an important role in infection control and prevention activities. Educating patients may decrease their risk of becoming infected or may decrease the sequelae of infection. Using appropriate barrier precautions, observing prudent hand hygiene, and ensuring aseptic care of intravenous catheters and other interventional equipment also assists in reducing infections.

## The Infectious Process

A complete chain of events is necessary for infection to occur. Figure 70-1 illustrates the elements of the chain and identifies weak links where health care workers' interventions can interrupt the chain. The necessary elements of infection include the following:

- A causative organism
- A reservoir of available organisms

- A portal or mode of exit from the reservoir
- A mode of transmission from reservoir to host
- A susceptible host
- A mode of entry to host

## ELEMENTS OF INFECTION

### Causative Organism

The types of microorganisms that cause infections are bacteria, rickettsiae, viruses, protozoa, fungi, and helminths.

### Reservoir

**Reservoir** is the term used for any person, plant, animal, substance, or location that provides nourishment for microorganisms and enables further dispersal of the organism. Infections may be prevented by eliminating the causative organisms from the reservoir.

### Mode of Exit

The organism must have a mode of exit from a reservoir. An infected host must shed organisms to another or to the environment before transmission can occur. Organisms exit through the respiratory tract, the gastrointestinal tract, the genitourinary tract, and the blood.

### Route of Transmission

A route of transmission is necessary to connect the infectious source with its new host. Organisms may be transmitted through sexual contact, skin-to-skin contact, percutaneous injection, or

## Glossary

**bacteremia:** laboratory-proven presence of bacteria in the bloodstream

**carrier:** person who carries an organism without apparent signs and symptoms; one who is able to transmit an infection to others

**Centers for Disease Control and Prevention (CDC):** federal agency responsible for monitoring endemic and epidemic disease, for recommending strategies to decrease disease incidence, and for developing guidelines to reduce risk to patients and health care workers

**colonization:** microorganisms present in or on a host, without host interference or interaction and without eliciting symptoms in the host

**disease:** state in which the infected host displays a decline in health due to the infection

**emerging infectious diseases:** human infectious diseases with incidence increased within the past two decades or potential increase in the near future

**fungemia:** a bloodstream infection caused by a fungal organism

**high-level disinfection:** removal of all microorganisms, with the possible exception of spores. This level of disinfection is appropriate for instruments that come in

contact with mucous membranes but that cannot be sterilized because of mechanical issues.

**host:** person who provides living conditions to support a microorganism

**immune:** person with protection from a previous infection or immunization who resists reinfection when re-exposed to the same agent

**incubation period:** time between contact and onset of signs and symptoms

**infection:** condition in which the host interacts physiologically and immunologically with a microorganism

**latency:** time interval after primary infection when a microorganism lives within the host without producing clinical evidence

**methicillin-resistant *Staphylococcus aureus* (MRSA):** *Staphylococcus aureus* bacterium that is not susceptible to extended-penicillin antibiotic formulas, such as methicillin, oxacillin, or nafcillin

**normal flora:** persistent nonpathogenic organisms colonizing a host

**nosocomial infection:** infection acquired in the hospital that was not present or incubating at the time of hospital admission

**reservoir:** any person, plant, animal, substance, or location that provides living

conditions for microorganisms and that enables further dispersal of the organism

**Standard Precautions:** strategy of assuming all patients may carry infectious agents and using appropriate barrier precautions for all health care worker-patient interactions

**sterilization:** complete removal of all microorganisms

**susceptible:** not possessing immunity to a particular pathogen

**transient flora:** organisms that have been recently acquired and are likely to be shed in a relatively short period

**Transmission-Based Precautions:** precautions used in addition to Standard Precautions when contagious or epidemiologically significant organisms are recognized. The three types of Transmission-Based Precautions are Airborne, Droplet, and Contact Precautions.

**vancomycin-resistant *Staphylococcus aureus* (VISA):** *Staphylococcus aureus* bacterium that is not susceptible to vancomycin

**vancomycin-resistant *Enterococcus* (VRE):** *Enterococcus* bacterium that is resistant to the antibiotic vancomycin

**virulence:** degree of pathogenicity of an organism

**Table 70-1 • Infectious Diseases, Causative Organisms, Modes of Transmission, and Usual Incubation Period**

DISEASE OR CONDITION	ORGANISM	USUAL MODE OF TRANSMISSION	USUAL INCUBATION PERIOD (INFECTION TO FIRST SYMPTOM)
Acquired immunodeficiency syndrome (AIDS)	Human immunodeficiency virus (HIV)	Sexual; percutaneous; perinatal	Median of 10 yr
Amebiasis	<i>Entamoeba histolytica</i>	Contaminated water	2–4 wk
Anthrax	<i>Bacillus anthracis</i>	Airborne or contact	2–60 days
Chancroid	<i>Haemophilus ducreyi</i>	Sexual	3–5 days
Chickenpox	Varicella zoster	Airborne or contact	About 14 days
Cholera	<i>Vibrio cholerae</i>	Ingestion of water contaminated with human waste	A few hours to 5 days
Cryptococcosis	<i>Cryptococcus neoformans</i>	Probably by inhalation	Unknown
Cryptosporidiosis	<i>Cryptosporidium</i> species	Ingestion of contaminated water; direct contact with carrier	Probably 1–12 days
Cytomegalovirus (CMV) infection	Cytomegalovirus	Transfusion and transplantation; sexual; perinatal	Highly variable: 3–8 wk after transfusion, 3–12 wk after delivery of newborn
Diarrheal disease (common causes)	<i>Campylobacter</i> species	Ingestion of contaminated food	3–5 days
	<i>Clostridium difficile</i>	Fecal–oral	Variable; in part related to the influence of antibiotics
	<i>Salmonella</i> species	Ingestion of contaminated food or drink	12–36 hr
	<i>Shigella</i> species	Ingestion of contaminated food or drink; direct contact with carrier	1–3 days
	<i>Yersinia</i> species	Ingestion of contaminated food or drink; direct contact with carrier	1–3 days
Ebola	Ebola virus	Contact with blood or body fluids	2–21 days
Gonorrhea	<i>Neisseria gonorrhoeae</i>	Sexual; perinatal	2–7 days
Hand, foot, and mouth disease	Coxsackievirus	Direct contact with nose and throat secretions and with feces of infected people	3–5 days
Hantavirus pulmonary syndrome (HPS)	Sin nombre virus	Contact (direct or indirect) with rodents	Unclear
Foodborne hepatitis	Hepatitis A virus	Ingestion of contaminated food or drink; direct contact with carrier	15–50 days
	Hepatitis E virus	Ingestion of contaminated food or drink; direct contact with carrier	Unclear
Bloodborne hepatitis	Hepatitis B virus	Sexual; perinatal; percutaneous	45–160 days
	Hepatitis C virus	Sexual; perinatal; percutaneous	6–9 mo
	Hepatitis D	Sexual; perinatal; percutaneous	Unclear
	Hepatitis G	Percutaneous	Unclear
Herpangina	Coxsackievirus	Direct contact with nose and throat secretions and feces of infected people	3–5 days
Herpes simplex	Human herpesvirus 1 and 2	Contact with mucous membrane secretions	2–12 days
Histoplasmosis	<i>Histoplasma capsulatum</i>	Inhalation of airborne spores	5–18 days
Hookworm disease	<i>Necator americanus</i> ; <i>Ancylostoma duodenale</i>	Contact with soil contaminated with human feces	A few weeks to many months
Impetigo	<i>Staphylococcus aureus</i>	Contact with <i>S. aureus</i> carrier	4–10 days
Influenza	Influenza virus A, B, or C	Droplet spread	24–72 hr
Lassa fever	Lassa virus	Contact with animal droppings; direct contact with blood or body fluids	7–21 days
Legionnaires' disease	<i>Legionella pneumophila</i>	Airborne from water source	2–10 days
Listeriosis	<i>Listeria monocytogenes</i>	Foodborne; perinatal	Unclear; probably 3–70 days
Lyme disease	<i>Borrelia burgdorferi</i>	Tick bite	14–23 days
Lymphogranuloma venereum	<i>Chlamydia inguinale</i>	Sexual	Weeks to years
Malaria	<i>Plasmodium vivax</i> ; <i>Plasmodium malariae</i> ; <i>Plasmodium falciparum</i> ; <i>Plasmodium ovale</i>	Bite from <i>Anopheles</i> species mosquito	12–30 days
Meningococcal meningitis or bacteremia	<i>Neisseria meningitidis</i>	Contact with pharyngeal secretions; perhaps airborne	2–10 days

(continued)

**Table 70-1 • Infectious Diseases, Causative Organisms, Modes of Transmission, and Usual Incubation Period (Continued)**

DISEASE OR CONDITION	ORGANISM	USUAL MODE OF TRANSMISSION	USUAL INCUBATION PERIOD (INFECTION TO FIRST SYMPTOM)
Mononucleosis	Epstein-Barr virus	Contact with pharyngeal secretions	4–6 weeks
Mycobacterial diseases (nontuberculosis species)	<i>Mycobacterium avium</i> ; <i>Mycobacterium kansasii</i> ; <i>Mycobacterium fortuitum</i> ; <i>Mycobacterium goodii</i> ; other <i>Mycobacterium</i> species	Variable; probably contact with soil, water, or other environmental source; none is transmissible person-to-person	Variable
Mycoplasma pneumoniae pneumonia	<i>Mycoplasma pneumoniae</i>	Droplet inhalation	14–21 days
Pediculosis	<i>Pediculus humanus capitis</i> (head louse); <i>Phthirus pubis</i> (crab louse)	Direct contact	1–2 wk
Pinworm disease	<i>Enterobius vermicularis</i>	Direct contact with egg-contaminated articles	4- to 6-wk life cycle; often takes months of infection before recognition
<i>Pneumocystis carinii</i> pneumonia	<i>Pneumocystis carinii</i>	Unknown; not transmitted person-to-person	Infants: 1–2 mo; adults: unclear
Pneumococcal pneumonia	<i>Streptococcus pneumoniae</i>	Droplet spread	Probably 1–3 days
Rabies	Rabies virus	Bite from rabid animal	2–8 wk
Respiratory syncytial disease	Respiratory syncytial virus	Self-inoculation by mouth or nose after contact with infectious respiratory secretions	3–7 days
Ringworm	<i>Microsporum</i> species; <i>Trichophyton</i> species	Direct and indirect contact with lesions	4–10 days
Rocky mountain spotted fever	<i>Rickettsia rickettsii</i>	Bite from infected tick	3–14 days
Roseola infantum	Human herpes virus 6	Saliva	10–15 days
Rotavirus gastroenteritis	Rotavirus	Fecal–oral route	About 48 hr
Rubella	Rubella virus	Droplet spread; direct contact	14–21 days
Scabies	<i>Sarcoptes scabiei</i>	Direct skin contact	2–6 wk
Smallpox	<i>Variola major</i>	Airborne and contact	7–14 days
Syphilis	<i>Treponema pallidum</i>	Sexual; perinatal	10 days to 10 wk
Tetanus	<i>Clostridium tetani</i>	Puncture wound	4–21 days
Trichinosis	<i>Trichinella spiralis</i>	Ingestion of insufficiently cooked foods, especially pork and beef	10–14 days
Tuberculosis	<i>Mycobacterium tuberculosis</i>	Airborne	4–12 wk to the formation of primary lesion

infectious particles carried in the air. A person who carries, or transmits, an organism and who does not have apparent signs and symptoms of infection is called a **carrier**.

It is important to recognize that different organisms require specific routes of transmission for infection to occur. For example, *Mycobacterium tuberculosis* is almost always transmitted by the airborne route. Health care providers do not “carry” *M. tuberculosis* bacteria on their hands or clothing. In contrast, bacteria such as *Staphylococcus aureus* are easily transmitted from patient to patient on the hands of health care providers.

When appropriate, the nurse should explain routes of disease transmission to patients. For example, a nurse may explain that sharing a room with a patient who is infected with human immunodeficiency virus (HIV) does not pose a risk because intimate contact (ie, sexual or parenteral) is necessary for transmission to occur.

### Susceptible Host

For infection to occur, the **host** must be **susceptible** (ie, not possessing immunity to a particular pathogen). Previous infection or vaccine administration may render the host **immune** (ie, not sus-

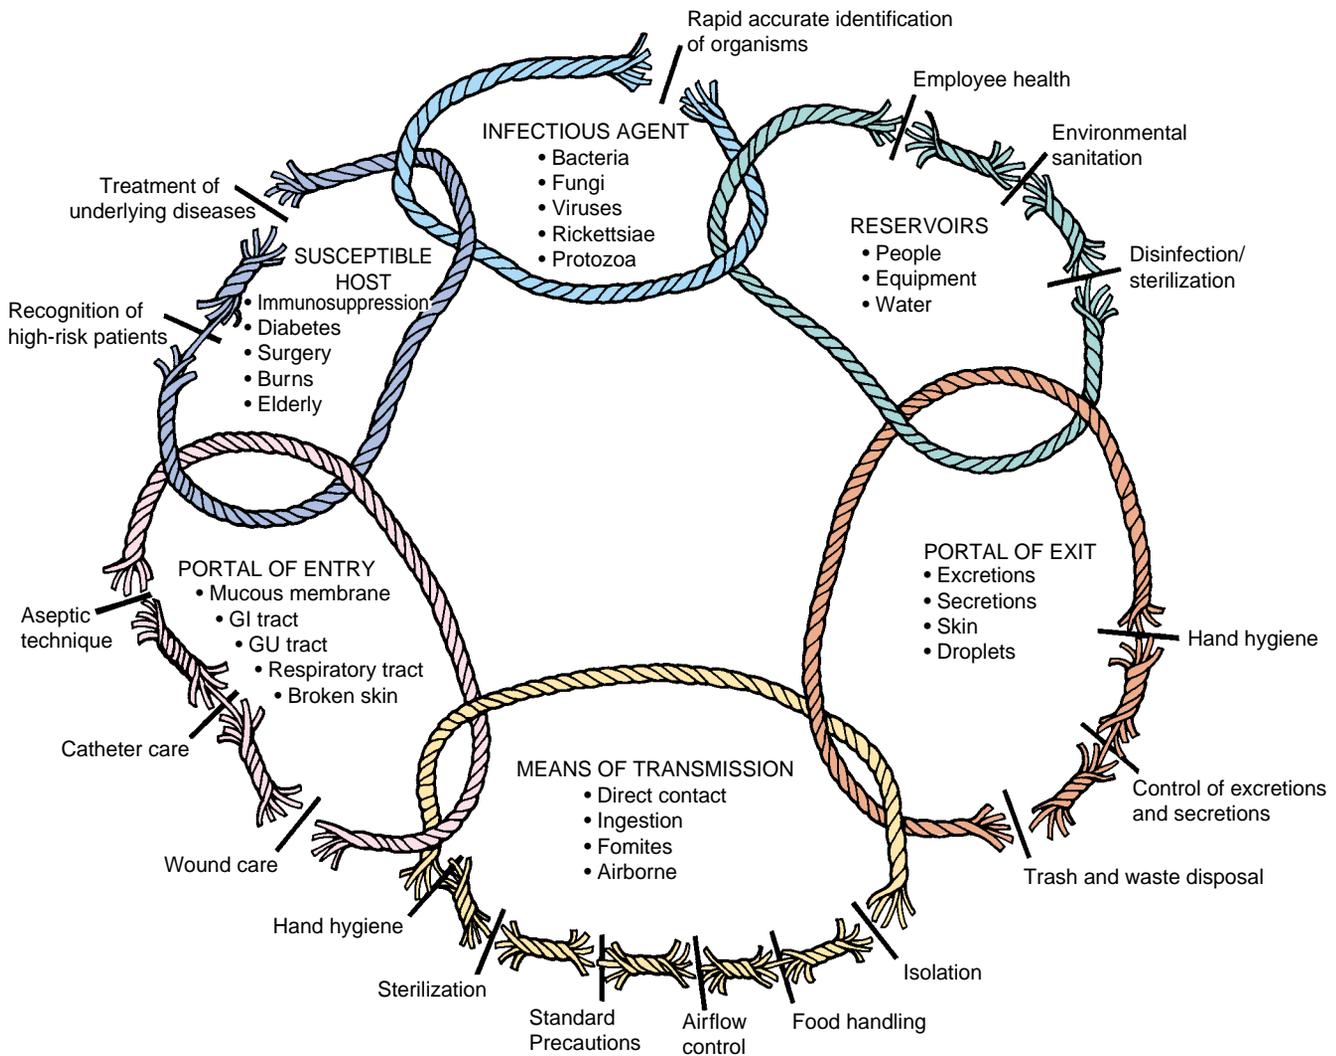

ceptible) to further infection with an agent. Many infections are prevented because of the powerful human immune defense. Although exposure to potentially infectious microorganisms occurs essentially on a constant basis, our elaborate immune systems generally prevent infection from occurring. The immune-suppressed person has much greater susceptibility than the normal, healthy host.

### Portal of Entry

A portal of entry is needed for the organism to gain access to the host. For example, airborne *M. tuberculosis* does not cause disease when it settles on the skin of an exposed host. The only entry route for the bacterium that is of concern is through the respiratory system.

### COLONIZATION, INFECTION, AND DISEASE

Relatively few anatomic sites (eg, brain, blood, bone, heart, vascular system) are sterile. Bacteria found throughout the body usually provide beneficial **normal flora** to compete with potential

**FIGURE 70-1** Health care workers' interventions used to break the chain of infection transmission.

pathogens, to facilitate digestion, or to work in other ways symbiotically with the host.

## Colonization

The term **colonization** is used to describe microorganisms present without host interference or interaction. Understanding the principle of colonization facilitates interpretation of microbiologic reports. Organisms reported in microbiology results often reflect colonization rather than infection.

## Infection

**Infection** indicates a host interaction with an organism. A patient colonized with *S. aureus* may have staphylococci on the skin without any skin interruption or irritation. If the patient had an incision, *S. aureus* could enter the wound, with an immune system reaction of local inflammation and routing of white cells to the site. Clinical evidence of redness, heat, and pain and laboratory evidence of white cells on the wound specimen smear suggest infection. In this example, the host identifies the staphylococci as *foreign*. Infection is recognized by the host reaction and by organism identification.

## Disease

It is important to recognize the difference between infection and **disease**. Infectious disease is the state in which the infected host displays a decline in wellness due to the infection. When the host interacts immunologically with an organism but remains symptom free, the definition of disease has not been met. *M. tuberculosis* is an example of an organism that often persists as infection without producing disease. The host may become infected after exposure to the tubercle bacillus. The person is *infected* when bacteria are first detected by nonspecific immunologic recognition and later as newly sensitized T cells propagate daughter lines of TB-specific protective cells. After this initial infection, the untreated host has a low probability of actually becoming ill. About 90% of hosts infected with the *M. tuberculosis* do not develop TB, the disease. Figure 70-2 depicts response to bacterial infection at the cellular level and at the host level.

## MICROBIOLOGY REPORT

The primary source of information about most bacterial infections is the microbiology report. The microbiology report should be viewed as a tool to be used along with clinical indicators to determine whether a patient is colonized, infected, or diseased.

**FIGURE 70-2** Biologic spectrum of response to bacterial infection at the cellular level (*left*) and of the intact host (*right*). Redrawn from Evans, A. S., & Brachman, P. S. (1998). *Bacterial infections in humans*. New York: Plenum.

When specimens are sent to the laboratory for culture, results usually show three components: the smear and stain, the culture and organism identification, and the antimicrobial susceptibility (ie, sensitivity). As a marker for the likelihood of infection, the smear and stain generally provides the most helpful information because it describes the mix of cells present at the site at the time of specimen collection. Culture and sensitivity processes specify which organisms are recognized and which antibiotics inhibit growth.

## Infection Control and Prevention

### ORGANIZATIONS INVOLVED IN INFECTION PREVENTION

The Centers for Disease Control and Prevention (CDC) and the Occupational Safety and Health Administration (OSHA) are federal agencies involved in controlling and preventing infection.

#### Centers for Disease Control and Prevention

The impact of infectious diseases changes through time as microorganisms mutate, as human behavior patterns shift, or as therapeutic options change. The **Centers for Disease Control and Prevention (CDC)** serve an important function in providing timely scientific recommendations about many of the situations that a nurse may face when caring for or teaching a patient with an infectious disease. The CDC routinely publishes recommendations, guidelines, and summaries. Through its Internet site (<http://www.cdc.gov>) and its weekly journal, the *Morbidity and Mortality Weekly Report* (MMWR), the CDC reports significant cases, outbreaks, environmental hazards, or other public health problems. Examples of important CDC guidelines and summaries are *Guide-*

*lines for Preventing the Transmission of Tuberculosis in Health Care Facilities, Recommendations for Prevention of HIV Transmission in Health Care Settings, Sexually Transmitted Diseases Treatment Guidelines, and Standards for Pediatric Immunization Practices.*

### Occupational Safety and Health Administration

In contrast to the CDC goal of *disease reduction*, the goal of the Occupational Safety and Health Administration (OSHA) is the *reduction of risk exposure*. CDC Guidelines are voluntary, whereas OSHA publishes mandatory regulations and imposes fines on those found to be noncompliant. OSHA requires that all health care providers have routine educational updates about prevention of bloodborne pathogens and about TB control. Because each health care institution is required to prepare and disseminate to its employees a bloodborne exposure plan and a TB exposure plan, nurses should be familiar with the details of control in their specific institutions.

### PREVENTING INFECTION IN THE COMMUNITY

Prevention and control of infection in the community are goals shared by the CDC and state and local public health departments. Much of public health emphasis is placed on prevention to avoid outbreaks and other situations that require control. Methods of infection prevention include sanitation techniques (eg, water purification, disposal of sewage and other potentially infectious materials), regulated health practices (eg, handling, storage, packaging, preparation of food by institutions), and immunization programs. In the United States, immunization programs have markedly decreased the incidence of infectious diseases.

## Vaccination Programs

The goal of vaccination programs is to use wide-scale efforts to prevent specific infectious diseases from occurring in a population. Public health decisions about vaccine campaign implementation efforts are complex. Risks and benefits for the individual and the community must be evaluated in terms of morbidity, mortality, and financial benefit.

The most successful vaccine programs are those for the prevention of smallpox, measles, mumps, rubella, chicken pox, polio, diphtheria, pertussis, and tetanus. Concerns that smallpox may be reintroduced as an act of biowarfare have led to a decision that medical first responders and selected others should again receive small pox vaccine. Bioterrorism is addressed in Chapter 72.

More than 25 vaccines are licensed in the United States. Vaccines are made of antigen preparations in a suspension and are intended to produce a human immune response to protect the host from future encounters with the organism. No vaccine is completely safe for all recipients. Some people are allergic to the antigen or the carrier substance. When live organisms are used as antigen, the actual disease (often with a modified course) may follow. Contraindications on package inserts of a vaccine must be heeded. These guidelines detail studied experience with allergy and other complications and provide crucial information about refrigeration, storage, dosage, and administration.

Variations to the recommended vaccination schedule should be made on a case-by-case basis, depending on the patient's risk factors and ability to return for follow-up vaccinations at the appointed time. For example, although the first dose of measles vaccine is recommended at the age of 12 to 15 months, babies in developing countries (where measles contributes significantly to childhood morbidity and mortality) should be vaccinated at 9 months.

The standard recommended vaccination schedule for infants and children as developed by the CDC is shown in Table 70-2. The schedule is revised as epidemiologic evidence warrants, and nurses are advised to consult the CDC to determine the most recent schedule.

Vaccine recommendations for adults are designed to protect those with underlying diseases that increase infection risk, those with potential for occupational exposure, and those who may be exposed to infectious agents during travel. Immunosuppressed adults (including those who have had splenectomy) should be vaccinated for pneumococcus (*Streptococcus pneumoniae*), meningococcus (*Neisseria meningitidis*), and *Haemophilus influenzae*. Health care workers should be immune to measles, mumps, rubella, hepatitis B, and varicella. It is strongly recommended that all of the previously described adult groups and those with asthma or other chronic respiratory conditions receive annual influenza vaccine.

Information about individual vaccines or the most current vaccine schedules may be found on the Internet (<http://www.cdc.gov/nip/publications/ACIP.list>). The CDC also provides a 24-hour telephone hotline (800-232-2522) for information about routine pediatric or adult vaccine advice. Advice about optimal vaccination for travelers is available on the Internet (<http://www.cdc.gov/travel/vaccinat>), by phone (877-FYI-TRIP), and by a toll-free fax number (888-232-3299) to request information.

Nurses should ask parents or adult vaccine recipients to provide information about any problems encountered after vaccination. As mandated by law, a Vaccine Adverse Event Reporting System (VAERS) form must be completed with the following

information: type of vaccine received, timing of vaccination, onset of the adverse event, current illnesses or medication, history of adverse events after vaccination and demographic information about the recipient. Forms are obtained by phoning 1-800-822-7967 or through the Internet (<http://www.cdc.gov/nip/vaers.htm>).

The incidence of vaccine-preventable diseases, such as measles, mumps, rubella, and diphtheria, is affected by immigration from developing countries. Vaccine campaigns in developing countries are often financially and logistically constrained, and immigrants from such areas may be more likely than U.S. residents to be unprotected and may increase the potential pathways for epidemic spread. Individual risk and epidemic risk are reduced when vaccination campaigns reach all communities, including those with a high proportion of immigrants.

## CONTRAINDICATIONS

Patients who have experienced previous anaphylaxis or similar reactions; patients who have developed encephalopathy within 7 days of a previous diphtheria, tetanus, and pertussis (DTP) dose; and those who have developed other moderate or severe sequelae after a previous dose should not receive further doses. DTP is often deferred for the child who previously developed a fever higher than 40°C (104°F) within 48 hours of vaccination or who had a seizure or developed a shocklike state within 3 days of previous vaccination. Live vaccines usually are not indicated for patients or close contacts of patients with severe immunosuppression (eg, HIV infection, leukemia, lymphoma, generalized malignancy, significant corticosteroid use, use of immunosuppressive medications to prevent transplant rejection). The measles, mumps, and rubella vaccine should not be administered to pregnant women.

## MEASLES, MUMPS, AND RUBELLA VACCINE

Since the measles, mumps, and rubella (MMR) vaccines were licensed, reported cases of these diseases have decreased by more than 99% in the United States (ie, fewer than 500 cases per year since 1999). All public health departments are encouraged to vigorously promote vaccination for all children and for susceptible adults unless contraindicated. Routine MMR vaccination should be given to children at 12 to 15 months of age, with repeat dosing at 4 to 6 years of age (Atkinson et al., 2002).

All who work in health care should demonstrate immunity to these three viruses by one of the following: birth date before 1957, documented administration of two doses of vaccine, laboratory evidence of immunity, or documentation of physician-diagnosed measles or mumps.

**Side Effects.** Epidemiologic evidence supports that the risk for side effects is greater in nonimmune vaccine recipients than in those receiving repeat doses. Patients should be advised that fever, transient lymphadenopathy, or hypersensitivity reaction might occur. Antipyretics may be used to decrease the risk for fever, but aspirin should be avoided in infants and children because of the risk for Reye's syndrome.

## VARICELLA (CHICKENPOX) VACCINE

Varicella zoster is the causative viral agent of chickenpox and herpes zoster. In its natural state, the varicella virus attacks most individuals as children, causing disseminated disease in the form of chickenpox. Chickenpox is often more severe in adults. Transmission occurs by the airborne and contact routes. With rare exception, varicella infects an individual only once. The in-

**Table 70-2 • Recommended Childhood Immunization Schedule, United States, 2002**

Vaccine ▼	Age ►	range of recommended ages				catch-up vaccination			preadolescent assessment			
		Birth	1 mos	2 mos	4 mos	6 mos	12 mos	15 mos	18 mos	24 mos	4-6 yrs	11-12 yrs
Hepatitis B <sup>1</sup>		Hep B #1 <small>only if mother HBsAg (-)</small>	Hep B #2		Hep B #3			Hep B series

<i>Haemophilus influenzae</i> Type b <sup>3</sup>			Hib	Hib	Hib	Hib						
Inactivated Polio			IPV	IPV	IPV					IPV		
Measles, Mumps, Rubella <sup>4</sup>						MMR #1				MMR #2	MMR #2	
Varicella <sup>5</sup>						Varicella				Varicella		
Pneumococcal <sup>6</sup>			PCV	PCV	PCV	PCV			PCV	PPV		
Vaccines below this line are for selected populations												
Hepatitis A <sup>7</sup>										Hepatitis A series		
Influenza <sup>8</sup>					Influenza (yearly)							

This schedule indicates the recommended ages for routine administration of currently licensed childhood vaccines, as of December 1, 2002, for children through age 18 years. Any dose not given at the recommended age should be given at any subsequent visit when indicated and feasible. Blue shading indicates age groups that warrant special effort to administer those vaccines not previously given. Additional vaccines may be licensed and recommended during the year. Licensed combination vaccines may be used whenever any components of the combination are indicated and the vaccine's other components are not contraindicated. Providers should consult the manufacturers' package inserts for detailed recommendations.

**1. Hepatitis B vaccine (HepB).** All infants should receive the first dose of hepatitis B vaccine soon after birth and before hospital discharge; the first dose may also be given by age 2 months if the infant's mother is HBsAg-negative. Only monovalent HepB can be used for the birth dose. Monovalent or combination vaccine containing HepB may be used to complete the series. Four doses of vaccine may be administered when a birth dose is given. The second dose should be given at least 4 weeks after the first dose, except for combination vaccines which cannot be administered before age 6 weeks. The third dose should be given at least 16 weeks after the first dose and at least 8 weeks after the second dose. The last dose in the vaccination series (third or fourth dose) should not be administered before age 6 months.

*Infants born to HBsAg-positive mothers* should receive HepB and 0.5 mL Hepatitis B Immune Globulin (HBIG) within 12 hours of birth at separate sites. The second dose is recommended at age 1–2 months. The last dose in the vaccination series should not be administered before age 6 months. These infants should be tested for HBsAg and anti-HBs at 9–15 months of age.

*Infants born to mothers whose HBsAg status is unknown* should receive the first dose of the HepB series within 12 hours of birth. Maternal blood should be drawn as soon as possible to determine the mother's HBsAg status; if the HBsAg test is positive, the infant should receive HBIG as soon as possible (no later than age 1 week). The second dose is recommended at age 1–2 months. The last dose in the vaccination series should not be administered before age 6 months.

**2. Diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP).** The fourth dose of DTaP may be administered as early as age 12 months, provided 6 months have elapsed since the third dose and the child is unlikely to return at age 15–18 months. Tetanus and diphtheria toxoids (Td) is recommended at age 11–12 years if at least 5 years have elapsed since the last dose of tetanus and diphtheria toxoid-containing vaccine. Subsequent routine Td boosters are recommended every 10 years.

**3. Haemophilus influenzae type b (Hib) conjugate vaccine.** Three Hib conjugate vaccines are licensed for infant use. If PRP-OMP (PedvaxHIB® or ComVax® [Merck]) is administered at ages 2 and 4 months, a dose at age 6 months is not required. DTaP/Hib combination products should not be used for primary immunization in infants at ages 2, 4 or 6 months, but can be used as boosters following any Hib vaccine.

**4. Measles, mumps, and rubella vaccine (MMR).** The second dose of MMR is recommended routinely at age 4–6 years but may be administered during any visit, provided at least 4 weeks have elapsed since the first dose and that both doses are administered beginning at or after age 12 months. Those who have not previously received the second dose should complete the schedule by the 11–12 year old visit.

**5. Varicella vaccine.** Varicella vaccine is recommended at any visit at or after age 12 months for susceptible children, ie, those who lack a reliable history of chickenpox. Susceptible persons aged ≥13 years should receive two doses, given at least 4 weeks apart.

**6. Pneumococcal vaccine.** The heptavalent pneumococcal conjugate vaccine (PCV) is recommended for all children age 2–23 months. It is also recommended for certain children age 24–59 months. Pneumococcal polysaccharide vaccine (PPV) is recommended in addition to PCV for certain high-risk groups. See MMWR 2000;49(RR-9):1–38.

**7. Hepatitis A vaccine.** Hepatitis A vaccine is recommended for children and adolescents in selected states and regions, and for certain high-risk groups; consult your local public health authority. Children and adolescents in these states, regions, and high risk groups who have not been immunized against hepatitis A can begin the hepatitis A vaccination series during any visit. The two doses in the series should be administered at least 6 months apart. See MMWR 1999;48(RR-12):1–37.

**8. Influenza vaccine.** Influenza vaccine is recommended annually for children age ≥6 months with certain risk factors (including but not limited to asthma, cardiac disease, sickle cell disease, HIV, diabetes, and household members of persons in groups at high risk; see MMWR 2002;51(RR-3):1–31), and can be administered to all others wishing to obtain immunity. In addition, healthy children age 6–23 months are encouraged to receive influenza vaccine if feasible because children in this age group are at substantially increased risk for influenza-related hospitalizations. Children aged ≤12 years should receive vaccine in a dosage appropriate for their age (0.25 mL if age 6–35 months or 0.5 mL if aged ≥3 years). Children aged ≤8 years who are receiving influenza vaccine for the first time should receive two doses separated by at least 4 weeks.

For additional information about vaccines, including precautions and contraindications for immunization and vaccine shortages, please visit the National Immunization Program Website at <http://www.cdc.gov/nip> or call the National Immunization Information Hotline at 800-232-2522 (English) or 800-232-0233 (Spanish).

Approved by the Advisory Committee on Immunization Practices (<http://www.cdc.gov/nip/acip>), the American Academy of Pediatrics (<http://www.aap.org>), and the American Academy of Family Physicians (<http://www.aafp.org>).

incubation period is about 2 weeks (range, 10 to 21 days). During a prodrome of general malaise (often noticed about 2 days before the rash develops), the newly infected host is capable of transmitting the virus to other susceptible contacts. Typically, the rash is vesicular and pustular and spreads rapidly from few to many lesions in a matter of hours. New lesion formation continues for 2 to 3 days, with lesions appearing at different stages throughout this time. By the fourth symptomatic day, the lesions begin to dry, and new lesions usually do not develop. Fever is common during the 4 to 6 days of rash progression. When the lesions have crusted, the patient is no longer contagious to others.

Herpes zoster, also known as shingles, is a localized rash caused by recurrent varicella. Vesicles are restricted to areas supplied by single associated nerve groups. Varicella may be transmitted from the rash of those with shingles to people who are susceptible to varicella.

The varicella vaccine was first recommended as part of the routine vaccine schedule in the United States in 1996. The vaccine is effective in preventing chickenpox in approximately 85% of those vaccinated and significantly reduces the severity in almost all those who get the disease despite vaccination (Atkinson et al., 2002). The vaccine should not be given to those who have depressed immune function, are pregnant, have received blood products in the past 6 months, or have demonstrated allergy to varicella vaccine.

## INFLUENZA VACCINE

Influenza is an acute viral disease that predictably and periodically causes worldwide epidemics. Epidemics occur every 2 to 3 years, with a highly variable degree of severity. An average estimated excess of 20,000 deaths per year have been attributed to influenza or its sequelae (ie, pneumonia and cardiopulmonary collapse) in vulnerable groups between 1977 and 1995 (Centers for Disease Control and Prevention [CDC], 2001d).

Each year, a new vaccine is available. It is composed of the three virus strains (usually two type A influenza and one type B influenza strains) considered most likely to occur in the coming season. When the presumed influenza agents have been correctly anticipated and included in that year's vaccine, vaccine offers approximately 70% to 90% protection for healthy children and young adults. Although less effective in the elderly (as low as 30% to 40% in the frail elderly), it decreases the severity of illness in those who do get infected, is 50% to 70% effective in preventing pneumonia and hospitalization, and is 80% effective in preventing death. In extended care facilities, risk of transmission is greatly reduced by vaccination of all residents (CDC, 2001d).

The Immunization Practices Advisory Committee of the Public Health Service recommends annual influenza vaccinations for the following groups at risk for influenza complications: those older than 50 years of age, residents of extended care facilities, those with chronic pulmonary or cardiovascular diseases, and those with diabetes, immunosuppression, or renal dysfunction. Vaccination is also advised for children (eg, those with juvenile rheumatoid arthritis) who require long-term aspirin therapy to reduce the likelihood of developing Reye's syndrome. Health care providers and household members of those in high-risk groups should receive the vaccine to reduce the risk of transmission to those vulnerable to influenza sequelae. Vaccine campaigns among health care workers and patients should be intensified when there is evidence of community influenza disease.

## PREVENTING INFECTION IN THE HOSPITAL

Nurses specializing in infection control are responsible for agency-wide policy development and program direction. Infection risk is significantly increased as patient care equipment becomes more complex and as more devices that disrupt naturally protective anatomic barriers are used. Staff nurses play an important role in risk reduction by paying careful attention to hand hygiene, by ensuring careful administration of prescribed antibiotics, and by following procedures to reduce the risks associated with patient care devices.

Each year, an estimated 2 million patients in the United States acquire **nosocomial infections** while hospitalized. Approximately 240,000 additional residents of long-term care facilities become infected each year. With the anticipated growth of the elderly population, this number may increase to approximately 750,000 by 2005 (Jarvis, 2001).

The CDC estimates that approximately one third of all nosocomial infections could be prevented with effective infection control programs. An effective program includes the following components: a program of surveillance for nosocomial infections and vigorous control efforts, at least one infection control practitioner for every 250 hospital beds, a trained hospital epidemiologist, and feedback to surgeons about individual surgical site infections. Unfortunately, many hospitals have not introduced all four required aspects, and only an estimated 9% of expected infections are prevented (Scheckler et al., 1998).

## Specific Organisms With Nosocomial Infection Potential

### CLOSTRIDIUM DIFFICILE

*Clostridium difficile* is a spore-forming bacterium with significant nosocomial potential. Infection is usually preceded by antibiotics that disrupt normal intestinal flora and allow the antibiotic-resistant *C. difficile* spores to proliferate within the intestine.

The organism causes pathology by releasing toxins into the lumen of the bowel. In pseudomembranous colitis, the most extreme form of *C. difficile* infection, debris from the injured lumen of the bowel and from white blood cells accumulate in the form of pseudomembranes or studded areas of the colon. The destruction of such a large anatomic area can produce profound sepsis.

Because antibiotics are used so extensively in the hospital setting, most hospitalized patients are at risk for infection with *C. difficile*. The nosocomial potential is increased because the spore is relatively resistant to disinfectants and can be spread on the hands of health care providers after contact with equipment that has previously been contaminated with *C. difficile*. Control is best achieved by intensifying cleaning, using Contact Precautions for infected patients, and stressing glove use and hand hygiene for all care workers.

### METHICILLIN-RESISTANT STAPHYLOCOCCUS AUREUS

**Methicillin-resistant *S. aureus* (MRSA)** is a common nosocomial infection in hospitals and extended care facilities. MRSA refers to *S. aureus* organisms that are resistant to methicillin or its comparable pharmaceutical agents, oxacillin and nafcillin. Because of the pathogenicity of *S. aureus*, there has been concern about antibiotic resistance since the discovery of penicillin in the 1940s. Soon after penicillin was introduced, *S. aureus* became all but universally penicillin resistant. Fortunately, alternative therapies in the form of cephalosporins and, more importantly, synthetic

penicillin solutions such as methicillin were introduced. It was not until the late 1970s that *S. aureus* showed resistance to methicillin. At that time, the prevalence of the organism was originally linked epidemiologically to the IV/injecting drug use community. Since the late 1960s, however, MRSA has become increasingly more prevalent, and transmission within hospitals and nursing homes has been well documented.

Linezolid and vancomycin are the preferred alternative treatments for serious MRSA infection. However, there is concern that MRSA will eventually also become resistant to these medications because they are used so commonly. For the first time, in April 2002, a patient in Michigan was diagnosed with an *S. aureus* infection that was fully resistant to vancomycin (ie, **vancomycin-resistant *S. aureus* [VRSA]**). The CDC and other professional organizations have focused preventive efforts against the threat of transmission of this strain and the development of similar strains in other patients. The threat of the growth of VRSA is considered a public health catastrophe because many patients with *S. aureus* infections are likely to have a poor outcome (CDC, 2002b).

Health care providers often transmit MRSA to patients because *S. aureus* easily colonizes skin. Because colonization is seldom recognized, the health care provider must assume that every patient contact offers the possibility of MRSA exposure. Although there is no evidence that MRSA is more virulent than other strains of staphylococci, the colonized patient faces the likelihood of infection with MRSA when invasive procedures, such as intravenous therapy, respiratory therapy, or surgery, are performed. The patient colonized with MRSA also serves as a reservoir of resistant organisms to be transmitted to others. MRSA acquired in the hospital may persist as normal flora in the patient in the future.

### VANCOMYCIN-RESISTANT ENTEROCOCCUS

*Enterococcus* is a gram-positive bacterium that is part of the normal flora of the gastrointestinal tract. It can produce significant disease when allowed to infect blood, wounds, or urine. *Enterococcus* is the second most frequently isolated source of nosocomial infection in the United States.

*Enterococcus* has several traits that make it an ideal nosocomial organism. The host carries an abundance of the organism even in a noninfected state; the organism is bile resistant and can withstand harsh anatomic sites, such as the intestine; *Enterococcus* has the potential for resistance to many antibiotics, so that therapeutic agents reducing local bacterial competition may leave it to replicate freely; and the organism endures well on the hands of health care providers and on environmental objects.

As a relatively resistant organism at baseline, therapy for *Enterococcus* has been essentially limited to penicillin formulations (eg, ampicillin) or vancomycin in combination with an aminoglycoside (eg, gentamicin). In the 1980s, resistance to all of these agents was first reported. Between 1994 and 1999, the CDC recorded a more than 40% increase in the percentage of cases of **vancomycin-resistant *Enterococcus* (VRE)** infections in intensive care unit patients (CDC, 2001c).

This rapidly growing problem has serious implications. Because many strains of VRE are resistant to all other antimicrobial therapies, clinicians are left without effective therapy for what was once seen as a relatively common infection. VRE infections may serve as a reservoir of genes coded for vancomycin resistance that may be transferred to the even more prevalent and virulent *S. aureus*. The first case of a patient infected with VRSA, illustrates this concern, as that patient was infected with VRE and VRSA.

The gene that commonly causes resistance in VRE was found in both organisms, which strongly suggested genetic transfer between species (CDC, 2002b).

### Preventing Nosocomial Bloodstream Infections (Bacteremia and Fungemia)

Reducing the risk of nosocomial bloodstream infections requires preventive activities (in addition to Standard and Transmission-Based Precautions, which are discussed later). If a nosocomial bloodstream infection occurs, early diagnosis is important to prevent complications, such as endocarditis and brain abscess. Mortality rates may be as high as 25% for infection with some organisms. The estimated cost attributed to catheter-related bloodstream infections is \$3,700 to \$29,000 per case (Mermel, 2000).

**Bacteremia** is defined as laboratory-proven presence of bacteria in the bloodstream. **Fungemia** is a bloodstream infection caused by a fungal organism. Any vascular access device (VAD) can serve as the source for a bloodstream infection. Contamination can occur from the patient's own flora traversing the exterior of a catheter or by contamination of internal tubing during manipulation. The intravenous fluid itself can become contaminated and serve as a source of infection. Most hospitalized patients receive VADs, and increasingly, long-term central catheters are used to provide intravenous therapy to outpatients in a clinic or home setting. In all instances, the nurse must use appropriate care to reduce the risk of bacteremia and to be alert for signs of bacteremia. Chart 70-1 identifies conditions that suggest the presence of nosocomial VAD-related bacteremia or fungemia.

### DISINFECTING SKIN

During the insertion of all VADs, there must be strict attention to aseptic technique. Those inserting VADs must vigorously wash their hands before insertion. Those inserting central catheters should use surgical technique, including sterile gloves, sterile gowns with long sleeves, masks, and a large drape over the patient. The preferred solution to disinfect the insertion site is chlorhexidine gluconate, which first became available as a skin preparation solution in the United States in 2001. Alternative solutions are povidone iodine or alcohol. Triple-antibiotic ointment should not be used on the insertion site because it has been

Chart  
70-1

#### Conditions That Suggest the Presence of Nosocomial Vascular Access Device-Related Bacteremia or Fungemia

- The patient has catheter in place, appears septic, but has no obvious reason to suggest predisposition to sepsis.
- There is no infection at another body site to indicate probable source of sepsis.
- The site of vascular line insertion is red, swollen, or draining (especially purulent drainage).
- The patient has a central vascular line in place at the onset of sepsis.
- The bloodstream infection is caused by *Candida* species or by common skin organisms such as coagulase-negative staphylococci, *Bacillus* species, or *Corynebacterium* species.
- The patient remains septic after appropriate therapy without removal of the vascular access device.

shown to lead to increased colonization with *Candida* species (Mermel, 2000).

There is no apparent difference in risk or benefit when comparing the use of transparent polyurethane dressings or gauze dressings. However, if blood is oozing from the catheter insertion site, a gauze dressing should be used. The most important aspects for either material are that the dressing should be applied using aseptic technique and that the dressing should be sealed along its entire perimeter (Mermel, 2000).

### USING GUIDE WIRES

Guide wires should not be used routinely when replacing central venous catheters. However, they may be used if there is no evidence of infection and insertion risk is unacceptably high, as when the patient has a coagulopathy or is obese.

### CHANGING INFUSION SETS, CAPS, AND SOLUTIONS

Infusion sets and stopcock caps should be changed no more frequently than every 4 days, unless an infusion set is used for the delivery of blood or lipid solutions. Infusion sets and tubing for blood, blood products, or lipid emulsions should be changed within 24 hours of initiating the infusion. Blood infusions should finish within 4 hours of hanging the blood; lipid solutions should be completed within 24 hours of hanging. There are no guidelines for the appropriate intervals for the hang time of other solutions. Injection ports should be cleaned with 70% alcohol or an iodophor before accessing the system (Mermel, 2000).

Nurses have an important role in the prevention of bloodstream infections as they assess patients for evidence of infection, make daily VAD site inspections, and monitor the interval of line changes. Signs of sepsis in patients with indwelling vascular lines should be promptly assessed and treated.

## Isolation Precautions

Isolation precautions are guidelines created to prevent transmission of microorganisms in hospitals. In 1997, the Hospital Infection

Control Practices Advisory Committee (HICPAC), along with the CDC, implemented two tiers of isolation precautions. The first tier, called Standard Precautions, was designed for the care of *all* patients in the hospital and is the primary strategy for preventing nosocomial infections. The second tier, called Transmission-Based Precautions, was designed for care of patients with known or suspected infectious diseases spread by airborne, droplet, or contact routes.

### STANDARD PRECAUTIONS

The tenets of **Standard Precautions** are that all patients are colonized or infected with microorganisms, whether or not there are signs or symptoms, and that a uniform level of caution should be used in the care of all patients. The elements of Standard Precautions include hand hygiene, use of gloves and other barriers (eg, mask, eye protection, face shield, gown), handling of patient care equipment and linen, environmental control, prevention of injury from sharps devices, and patient placement. Hand hygiene, glove use, needlestick prevention, and avoidance of splash or spray of body fluids are discussed in the following sections. Chart 52-3 in Chapter 52 describes the Standard Precautions in detail.

**Hand Hygiene.** The most frequent cause of infection outbreaks in health care institutions is transmission by the hands of health care workers. Hands should be washed or decontaminated frequently during patient care. Table 70-3 describes the recommended situations for hand hygiene.

When hands are visibly dirty or contaminated with biologic material from patient care, hands should be washed with soap and water. In intensive care units and other locations in which virulent or resistant organisms are likely to be present, antimicrobial agents (eg, chlorhexidine gluconate, iodophors, chloroxylenol, triclosan) may be used. Effective hand washing requires at least *15 seconds of vigorous scrubbing* with special attention to the area around nail beds and between fingers, where there is high bacterial burden. Hands should be thoroughly rinsed after this washing.

If hands are not visibly soiled, health care providers are strongly encouraged to use alcohol-based, waterless antiseptic agents for routine hand decontamination. These solutions are superior to soap or antimicrobial handwashing agents in their speed of action and effectiveness against bacteria and viruses. Because they are formulated with emollients, they are usually better tolerated than other agents, and because they can be used without sinks and towels, health care workers have been found to be more compliant with their use. Nurses working in home health care or other settings where they are relatively mobile should carry pocket-sized containers of alcohol-based solutions (Zaragoza et al., 1999).

Normal skin flora usually consist of coagulase-negative staphylococci or diphtheroids. In the health care setting, employees may temporarily carry bacteria (ie, **transient flora**) such as *S. aureus*, *Pseudomonas aeruginosa*, and other organisms with strong pathogenic potential. Generally, transient flora are superficially attached and are shed with hand hygiene and skin regeneration.

Hand washing or disinfection reduces the amount of benign normal flora and transient bacteria and decreases the risk of transfer to other patients. All health care settings should have programs to evaluate compliance with hand disinfection by all who care for patients.

Nurses should not wear artificial fingernails or extenders when providing patient care. These items have been epidemiologically linked to several significant outbreaks of infections. Natural nails should be kept less than 0.25-inch (0.6-cm) long, and nail polish should be removed when chipped, because it can support increased bacterial growth (CDC, 2002a).

**Table 70-3 • Comparing Hand Hygiene Methods**

#### **Hand Decontamination with Alcohol-Based Product**

- After contact with body fluids, excretions, mucous membranes, nonintact skin, or wound dressings as long as hands are not visibly soiled
- After contact with a patient's intact skin (as after taking pulse or blood pressure or lifting a patient)
- In patient care, when moving from a contaminated body site to a clean body site
- After contact with inanimate objects in the patient's immediate vicinity
- Before caring for patients with severe neutropenia or other forms of severe immune suppression
- Before donning sterile gloves when inserting central catheters
- Before inserting urinary catheters or other devices that do not require a surgical procedure
- After removing gloves

#### **Hand Washing**

- When hands are visibly dirty or contaminated with biologic material from patient care
- When healthcare workers do not tolerate waterless alcohol product

**Glove Use.** Gloves provide an effective barrier for hands from the microflora associated with patient care. Gloves should be worn when a health care worker has contact with any patient's secretions or excretions and must be discarded after each patient care contact. Because hospital organisms colonizing health care workers' hands can proliferate in the warm, moist environment provided by gloves, hands must be thoroughly washed with soap after gloves are removed. As patient advocates, nurses have an important role in promoting hand washing and glove use by other hospital workers, such as laboratory personnel, technicians, and others who have contact with patients.

Latex gloves are often preferred over vinyl gloves because of greater comfort and fit and because some studies indicate that they afford greater protection from exposure. Their increased use in recent years, however, has been accompanied by increased reports of allergic reactions to latex among health care workers. Reactions range from local skin irritation to more severe reactions, including generalized dermatitis, conjunctivitis, asthma, angioedema, and anaphylaxis (see Chap. 53).

The nurse who experiences irritation or allergic reaction associated with exposure to latex should report symptoms to an occupational health specialist or private physician. Suggested methods for reducing the incidence of such reactions include use of vinyl gloves, powder-free gloves, or "low-protein" latex gloves.

**Needlestick Prevention.** The most important aspect of reducing the risk of bloodborne infection is avoidance of percutaneous injury. Extreme care is essential in all situations in which needles, scalpels, and other sharp objects are handled. Used needles should not be recapped. Instead, they are placed directly into puncture-resistant containers in the vicinity of their use. If a situation dictates that a needle must be recapped, the nurse must use a mechanical device to hold the cap or use a one-handed approach to decrease the likelihood of skin puncture. Since 2001, OSHA has required nurses to use needleless devices and other instruments designed to prevent injury from sharps when appropriate (Occupational Safety and Health Administration [OSHA], 2001).

**Avoidance of Spray and Splash Exposure.** When the health care provider is involved in an activity in which body fluids may be sprayed or splashed, appropriate barriers must be used. If a splash to the face may occur, goggles and facemask are warranted. If the health care worker is handling material that may soil clothing or is involved in a procedure in which clothing may be splashed with biologic material, a cover gown should be worn.

### TRANSMISSION-BASED PRECAUTIONS

Some microbes are so contagious or epidemiologically significant that precautions in addition to the Standard Precautions should be used when such organisms are recognized. The CDC recommends a second tier of precautions, called Transmission-Based Precautions. The additional safety measures are called Airborne, Droplet, and Contact Precautions (Garner, 1996).

*Airborne Precautions* are required for patients with presumed or proven pulmonary TB or chickenpox. Airborne Precautions are also advised if, as a victim of bioterrorism, a patient is suspected of having smallpox. When hospitalized, patients should be put in rooms with negative air pressure; the door should remain closed, and health care providers should wear an N-95 respirator (ie, protective mask) at all times while in the patient's room.

*Droplet Precautions* are used for organisms that can be transmitted by close, face-to-face contact, such as influenza or meningococcal meningitis. While taking care of a patient requiring

Droplet Precautions, the nurse should wear a facemask, but because the risk of transmission is limited to close contact, the door may remain open. The CDC advises that negative-pressure rooms should be used in hospitals if available.

*Contact Precautions* are used for organisms that are spread by skin-to-skin contact, such as antibiotic-resistant organisms or *C. difficile*. Contact Precautions are designed to emphasize cautious technique for organisms that have serious epidemiologic consequences or those easily transmitted by contact between health care worker and patient. The principles of transmission control used in the Standard Precautions are accentuated. When possible, the patient requiring contact isolation is placed in a private room to facilitate hand hygiene and protection of garments from environmental contamination. Masks are not needed, and doors do not need to be closed (Chart 70-2).

## Emerging Infectious Diseases

As defined by the CDC, **emerging infectious diseases** are diseases of infectious origin with human incidences that have increased within the past two decades or that are likely to increase in the near future (CDC, 1994). Examples of emerging infectious diseases are presented within this section: West Nile virus, Legionnaires' disease, Lyme disease, hantavirus pulmonary syndrome, Ebola and Marburg viruses, and Severe Acute Respiratory Syndrome (SARS). Table 70-1 provides an overview of infectious diseases, including emerging infectious diseases.

Many factors contribute to newly emerging or re-emerging infectious diseases. These include travel, globalization of food supply and central processing of food, population growth and increased urban crowding, population movements (eg, war, famine, disaster), ecologic changes, human behavior (eg, risky sexual behavior, IV/injection drug use), antimicrobial resistance, environmental sources, and breakdown in public health measures.

These diseases are important from an epidemiologic standpoint because their incidence has not yet stabilized. As physicians and scientists are learning about the pattern of disease in a community, patients and their families often have increased anxiety about these diseases. During times of increased concern about bioterrorism, whether triggered by actual events or by hoaxes, nurses have an increased responsibility to rationally separate facts from fears. In discussions with patients and other caregivers, it is important to keep the focus on what is known and to clarify the plan for diagnosis, treatment, and containment.

### WEST NILE VIRUS

The West Nile virus was first recognized in the 1930s in Africa and first seen in humans the United States in 1999. The 1999 epidemic was distressing as residents of New York City reported to hospitals with initially undiagnosable meningitis. Most human infections are asymptomatic. When symptoms are present, headache and fever are most frequently reported. Less than 1% of those infected develop more severe illness, including meningitis (CDC, 2001e).

The incubation period (ie, from mosquito bite to onset of symptoms) is between 5 and 15 days. There is no treatment for West Nile virus infection. Patients are supported by fluid replacement, airway management, and standard nursing care when meningitis symptoms are present.

Birds are the natural reservoir for the virus and since 1999, the population of infected birds in the eastern United States has in-

Chart  
70-2

## Synopsis of Types of Precautions and Patients Requiring the Precautions

**Standard Precautions**

Use Standard Precautions for the care of all patients.

**Airborne Precautions**

In addition to Standard Precautions, use Airborne Precautions for patients known or suspected to have serious illnesses transmitted by airborne droplet nuclei. Examples of such illnesses include the following:

- Measles
- Varicella (including disseminated zoster)\*
- Tuberculosis

**Droplet Precautions**

In addition to Standard Precautions, use Droplet Precautions for patients known or suspected to have serious illnesses transmitted by large particle droplets. Examples of such illnesses include:

- Invasive *Haemophilus influenzae* type b disease, including meningitis, pneumonia, epiglottitis, and sepsis
- Invasive *Neisseria meningitidis* disease, including meningitis, pneumonia, and sepsis
- Other serious bacterial respiratory infections spread by droplet transmission, including:
  - Diphtheria (pharyngeal)
  - Primary atypical pneumonia (*Mycoplasma pneumoniae*)
  - Pertussis
  - Pneumonic plague
  - Streptococcal (group A) pharyngitis, pneumonia, or scarlet fever in infants and young children
- Serious viral infections spread by droplet transmission, including:
  - Adenovirus\*
  - Influenza
  - Mumps
  - Parvovirus B19
  - Rubella

\*Certain infections require more than one type of precaution.  
From Centers for Disease Control and Prevention, Atlanta, GA, 1997.

**Contact Precautions**

In addition to Standard Precautions, use Contact Precautions for patients known or suspected to have serious illnesses easily transmitted by direct patient contact or by contact with items in the patient's environment. Examples of such illnesses include:

Gastrointestinal, respiratory, skin, or wound infections or colonization with multidrug-resistant bacteria judged by the infection control program, based on current state, regional, or national recommendations, to be of special clinical and epidemiologic significance

Enteric infections with a low infectious dose or prolonged environmental survival, including:

*Clostridium difficile*

For diapered or incontinent patients: enterohemorrhagic *Escherichia coli* O157:H7, *Shigella* species, hepatitis A, or rotavirus

Respiratory syncytial virus, parainfluenza virus, or enteroviral infections in infants and young children

Skin infections that are highly contagious or that may occur on dry skin, including:

Diphtheria (cutaneous)

Herpes simplex virus (neonatal or mucocutaneous)

Impetigo

Major (noncontained) abscesses, cellulitis, or pressure ulcers

Pediculosis

Scabies

Staphylococcal furunculosis in infants and young children

Zoster (disseminated or in the immunocompromised host)\*

Viral and hemorrhagic conjunctivitis

Viral hemorrhagic infections (Ebola, Lassa, or Marburg)

creased steadily. Mosquitoes become infected when feeding on birds and can transmit the virus to animals and humans. Most communities in the eastern United States have developed a public health surveillance system to estimate the prevalence in birds and mosquitoes. There is no human-to-human transmission of the virus and no evidence of transfer from infected birds to humans. However, as a precaution, it is wise to teach people in affected areas to wear gloves if handling a dead bird (CDC, 2002c).

**LEGIONNAIRES' DISEASE**

Legionnaires' disease is a multisystem illness that usually includes pneumonia and is caused by the gram-negative bacteria, *Legionella pneumophila*. Named after an outbreak of the disease among people attending a convention of the American Legion in 1976, its potential to cause outbreaks has been demonstrated numerous times in hospitals and other settings. *Legionella* organisms are found in many man-made and naturally occurring water sources. Although the organisms may initially be introduced in low numbers, growth is enhanced by water storage, scaling (biofilm) on the inside of water towers, temperatures ranging from 25° to 42°C (77° to 107°F), and certain amoebae frequently present in water that can support intracellular growth of legionellae.

**Pathophysiology**

*L. pneumophila* is transmitted by an aerosolized route from an environmental source to an individual's respiratory tract. It is not transmitted from person to person. In hospitals, patients may be exposed to aerosols created by cooling towers, water sources from plumbing, and respiratory therapy equipment. Because underlying medical conditions can increase host susceptibility and subsequent severity of disease and because hospital plumbing systems are often very complex, outbreaks occur in hospitals more frequently than at other centers within the community. Mortality rates among hospitalized patients are about twofold greater than those for people with community-acquired *Legionella* pneumonia (CDC, 2002e).

**Risk Factors**

Risk factors strongly associated with *Legionella* infection include diseases that lead to severe immunosuppression, such as acquired immunodeficiency syndrome (AIDS), hematologic malignancy, end-stage renal disease, or use of immunosuppressive agents. Other factors associated with increased risk include advanced age, diabetes, alcohol abuse, smoking, and other pulmonary disease.

## Clinical Manifestations

The lungs are the principal organs of infection; however, disease without pulmonary involvement has been reported. Other organs may also be involved. The incubation period ranges from 2 to 10 days. Early symptoms may include malaise, myalgias, headache, and dry cough. With disease progression, the patient develops increased pulmonary symptoms, including productive cough, dyspnea, and chest pain. Patients are usually febrile, and body temperatures may reach 103°F (39.4°C) and higher. Diarrhea and other gastrointestinal complaints commonly accompany the array of pulmonary symptoms. In severe cases, multiorgan involvement and failure may follow.

## Assessment and Diagnostic Findings

Laboratory tests available for the diagnosis of *Legionella* include culture (ie, using special microbiologic methods and media), immunofluorescent microscopy, antibody titer interpretation, and urinary antigen detection. Diagnosis of *Legionella* by antibody titer requires evidence that titers have increased at least fourfold over time. A single elevated titer is not sufficient to determine current disease. The urinary antigen test (for *L. pneumophila* serotype 1, the most prevalent subspecies) is helpful because urine is easy to obtain and the test remains positive after initial antibiotic treatment. This persistent marker especially aids in the diagnosis of community-acquired pneumonia as patients are frequently treated empirically. *Legionella* cultures rapidly become negative after antibiotic treatment, even when the patient's condition is deteriorating. Frequently, more than one laboratory test is used in the diagnosis of *Legionella* because no one test is 100% sensitive. The diagnostic approach generally involves accumulation of information obtained from the history, physical examination, x-rays, laboratory findings, and assessment of therapeutic effectiveness. Chest x-ray abnormalities may vary in severity and in location of the diseased site.

## Medical Management

Azithromycin (Zithromax) is considered the antibiotic of choice. Other options include clarithromycin (Biaxin), erythromycin (Ilotycin), and levofloxacin (Levaquin).

## Nursing Management

The nursing management described for the patient with any pneumonia (see Chap. 23) should form the basis of care for the patient with *Legionella* pneumonia. Special isolation techniques are not used for these patients because there is no evidence of transmission between humans.

## LYME DISEASE

Lyme disease, caused by the spirochete *Borrelia burgdorferi*, is transmitted to humans by ticks. It is more common in the Northeast and Mid-Atlantic states, where the deer tick (*Ixodes dammini*) is prevalent. Ticks may feed on infected white-tailed deer or white-footed mice and then serve as a vector to transmit disease to humans. Lyme disease is less common in the western U.S. states, where the California black-legged tick (*Ixodes pacificus*), capable of transmitting Lyme disease, prefers to feed on reptiles, which do not carry *B. burgdorferi*.

Lyme disease can be manifested by a wide range of symptoms and severity. In its early form, a rash is often present and may be accompanied by regional lymphadenopathy. In later stages, neurologic manifestations ranging from Bell's palsy to Guillain-Barré-like syndrome or dementia are possible. Other sites that may be affected include skin, joints, heart, and eyes.

## Assessment and Diagnostic Findings

The rash frequently associated with Lyme disease, known as erythema migrans, is often described as having an expanding bull's-eye appearance. It may be confused with a spider bite. The diagnosis may be made when a patient has this typical rash and at least one late manifestation (eg, arthritis, facial palsy, meningitis, carditis) along with laboratory confirmation of infection.

## Medical Management

Doxycycline (Vibramycin), ceftriaxone (Rocephin), and azithromycin are among the commonly used antibiotics. Treatment regimens are usually for 3 to 4 weeks. Patients should be encouraged to complete the full course of therapy and to report changes in symptoms during therapy, because the regimen may need to be altered if treatment appears to be failing.

## HANTAVIRUS PULMONARY SYNDROME

Hantavirus pulmonary syndrome (HPS) is caused by a member of the Hantavirus family of viruses. In the United States, the Sin Nombre hantavirus causes severe cardiopulmonary illness with a case mortality rate of approximately 50%. Cases occur most frequently in the western U.S. states, but the rodents known to carry the virus are found throughout the country (Vaheri & Calisher, 2002).

The diagnosis of HPS should be suspected in patients who live in rural areas, who may have had exposure to rodents, and who report fever, aching muscles, and nausea. Thrombocytopenia and hemoconcentration are also common.

Although no specific treatment for HPS has been approved, early treatment with ribavirin (Virazole) may reduce mortality. Early identification, assessment, and maintenance of respiratory status are the most important aspects of care for these patients. Intake and output should be monitored closely, because overhydration is possible with resultant cardiopulmonary compromise.

Reduction of risk requires strategies to reduce human contact with rodents and their droppings. Public health programs and clinics in rural areas should regularly teach people to eliminate food sources of rodents in areas close to humans. Openings in walls or cabinets should be sealed. Traps should be used in areas such as sheds and barns in which rodents may enter and in which humans work. Gloves should be worn when removing the animal from the trap. The trap should be disinfected with a 1:10 bleach solution. People entering such areas should be taught to avoid stirring up dust or breathing potentially contaminated dust. Brooms and vacuum cleaners should be used with caution; areas that may emit dust while being cleaned should be first dampened with a bleach solution to reduce viral contaminants and the potential for dust dispersion.

## EBOLA AND MARBURG VIRUSES

The Ebola and Marburg viruses are known as filoviruses. Since the 1960s, they have been the source for approximately 20 out-

breaks. Both viruses have been prepared as biological weapons and cause great concern because of the extreme virulence and high mortality rates associated with infection.

The clinical course differs among patients, but often includes fever, rash, and encephalitis. Symptoms usually occur rapidly, and with both viruses, the course of the illness often progresses rapidly to profound hemorrhage, organ destruction, and shock. The mortality rate approaches 90%. When patients survive, the recovery period is often prolonged, with weakness, malaise, and cachexia common.

Despite aggressive research, the natural reservoirs for filoviruses have not yet been found, but it is thought that humans are infected only incidentally after exposure to an unrecognized host or by insect bite. Human-to-human transmission usually occurs after exposure to blood or other body fluid. When transmission is percutaneous, it appears that a very low inoculum of contaminated blood is required for transmission to occur. The virus can also be spread by mucous membrane exposure. Although airborne transmission does not appear to be a likely mode of transmission, the possibility has not been entirely eliminated. All involved in caring for patients with filoviruses must adhere to strict infection control measures. It is advisable that systems be set up to have objective monitors to ensure that each nurse or other health care worker wears complete protective equipment in the form of cap, goggles, masks, gown, gloves, and shoe covers.

Because there have been no cases diagnosed in the United States, it is likely that early signs of disease may be initially misclassified. The diagnosis should be considered in a patient who has a febrile, hemorrhagic illness after traveling to Asia or Africa or who has handled animals or animal carcasses from those parts of the world. Because neither hospital nor local public health laboratories would be able to confirm a diagnosis, the CDC should be contacted immediately when Ebola and Marburg viruses are suspected to be the cause of illness.

No antivirals have been approved or show promise against Ebola and Marburg. Treatment is largely supportive maintenance of the circulatory system and respiratory systems. It is likely that the infected patient would need ventilator and dialysis support through the acute phases of illness.

Supportive care for a patient with such a devastating disease requires psychological support for the patient and family. The natural fear of an untreatable, aggressive disease would likely be intensified because of the rarity of the disease. The patient, his family, health care workers, and others in the community will need substantial, coordinated education about the known and unknown elements. Intervention may be required from those trained to provide psychological support for traumatic or terrorist events.

## SEVERE ACUTE RESPIRATORY SYNDROME (SARS)

In March 2003, the World Health Organization issued a global warning about the appearance of a newly recognized type of pneumonia, Severe Acute Respiratory Syndrome (SARS). SARS is an influenza-like disease, with patients presenting with fever and cough. A minority will progress to experience respiratory distress. The disease was first recognized in China, with a second generation of cases erupting quickly in Hong Kong, Vietnam, and over 17 other countries in a number of weeks.

The pattern of worldwide dissemination was largely attributed to travel because of strong epidemiologic evidence that patients

from many countries had shared common exposures. SARS serves as an example of how suddenly benign microorganisms, especially viruses, can mutate to become important human pathogens. The epidemic illustrates important principles of public health and infection control. Before the disease came to the attention of the WHO, transmission to nurses and other health care professionals occurred frequently. Once patients were appropriately isolated, with health care workers using barrier precautions and cleaning contaminated surfaces carefully, transmission was effectively reduced or prevented.

## TRAVEL AND IMMIGRATION

Historically, migration of populations has often led to epidemics of disease in countries where people have no immunity to the disease. Because of trade, immigration, and wars, yellow fever, malaria, hookworm, leprosy, smallpox, measles, mumps, syphilis, and many other infectious diseases have been brought to the Western Hemisphere. More recently, the HIV epidemic was transmitted worldwide by means of travel and immigration.

Few diseases carried by travelers spread efficiently in the United States environment because of enforced vaccination, clean water, and insect and rodent control. However, there is growing concern that vector-borne diseases, such as dengue, may be transmitted by mosquitoes if a reservoir of infected humans is established. The CDC maintains an active surveillance system to prospectively monitor and halt the incidence of many diseases.

### Immigration and Acquired Immunodeficiency Disease Syndrome

The fact that AIDS reached pandemic proportions in less than a decade after its recognition attests to the efficiency of world travel in spreading disease. The significance of such rapid transmission rates is especially dramatic in that HIV essentially requires intimate contact between two people through sexual activity or sharing blood through needles.

The reservoir of HIV-1 in the United States is estimated to be approximately 800,000 to 900,000 people, with approximately 40,000 new cases each year. It was probably first introduced in the 1970s when asymptotically infected travelers returned to the United States after having acquired the virus in other countries. HIV-2, which is similar to HIV-1 in causing immunodeficiency but less contagious in the early stages, is most prevalent in West Africa. The public health challenge is to set up surveillance and control mechanisms for this disease so that it is not regularly introduced into the United States. Because HIV-2 is rare, patients with signs of immune dysfunction do not need to be routinely tested for it. However, patients with immunodeficiency should be tested for HIV-2 if they have negative HIV-1 confirmatory test results or have traveled from countries where HIV-2 is prevalent. All donated blood must be screened for HIV-2. Routine seroprevalence studies are conducted to validate low prevalence in the United States (Grant & DeCock, 2001).

### Immigration and Tuberculosis

Although there are substantive plans to eliminate TB in the United States, it remains a growing epidemic in developing nations. Immigration has always been an important influence in the dynamic epidemiology of TB in the United States. In 2001, the incidence

of TB was eight times greater in the foreign-born than in the native-born population of the United States (CDC, 2001h).

The association between immigration and transmission risk is greatest in urban areas because these locations are frequently heavily populated and visited by foreign-born people. These locales are also often the epicenter of the HIV epidemic, a population with suppressed immunity to TB. The combination of social, financial, and immunologic risks makes the goal of TB elimination in the United States very challenging.

A positive purified protein derivative (PPD) skin test establishes that TB infection has occurred at some time in a person's life. Because it does not provide information about current infectivity, it cannot be used to determine transmission potential. The complexity of PPD interpretation is increased because of the common use of the bacillus Calmette-Guérin (BCG) vaccine in many foreign countries. After receiving BCG, individuals are often PPD positive for a prolonged time, decreasing the ability of the PPD to serve as a TB screen.

## Immigration and Vector-Borne Diseases

Malaria, yellow fever, and dengue are diseases that cause significant morbidity and mortality throughout the developing world. These diseases are spread by infected mosquitoes. Many other vector-borne parasitic diseases in developing countries rely on mosquitoes and other organisms to complete their life cycles and transmit disease.

Dengue fever is an example of the risk of imported vector-borne disease. The disease is caused by a virus that is spread through human populations by the *Aedes aegypti* mosquito. The mosquitoes thrive in tropical zones and breed in stagnant water sources. Travelers, immigrants, and returning military personnel can serve as reservoirs of infection. A recent increase of dengue virus in the Caribbean has caused concern that outbreaks may occur in the United States in areas where there are vector mosquitoes.

Infection from dengue produces flulike symptoms of fever, chills, eye pain, joint pain, and sometimes, a hyperpigmented rash. Symptoms often wax and wane and are generally self-limited. A small proportion of patients may develop hemorrhagic disease, which can be life-threatening in extreme forms. There is no specific treatment for this infection. Control efforts rely on local effective mosquito control.

## DIARRHEAL DISEASES

In developing countries of the world, infectious diarrhea kills about 4 million people per year. In the United States, it is estimated that children younger than 5 years of age experience more than 20 million episodes of diarrheal diseases each year, with about 400 deaths per year attributed to such episodes. Dehydration is the most important factor for the morbidity and mortality associated with diarrheal disease. Dehydration is largely controllable by using rehydration therapy (Guerrant & Steiner, 2000).

### Transmission

The portal of entry of all diarrheal pathogens is oral ingestion. Although the food we eat is far from sterile, the high acidity of the stomach and the antibody-producing cells of the small bowel generally serve to decrease the potential of pathogens. If the number of organisms is large enough, or if the food neutralizes the acidic environment, infection can occur. Decreased gastric acid-

ity with disruption of normal bowel flora (as occurs after surgery), use of antimicrobial agents, and the immune dysfunction of AIDS all decrease intestinal defenses.

## Specific Causes

There are many viral, bacterial, and parasitic causes for diarrheal diseases. Rotavirus is the most significant viral cause of diarrhea in young children. Common causes of bacterial infection include *Escherichia coli* and *Salmonella*, *Shigella*, *Campylobacter*, and *Yersinia* species. Parasitic infections of importance include *Giardia* and *Cryptosporidium* species and *Entamoeba histolytica*.

### ESCHERICHIA COLI

*E. coli* is the most common aerobic organism colonizing the large bowel. When *E. coli* organisms are cultured from fecal specimens, the results seldom suggest pathology, but rather reflect normal flora. However, certain strains of *E. coli* with increased **virulence** (ie, degree of pathogenicity of an organism) have been responsible for significant outbreaks in recent years. These stronger pathologic strains are subgrouped as enterotoxigenic *E. coli* (ETEC) because of their production of enterotoxins. ETEC strains often cause cholera-like disease, with rapid, severe dehydration and an increased risk of death.

Recent outbreaks of an *E. coli* species, 0157:H7, have often been linked to the ingestion of undercooked beef. This bacterium lives in the intestines of cattle and can be introduced into meat at the time of slaughter. Prevention of disease from this strain of *E. coli* is aimed at teaching the public to cook ground beef thoroughly (ie, until the meat is no longer pink and the juices run clear).

### SALMONELLA INFECTION

*Salmonella* is a gram-negative bacillus with many species, including the very pathogenic *Salmonella typhi* (ie, typhoid fever). Of the nontyphi species, most organisms are prevalent in animal food sources. It is estimated that *Salmonella* species contaminate more than 50% of commercially available chicken products and are frequently found in eggs (intact and with broken shells), in raw milk, and occasionally in beef (Crump et al., 2002). Approximately 40% of the deaths caused by *Salmonella* occur in nursing home residents. The high mortality rate reflects the seriousness of the infection in the elderly, who often have weakened immune systems (CDC, 2000a).

There is great variability of symptoms associated with *Salmonella* species infection, including an asymptomatic carrier state, gastroenteritis, and systemic infection. Diarrhea with gastroenteritis is common. Disseminated disease and bacteremia, whether accompanied by diarrhea or not, is less common.

The person with *Salmonella*-caused diarrhea can be a source for transmission to others. The importance of good hygiene should be emphasized, and health care workers should use special care when handling bedpans, stool specimens, or other objects that may have fecal contamination. Hand washing is imperative after any contact with a person with *Salmonella* diarrhea. Patients with gastroenteritis generally are not treated with antibiotics because antibiotic use may increase the period of time that the patient carries the bacteria while not improving the clinical outcome. However, those with systemic salmonellosis require antimicrobial therapy.

### SHIGELLA INFECTION

The *Shigella* species is a gram-negative organism that invades the lumen of the intestine and causes disease and severe watery (pos-

sibly bloody) diarrhea. *Shigella* species spread through the fecal-oral route, with easy transmission from one person to another. Small numbers of organisms are needed to cause disease. Because transmission occurs easily with improper hygiene, it is not surprising that *Shigella* organisms disproportionately affect pediatric populations. Disease in the very young may infrequently be complicated by pulmonary or neurologic symptoms.

Antimicrobial therapy should be instituted early. Frequently, initial therapy choices must be altered when final microbiologic testing reveals the organism's sensitivity.

### CAMPYLOBACTER INFECTIONS

In the United States, diarrheal disease attributed to *Campylobacter* species surpasses that recorded for *Salmonella* and *Shigella* species. The organism is found abundantly in animal food sources. It is especially common in poultry but can also be found in beef and pork. Transmission appears to be almost entirely by the fecal-oral route, with food sources representing the reservoir of organism. Direct person-to-person transmission appears to be less common than for other enteric pathogens, such as *Shigella*.

Cooking and storing food at appropriate temperatures protects against *Campylobacter*. It is important that kitchen utensils used in meat preparation be kept away from other food to prevent *Campylobacter* transmission.

After a person is infected, the organism directly attacks the lumen of the intestine and may cause disease through enterotoxin release. Symptoms can range from mild abdominal cramping and minimal diarrhea to severe disease with profuse watery bloody diarrhea and debilitating abdominal cramping. Antimicrobial therapy is recommended only for those who are seriously ill.

### GIARDIA LAMBLIA

*Giardia lamblia* is a protozoan. Transmission occurs when food or drink is contaminated with viable cysts of the organism. People often become infected while traveling to endemic areas in industrialized and nonindustrialized countries of the world or by drinking contaminated water from mountain streams within the United States. The organism can be transmitted by close contact, as occurs in day care settings. Transmission by sexual contact has also been documented.

Frequently, the infection goes unnoticed. Infection is often recognized more easily in children than in adults. In extreme cases, the patient may experience abdominal pain and chronic diarrhea, usually described as containing mucus and fat but not blood. Microscopic examination of stool specimens reveals the trophozoite or cyst stages of the parasitic life cycle.

Metronidazole (Flagyl) is commonly used to treat *Giardia*, but success rates for this and alternative therapies are inconsistent. Patients with *Giardia* infections should be instructed that the organism can be easily transmitted in family or group settings. Personal hygiene measures should be reinforced, and those who travel or camp where water is not treated and filtered should be advised to avoid local water supplies unless water is purified before drinking or used in cooking.

### VIBRIO CHOLERA

Although reported cases of cholera have been rare in the United States in recent decades, no discussion of infectious diarrhea is complete without mention of this very serious infectious disease. Historically, epidemics of cholera have influenced all aspects of life—from medical to political—and infection rates have been

significant enough to destroy governments and armies. Cholera is always a concern when wars or natural disasters result in inadequately processed wastewater. *Vibrio cholera* also may be found naturally in brackish rivers and coastal waters.

The *V. cholera* organism is a gram-negative organism with several different serotypes. The type usually associated with epidemics is toxigenic *V. cholera* 01. The organism is transmitted by contaminated food or water. Most recent cases in the United States have been from contaminated shellfish found in the Gulf of Mexico or by visitors who have brought contaminated shellfish into the United States.

Cholera causes disease with a very rapid onset of copious diarrhea in which up to 1 L of fluid per hour can be lost. Dehydration, with subsequent cardiopulmonary collapse may cause rapid progression from onset of signs and symptoms to death. The principal therapy is rehydration. Rehydration efforts should be vigorous and sustained. If oral rehydration cannot be accomplished, the patient should be hospitalized for intravenous therapy support.

In the United States, cholera should be suspected in patients who have watery diarrhea after eating shellfish harvested from the Gulf of Mexico. Confirmation of the causative organism can be made by stool culture. It is imperative that all cases are reported to local and state public health authorities. People traveling to areas where cholera occurs regularly should remember the simple rule of thumb: “boil it, cook it, peel it, or forget it”.

## NURSING PROCESS: THE PATIENT WITH INFECTIOUS DIARRHEA

### Assessment

The most important element of assessment in the patient with diarrhea is to determine hydration status. The goal of rehydration is to correct the dehydration. Assessment includes evaluation for thirst, oral mucous membrane dryness, sunken eyes, a weakened pulse, and loss of skin turgor. Careful observation for these signs is especially important in cases of rapidly dehydrating diseases (most notably cholera) and in younger children.

Intake and output measurements are crucial in determining fluid balance. Liquid stool should be measured and recorded along with a record of the frequency of stools. It is important to note the consistency and appearance of stool as key indicators of the type and severity of the diarrheal disease. The presence of mucus or blood should also be documented.

When conducting a health history, the nurse must determine whether the patient has recently traveled, whether the patient is being treated with antibiotics, whether the patient has been in contact with anyone who has recently had diarrheal disease, and what the patient has recently eaten. Frequently, patients attribute the most recent meals eaten as the cause of symptoms. However, the incubation period for most diarrheal conditions is longer than the time interval between meals, and the nurse needs to get detailed information about the meal preceding the illness and about all food intake in the previous 3 to 4 days. When eliciting this kind of history, it is helpful to ask the patient to list every food tasted. The nurse also asks patients if they are employed in a food preparation service, because the local public health departments should be notified about any patient with infectious diarrhea who works in the food industry.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Deficient fluid volume related to fluid lost through diarrhea
- Deficient knowledge about the infection and the risk of transmission to others

### COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include the following:

- Bacteremia
- Hypovolemic shock

## Planning and Goals

The most important goals are maintenance of fluid and electrolyte balance, increased knowledge about the disease and risk of transmission, and absence of complications.

## Nursing Interventions

### CORRECTING DEHYDRATION ASSOCIATED WITH DIARRHEA

The patient is assessed to determine the degree of dehydration. This assessment helps determine the amount and route of rehydration needed. Oral therapy can rehydrate most patients. Oral rehydration therapy is a strategy used to reduce the severe complications of diarrheal disease regardless of causative agent. It is inexpensive and effective, but it is often underused because of sustained cultural beliefs discouraging oral intake during episodes of diarrhea. After much refinement of the formula, the World Health Organization (WHO) and the United Nation's International Children's Emergency Fund (UNICEF) agreed on the makeup of a single solution for treatment of dehydration and electrolyte imbalance associated with cholera and other forms of diarrheal disease. The solution contains (in millimoles per liter) sodium, 90; potassium, 20; chloride, 80; citrate, 10; and glucose, 111.

### Mild Dehydration

The patient exhibits dry mucous membranes of the mouth and increased thirst. The rehydration goal at this level is to deliver about 50 mL of oral rehydration solution (ORS) per 1 kg of weight over a 4-hour interval.

### Moderate Dehydration

Sunken eyes, loss of skin turgor, and dry oral mucous membranes are common manifestations. An infant may have a sunken fontanel. The rehydration goal is about 100 mL/kg over 4 hours for the patient with moderate dehydration.

### Severe Dehydration

The patient with severe dehydration shows signs of shock (ie, rapid thready pulse, cyanosis, cold extremities, rapid breathing, lethargy, or coma) and should receive intravenous replacement until hemodynamic and mental status return to normal. When improvement is evident, the patient can be treated with ORS.

### ADMINISTERING REHYDRATION THERAPY

In the United States, commercially available preparations, such as Pedialyte and Rice-Lyte, have been effective fluid and electrolyte replacements for children with viral diarrheal disorders common

in this country. When diarrheal losses are very high (>10 mL/kg per hour), however, the lower sodium concentrations of these formulas make them less appropriate than the WHO formula.

For the hospitalized child, diarrheal fluid loss should be weighed, and ORS should be administered at a rate of 1 mL for each gram of diarrheal stool. Stool losses can be estimated so that the patient receives about 10 mL/kg ORS for each diarrheal stool.

It is important for children and adults suffering from acute diarrheal symptoms to maintain caloric intake. Infants who are breastfed should continue to feed on demand; those who are receiving formula should receive full-strength, lactose-free or lactose-reduced formulas immediately after rehydration. Children who normally eat semisolid or solid food should have that food offered. Recommended foods include starches, cereals, yogurt, fruits, and vegetables. Foods that are high in simple sugars, such as undiluted apple juice or gelatin, should be avoided.

Because diarrheal episodes are often accompanied by vomiting, rehydration and refeeding can be difficult. Oral rehydration therapy should be delivered frequently in small amounts. When vomiting is persistent, small children often require frequent administration of fluids by spoonfuls rather than by drinking from a bottle or a cup. Intravenous therapy is necessary for the patient who is severely dehydrated or in shock.

### INCREASING KNOWLEDGE AND PREVENTING SPREAD OF INFECTION

Public health nurses, school nurses, and others who are involved in patient teaching should emphasize principles of safe food preparation, with special attention to meat preparation and cooking. Ground beef should be cooked until no longer pink, and all meat should be maintained at temperatures below 40°F or above 140°F. In planning events for groups of people, adequate provision for storage and reheating to meet temperature thresholds is important. When preparing food, it is important to use different surfaces, knives, and other equipment for meat and nonmeat items.

Diarrheal diseases discussed in this section must be reported to local or state health departments. The goal of reporting is to provide information that will be used to assess disease incidence trends and to identify at the earliest point if there is a restaurant or other food preparation establishment that has served contaminated food.

The need for rehydration and refeeding should be taught to parents of children with diarrheal disease. Beliefs about illness and food patterns may have a traditional or cultural basis, and any teaching of health facts requires cultural sensitivity.

Good hygiene in the health care delivery and home settings must be a focus when caring for patients with infectious diarrheal diseases. The principles of hand washing and glove use that are emphasized with Standard Precautions are important aspects of disease control.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

#### Bacteremia

*E. coli* and *Salmonella* and *Shigella* species are all organisms that can be introduced into the bloodstream and disseminate to other organs. Blood cultures should be done for the acutely febrile patient with diarrhea. If initial smear results reveal gram-negative organisms, antibiotic therapy is instituted.

#### Hypovolemic Shock

Shock associated with diarrheal diseases demands accurate intake and output assessment and vigorous fluid replacement. In rare instances, patients with severe fluid imbalance require intensive care nursing support with aggressive hemodynamic monitoring.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Attains fluid balance
  - a. Output approximates intake
  - b. Mucous membranes appear moist
  - c. Normal skin turgor
  - d. Adequate amounts of fluids and calories ingested
  - e. Absence of vomiting
  - f. Stools of normal color and consistency
2. Acquires knowledge and understanding about infectious diarrhea and transmission potential
  - a. Takes proper precautions to prevent spread of infection to others
  - b. Describes principles and techniques of safe food storage, preparation, and cooking
3. Absence of complications
  - a. Temperature within normal range
  - b. Negative blood culture reports
  - c. Achieves fluid balance

## Sexually Transmitted Diseases

A sexually transmitted disease (STD) is a disease acquired through sexual contact with an infected person. Table 70-4 identifies diseases that can be classified as STDs.

Other organisms can be transmitted during sexual contact, although they are generally not considered to be STDs. For example, *G. lamblia*, usually associated with contaminated water, can also be transmitted through sexual exposure.

STDs are the most common infectious diseases in the United States and are epidemic in most parts of the world (Chart 70-3). Portals of entry of STD microorganisms and sites of infection include the skin and mucosal linings of the urethra, cervix, vagina, rectum, and oropharynx.

In June 2001, U.S. Surgeon General Satcher published a document entitled, *The Surgeon General's Call to Action to Promote Sexual Health and Responsible Sexual Behavior*. This document discusses the public health impact of sexually transmitted diseases

Chart 70-3

### Risk Factors for Sexually Transmitted Diseases (STDs)

The risk for acquiring STDs increases for individuals who engage in the following high-risk behaviors:

- Having sexual relations with infected individuals, with multiple partners, or with prostitutes
- Engaging in oral or anal sex
- Using IV/injection drugs

In addition, the rising incidence of STDs in adolescents reflects an increase in sexual activity among individuals in that age group.

and other problems associated with lack of sexual responsibility. The Surgeon General reports that approximately 12 million Americans become infected with an STD each year. He encourages educators and health care providers to study methods of influencing irresponsible behavior and to provide education and services appropriate to the communities they serve (Satcher, 2001). STDs (eg, human papillomavirus, herpesvirus, *Chlamydia*, gonorrhea) are also discussed in Chapter 47.

## Prevention

Education about prevention of STDs includes information about risk factors and behaviors that can lead to infection. Included in this education is information about the relative value of condoms in reducing risk for infection.

The use of a condom to provide a protective barrier from transmission of STD-related organisms has been broadly promoted, especially since the recognition of HIV/AIDS. At first referred to as a method to ensure *safe sex*, the use of condoms has been shown to reduce but not eliminate the risk of transmission of HIV and other venereal diseases. The term *safer sex* more appropriately connotes the public health message to be used when promoting the use of condoms.

## Significance

STDs provide a unique set of challenges for nurses, physicians, and public health officials. Because of perceived stigma and possible threat to emotional relationships, those with symptoms of STDs are often reluctant to seek health care in a timely fashion. Similar to many other infectious diseases, STDs may progress without symptoms. A delay in diagnosis and treatment is potentially harmful because the risk of complications for the infected individual and the risk of transmission to others increase over time.

Infection with one STD suggests the possibility of infection with other organisms as well. After one STD is identified, diagnostic evaluation for others should be performed. The possibility of HIV infection should be pursued when any STD is diagnosed.

## HUMAN IMMUNODEFICIENCY VIRUS

HIV is the causative agent of AIDS. The definition of AIDS, as determined by the CDC, has changed several times since the syndrome was first recognized in 1981. In general, the definition sets a point in the continuum of HIV pathogenesis in which the host has clinically demonstrated profound immune dysfunction. Many opportunistic infections and neoplasms serve as markers

Table 70-4 • Conditions Classified as Sexually Transmitted Diseases (STDs) and Their Routes of Transmission

DISEASE	ROUTE(S) OF TRANSMISSION
Chancroid, <i>Lymphogranuloma venereum</i> , and <i>Granuloma inguinale</i>	Sexual
Chlamydia	Sexual
Cytomegalovirus (CMV)	Sexual, less intimate contact
Gonorrhea	Sexual, perinatal
Hepatitis B (HBV)	Sexual, percutaneous, perinatal
Hepatitis C (HCV)	Percutaneous, probably sexual, probably perinatal
Herpes simplex	Sexual
HIV infection/AIDS	Sexual, percutaneous, perinatal
Human papillomavirus (HPV)	Sexual
Syphilis	Sexual, perinatal

for immunosuppression severity. Since 1993, the AIDS definition has also included a CD4-positive (CD4<sup>+</sup>) cell count of less than 200 as a threshold criterion. CD4<sup>+</sup> cells are a subset of lymphocytes and one of the targets of HIV infection.

HIV is transmitted through sexual contact, percutaneous injection of contaminated blood, or perinatally from infected mother to fetus. Most people infected by the percutaneous route are intravenous or injecting drug users who share contaminated needles, but transmission is also remotely possible through contaminated blood transfusion. Since 1985, all blood transfusions have been screened, and transfusion-related transmission of HIV is now extremely unlikely. Additional information on HIV is provided in Chapter 52.

## Risk to Health Care Workers

### NEEDLESTICK INJURIES

Health care workers can be infected through the percutaneous route if needlestick or other injury from a sharp object introduces contaminated blood. Prospective studies of this risk demonstrate that less than 1% of such occupational exposures (in which the source patient is infected with HIV) lead to transmission (CDC 2001a). Despite the rarity of transmission, health care workers are advised to take extreme care to avoid needlestick or mucous membrane exposure to blood of all patients. Since 2001, em-

ployers in health care institutions are required to provide devices designed to reduce the risk of needlestick and other injury when such devices are found to be beneficial. Since 1996, the CDC has recommended postexposure prophylaxis for significant occupational exposures to HIV. Counseling about the advisability of prophylaxis and appropriate medication and dose selection should be made on a case-by-case basis. Table 70-5 provides the recommended algorithm to determine which combination of antiretroviral drugs should be offered to the exposed health care worker. All health care workers should understand the need to report a needlestick or other percutaneous exposure immediately (CDC, 2001f).

## SYPHILIS

Syphilis is an acute and chronic infectious disease caused by the spirochete *Treponema pallidum*. It is acquired through sexual contact or may be congenital in origin.

### Stages of Syphilis

In the untreated person, the course of syphilis can be divided into three stages: primary, secondary, and tertiary. These stages reflect the time from infection and the clinical manifestations observed in that period, and are the basis for treatment decisions.

**Table 70-5 • Recommended Algorithm to Determine Post Exposure Prophylaxis (PEP)**

EXPOSURE TYPE	SOURCE HIV POSITIVE ASYMPTOMATIC OR VIRAL LOAD <1,500 RNA COPIES/ML	SOURCE HIV POSITIVE SYMPTOMATIC OR KNOWN HIGH VIRAL LOAD	SOURCE WITH UNKNOWN HIV STATUS	UNKNOWN SOURCE	SOURCE HIV NEGATIVE
Less severe percutaneous exposure (solid needle and superficial injury)	Basic two-drug regimen*	Basic two-drug regimen* and one drug from expanded drug list <sup>†</sup>	Generally, no PEP warranted, but consider basic two-drug regimen* if source has HIV risk factors	Generally, no PEP warranted, but consider basic two-drug regimen* in settings where exposure to HIV-infected persons is likely	No prophylaxis is warranted
More severe percutaneous exposure (large-bore hollow needle, deep puncture, visible blood on device, needle used in patient's artery or vein)	Basic two-drug regimen* and one drug from expanded drug list <sup>†</sup>	Basic two-drug regimen* and one drug from expanded drug list <sup>†</sup>	Same as above	Same as above	Same as above
Small-volume mucous membrane exposure or nonintact skin exposure (a few drops)	Basic two-drug regimen*	Basic two-drug regimen*	Same as above	Same as above	Same as above
Large volume mucous membrane exposure or nonintact skin exposure (large volume splash or spray)	Basic two-drug regimen*	Basic two-drug regimen* and one drug from expanded drug list <sup>†</sup>	Same as above	Same as above	Same as above

d4T, stavudine (Zerit); ddI, didanosine (Videx<sup>TM</sup>); 3TC, lamivudine (EpiVir); ZDV, zidovudine (Retrovir [AZT])

\*Basic two-drug regimen = (ZDV and 3TC) or (3TC and d4T) or (d4T and ddI).

<sup>†</sup>Expanded drug list: indinavir (Crixivan), nelfinavir (Viracept), abacavir (Ziagen), efavirenz (Sustiva)

Recommendations based on: Centers for Disease Control and Prevention. (2001). Updated U.S. Public Health Service guidelines for the management of occupational exposures to HBV, HCV, and HIV and recommendations for postexposure prophylaxis. *Morbidity and Mortality Weekly Report*, 50 (RR-11), 1–42.

*Primary syphilis* occurs 2 to 3 weeks after initial inoculation with the organism. A painless lesion at the site of infection is called a *chancre*. Untreated, these lesions usually resolve spontaneously within about 2 months.

*Secondary syphilis* occurs when the hematogenous spread of organisms from the original chancre leads to generalized infection. The rash of secondary syphilis generally occurs about 2 to 8 weeks after the chancre and involves the trunk and the extremities, including the palms of the hands and the soles of the feet. Transmission of the organism can occur through contact with these lesions. Generalized signs of infection may include lymphadenopathy, arthritis, meningitis, hair loss, fever, malaise, and weight loss.

After the secondary stage, there is a period of **latency**, during which the infected person has no signs or symptoms of syphilis. Latency can be interrupted by a recurrence of secondary syphilis.

*Tertiary syphilis* is the final stage in the natural history of the disease. It is estimated that between 20% and 40% of those infected do not exhibit signs and symptoms of this final stage. In this stage, syphilis presents as a slowly progressive, inflammatory disease with the potential to affect multiple organs. The most common manifestations at this level are aortitis and neurosyphilis, as evidenced by dementia, psychosis, paresis, stroke, or meningitis.

## Assessment and Diagnostic Findings

Because syphilis shares symptoms with many diseases, clinical history and laboratory evaluation are important. The conclusive diagnosis of syphilis can be made by direct identification of the spirochete obtained from the chancre lesions of primary syphilis. Serologic tests used in the diagnosis of secondary and tertiary syphilis require clinical correlation in interpretation. The serologic tests are summarized as follows:

- *Nontreponemal* or *reagin* tests, such as the Venereal Disease Research Laboratory (VDRL) or the rapid plasma reagin circle card test (RPR-CT), are generally used for screening and diagnosis. After adequate therapy, the test result is expected to decrease quantitatively until it is read as negative, usually about 2 years after therapy is completed.
- *Treponemal* tests, such as the fluorescent treponemal antibody absorption test (FTA-ABS) and the microhemagglutination test (MHA-TP), are used to verify that the screening test did not represent a false-positive result. Positive results usually are positive for life and therefore are not appropriate to determine therapeutic effectiveness.

## Medical Management

Treatment of all stages of syphilis is administration of antibiotics. Penicillin G benzathine is the medication of choice for early syphilis or latent syphilis of less than 1 year's duration. It is administered by intramuscular injection at a single session. The same therapy is recommended for patients with early latent syphilis. Patients with late latent or latent syphilis of unknown duration should receive three injections at 1-week intervals. Patients who are allergic to penicillin are usually treated with doxycycline. The patient treated with penicillin is monitored for 30 minutes after the injection to observe for a possible allergic reaction.

Treatment guidelines established by the CDC are updated on a regular basis. Recommendations provide special guidelines for treatment in the setting of pregnancy, allergy, HIV infection, pediatric infection, congenital infection, and neurosyphilis (CDC, 2002d).

## Nursing Management

Syphilis is a reportable communicable disease. In any health care facility, a mechanism should be in place to ensure that all patients who are diagnosed are reported to the state or local public health department to ensure community follow-up. The public health department is responsible for interviewing the patient to determine sexual contacts, so that contact notification and screening can be initiated.

Lesions of primary and secondary syphilis may be highly infective. Gloves are worn when having direct contact with lesions, and hands are washed after gloves are removed. Isolation in a private room is not required (Chart 70-4).

## GONORRHEA

*N. gonorrhoeae* is a gram-negative bacterium that is transmitted primarily through sexual contact. Infection can also occur in neonates as a result of contact during birth. *N. gonorrhoeae* can cause mucosal, local, or disseminated infection. Asymptomatic infection is somewhat common.

## Clinical Manifestations

Gonorrhea most frequently manifests with local manifestations. In men, urethritis and epididymitis are the most common symptoms. Gonorrhea is more likely to be asymptomatic in women than in men. The uterine cervix is the primary site of local infection, and symptoms often include urinary tract infection, increased vaginal discharge, and itching. The most common complication of localized gonococcal infection in women is pelvic inflammatory disease (PID), in which the organism infects the uterus, fallopian tubes, or peritoneal fluid. A complication of gonococcal PID is increased risk for ectopic pregnancy and bilateral tubal occlusion, which results in infertility.

In rare circumstances, the organism may disseminate in untreated, infected people. Other systemic signs, such as arthritis or dermatitis, can accompany bacteremia. In rare instances, valves of the heart can be infected with *N. gonorrhoeae*, or gonococcal meningitis can develop.

## Assessment and Diagnostic Findings

The patient is assessed for fever; for urethral, vaginal, and rectal discharge; and for signs of arthritis. Culture and sensitivity studies are the usual and preferred methods of diagnosing and verifying effectiveness of therapy. In the male patient, specimens are obtained from the urethra, anal canal, and pharynx. In the female

### Chart 70-4 • PATIENT EDUCATION Treating and Preventing the Spread of Syphilis

- The patient is instructed to complete the full course of therapy if multiple penicillin injections are required.
- The patient with primary or secondary syphilis is assured that with proper treatment, skin lesions and other sequelae of infection will improve, and serology eventually will reflect cure.
- The patient is instructed to refrain from sexual contact with previous or current partners until they have been treated.

patient, cultures are obtained from the endocervix, pharynx, and anal canal. When obtaining these cultures, the nurse should wear disposable gloves and wash hands thoroughly after glove removal. Lubricating jelly is not used for the vaginal examination because it may contain substances that inhibit growth or kill some pathogens, decreasing the microbiologic test accuracy. Instead, water is used as the lubricant. Because *N. gonorrhoeae* organisms are susceptible to environmental changes, specimens must be delivered to the laboratory immediately after they are obtained.

## Medical Management

The CDC-recommended treatment for gonorrheal infections is administration of ceftriaxone (Rocephin) (or cefixime [Suprax], ciprofloxacin [Cipro], or ofloxacin [Floxin]) along with doxycycline. Doxycycline is added to first-line therapy to treat presumptive *Chlamydia trachomatis*, which commonly causes coinfection in patients with gonorrhea. Patients with uncomplicated gonorrhea who are treated with CDC-recommended therapy do not routinely need to return for a proof-of-cure visit. If the patient reports a new episode of symptoms or tests reveal gonorrhea again, the most likely explanation is reinfection rather than treatment failure. Serologic testing for syphilis and HIV should be offered to patients with gonorrhea, because any STD increases the risk for other STD infections.

## Nursing Management

Gonorrhea is a reportable communicable disease. In any health care facility, a mechanism should be in place to ensure that all patients diagnosed with gonorrhea are reported to the local public health department to ensure follow-up of the patient. The public health department also is responsible for interviewing the patient to identify sexual contacts, so that contact notification and screening can be initiated.

## CHLAMYDIA TRACHOMATIS

*C. trachomatis* is a bacterium that requires attachment to the host cell, invasion, intracellular growth, and replication. This requirement for intracellular growth, which is similar to that of viruses, has made the identification and laboratory testing more difficult than for organisms that grow and replicate independently, but advances have made diagnosis and screening much more available.

## Clinical Manifestations

In women, the most frequent clinical manifestation is PID, but symptoms often are so subtle that pathologic progression can occur without detection. Long-term effects may include chronic pain, increased risk for ectopic pregnancy, postpartum endometritis, and infertility.

Transmission of infection from an infected pregnant woman to her vaginally born infant is common. About 20% to 50% of infected infants develop chlamydial conjunctivitis, and about 20% develop chlamydial pneumonia (Schacter & Grossman, 2001).

Although men infected with *Chlamydia* are frequently asymptomatic, they easily transmit the infection to their sexual partners.

Urethritis is the most common illness associated with infection in the heterosexual man with symptoms. Among homosexual men, the rectum is the common site of infection.

## Assessment and Diagnostic Findings

*Chlamydia* should be suspected in cases of gonorrhea, nongonorrheal urethritis, PID, and epididymitis. Diagnostic tools include cell culture techniques and a relatively wide range of nonculture techniques, including immunologic assays, DNA probes, and enzyme-sensitive tests.

## Medical Management

Treatment of chlamydial infection is usually administration of doxycycline or azithromycin. Neither of these antibiotics is recommended during pregnancy. CDC guidelines should be used to determine alternative therapy for the patient who is pregnant or allergic or who has complicated chlamydial infection. The patient and the sexual partner must be treated.

## Prevention and Patient Education

The target group for preventive patient teaching about *C. trachomatis* is the adolescent and young adult population. Abstinence, postponing the age of initial sexual exposure, limiting the number of sexual partners, and use of condoms for barrier protection should be promoted. It should also be stressed that screening for *Chlamydia* and treating infection at an early stage are important to decrease disease progression common to women and to decrease the likelihood of infection in infants.

## NURSING PROCESS: THE PATIENT WITH A SEXUALLY TRANSMITTED DISEASE

### Assessment

The patient should be asked to describe the onset and progression of symptoms and to characterize any lesions by location and by describing drainage, if present. Protecting confidentiality is important when discussing sexual issues. When a detailed sexual history is necessary, it is important to respect the patient's right to privacy. Brief explanations of why the information is asked are often helpful. Clarification of terms may be necessary if the patient or nurse uses words unfamiliar to the other. Asking specific information about sexual contacts usually should be done only when the nurse is part of a team that will contact the partners for follow-up. In the history-taking process, discussion about the patient's understanding of responsibility to inform sexual partners may be helpful in determining patient teaching goals.

During physical examination, the examiner looks for rashes, lesions, drainage, discharge, or swelling. Inguinal nodes are palpated to elicit tenderness and to assess swelling. Women are examined for abdominal or uterine tenderness. The mouth and throat are examined for signs of inflammation or exudate. The nurse wears gloves while examining the mucous membranes, and gloves are changed and replaced after vaginal or rectal examination.

## Diagnosis

### NURSING DIAGNOSES

Based on assessment data, the patient's major nursing diagnoses may include the following:

- Deficient knowledge about the disease and risk for spread of infection and reinfection
- Anxiety related to anticipated stigmatization and to prognosis and complications
- Noncompliance with treatment

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on assessment data, potential complications that may develop include the following:

- Increased risk for ectopic pregnancy
- Infertility
- Transmission of infection to fetus resulting in congenital abnormalities and other outcomes
- Neurosyphilis
- Gonococcal meningitis
- Gonococcal arthritis
- Syphilitic aortitis
- HIV-related complications

## Planning and Goals

Major goals are increased patient understanding of the natural history and treatment of the infection, reduction in fear, increased compliance with therapeutic and preventive goals, and absence of complications.

## Nursing Interventions

### INCREASING KNOWLEDGE AND PREVENTING SPREAD OF DISEASE

Education about and prevention of the spread of STDs to others is often accomplished simultaneously. Discussion about risk factors should emphasize that the same behaviors that led to infection with one STD may introduce risk for any other STD, including HIV. Methods used to contact sexual partners should be discussed. The patient should understand that, until the partner has been treated, continued sexual exposure to the same person may lead to reinfection. Patients may need help in planning discussion with partners. If the patient is especially apprehensive about this aspect, referral to a social worker or other specialist may be appropriate. Such support is especially important when the patient has newly diagnosed HIV infection.

The relative value of condoms in reducing the risk for infection with STDs should be addressed. When appropriate, the patient should be encouraged to discuss any reasons for resistance to condom use, so that decision making about this preventive method can be facilitated.

The infected patient should be told what the causative organism is and should receive an explanation of the usual course of the infection (including interval of potential communicability to others) and possible complications. The nurse should stress the importance of following therapy as prescribed and the need to report any therapeutic side effects or symptom progression.

### REDUCING ANXIETY

When appropriate, the patient is encouraged to discuss anxieties and fear associated with the diagnosis, therapy, or prognosis. By individualizing teaching efforts, factual information applied to specific needs may offer reassurance. For example, patients with HIV should be encouraged to participate in well-coordinated programs in which support, education, counseling, and therapeutic goals are combined. Such programs are designed to offer coordinated care throughout the course of disease progression.

### INCREASING COMPLIANCE

In group settings (eg, offered in an outpatient obstetric setting) or in a one-on-one setting, open discussion about STD information facilitates patient teaching. Discomfort can be reduced by factual explanation of causes, consequences, treatments, prevention, and responsibilities. Because most communities have expanded STD prevention resources, referrals to appropriate agencies can complement individual educational efforts and ensure that later questions or uncertainties can be addressed by experts. Patients can obtain more information by using the CDC website (<http://www.cdc.gov/nchstp/dstd/disease>) or by using the voice mail number (1-888-CDC FACT).

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

#### Infertility and Increased Risk for Ectopic Pregnancy

STDs may lead to PID and, with it, increased risk for ectopic pregnancy and infertility.

#### Congenital Infections

All STDs can be transmitted to infants in utero or at the time of birth. Complications of congenital infection can range from localized infection (eg, throat infection with *N. gonorrhoeae*) to congenital abnormalities (eg, stunting of growth or deafness from congenital syphilis), to life-threatening disease (eg, congenital herpes simplex virus).

#### Neurosyphilis, Gonococcal Meningitis, Gonococcal Arthritis, Syphilitic Aortitis

STDs can cause disseminated infection. The central nervous system may be infected, as seen in cases of neurosyphilis or gonococcal meningitis. Gonorrhea that infects the skeletal system may result in gonococcal arthritis. Syphilis can infect the cardiovascular system by forming vegetative lesions on the mitral or aortic valves.

#### Human Immunodeficiency Virus–Related Complications

HIV, which is primarily spread as an STD, leads to the profound immunosuppression of AIDS. Complications of HIV infection include many opportunistic infections, including *Pneumocystis carinii*, *Cryptococcus neoformans*, cytomegalovirus, and *Mycobacterium avium*.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Acquires knowledge and understanding of STDs
2. Demonstrates a less anxious demeanor
  - a. Discusses anxieties and goals for treatment
  - b. Inspects self for lesions, rashes, and discharge

Chart 70-5

## Home Care Checklist • Prevention of Infection in the Home Care Setting

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Demonstrate aseptic technique in the care of technical equipment such as intravenous catheter, indwelling urinary catheter.	✓	✓
• Demonstrate thorough hand washing after patient care.	✓	✓
• Provide assurance of compliance with antibiotic regimen or with completion of vaccination series.	✓	✓
• State the rationale for thoroughly cooking all foods and storing meat products separate from other food groups.	✓	✓
• Use separate eating utensils and towels.	✓	✓
• Avoid contact with someone who has a known infectious disease.	✓	✓

- c. Accepts support education, and counseling when indicated
- d. Assists with sharing information about infection to sexual partners
- e. Discusses risk-reduction behaviors and safer sex practices
3. Complies with treatment
  - a. Achieves effective treatment
  - b. Reports for follow-up examination if necessary
4. Absence of complications

## Home-Based Care of the Patient With an Infectious Disease

### REDUCING RISK

The nurse who cares for the patient in the home should provide infection risk prevention for the patient, the family, and the caregiver (Chart 70-5).

#### Reducing Risk to the Patient

Patients requiring home care are often those with immunosuppression from underlying conditions, such as HIV infection or cancer, or those who have therapy-induced immunosuppression, as occurs with many antineoplastic agents. Careful assessment for signs of infection is important.

#### HAND HYGIENE

Hand washing or use of an alcohol-based hand disinfectant in the home is an important preventive strategy. Whether a treatment is performed by the nurse, the family, or the patient, appropriate hand hygiene reduces the risk of transient flora.

#### EQUIPMENT CARE

Health care equipment increases infection risk because it is complex and invasive. All caregivers must be taught to pay careful attention to disinfection and aseptic technique. The nurse and the family members should be alert for any redness, swelling, or drainage around a catheter insertion site. Catheter-related sepsis should be suspected in a patient who has unexplained fever.

There is no recommended interval for the changing of indwelling urinary catheters. The nurse should promptly report to the patient's physician signs of urinary tract infection or of generalized sepsis.

#### PATIENT TEACHING

When assessing the immune-suppressed patient in the home environment for infectious risk, it is important to realize that intrinsic colonizing bacteria and latent viral infections present a greater risk than do extrinsic environmental contaminants. The patient and family need reassurance that their home should be clean but not sterile. Common-sense approaches to cleanliness and risk reduction are helpful. The severely neutropenic patient should refrain from eating uncooked fruits and vegetables. For patients with neutropenia or with T-cell dysfunction (eg, patients with AIDS), it is wise to restrict visits of people with potentially contagious illnesses.

#### Reducing Risk to Household Members

##### ESTABLISHING BARRIERS AND PRECAUTIONS

Establishing careful barriers to infection transmission in the household is an important part of home care. The route of transmission of the organism in question must first be determined. The nurse can then teach household members strategies to reduce their risk of becoming infected. If the patient has active pulmonary TB, the public health department should be contacted to provide screening and treatment for family members. If a patient has shingles (herpes zoster), family members who have had varicella vaccine or who have previously had chickenpox are considered immune and need no precautions. However, if a family member is immunosuppressed or otherwise susceptible to varicella, maintaining physical separation may be an important strategy during the time when the patient has draining lesions.

##### FOOD PREPARATION AND PERSONAL HYGIENE

Organisms transmitted by the fecal-oral route may be readily spread in a household setting unless careful attention to food preparation and personal hygiene is maintained. Family caregivers may be vulnerable to acquiring organisms such as *Shigella* species and *C. difficile* when assisting in personal care. Hands should be thoroughly disinfected after such contact. The family should be reassured that common household disinfectants are effective in killing environmental sources of such organisms.

##### BLOODBORNE INFECTION RISK

Family members who assist in the care of a patient with a bloodborne infection such as HIV or hepatitis C should be alert for the potential of transmission if sharp objects contaminated with blood are handled. Family teaching may be designed to discuss the need for caution when shaving the patient, performing dress-

ing changes, or administering any intravenous, intramuscular, or subcutaneous medication. It is important to set up an impenetrable container for the collection of needles, syringes, and vascular access equipment.

The nurse should also teach the family about infections that are and are not contagious to family members. With the exception of TB, the opportunistic infections associated with AIDS do not pose a risk to the healthy family member. Family members should be reassured that dishes are safe to use after being washed with hot water and that linens and clothing are safe to use after being washed in a hot-water cycle.

## Reducing Risk to the Caregiver

Recognizing that a health history may not identify all active or latent infections, the caregiver should carefully follow Standard Precautions in the home. Setting up a work environment in which hand disinfection and aseptic technique can be accomplished as carefully as they are in a hospital setting is important.

It is important for the home caregiver to receive annual influenza vaccine. This is especially true if the caregiver or the patient is older than 50 years of age, has underlying cardiac or pulmonary disease, or has underlying immunosuppression.

## Nursing Process: The Patient With an Infectious Disease

### Assessment

Symptoms of infectious diseases vary significantly between and within diseases. For some infections, such as chickenpox (varicella), widely disseminated rash represents the first suggestion of infection, and it occurs in most newly infected people. In other infections, such as TB and HIV, latency is prolonged, and most of those infected do not have symptoms; instead, infection is determined through diagnostic procedures.

History taking, physical examination, and the use of diagnostic tests are important for determining the presence of infection and infectious diseases. The goals of eliciting the history are to establish the likelihood and probable source of infection and the degree of associated pathology and symptoms. The patient's previous medical record is reviewed when possible. In obtaining a health history, some of the following questions may be asked:

- Does the patient have a history of previous or recurrent infections? Is the patient aware of infection with an organism associated with prolonged latency, such as HIV, herpesvirus, or TB?
- Has there been fever? How high has the patient's temperature been? What is the fever pattern? Is the temperature constant, or does it rise and fall? Has fever been associated with chills? Has the patient taken medication to relieve fever?
- Is there cough? Is the cough chronic or acute? Is it associated with shortness of breath? Does the cough produce sputum? Is the sputum bloody? Has the patient had a PPD test performed recently? If so, what were the results? Has the patient been given isoniazid (INH) prophylaxis for TB infection? Has the patient been treated for TB in the past?

- Is there pain? Where is the pain? What is the nature of the pain? Does the patient have sore throat, headache, myalgias, or arthralgias? Is there pain on urination or other activity?
- Is there swelling? Is there drainage associated with the swelling? Is the swollen area warm to touch?
- Is there a draining site? Is the drainage associated with trauma or a previous procedure? Is the drainage purulent or clear?
- Does the patient have diarrhea, vomiting, or abdominal pain?
- Is there rash? What is the nature of the rash—is it flat, raised, red, crusted, purulent, or lacelike?
- What is the patient's vaccination history?
- Has the patient taken medications that could induce rash?
- Has there been exposure to another person who has an identified infectious disease or rash?
- Has there been an insect or animal bite? Has there been an animal scratch or other exposure to pets, farm animals, or experimental animals?
- What medications are used? Have antibiotics been taken recently or long-term? Is the patient being treated with corticosteroids, immunosuppressing agents, or chemotherapy?
- Is there a history of substance abuse?
- Has the patient been treated in the past for other infectious diseases? Has the patient been hospitalized for infectious diseases?
- If sexual history is pertinent, has there been sexual exposure to another person with a known STD? Has the patient been treated for STDs in the past? Is the patient pregnant, or has she recently been pregnant? Has the patient been tested for HIV?
- Has the patient traveled to or from a developing country or abroad? What was the immunization or antimicrobial prophylaxis used for protection while traveling?
- What is the patient's occupation?

Because infection may occur in any body system, physical examination may reveal signs of infection at any body site. Generalized signs of chronic infection may include significant weight loss or pallor associated with anemia of chronic diseases. Acute infection may manifest with fever, chills, lymphadenopathy, or rash. Localized signs vary significantly according to the source of infection. Purulence, pain, swelling, and redness are strongly associated with localized infection. Cough and shortness of breath may be caused by influenza, pneumonia, or TB, as well as many noninfectious causes.

## Diagnosis

### NURSING DIAGNOSES

Based on assessment data, the patient's major nursing diagnoses related specifically to infection may include the following:

- Risk for infection transmission
- Deficient knowledge about the disease, cause of infection, treatment, and prevention measures
- Risk for imbalanced body temperature (fever) related to the presence of infection

Infection may interrupt normal function of any affected body system. These system alterations can be reviewed through the nursing diagnoses for body systems listed in the appropriate chapters.

### COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include the following:

- Septicemia, bacteremia, or sepsis
- Septic shock
- Dehydration
- Abscess formation
- Endocarditis
- Infectious disease–related cancers
- Infertility
- Congenital abnormalities

### Planning and Goals

Major goals for the patient may include prevention of spread of infection, increased knowledge about the infection and its treatment, control of fever and related discomforts, and absence of complications.

### Nursing Interventions

#### PREVENTING INFECTION TRANSMISSION

Preventing the spread of infection requires an understanding of the usual routes of transmission of the organism. The hospitalized patient may serve as a risk for transmission to other patients if the patient's disease was spread by the airborne route or if infected by an organism such as *C. difficile*, which can be spread directly to others by persistence of spores in the environment. In these situations, strict adherence to isolation measures is important in reducing the opportunity for spread. Preventing transmission of organisms from patient to patient usually requires participation of the health care team. Transmission of organisms on the hands and gloves of health care workers remains a common source of cross-infection in the hospital or clinic setting.

Nurses serve an important role in preventing the transfer of organisms in two ways. First, as the health professionals who often spend the most time with patients, nurses have a greater opportunity for spreading organisms. It is imperative that nurses disinfect their hands before and after contact with patients and after performing a potentially hand-contaminating activity. Hands must be disinfected each time gloves are removed. For example, the nurse who has performed endotracheal suctioning should remove gloves and wash hands before performing wound care on the same patient.

The second way that nurses reduce hand-to-hand spread is to serve as patient advocates. With the number of health care workers involved in patient care each day, there is a significant opportunity for breaks in hand-hygiene technique. To the degree feasible, the nurse should observe the hand-hygiene activities of other professionals and discuss them when lapses in technique are observed.

#### TEACHING ABOUT THE INFECTIOUS PROCESS

For infectious diseases, interruption of transmission requires diagnosis and patient compliance with the treatment regimen. The nurse's role is to educate and, in some situations, to report the case to public health officials for contact tracing and verification of follow-up.

The nurse must stress the importance of immunization to parents of young children and to others for whom vaccines are recommended, such as patients who are elderly, are immunosuppressed, or have chronic illnesses. Nurses should recognize their

personal responsibility to receive hepatitis B and annual influenza vaccine to reduce potential transmission to self and vulnerable patient groups.

Infectious diseases often seem mysterious and frequently are socially stigmatizing. Patient teaching efforts require empathy and sensitivity. For example, in the past, TB was considered a stigmatized disease. The nurse may need to provide core information to the patient who needs INH prophylaxis in order to promote understanding and allay guilt that the patient may feel.

#### CONTROLLING FEVER AND ACCOMPANYING DISCOMFORTS

Fever must always be investigated to determine whether infection is the source. There is evidence that fever, mediated by the hypothalamus, may potentiate beneficial functions in the syndrome of reactions known as *acute-phase reaction*. These reactions include changes in liver protein synthesis; alterations in serum metals, such as iron; and increased production of certain classes of white blood cells and other immune system cells. Most fevers are physiologically controlled to stay below 105.8°F (41°C). However, severe fever, as occurs with meningococcal meningitis, may cause heat stroke and other complications. Even milder fevers accompanied by fatigue, chills, and diaphoresis are often uncomfortable for the patient. The physician makes decisions regarding fever control. Whether fever is treated or untreated, adequate fluid intake is important during febrile episodes.

**NURSING ALERT** Because fever offers clues about infection severity and success of antibiotic therapy, outpatients with fever should be taught to obtain accurate temperature readings. Frequently, parents know that a child has warm skin but do not disturb the child by taking a temperature reading. Body temperature information can be very helpful in adjusting therapy or in reevaluating a preliminary diagnosis.

#### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

The patient with a rapidly progressive infectious disease should have vital signs and level of consciousness closely monitored. X-ray findings and microbiologic, immunologic, hematologic, cytologic, and parasitologic laboratory values must be interpreted in the context of other clinical findings to assess the infectious disease course.

Antibiotic therapy is frequently complex, with modifications necessary because of sensitivity test results and disease progression. It is important to initiate antibiotic therapy as soon as it is prescribed, rather than waiting until routine medication scheduling times. This ensures that therapeutic blood levels can be attained as quickly as possible. The Plan of Nursing Care describes nursing interventions for specific complications of infection.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Uses appropriate methods to prevent the spread of infection
2. Acquires knowledge about the infectious process
3. Exhibits absence of elevated body temperature

(text continues on page 2145)

## Plan of Nursing Care

### Care of the Patient With An Infectious Disease

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Risk for infection transmission

**Goal:** Preventing transmission of infectious agents

<p>1. Prevent patient-to-patient infection spread</p> <p>a. Provide isolation according to CDC guidelines and Standard Precautions</p> <p>b. Ensure that patients with airborne infections remain in private rooms during hospital stay. If they must leave their rooms, arrangements should be made to decrease the likelihood of contact with other patients. Rooms should be ventilated according to CDC criteria. Personal protective equipment in the form of N95 respirators should be worn as indicated.</p> <p>The N95 respirator is the minimal level of personal protection for tuberculosis control. The “N” indicates the filter resistance to oil aerosols; and the “95” indicates that the respirator has 95% effectiveness in filtering test particles (CDC, 1998c).</p> <p>In any care setting where patients may have increased risk for the sequelae of influenza, annual influenza vaccination should be encouraged for personnel and patients.</p> <p>c. Ensure that patients with highly transmissible, nonairborne organisms such as <i>Clostridium difficile</i> and <i>Shigella</i> species are physically separated from other patients if hygiene or institutional policy dictates.</p> <p>2. Prevent health care worker’s transfer of organisms from patient to patient</p> <p>a. Perform hand hygiene (by hand washing or by use of alcohol-based solution) consistently and thoroughly, disinfecting hands before and after each patient contact, and after procedures that offer contamination risk while caring for an individual patient</p> <p>b. Use gloves when handling any body fluid from any patient. Change gloves between patient care activities, and disinfect hands after gloves are removed.</p> <p>c. Avoid wearing artificial fingernails or extenders when providing patient care. Keep natural nails less than ¼ inch long</p>	<p>1. Organisms that are spread through an airborne route or are very contagious through direct contact can be transmitted in a health care setting.</p> <p>a. CDC isolation strategies are developed to reduce the likelihood of transmission from patient to patient.</p> <p>b. Engineering controls are important in the prevention of airborne diseases. Influenza vaccine safely reduces risk of illness associated with this highly communicable, and frequently virulent, condition.</p> <p>c. Increased prevention strategies are needed when the organism has high epidemic potential.</p> <p>2. Transfer of organisms on the hands of health care workers is a common route of transmission. Hospital organisms colonizing the hands of health care workers may be virulent.</p> <p>a. Hand hygiene is important in reducing transient flora on outer epidermal layers of skin. Alcohol-based hand disinfectants are effective methods to reduce transient flora.</p> <p>b. Gloves provide effective barrier protection. Gloves quickly become contaminated and then become a potential vehicle for the transfer of organisms between patients. Microflora on hands are likely to proliferate while gloves are worn.</p>	<ul style="list-style-type: none"> <li>• No evidence of patient-to patient transmission of infection</li> <li>• No evidence of transmission via health care workers</li> <li>• No occupationally acquired infections in nurses and other health care workers</li> <li>• No evidence of transmission due to contaminated equipment</li> <li>• Absence of bacteremia, septicemia, and sepsis</li> <li>• Absence of urinary tract infections</li> <li>• Absence of pneumonia</li> </ul>
---	--	--

(continued)

## Plan of Nursing Care

### Care of the Patient With An Infectious Disease (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<p>d. Monitor the hand hygiene and glove use behaviors of health care professionals caring for the patient.</p> <p>3. Prevent patient-to-health care worker transmission of infection.</p> <p>a. Avoid risk of infection with tuberculosis</p> <p>(1) Participate in the early identification of patients with active disease. Patients will be asked about risk factors, symptoms, previous exposure, and PPD status.</p> <p>(2) Expedite diagnostic work-up with chest x-ray, sputum analysis for organisms, and PPD administration as appropriate.</p> <p>(3) Maintain engineering controls. Keep the patient in a private room with a closed door.</p> <p>(4) Use protection in isolation room or when participating in procedures that are likely to generate cough, such as suctioning, intubation, or administering nebulized medications.</p> <p>b. Avoid risk of transmission of blood-borne diseases such as hepatitis B, hepatitis C, and the human immunodeficiency virus</p> <p>(1) Get hepatitis B vaccination</p> <p>(2) Use Standard Precautions as defined by the CDC</p> <p>(3) Use “needleless” syringes and other injury-preventing devices</p>	<p>d. Poor compliance with hand hygiene among health care workers has been well documented and should be anticipated. It is important for the nurse as the patient’s advocate to communicate protective behavior.</p> <p>3. Health care workers may acquire infections occupationally due to close contact with patients.</p> <p>a. The most important element in the reduction of tuberculosis is early identification. Many of the symptoms of tuberculosis are subtle, and may be first observed by the nurse who has prolonged contact with the patient.</p> <p>(1) Identification of patients at risk can help to prevent exposure.</p> <p>(2) Confirmation of diagnosis facilitates development of an appropriate treatment plan, including prevention of spread of infection.</p> <p>(3) Confining airflow to the immediate vicinity of the patient and exhausting air to the outside reduce the likelihood of transmission to health care workers in areas outside of the patient room.</p> <p>(4) N95 respirators are designed to reduce health care worker risk.</p> <p>b. Health care workers can contract blood-borne diseases via percutaneous injury such as needlestick or by contact with blood or bloody body fluids to mucous membranes, such as eyes and mouth.</p> <p>(1) Hepatitis B vaccine should be administered to reduce risk from this contagious bloodborne virus.</p> <p>(2) Standard Precautions are based on the recognition that most patients are not identified as infected by physical assessment or history taking. Health care workers must assume that all patients may be infected with bloodborne or other infection and must use barrier precautions appropriately for <i>all</i> patients.</p> <p>(3) Use of injury-preventing devices decreases risk of transmission of blood-borne diseases.</p>	

(continued)

## Plan of Nursing Care

### Care of the Patient With An Infectious Disease (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<p>c. Avoid risk of airborne diseases.</p> <p>(1) Get influenza vaccination annually.</p> <p>(2) Get vaccinated or produce proof of immunity to measles, mumps, rubella, and varicella.</p> <p>4. Prevent patient exposure to contaminated medical equipment.</p> <p>a. Ensure that equipment that is inserted through intact skin is sterilized between patient uses.</p> <p>b. Ensure that equipment that has contact with mucous membranes is sterilized or receives “high-level disinfection” between patient uses.</p> <p>c. Ensure that equipment used against intact skin is thoroughly cleaned and receives “low-level disinfection” between patient uses.</p> <p>5. Follow established guidelines for the routine removal and replacement of intravenous devices.</p> <p>6. Remove urinary catheters at the earliest time possible.</p> <p>7. Remove endotracheal and nasogastric tubes as soon as possible.</p>	<p>c. Influenza vaccine is recommended for health care workers to reduce the likelihood of transmission in health care settings where immunocompromised patients can become exposed.</p> <p>4. Technologic advances offer increased opportunity for invasive procedures. Equipment may be complex and difficult to clean.</p> <p>a. Sterilization renders equipment free of all microorganisms.</p> <p>b. High-level disinfection renders an object free of all microorganisms with the possible exception of spore-producing organisms.</p> <p>c. The disinfection goal for low-level disinfection is to reduce the load of microorganisms to a level that is not threatening to the host with intact skin.</p> <p>5. Indwelling intravascular devices can serve as a conduit for organisms to migrate into the bloodstream.</p> <p>6. The risk of urinary tract infections is directly proportional to the length of time that a urinary catheter remains in place.</p> <p>7. The risk for pneumonia is increased as the duration of indwelling equipment increases.</p>	

**Nursing Diagnosis:** Deficient knowledge about disease, cause of infection, and preventive measures

**Goal:** Acquisition of knowledge about the infectious process

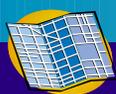

<p>1. Listen carefully to what the patient says about illness and previous treatment.</p> <p>2. Provide pertinent explanations about:</p> <p>a. Organism and route of transmission</p> <p>b. Treatment goals</p> <p>c. Follow-up schedule</p> <p>d. Prevention of transmission to others</p> <p>3. Allow opportunities for questions and discussions</p> <p>4. Teach the patient and family about:</p> <p>a. Prophylaxis or immunization, if recommended</p> <p>b. Community resources, if necessary</p> <p>c. Means of preventing transmission within the home</p>	<p>1. Listening facilitates detection of misunderstanding and misinformation and provides opportunity for education.</p> <p>2. Knowledge about specific diagnoses and treatments may increase compliance.</p> <p>3. The patient’s questions indicate issues that need clarification.</p> <p>4. Understanding of the risks and precautions associated with an infectious disease may reduce the opportunity for further spread.</p>	<ul style="list-style-type: none"> <li>• Patient actively participates in treatment.</li> <li>• Patient complies with infection control measures</li> </ul>
---	--	---

**Nursing Diagnosis:** Risk for imbalanced body temperature (fever) related to the presence of infection

**Goal:** Patient comfort and return of normal temperature

<p>1. Monitor temperature, pulse, and respirations at regular intervals</p>	<p>1. Graph fever curve to help evaluate when fever occurs, how long it lasts, and whether it responds to therapy.</p>	<ul style="list-style-type: none"> <li>• Body temperature within normal limits</li> <li>• Maintenance of fluid and electrolyte balance</li> <li>• Patient comfortable</li> </ul>
---	--	--

(continued)

## Plan of Nursing Care

### Care of the Patient With An Infectious Disease (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<p><b>Collaborative Problems:</b> Among potential complications are septicemia, bacteremia, or sepsis, septic shock, dehydration, abscess formation, endocarditis, infectious disease–related cancers, and infertility.</p>		
<p><b>Goal:</b> Absence of complications</p>		
<p><b>Septicemia, Bacteremia, Sepsis</b></p>		
<ol style="list-style-type: none"> <li>1. Monitor patient for evidence of infection at any location.</li> <li>2. Assess treatment effectiveness of all identified infections.</li> <li>3. Administer antibiotics as prescribed with first dose given at the earliest time possible.</li> </ol>	<ol style="list-style-type: none"> <li>1. Vigilance for bacterial or fungal infection at any site promotes early recognition and treatment and reduces the likelihood of secondary infections.</li> <li>2. The natural course of some infections may be rapid unless antibiotics are administered promptly.</li> <li>3. Prompt treatment will improve outcomes.</li> </ol>	<ul style="list-style-type: none"> <li>• No episode of infection</li> <li>• Effective treatment of identified bacterial and fungal infections without progression to bloodstream infection</li> <li>• Early improvement in septic course</li> </ul>
<p><b>Septic Shock</b></p>		
<ol style="list-style-type: none"> <li>1. Routinely, and as warranted, monitor vital signs for patients with recognized infections and severely immune suppressed patients at risk for shock. In particular, be alert for signs of:               <ol style="list-style-type: none"> <li>a. Fever</li> <li>b. Tachycardia (more than 90 bpm)</li> <li>c. Tachypnea (more than 20 breaths/min)</li> <li>d. Evidence of decreased perfusion or dysfunction of vital organs in the form of                   <ol style="list-style-type: none"> <li>(1) Change of mental status</li> <li>(2) Hypoxemia as measured by arterial blood gases</li> <li>(3) Elevated lactate levels</li> <li>(4) Urine output (less than 30 mL/h)</li> </ol> </li> </ol> </li> <li>2. Administer antibiotics, fluid replacement, vasopressors, and oxygen as prescribed.</li> </ol>	<ol style="list-style-type: none"> <li>1. Early recognition of the signs and prompt treatment of impending shock may reduce the associated severity or mortality.</li> <li>2. Therapeutic maintenance of hemodynamic and respiratory status is necessary until infection is effectively treated with antimicrobial regimen.</li> </ol>	<ul style="list-style-type: none"> <li>• Absence of symptoms of septic shock</li> <li>• Hemodynamic and respiratory status within normal range</li> </ul>
<p><b>Dehydration</b></p>		
<ol style="list-style-type: none"> <li>1. Assess for dehydration (thirst, dryness of mucous membranes, loss of skin turgor, reduced peripheral pulses, urine output less than 30 mL/h).</li> <li>2. Monitor weight.</li> <li>3. Monitor intake and output and serum electrolyte levels.</li> <li>4. Replace fluids as needed. If the patient can tolerate oral fluids, offer fluids every 2–4 hours. Administer intravenous fluids as prescribed.</li> </ol>	<ol style="list-style-type: none"> <li>1. Signs of dehydration provide a basis for fluid replacement and suggest possible further complications of circulatory collapse.</li> <li>2. Rapid changes in weight indicate fluid volume changes.</li> <li>3. Dehydration produces a deficit in some electrolytes. Decreased urine production may indicate hypovolemia and decreased renal perfusion.</li> <li>4. When possible, oral hydration is preferable because the patient can select the beverage, control the rate and interval of replacement, and care for self at home. Additionally, the risks associated with vascular devices are avoided. If intravenous fluid is required, intravenous solutions are formulated to facilitate intestinal reabsorption of fluid and electrolytes.</li> </ol>	<ul style="list-style-type: none"> <li>• Attains fluid balance (output approximates intake; body weight unchanged)</li> <li>• Mucous membranes appear moist; normal skin turgor</li> <li>• Serum electrolytes are within normal limits</li> </ul>

(continued)

## Plan of Nursing Care

### Care of the Patient With An Infectious Disease (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<b>Abscess Formation</b>		
<ol style="list-style-type: none"> <li>1. Assess vascular access sites, wound sites, pressure ulcers, and other appropriate sites for apparent collections of purulent material.</li> <li>2. Assess the patient who has had abdominal surgery or trauma to abdominal area for localized signs of intra-abdominal abscess. These signs include:               <ol style="list-style-type: none"> <li>a. Low-grade fever</li> <li>b. Elevated peripheral white blood cell count</li> <li>c. Localized pain</li> <li>d. Abdominal tenderness</li> <li>e. Visible or palpable mass</li> <li>f. Postoperative diarrhea</li> <li>g. GI bleeding</li> </ol> </li> <li>3. Assess patient who has had percutaneous abscess drainage to determine whether drainage has been successful. Be alert for all of the above signs and symptoms.</li> <li>4. Administer antibiotics as prescribed</li> </ol>	<ol style="list-style-type: none"> <li>1. Collections of purulent material often require drainage before antimicrobial therapy is effective.</li> <li>2. Intra-abdominal abscess formation is most common following traumatic or surgical disruption of the GI tract. Signs are often initially subtle.</li> <li>3. After percutaneous drainage, recurrent or persistent signs of abscess may indicate the need for surgical treatment.</li> <li>4. Antibiotics, along with drainage, are the most important elements of intra-abdominal abscess management.</li> </ol>	<ul style="list-style-type: none"> <li>• Absence of abscess</li> <li>• Takes antibiotics as prescribed.</li> </ul>
<b>Endocarditis</b>		
<i>Prevention</i>		
<ol style="list-style-type: none"> <li>1. Teach patients with the following conditions about the value of antibiotic prophylaxis for events and procedures that may introduce the risk of endocarditis:               <ol style="list-style-type: none"> <li>a. Valvular disease</li> <li>b. Congenital heart disease</li> <li>c. Intracardiac prosthesis</li> <li>d. Previous endocarditis</li> </ol> </li> </ol>	<ol style="list-style-type: none"> <li>1. Patients with underlying valvular disease and other cardiac abnormalities are at increased risk for “seeding” of the cardiac valves during procedures that can cause bacteremia.</li> </ol>	<ul style="list-style-type: none"> <li>• Informs health care professionals of cardiac conditions that require antibiotic prophylaxis before invasive procedures</li> <li>• Takes prophylactic antibiotics as prescribed</li> </ul>
<i>Management</i>		
<ol style="list-style-type: none"> <li>1. Obtain blood cultures as prescribed; carefully record results. Note persistent bloodstream infections with a particular organism.</li> <li>2. Obtain a detailed history about the duration of fever in the absence of well-recognized cause.</li> <li>3. Administer intravenous antibiotic therapy at prescribed time schedule.</li> </ol>	<ol style="list-style-type: none"> <li>1. A definitive diagnosis of endocarditis requires blood culture confirmation.</li> <li>2. Endocarditis should be suspected in patients who report an unexplained fever of more than 1 week’s duration</li> <li>3. Intravenous therapy is usually required for cure. The goal of therapy is complete eradication of all organisms. Careful adherence to following the scheduled administration is therefore essential.</li> </ol>	<ul style="list-style-type: none"> <li>• Endocarditis is diagnosed, treated, and cured.</li> </ul>

#### Infectious Disease-Related Cancers and Infertility

These potential complications of infectious diseases are prevented by primary avoidance of infection. Management of them is directed toward treating each of them as a non-infectious entity. For example, the management of cancer secondary to hepatitis B is handled as an oncology issue, not as an infectious disease issue.

## Critical Thinking Exercises

- Several patients on your nursing unit have become infected with the same bacteria. The staff wants to develop a campaign to reduce the risk of bacterial transmission between patients. What issues should be stressed? What products should be available? How can the situation be monitored? What outcome measures can be used to determine success of the campaign?
- You are supervising a patient care technician who is preparing to perform a venipuncture. The equipment that he has brought into the patient's room does not include gloves. How would you evaluate this situation, and what action would you take? Explain the rationale for your decision.
- An elderly patient with cardiac disease and diabetes asks you why her physician suggested that she receive influenza and pneumococcal vaccinations. She states that she is afraid the vaccinations will "make me sick." How would you respond to her and explain the situation? Describe the line of reasoning you would follow to persuade her to get the vaccine. If she rejects your explanation, examine the different courses of action you could take and the pros and cons of each strategy.

# Emergency Nursing

## LEARNING OBJECTIVES

*On completion of this chapter, the learner will be able to:*

1. Explain emergency care as a collaborative, holistic approach that includes the patient, the family, and significant others.
2. Discuss priority emergency measures instituted for any patient with an emergency condition.
3. Describe the emergency management of patients with intra-abdominal injuries.
4. Identify the priorities of care for the patient with multiple injuries.
5. Compare and contrast the emergency management of patients with heat stroke, frostbite, and hypothermia.
6. Specify the similarities and differences for the emergency management of patients with swallowed or inhaled poisons, skin contamination, and food poisoning.
7. Discuss the emergency management of patients with drug overdose and with acute alcohol intoxication.
8. Describe the significance of crisis intervention in the care of the rape victim.
9. Differentiate between the emergency care of patients who are over-active, those who are violent, those who are depressed, and those who are suicidal.

The term *emergency management* traditionally refers to care given to patients with urgent and critical needs. Because many people lack access to health care, however, the emergency department (ED) is increasingly used for non-urgent problems. Therefore, the philosophy of emergency management has broadened to include the concept that an emergency is whatever the patient or the family considers it to be.

Large numbers of people seek emergency care for serious life-threatening cardiac conditions, such as myocardial infarction, acute heart failure, pulmonary edema, and cardiac dysrhythmias. Priorities for managing these cardiac conditions are discussed in Chapters 27, 28, and 30. Emergency management of trauma and other conditions not found elsewhere in this book are discussed in this chapter. It is assumed that care and treatment are provided under the direction of a physician or emergency nurse practitioner.

## Scope and Practice of Emergency Nursing

The emergency nurse has had specialized education, training, and experience to gain expertise in assessing and identifying patients' health care problems in crisis situations. In addition, the emergency nurse establishes priorities, monitors and continuously assesses acutely ill and injured patients, supports and attends to families, supervises allied health personnel, and teaches patients and families within a time-limited, high-pressured care environment. Nursing interventions are accomplished interdependently, in consultation with or under the direction of a licensed physician or nurse practitioner. The strengths of nursing and medicine are complementary in an emergency situation. Appropriate nursing and medical interventions are anticipated based on assessment data. The emergency health care staff members work as a team in performing the highly technical, hands-on skills required to care for patients in an emergency situation.

The nursing process provides a logical framework for problem solving in this environment. Patients in the ED have a wide variety of actual or potential problems, and their condition may change constantly. Therefore, nursing assessment must be continuous, and nursing diagnoses change with the patient's condition. Although a patient may have several diagnoses at a given time, the focus is on the most life-threatening ones; often, both independent and interdependent nursing interventions are required.

## ISSUES IN EMERGENCY NURSING CARE

Emergency nursing is demanding because of the diversity of conditions and situations that, if not unique to the ED, certainly present a challenge (Chart 71-1). These issues include legal issues, occupational health and safety risks for ED staff, and the challenge of providing holistic care in the context of a fast-paced, technology-driven environment in which serious illness and death are confronted on a daily basis. Another dimension of emergency nursing is nursing in disasters. With the increasing use of weapons of terror and mass destruction, the emergency nurse must expand his or her knowledge base to encompass recognizing and treating patients exposed to biologic and other terror weapons and anticipate nursing care in the event of a mass casualty incident. See Chapter 72 for a full discussion of nursing care in disasters, including caring for victims of terrorism.

### Documentation of Consent

Consent to examine and treat the patient is part of the ED record. The patient must consent to invasive procedures (eg, angiography, lumbar puncture) unless he or she is unconscious or in critical condition and unable to make decisions. If the patient is unconscious and brought to the ED without family or friends, this fact should be documented. Monitoring of the patient's condition, as well as all instituted treatments and the times at which they were performed, must be documented. After treatment, a notation is made on the record about the patient's condition on discharge or transfer and about instructions given to the patient and family for follow-up care.

### Limiting Exposure to Health Risks

Because of the increasing numbers of people infected with hepatitis B and with human immunodeficiency virus (HIV), health care providers are at an increased risk for exposure to communicable diseases through blood or other body fluids. This risk is further compounded in the ED because of the common use of invasive treatments in addition to the wide range of patient conditions. All emergency health care providers should adhere strictly to standard precautions for minimizing exposure.

The reemergence of tuberculosis, a major health problem, is complicated by multidrug-resistant tuberculosis and by tuberculosis concomitant with HIV infection. Early identification and

## Glossary

**antivenin:** antitoxin manufactured from venom of poisonous snakes to assist the patient's immune system response to an envenomation

**carboxyhemoglobin:** hemoglobin that is bound to carbon monoxide and therefore is unable to bind with oxygen, resulting in hypoxemia

**corrosive poison:** alkaline or acidic agent, causes tissue destruction after contact

**cricothyroidotomy:** surgical opening of the cricothyroid membrane to obtain an airway that is maintained with a tracheostomy or endotracheal tube

**diagnostic peritoneal lavage:** instillation of lactated Ringer's or normal saline solution into the abdominal cavity to detect red blood cells, white blood cells, bile, bacteria, amylase, or gastro-intestinal contents indicative of abdominal injury

**emergent:** triage category signifying life-threatening or potentially life-threatening injuries or illnesses requiring immediate treatment

**evenomation:** injection of a poisonous material by sting, spine, bite, or other means

**fasciotomy:** surgical incision of the extremity to the level of the fascia to relieve pres-

sure and restore neurovascular function to the extremity

**Hare traction:** portable in-line traction applied to the lower extremity to manage femur or hip fractures or dislocations

**non-urgent:** triage category signifying episodic or minor injury or illness in which treatment may be delayed several hours or longer without increased morbidity

**triage:** process of assessing patients to determine management priorities

**urgent:** triage category signifying serious illness or injury that is not immediately life-threatening

Chart  
71-1

## Facts About Emergency Department Visits

There were 108 million visits to emergency departments (EDs) in 2000, up 14% from 1997. The increase in visits to the ED is a result of overall population growth and an increase in the number of seniors.

- Persons age 75 years and older had the highest rate of ED visits—65 visits per 100 persons per year. The national average is 39 visits per 100 persons per year.
- Stomach and abdominal pain, chest pain, and fever were the most commonly recorded reasons for a visit to the ED.
- There were 1.3 million visits in 2000 due to adverse drug reactions or other complications from medical care.
- Persons age 15 to 24 years had the highest injury visit rate. The most frequently recorded injury diagnosis was open wound (18%), and the most commonly mentioned body site injured was hand, wrist, or fingers (13%).
- About 12% of patients seen in the ED were admitted to the hospital.

National Hospital Ambulatory Medical Care Survey. 2000 Emergency department summary. Advance Data No. 326. Available at: <http://www.cdc.gov/od/oc/media/pressure/r020422.htm>.

adherence to transmission-based precautions for patients who are potentially infectious is crucial. Nurses in the ED are usually fitted with a personal high-efficiency particulate air (HEPA)-filter mask apparatus to use when treating patients with airborne diseases.

The potential for exposure to highly contagious organisms, hazardous chemicals or gases, and radiation related to acts of terrorism or natural or manmade disasters present additional risks to ED staff. Refer to Chapter 72 for information about decontamination procedures.

## Providing Holistic Care

Sudden illness or trauma is a stress to physiologic and psychological homeostasis that requires physiologic and psychological healing. Patients and families experiencing sudden injury or illness often are overwhelmed by anxiety because they have not had time to adapt to the crisis. They experience real and terrifying fear of death, mutilation, immobilization, and other assaults on their personal identity and body integrity. When confronted with trauma, severe disfigurement, severe illness, or sudden death, the family experiences several stages of crisis. The stages begin with anxiety and progress through denial, remorse and guilt, anger, grief, and reconciliation. The initial goal for the patient and family is anxiety reduction, a prerequisite to recovering the ability to cope.

Assessment of the patient and family's psychological function includes evaluating emotional expression, degree of anxiety, and cognitive functioning. Possible nursing diagnoses include anxiety related to uncertain potential outcomes of the illness or trauma and ineffective individual coping related to acute situational crisis. In addition to anxiety, possible nursing diagnoses for the family include anticipatory grieving and alterations in family processes related to acute situational crises.

## PATIENT-FOCUSED INTERVENTIONS

Those caring for the patient should act confidently and competently to relieve anxiety. Reacting and responding to the patient in a warm manner promotes a sense of security. Explanations should be given on a level that the patient can understand, because

an informed patient is better able to cope positively with stress. Human contact and reassuring words reduce the panic of the severely injured person and aid in dispelling fear of the unknown.

The unconscious patient should be treated as if conscious. That is, the patient should be touched, called by name, and given an explanation of every procedure that is performed. As the patient regains consciousness, the nurse should orient the patient by stating his or her name, the date, and the location. This basic information should be provided repeatedly, as needed, in a reassuring way.

## FAMILY-FOCUSED INTERVENTIONS

The family is kept informed about where the patient is, how he or she is doing, and the care that is being given. Allowing the family to stay with the patient, when possible, also helps allay their anxieties. Additional interventions are based on the assessment of the stage of crisis that the family is experiencing. Measures to help family members cope with sudden death are presented in Chart 71-2.

**Anxiety and Denial.** During these stages, family members are encouraged to recognize and talk about their feelings of anxiety. Asking questions is encouraged. Honest answers given at the level of the family's understanding must be provided. Although denial is an ego-defense mechanism that protects one from recognizing painful and disturbing aspects of reality, prolonged denial is not encouraged or supported. The family must be prepared for the reality of what has happened and what may come.

**Remorse and Guilt.** Expressions of remorse and guilt may be heard, with family members accusing themselves (or each other) of negligence or minor omissions. Family members are urged to

Chart  
71-2

## Helping Family Members Cope With Sudden Death

- Take the family to a private place.
- Talk to the family together, so that they can mourn together.
- Reassure the family that everything possible was done; inform them of the treatment rendered.
- Avoid using euphemisms such as "passed on." Show the family that you care by touching, offering coffee, and offering the services of a chaplain.
- Encourage family members to support each other and to express emotions freely (grief, loss, anger, helplessness, tears, disbelief).
- Avoid giving sedation to family members; this may mask or delay the grieving process, which is necessary to achieve emotional equilibrium and to prevent prolonged depression.
- Encourage the family to view the body if they wish; this action helps to integrate the loss. Cover disfigured and injured areas before the family sees the body. Go with the family to see the body. Show acceptance by touching the body to give the family "permission" to touch.
- Spend time with the family, listening to them and identifying any needs that they may have for which the nursing staff can be helpful.
- Allow family members to talk about the deceased and what he or she meant to them; this permits ventilation of feelings of loss. Encourage the family to talk about events preceding admission to the emergency department. Do not challenge initial feelings of anger or denial.
- Avoid volunteering unnecessary information (eg, patient was drinking).

verbalize their feelings until they realize that there was probably little that they could have done to prevent the injury or illness.

**Anger.** Expressions of anger, common in crisis situations, are a way of handling anxiety and fear. Anger is frequently directed at the patient, but it is also often expressed toward the physician, the nurse, or admitting personnel. The therapeutic approach is to allow the anger to be ventilated, then assist the family to identify their feelings of frustration.

**Grief.** Grief is a complex emotional response to anticipated or actual loss. The key nursing intervention is to help family members work through their grief and to support their coping mechanisms, letting them know that it is normal and acceptable for them to cry, feel pain, and express loss. The hospital chaplain and social services staff both serve as invaluable members of the team when assisting families to work through their grief.

## EMERGENCY NURSING AND THE CONTINUUM OF CARE

As stated previously, one principle underlying emergency care is that the patient will be rapidly assessed, treated, and referred to the appropriate setting for ongoing care. This makes the ED a very temporary point on the continuum of care. Most patients who receive emergency care are discharged directly from the ED to their homes, and emergency nurses must plan and facilitate the patient's safe discharge and follow-up care in the home and the community.

### Discharge Planning

Before discharge, instructions for continuing care are given to the patient and the family or significant others. All instructions should be given not only verbally but also in writing, so that the patient can refer to them later. Many EDs have preprinted standard instruction sheets for the more common conditions. These instructions are then individualized for each patient. These instructions may be available in a variety of languages. If they are not available in the language that the patient needs, an interpreter should be used. Instructions should include information about prescribed medications, treatments, diet, activity, and when to contact a health care provider or schedule follow-up appointments. It is imperative that instructions are written legibly, use simple language, and are clear in their teaching. When providing discharge instructions, the nurse also considers any special needs the patient may have related to hearing or visual deficits.

### Community Services

Before discharge, some patients require the services of a social worker to help them meet continuing health care needs. For patients and families who cannot provide care at home, community agencies (eg, Home Care Nursing Services, Visiting Nurse Association) may be contacted before discharge to arrange services. This is particularly important for elderly patients who need assistance. Identifying continuing health care needs and making arrangements for meeting these needs can prevent return visits to the ED and readmission to the hospital.

For patients who are returning to extended care facilities and for those who already rely on community agencies for continuing health care, communication about the patient's condition

and any changes in health care needs that have occurred must be provided to the appropriate facilities or agencies. This communication is essential to promote continuity of care and to ensure ongoing care to meet the patient's changing health care needs.

### Gerontologic Considerations

The ED is a common point of entry into the health care system for patients 65 years of age and older. In fact, patients in this age group account for more than 99 million visits to emergency facilities each year (see Chart 71-1). Elderly patients typically arrive with one or more presenting conditions involving the skin, cardiovascular system, or abdomen. Nonspecific symptoms, such as weakness and fatigue, episodes of falling, incontinence, and change in mental status, may be manifestations of acute, potentially life-threatening illness in the elderly person. Emergencies in this age group may be more difficult to manage because elderly patients may have

- An atypical presentation
- An altered response to treatment
- A greater risk of developing complications

The elderly patient may perceive the emergency as a crisis signaling the end of an independent lifestyle or even resulting in death. The nurse should give attention to the patient's feelings of anxiety and fear.

The older patient may have fewer sources of social and financial support in addition to frail health. The nurse should assess the psychosocial resources of the patient (and of the caregiver, if necessary) and anticipate discharge needs. Referrals for support services (eg, to the social service department or a gerontologic nurse specialist) may be necessary.

## Principles of Emergency Care

By definition, emergency care is care that must be rendered without delay. In a hospital ED, several patients with diverse health problems—some life-threatening, some not—may present to the ED simultaneously. One of the first principles of emergency care is triage.

### TRIAGE

The word **triage** comes from the French word *trier*, meaning “to sort.” In the daily routine of the ED, triage is used to sort patients into groups based on the severity of their health problems and the immediacy with which these problems must be treated.

Hospital EDs use various triage systems with differing terminology, but all share this characteristic of a hierarchy based on the potential for loss of life. A basic and widely used system uses three categories: emergent, urgent, and non-urgent (Berner, 2001). **Emergent** patients have the highest priority—their conditions are life threatening, and they must be seen immediately. **Urgent** patients have serious health problems, but not immediately life-threatening ones; they must be seen within 1 hour. **Non-urgent** patients have episodic illnesses that can be addressed within 24 hours without increased morbidity (Berner, 2001). A fourth, increasingly used class is “fast-track.” These patients require simple first aid or basic primary care. They may be treated in the ED or safely referred to a clinic or physician's office.

Triage is an advanced skill; emergency nurses spend many hours learning to classify different illnesses and injuries to ensure

that patients most in need of care do not wait to receive it. Protocols may be followed to initiate laboratory or x-ray studies from the triage area while the patient waits for a bed in the ED. Collaborative protocols are developed and used by the triage nurse based on his or her level of experience. Also, nurses in the triage area collect crucial initial data: vital signs and history, neurologic assessment findings, and diagnostic data if necessary. The following questions reflect the minimum information that should be obtained from the patient or from the person who accompanied the patient to the ED. Of course, all answers are documented for reference by other health care providers.

- What were the circumstances, precipitating events, location, and time of the injury or illness?
- When did the symptoms appear?
- Was the patient unconscious after the injury or onset of illness?
- How did the patient get to the hospital?
- What was the health status of the patient before the injury or illness?
- Is there a medical or surgical history? A history of admissions to the hospital?
- Is the patient currently taking any medications, especially hormones, insulin, digitalis, anticoagulants?
- Does the patient have any allergies? If so, what are they?
- Does the patient have any bleeding tendencies?
- When was the last meal eaten? (This is important if general anesthesia is to be given or if the patient is unconscious.)
- Is the patient under a physician's care? What are the name and location of the physician?
- What was the date of the patient's most recent tetanus immunization?

Routine ED triage protocols differ significantly from the triage protocols used in disasters and mass casualty incidents (field triage). Routine hospital triage directs all available resources to the patients who are most critically ill, regardless of potential outcome. In field triage (or hospital triage during a disaster), scarce resources must be used to benefit the most people possible. This distinction affects triage decisions. Refer to Chapter 72 for a complete discussion of triage in mass casualty situations.

## ASSESS AND INTERVENE

For the patient with an emergent or urgent health problem, stabilization, provision of critical treatments, and prompt transfer to the appropriate setting (intensive care unit, operating room, general care unit) are the priorities of emergency care. Although treatment is initiated in the ED, ongoing definitive treatment of the underlying problem is provided in other settings, and the sooner the patient is stabilized and moved to that area, the better.

A systematic approach to effectively establishing and treating health priorities is the primary survey/secondary survey approach. The primary survey focuses on stabilizing life-threatening conditions. The ED staff work collaboratively and follow the ABCD (airway, breathing, circulation, disability) method:

- Establish a patent airway.
- Provide adequate ventilation, employing resuscitation measures when necessary. (Trauma patients must have the cervical spine protected and chest injuries assessed first.)
- Evaluate and restore cardiac output by controlling hemorrhage, preventing and treating shock, and maintaining or restoring effective circulation.

- Determine neurologic disability by assessing neurologic function using the Glasgow Coma Scale (see Chapter 65).

After these priorities have been addressed, the ED team proceeds with the secondary survey. This includes

- A complete health history and head-to-toe assessment
- Diagnostic and laboratory testing
- Insertion or application of monitoring devices such as electrocardiogram (ECG) electrodes, arterial lines, or urinary catheters
- Splinting of suspected fractures
- Cleaning and dressing of wounds
- Performance of other necessary interventions based on the individual patient's condition

Once the patient has been assessed, stabilized, and tested, appropriate medical and nursing diagnoses are formulated, initial important treatment is started, and plans for the proper disposition of the patient are made. Many emergent and urgent conditions and priority emergency interventions are discussed in detail in the remaining sections of this chapter.

## Airway Obstruction

Acute upper airway obstruction is a life-threatening medical emergency. The airway may be partially or completely occluded. If the airway is completely obstructed, permanent brain damage or death will occur within 3 to 5 minutes secondary to hypoxia. Partial obstruction of the airway can lead to progressive hypoxia, hypercarbia, and respiratory and cardiac arrest.

## Pathophysiology

Upper airway obstruction has a number of causes, including aspiration of foreign bodies, anaphylaxis, viral or bacterial infection, trauma, and inhalation or chemical burns. In adults, aspiration of a bolus of meat is the most common cause of airway obstruction. In children, small toys, buttons, coins, and other objects are commonly aspirated in addition to food. Peritonsillar abscesses, epiglottitis, and other acute infectious processes of the posterior pharynx can result in airway obstruction.

## Clinical Manifestations

Common signs and symptoms include choking, apprehensive appearance, inspiratory and expiratory stridor, labored breathing, use of accessory muscles (suprasternal and intercostal retraction), flaring nostrils, increasing anxiety, restlessness, and confusion. Cyanosis and loss of consciousness develop as hypoxia worsens.

## Assessment and Diagnostic Findings

Assessment of the patient who has a foreign object occluding the airway may involve simply asking the person whether he or she is choking and requires help. If the person is unconscious, inspection of the oropharynx may reveal the offending object. X-rays, laryngoscopy, or bronchoscopy also may be performed.

## Gerontologic Considerations

For elderly patients, especially those in extended care facilities, sedatives and hypnotic medications, diseases affecting motor coordination (eg, Parkinson's disease), and mental dysfunction

(eg, dementia, mental retardation) are risk factors for asphyxiation by food. Nursing staff involved in the care of elderly patients must be aware of the symptoms of upper airway obstruction and be skillful in performing the Heimlich maneuver. Typically, the victim with a foreign body airway obstruction cannot speak, breathe, or cough. The patient may clutch the neck between the thumb and fingers (*universal distress signal*). The first response is to ask this person whether he or she is choking.

If the patient can breathe and cough spontaneously, a partial obstruction should be suspected. The victim is encouraged to cough forcefully and to persist with spontaneous coughing and breathing efforts as long as good air exchange exists. There may be some wheezing between coughs. If the patient demonstrates a weak, ineffective cough, high-pitched noise while inhaling, increased respiratory difficulty, or cyanosis, the patient should be managed as if there were complete airway obstruction.

After the obstruction is removed, rescue breathing is initiated. If the patient has no pulse, cardiac compressions are instituted. These measures provide oxygen to the brain, heart, and other vital organs until definitive medical treatment can restore and support normal heart and ventilatory activity.

## Management

Establishing an airway may be as simple as repositioning the patient's head to prevent the tongue from obstructing the pharynx. Alternatively, other maneuvers, such as abdominal thrusts, the head-tilt–chin-lift maneuver, the jaw-thrust maneuver, or insertion of specialized equipment may be needed to open the airway, remove a foreign body, or maintain the airway (Chart 71-3). In all maneuvers, the cervical spine must be protected from injury.

### HEAD-TILT–CHIN-LIFT MANEUVER

The patient is placed supine on a firm, flat surface. If the patient is lying face down, the body is turned as a unit so that the head, shoulders, and torso move simultaneously with no twisting. Next, the airway is opened using either the head-tilt–chin-lift maneuver or the jaw-thrust maneuver. In the head-tilt–chin-lift maneuver, one hand is placed on the victim's forehead, and firm backward pressure is applied with the palm to tilt the head back. The fingers of the other hand are placed under the bony part of the lower jaw near the chin and lifted up. The chin and the teeth are brought forward almost to occlusion to support the jaw.

**NURSING ALERT** The head-tilt–chin-lift maneuver, which helps to tilt the head back, should be used only if it is determined that the patient's cervical spine is not injured.

### JAW-THRUST MANEUVER

After one hand is placed on each side of the patient's jaw, the angles of the victim's lower jaw are grasped and lifted, displacing the mandible forward. This is a safe approach to opening the airway of a victim with suspected neck injury because it can be accomplished without extending the neck.

### OROPHARYNGEAL AIRWAY INSERTION

An oropharyngeal airway is a semicircular tube or tubelike plastic device that is inserted over the back of the tongue into the lower posterior pharynx in a patient who is breathing spontaneously but unconscious (Chart 71-4). This type of airway pre-

vents the tongue from falling back against the posterior pharynx and obstructing the airway. It also allows health care providers to suction secretions.

### ENDOTRACHEAL INTUBATION

The purpose of endotracheal intubation is to establish and maintain the airway in patients with respiratory insufficiency or hypoxia. Endotracheal intubation is indicated for the following reasons: (1) to establish an airway for patients who cannot be adequately ventilated with an oropharyngeal airway, (2) to bypass an upper airway obstruction, (3) to prevent aspiration, (4) to permit connection of the patient to a resuscitation bag or mechanical ventilator, and (5) to facilitate the removal of tracheobronchial secretions (Fig. 71-1). Because the procedure requires skill, endotracheal intubation is performed only by those who have had extensive training. These include physicians, nurse anesthetists, respiratory therapists, flight nurses, and nurse practitioners. The emergency nurse, however, is commonly called upon to assist with intubation.

### ALTERNATIVE INTUBATION METHOD

If the patient is outside the hospital and cannot be intubated in the field, the emergency medical personnel may insert a Combitube. The tube rapidly provides pharyngeal ventilation. When the tube is inserted into the trachea, it functions like an endotracheal tube.

One of the two balloons around the tube can be inflated. One balloon is large (100 mL) and occludes the oropharynx. This could effectively provide for ventilation through forced air by way of the larynx. The smaller balloon is inflated with 15 mL of air and can effectively occlude the trachea if placed there. Breath sounds are auscultated to make sure that the oropharyngeal cuff does not obstruct the glottis. Patients can be ventilated through either port of the tube, depending on its placement.

### CRICOTHYROIDOTOMY (CRICOTHYROID MEMBRANE PUNCTURE)

**Cricothyroidotomy** is the opening of the cricothyroid membrane to establish an airway. This procedure is used in emergency situations in which endotracheal intubation is either not possible or contraindicated, as in airway obstruction from extensive maxillofacial trauma, cervical spine injuries, laryngospasm, laryngeal edema (after an allergic reaction), hemorrhage into neck tissue, or obstruction of the larynx.

After these maneuvers are performed, the patient is assessed for breathing by watching for chest movement and listening and feeling for air movement.

In such a case, nursing diagnoses would include ineffective airway clearance due to obstruction of the tongue, object, or fluids (blood, saliva). The nursing diagnosis may also be ineffective breathing pattern due to obstruction or injury.

## Hemorrhage

Only a few conditions, such as obstructed airway or a sucking wound of the chest, take precedence over the immediate control of hemorrhage. Stopping bleeding is essential to the care and survival of patients in an emergency or disaster situation. Hemorrhage that results in the reduction of circulating blood volume is a primary cause of shock. Minor bleeding, which is usually venous, generally stops spontaneously unless the patient has a bleeding disorder or has been taking anticoagulants.

Chart 71-3

## GUIDELINES FOR Managing a Foreign Body Airway Obstruction

### ACTION

#### ASSESS FOR INDICATIONS OF AIRWAY OBSTRUCTION

- Victim may clutch the neck between thumb and fingers
- Weak, ineffective cough; high-pitched noises on inspiration
- Increased respiratory distress
- Inability to speak, breathe, or cough
- Collapse

#### HEIMLICH MANEUVER (subdiaphragmatic abdominal thrusts)

##### For standing or sitting conscious patient:

Stand behind the patient; wrap your arms around the patient's waist, and proceed as follows:

1. Make a fist with one hand, placing the thumb side of the fist against the patient's abdomen, in the midline slightly above the umbilicus and well below the xiphoid process. Grasp the fist with the other hand.
2. Press your fist into the patient's abdomen with a quick inward and upward thrust. Each new thrust should be a separate and distinct maneuver.

##### For patient lying (unconscious):

1. Position patient on the back.
2. Kneel astride the patient's thighs, facing the head.
3. Place the heel of one hand against the patient's abdomen, in the midline slightly above the umbilicus and well below the tip of the xiphoid; place the second hand directly on top of the first.
4. Press into the abdomen with a quick upward thrust.

##### Finger sweep:

1. Open the adult patient's mouth by grasping both the tongue and lower jaw between the thumb and fingers and lifting the mandible (tongue-jaw lift).
2. Insert the index finger of the other hand down along the inside of the cheek and scrape across the back of the throat.
3. Use a hooking action to dislodge the foreign body and maneuver it into the mouth for removal.

##### Chest thrusts with conscious patient standing or sitting:

1. Stand behind patient with arms under patient's axillae to encircle patient's chest.
2. Place thumb side of your fist on middle of patient's sternum, taking care to avoid xiphoid process and margins of rib cage.
3. Grasp your fist with the other hand and perform backward thrusts until the foreign body is expelled or patient becomes unconscious.

##### Chest thrust with patient lying (unconscious):

1. Place the patient on the back and kneel close to the side of the patient's body.
2. Place the heel of your hand on the lower half of the sternum.
3. Deliver each chest thrust slowly and distinctly with the intent of relieving the obstruction.

Adapted from *Cardiopulmonary resuscitation (CPR)*. Tulsa, OK: CPR Publishers, 2001.

### RATIONALE/AMPLIFICATION

Air movement is absent in the presence of *complete airway obstruction*. Oxygen saturation in the blood decreases rapidly because the obstructed airway prevents entry of air into the lungs. Oxygen deficit occurs in the brain, resulting in unconsciousness, with death following rapidly.

The term *Heimlich maneuver* is used for the sake of uniformity. The terms *subdiaphragmatic abdominal thrusts* and *abdominal thrusts* are used interchangeably, depending on the circumstances.

A subdiaphragmatic abdominal thrust, by elevating the diaphragm, can force air from the lungs to create an artificial cough intended to move and expel an obstructing foreign body from the airway.

This maneuver is to be used *only in the unconscious adult patient*. This action draws the tongue away from the back of the throat and away from the foreign body that may be lodged there.

Care is used to avoid forcing the object deeper into the throat.

This technique is to be used *only in the patient in advanced stages of pregnancy or in the markedly obese person*.

Each thrust should be administered with the intent of relieving the obstruction.

This maneuver is *used only in the patient in advanced stages of pregnancy or when the rescuer cannot apply the Heimlich maneuver effectively to the unconscious, markedly obese person*.

The patient is assessed for signs and symptoms of shock: cool, moist skin (resulting from poor peripheral perfusion), falling blood pressure, increasing heart rate, delayed capillary refill, and decreasing urine volume (a late sign) (Chart 71-5). The goals of emergency management are to control the bleeding, maintain an adequately circulating blood volume for tissue oxygenation, and prevent shock. Patients who hemorrhage are at risk for cardiac arrest caused by hypovolemia with secondary anoxia. Nursing interventions are carried out collaboratively with other members of the emergency health care team.

## Management

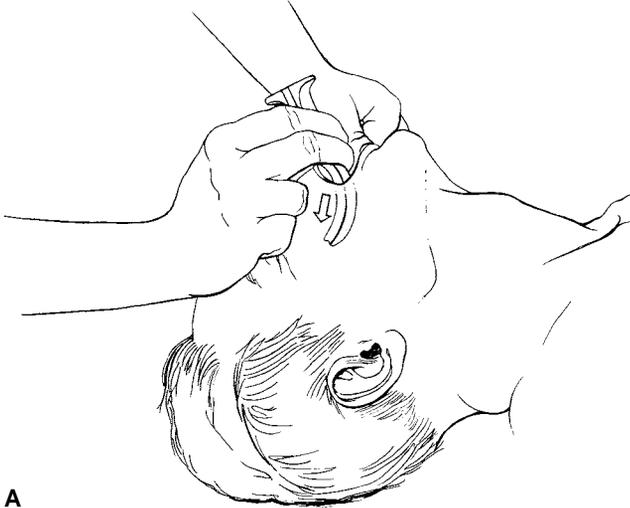

### FLUID REPLACEMENT

Whenever a patient is experiencing hemorrhage—whether external or internal—a loss of circulating blood results in a fluid volume deficit and decreased cardiac output. Therefore, fluid replacement is imperative to maintain circulation. Typically, two large-bore intravenous cannulae are inserted to provide a means for fluid and blood replacement, and blood samples are obtained for analysis, typing, and cross-matching. Replacement fluids are

Chart  
71-4

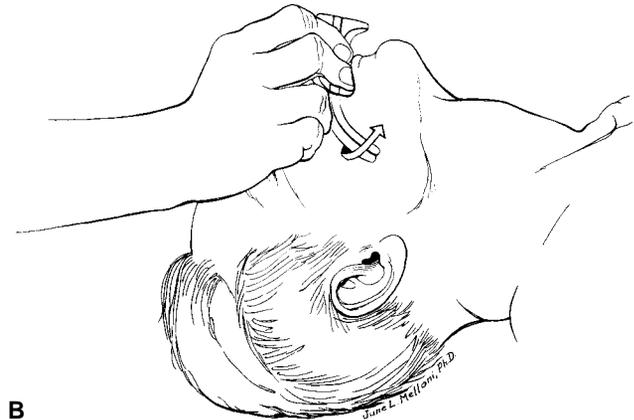

## Inserting an Oropharyngeal Airway

1. Measure the oral airway alongside the head. The airway should reach from lip to ear.
2. Extend the patient's head by placing one hand under the bony chin (*only if the cervical spine is uninjured*). With the other hand, tilt the head backward by applying pressure to the forehead while simultaneously lifting the chin forward.
3. Open the patient's mouth.

A

4. (A) Insert the oropharyngeal airway with the tip facing up toward the roof of the mouth until it passes the uvula. (B) Rotate the tip 180 degrees so that the tip is pointed down toward the pharynx. This displaces the tongue anteriorly, and the patient then breathes through and around the airway.
5. The distal end of the oropharyngeal airway is in the hypopharynx, and the flange is approximately at the patient's lips. Make sure that the tongue has not been pushed into the airway.

B

administered as prescribed, depending on clinical estimates of the type and volume of fluid lost. Replacement fluids may include isotonic electrolyte solutions (lactated Ringer's, normal saline), colloid, and blood component therapy.

Packed red blood cells are infused when there is massive blood loss. In emergencies, O-negative blood is used for women of childbearing age and O-positive blood is used for men and for postmenopausal women. In an emergent situation, there is

not time to type and cross-match or type and screen blood. O-negative blood provides safe administration of blood immediately without sensitizing an Rh-negative woman to Rh-positive blood. Sensitization can result in difficulties during pregnancy later.

Additional platelets and clotting factors are given when large amounts of blood are needed, because replacement blood is deficient in clotting factors.

Chart  
71-5

## Signs and Symptoms of Hypovolemic Shock

Decreasing arterial pressure  
 Increasing pulse rate  
 Cold, moist skin  
 Delayed capillary refill  
 Pallor  
 Thirst  
 Diaphoresis  
 Altered sensorium  
 Oliguria  
 Metabolic acidosis  
 Hyperpnea

**NURSING ALERT** The infusion rate is determined by the severity of the blood loss and the clinical evidence of hypovolemia. If massive blood replacement is necessary, the blood must be warmed in a commercial blood warmer, because administration of large amounts of blood that has been refrigerated has a core cooling effect that may lead to cardiac arrest.

## CONTROL OF EXTERNAL HEMORRHAGE

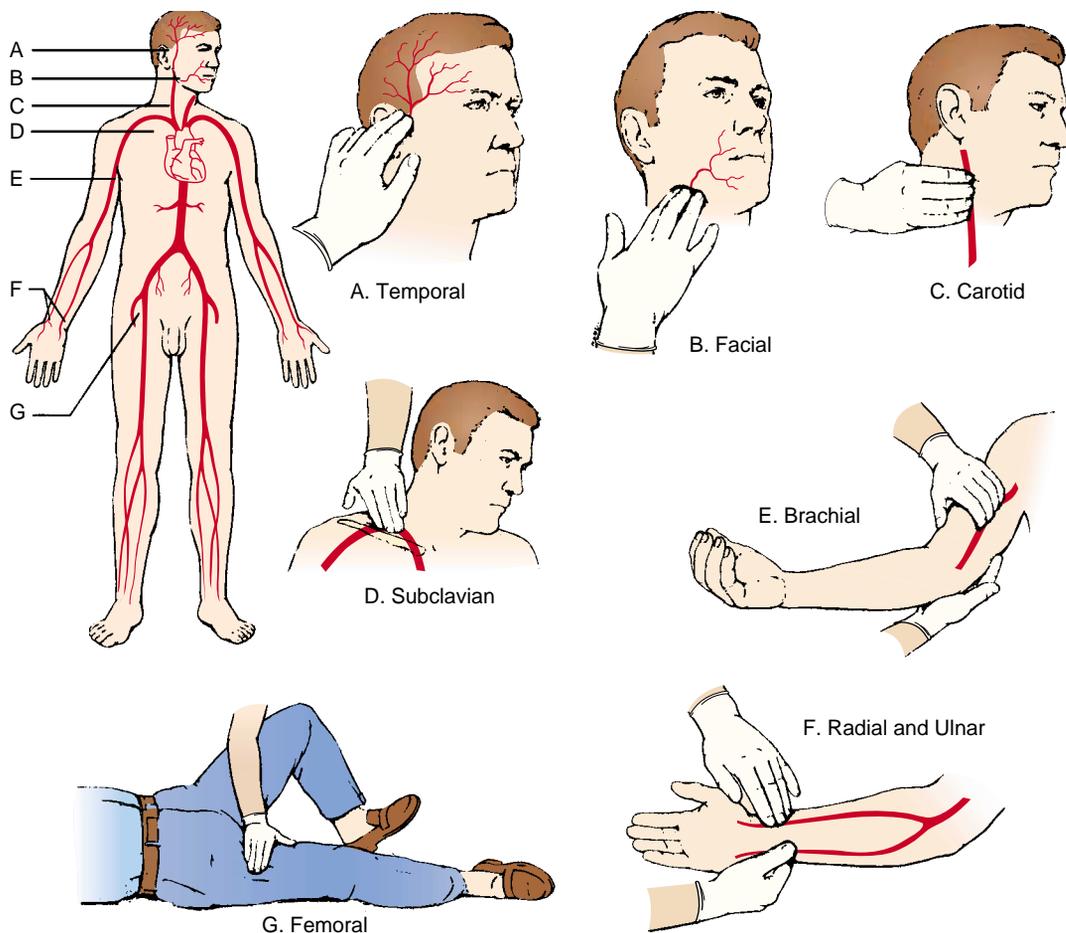

If a patient is hemorrhaging externally (eg, from a wound), a rapid physical assessment is performed as the patient's clothing is

cut away in an attempt to identify the area of hemorrhage. Direct, firm pressure is applied over the bleeding area or the involved artery (Fig. 71-2). Most bleeding can be stopped or at least controlled by application of direct pressure. Otherwise, unchecked arterial bleeding results in death. A firm pressure dressing is applied, and the injured part is elevated to stop venous and capillary bleeding if possible. If the injured area is an extremity, the extremity is immobilized to control blood loss.

**Tourniquets.** A tourniquet is applied to an extremity only as a *last resort* when the external hemorrhage cannot be controlled in any other way. Care must be taken when applying a tourniquet because of the risk of loss of the extremity. The tourniquet is applied just proximal to the wound and tied tightly enough to control arterial blood flow. The patient is tagged with a skin-marking pencil or on adhesive tape on the forehead with a "T," stating the location of the tourniquet and the time applied. Periodically, the tourniquet is loosened to prevent irreparable vascular or neurologic damage. If there is arterial bleeding, the tourniquet is removed and a pressure dressing is applied. If the patient has suffered a traumatic amputation with uncontrollable hemorrhage, the tourniquet remains in place until the patient is in the operating room.

## CONTROL OF INTERNAL BLEEDING

If the patient shows no external signs of bleeding but exhibits tachycardia, falling blood pressure, thirst, apprehension, cool and

**FIGURE 71-2** Pressure points for control of hemorrhage.

moist skin, or delayed capillary refill, internal hemorrhage is suspected. Typically, packed red blood cells (O-negative) are administered at a rapid rate, and the patient is prepared for more definitive treatment (eg, surgery, pharmacologic therapy). Additionally, arterial blood specimens are obtained to evaluate pulmonary function and tissue perfusion and to establish baseline hemodynamic parameters, which are then used as an index for determining the amount of fluid replacement the patient can tolerate and the response to therapy. The patient is maintained in the supine position and monitored closely until hemodynamic or circulatory parameters improve, or until transport to the operating room or intensive care.

## Hypovolemic Shock

Shock is a condition in which there is loss of effective circulating blood volume. Inadequate organ and tissue perfusion follow, ultimately resulting in cellular metabolic derangements. In any emergency situation, the onset of shock should be anticipated by assessing all injured people immediately. The underlying cause of shock (hypovolemic, cardiogenic, neurogenic, or septic) must be determined. Of these, hypovolemia is the most common cause (see Chap. 14).

Altered tissue perfusion related to failing circulation, impaired gas exchange related to a ventilation–perfusion imbalance, and decreased cardiac output related to decreased circulating blood volume are possible problems associated with hypovolemic shock. Therefore, the goals of treatment are to restore and maintain tissue perfusion and to correct physiologic abnormalities.

## Management

For the patient experiencing hypovolemic shock, ensuring a patent airway and maintaining breathing are crucial. Additional ventilatory assistance is given as required. A rapid physical examination is performed to determine the cause of shock.

Restoration of the circulating blood volume is accomplished with rapid fluid and blood replacement as prescribed based on the patient's response to therapy. Blood component therapy helps to optimize cardiac preload, correct hypotension, and maintain tissue perfusion.

Large-gauge intravenous needles or catheters are inserted into peripheral veins. Two or more catheters are necessary for rapid fluid replacement and reversal of hemodynamic instability. The emphasis is on volume replacement. If it is suspected that a major vessel in the chest or abdomen has been disrupted, intravenous lines may be established in both upper and lower extremities.

A central venous pressure (CVP) catheter also may be inserted (in or near the right atrium) to serve as a guide for fluid replacement. Continuous CVP readings give the direction and degree of change from baseline readings. The catheter is also a vehicle for emergency fluid volume replacement.

Intravenous fluids are infused at a rapid rate until systolic blood pressure or CVP rises to a satisfactory level above the baseline measurement or until there is improvement in the patient's clinical condition. Infusion of lactated Ringer's solution is useful initially because it approximates plasma electrolyte composition and osmolality, allows time for blood typing and screening, restores circulation, and serves as an adjunct to blood component therapy.

Blood component therapy may also be prescribed, especially if blood loss has been severe or if the patient continues to hemorrhage. Measures to control hemorrhage are instituted because

hemorrhage compounds the shock state. Serial hematocrit values are obtained if continued bleeding is suspected. Also, the feet are elevated slightly to improve cerebral circulation and promote venous return to the heart. However, this position is contraindicated for patients with head injuries. Unnecessary movement is also avoided.

An indwelling urinary catheter is inserted to record urinary output every hour. Urine volume indicates the adequacy of kidney perfusion. However, fluid replacement should not be delayed.

Ongoing nursing surveillance of the *total patient* is maintained. Blood pressure, heart and respiratory rates, skin temperature, color, pulse oximetry, neurologic status, CVP, arterial blood gases, ECG recordings, hematocrit, hemoglobin, coagulation profile, electrolytes, and urinary output are monitored serially to assess patient response to treatment. Commonly, a flow sheet is used to document these parameters, providing an analysis of trends rather than single values to reveal improvement or deterioration of the patient's condition.

Additionally, the body's defense mechanisms should be supported. The patient should be reassured and comforted. Sedation may be necessary to relieve apprehension. Analgesics are used cautiously to relieve pain. Body temperature is maintained within normal limits to prevent increasing metabolic demands that the body may be unable to meet.

Resuscitation of the patient goes well beyond a normal blood pressure and visual evidence of perfusion. Lactic acidosis is a common side effect of hemorrhage and injury. It is associated with poor cardiac performance and higher rates of morbidity and mortality. Base deficit and lactate are measures of successful and complete resuscitation. End points for resuscitation include a serum lactic acid level lower than 2.5 mmol/L within 24 hours after injury and normalizing vital signs without ongoing hemorrhage.

## Wounds

Wounds involving injury to soft tissues can vary from minor tears to severe crushing injuries. The types of wounds that may occur are defined in Chart 71-6. The primary goal is to restore the physical integrity and function of the injured tissue, with minimal scarring and without infection. Proper documentation of the wound, using precise descriptions and correct terminology, is essential. Such information may be needed in the future for

Chart  
71-6

### Definition of Terms: Wounds

**Laceration:** skin tear with irregular edges and vein bridging

**Avulsion:** tearing away from supporting structures

**Abrasion:** denuded skin

**Echymosis/contusion:** blood trapped under the surface of the skin

**Hematoma:** tumorlike mass of blood trapped under the skin

**Stab:** incision of the skin with well-defined edges, usually caused by a sharp instrument; a stab wound is typically deeper than long

**Cut:** incision of the skin with well-defined edges, usually longer than deep

**Patterned:** wound representing the outline of the object (eg, steering wheel) causing the wound

forensic evidence. Photographs are helpful because they provide an accurate, visible description of the wound.

Determining *when* and *how* the wound occurred is important, because a treatment delay exceeding 3 hours increases infection risk. Using aseptic technique, the clinician inspects the wound to determine the extent of damage to underlying structures. Sensory, motor, and vascular function are evaluated for changes that might indicate complications.

## Management

### WOUND CLEANSING

Hair around the wound may be clipped or shaved (only as directed) if it is anticipated that the hairs will interfere with wound closure. Typically, the area around the wound is cleaned with normal saline solution or a polymer agent (eg, SureClens). Antibacterial agents, such as povidone-iodine (Betadine) or hydrogen peroxide, should not be allowed to get deep into the wound without thorough rinsing. These agents are used only for the initial cleansing because they injure exposed and healthy tissue, resulting in further cell injury.

If indicated, the area is infiltrated with a local intradermal anesthetic through the wound margins or by regional block. Patients with soft tissue injuries usually have localized pain at the site of injury. The nurse then assists the physician, nurse practitioner, or physician's assistant in cleaning and debriding the wound.

The wound is irrigated gently and copiously with sterile isotonic saline solution to remove surface dirt. Devitalized tissue and foreign matter are removed because they impede healing and may encourage infection. Any small bleeding vessels are clamped or tied. Alternatively, hemostasis may be achieved with cauterization. After wound treatment, a nonadherent dressing is commonly applied to protect the wound. The dressing may serve as a splint and also as a reminder to the patient that the area is injured.

### PRIMARY CLOSURE

The decision to suture a wound depends on the nature of the wound, the time since the injury was sustained, the degree of contamination, and the vascularity of tissues. If primary closure is indicated, the wound is sutured, usually by the physician, with the patient receiving a form of anesthesia known as moderate sedation. Wound closure begins when subcutaneous fat is brought together loosely with a few sutures to close off the dead space. The subcuticular layer is then closed, and finally the epidermis is closed. Sutures are placed near the wound edge, with the skin edges leveled carefully to promote optimal healing. Instead of sutures, sterile strips of reinforced microporous tape or a bonding agent (skin glue) may be used to close clean, superficial wounds.

### DELAYED PRIMARY CLOSURE

Delayed primary closure may be indicated if tissue has been lost or there is a high potential for infection.

A thin layer of gauze (to ensure drainage and prevent pooling of exudate), covered by an occlusive dressing, may be used. Other options include split-thickness cadaver or porcine xenografts to simulate the function of epithelium. The wound is splinted in a functional position to prevent motion and decrease the possibility of contracture.

If there are no signs of suppuration, the wound may be sutured (with the patient receiving a local anesthetic). Use of antibiotics to prevent infection depends on factors such as how the

injury occurred, the age of the wound, and the risk for contamination. The site is immobilized and elevated to limit accumulation of fluid in the interstitial spaces of the wound.

Tetanus prophylaxis is administered as prescribed, based on the condition of the wound and the patient's immunization status. The patient is instructed about signs and symptoms of infection and is told to contact the health care provider or clinic if there is sudden or persistent pain, fever or chills, bleeding, rapid swelling, foul odor, drainage, or redness surrounding the wound.

## Trauma

Trauma, the unintentional or intentional wound or injury inflicted on the body from a mechanism against which the body cannot protect itself, is the fourth leading cause of death in the United States. Trauma is the leading cause of death in children and in adults younger than 44 years of age (McQuillan, VonReuden, Hartsock, Flynn, & Whalen, 2002). The incidence is increasing in adults older than 44 years of age. Alcohol and drug abuse are often implicated as factors in both blunt and penetrating trauma.

### Collection of Forensic Evidence

In assessing and managing any patient with an emergency condition, but especially the patient experiencing trauma, documentation of all that occurs is essential. Included in documentation are descriptions of all wounds, mechanism of injury, time of events, and collection of evidence. In trauma care, the nurse must be exceedingly careful with all potential evidence, handling and documenting it properly.

The basics of care management for patients with traumatic injury include an understanding that trauma in any patient (living or dead) has potential legal, or forensic, implications. Hence, proper management from both a medical and forensic perspective is essential.

When clothing is removed from the patient who has experienced trauma, the nurse must be careful not to cut through or disrupt any tears, holes, blood stains, or dirt present on the clothing. Each piece of clothing should be placed in an individual paper bag. If the clothing is wet, it should be hung to dry. Clothing should not be given to families. Valuables should be placed in the hospital safe or clearly documented as to which family member they were given. If a police officer is present to collect clothing or any other items from the patient, each item is labeled. The transfer of custody to the officer, the officer's name, the date, and the time are documented.

If suicide or homicide is suspected in a deceased trauma patient, the medical examiner will examine the body on site or have the body moved to the coroner's office for autopsy. All tubes and lines must remain in place. The patient's hands must be covered with paper bags to protect evidence on the hands or under the fingernails. In the surviving patient, tissue specimens may be swabbed from the hands and nails as potential evidence. Photographs of wounds or clothing are essential and should include a reference ruler in one photo and one without the ruler.

Documentation should also include any statements made by the patient in the patient's own words and surrounded by quotation marks. A chain of evidence is essential. If the patient's case is adjudicated in the future, clear documentation will assist the judicial process and help to identify the activities that occurred in the ED.

## Injury Prevention

Any discussion of trauma management must include a discussion of injury prevention. A component of the emergency nurse's daily role is to provide injury prevention information to every patient with whom there is contact, including patients admitted for reasons other than injury. The only way to reduce the incidence of trauma is to prevent the injuries in the first place. Everyone can benefit from injury prevention information. Using the information after leaving the ED or other health care site is the patient's responsibility. However, the information must be provided.

The key to decreasing the incidence of trauma and saving the lives of productive members of society and children is injury prevention. The emergency nurse should make injury prevention part of daily nursing practice.

There are three components of injury prevention. The first is education. Providing information and materials to help prevent violence and to maintain safety at home and in vehicles is important. Involvement in local injury prevention organizations, nursing organizations, and health fairs promotes wellness and safety. In practice, nursing and other health care professionals should avoid using the word "accident," because trauma events are *preventable* and should be viewed as such rather than as "fate" or "happenstance." Responsibility and accountability must be assigned to traumatic incidents, particularly because of the high rate of trauma recidivism. Those who are at risk for trauma and repeated trauma should be identified and provided with education and counseling directed toward altering risky behaviors and preventing further trauma.

The second component of injury prevention is legislation. Nurses should be actively involved in safety legislation at the local, state, and federal levels. Such legislation is meant to provide universal safety measures, not to infringe on rights.

The third component is automatic protection. Airbags and automatic safety belts are in this category. These mechanisms provide for safety without requiring personal intervention.

## INTRA-ABDOMINAL INJURIES

Intra-abdominal injuries are categorized as penetrating or blunt trauma. *Penetrating* abdominal injuries (ie, gunshot wounds, stab wounds) are serious and usually require surgery. Penetrating abdominal trauma results in a high incidence of injury to hollow organs, particularly the small bowel. The liver is the most frequently injured solid organ. In gunshot wounds, the most important factor is the velocity at which the missile enters the body. High-velocity missiles (bullets) create extensive tissue damage. All abdominal gunshot wounds that cross the peritoneum or are associated with peritoneal signs require surgical exploration. Stab wounds may be managed nonoperatively.

*Blunt* trauma to the abdomen may result from motor vehicle crashes, falls, blows, or explosions. Blunt trauma is commonly associated with extra-abdominal injuries to the chest, head, or extremities. Patients with blunt trauma are a challenge because of injuries that may be hidden and difficult to detect. The incidence of delayed and trauma-related complications is greater than for penetrating injuries. This is especially true of blunt injuries involving the liver, kidneys, spleen, or blood vessels, which can lead to massive blood loss into the peritoneal cavity.

## Assessment and Diagnostic Findings

In conjunction with the history, the abdomen is inspected for obvious signs of injury, including penetrating injuries, bruises, and abrasions. Abdominal assessment continues with auscultation of bowel sounds to provide baseline data from which changes can be noted. Absence of bowel sounds may be an early sign of intra-peritoneal involvement, although stress can also decrease or eliminate bowel sounds. Further abdominal assessment may reveal progressive abdominal distention, involuntary guarding, tenderness, pain, muscular rigidity, or rebound tenderness along with changes in bowel sounds, all of which are signs of peritoneal irritation. Hypotension and signs and symptoms of shock may also be noted. Additionally, the chest and other body systems are assessed for injuries that frequently accompany intra-abdominal injuries.

Laboratory studies that aid in assessment include the following:

- Urinalysis to detect hematuria (indicative of a urinary tract injury)
- Serial hematocrit levels to evaluate trends reflecting the presence or absence of bleeding
- White blood cell count to detect elevation (generally associated with trauma)
- Serum amylase analysis to detect rising levels, which suggest pancreatic injury or perforation of the gastrointestinal tract

### INTERNAL BLEEDING

Hemorrhage frequently accompanies abdominal injury, especially if the liver or spleen has been traumatized. Therefore, the patient is assessed continuously for signs and symptoms of external and internal bleeding. The front of the body, flanks, and back are inspected for bluish discoloration, asymmetry, abrasion, and contusion. Abdominal CT scans permit detailed evaluation of abdominal contents and retroperitoneal examination. Abdominal ultrasound studies can rapidly assess hemodynamically unstable patients to detect intraperitoneal bleeding and pericardial tamponade. This is referred to as the FAST (Focused Assessment with Sonographic Examination of the Trauma Patient) examination. Pain in the left shoulder is common in a patient with bleeding from a ruptured spleen, whereas pain in the right shoulder can result from laceration of the liver. Even though the patient complains of pain, administration of opioids is avoided during the observation period because their effect may obscure the clinical picture.

### INTRAPERITONEAL INJURY

The abdomen is assessed for tenderness, rebound tenderness, guarding, rigidity, spasm, increasing distention, and pain. Referred pain is a significant finding because it suggests intraperitoneal injury. To determine whether there is intraperitoneal injury and bleeding, the patient is usually prepared for diagnostic procedures, such as peritoneal lavage, abdominal ultrasonography, or abdominal computed tomography (CT) scanning. **Diagnostic peritoneal lavage** involves the instillation of 1 L of warmed lactated Ringer's or normal saline solution into the abdominal cavity. After a minimum of 400 mL has been returned, a fluid specimen is sent to the laboratory for analysis. Positive laboratory findings include a red blood cell count higher than 100,000/mm<sup>3</sup>, a white blood cell count exceeding 500/mm<sup>3</sup>, or the presence of bile, feces, or food.

In patients with stab wounds, sinography may be performed to detect peritoneal penetration. With this procedure, a purse-string suture is placed around the wound, and a small catheter is introduced through the wound. A contrast agent is then introduced through the catheter, and x-rays are taken to identify any peritoneal penetration.

### GENITOURINARY INJURY

A rectal or vaginal examination is performed to determine any injury to the pelvis, bladder, and intestinal wall. To decompress the bladder and monitor urine output, an indwelling catheter is inserted after a rectal examination (not before). In the male patient, a high-riding prostate gland (abnormal position) discovered during a rectal examination indicates a potential urethral injury.

**NURSING ALERT** Urethral catheter insertion with a possible urethral injury is contraindicated; a urology consultation and further evaluation of the urethra are required.

### Management

As indicated by the patient's condition, resuscitation procedures (restoration of airway, breathing, and circulation) are initiated. A patent airway is maintained, and attempts to stabilize the respiratory, circulatory, and nervous systems are made. Bleeding is controlled by application of direct pressure to any external bleeding wounds and by occlusion of any chest wounds. Circulating blood volume is maintained with intravenous fluid replacement, including blood component therapy. The patient is monitored for signs and symptoms of shock after an initial response to transfusion therapy, because these are often the first signs of internal hemorrhage.

With blunt trauma, the patient is kept on a stretcher to immobilize the spine. A backboard may be used for transporting the patient to the x-ray department, to the operating room, or to the intensive care unit. Cervical spine immobilization is maintained until cervical x-rays have been obtained and cervical spine injury ruled out.

Knowing the mechanism of injury (eg, penetrating force from a gunshot or knife, blunt force from a blow), is essential to determining the type of management needed. All wounds are located, counted, and documented. If abdominal viscera protrude, the area is covered with sterile, moist saline dressings to keep the viscera from drying.

Typically, oral fluids are withheld in anticipation of surgery, and the stomach contents are aspirated with a nasogastric tube to reduce the risk of aspiration. Nasogastric aspiration also decompresses the stomach in preparation for diagnostic procedures.

Trauma predisposes the patient to infection by disruption of mechanical barriers, exposure to exogenous bacteria from the environment at the time of injury, and diagnostic and therapeutic procedures (nosocomial infection). Tetanus prophylaxis and broad-spectrum antibiotics are administered as prescribed.

Throughout the stay in the ED, the patient's condition is continuously monitored for changes. If there is continuing evidence of shock, blood loss, free air under the diaphragm, evisceration, hematuria, or suspected or known abdominal injury, the patient is rapidly transported to surgery. In most cases, blunt liver and spleen injuries are managed nonoperatively.

## CRUSH INJURIES

Crush injuries occur when a person is caught between objects, run over by a moving vehicle, or compressed by machinery.

### Assessment and Diagnostic Findings

The patient is observed for the following:

- Hypovolemic shock resulting from extravasation of blood and plasma into injured tissues after compression has been released
- Paralysis of a body part
- Erythema and blistering of skin
- Damaged body part (usually an extremity) appearing swollen, tense, and hard
- Renal dysfunction (prolonged hypotension causes kidney damage and acute renal insufficiency; myoglobinuria secondary to muscle damage can cause acute renal failure)

### Management

In conjunction with maintaining the airway, breathing, and circulation, the patient is observed for acute renal insufficiency. Injury to the back can cause severe kidney damage. Severe muscular damage causes a significant release of myoglobin, which can result in acute tubular necrosis. Additionally, major soft tissue injuries are splinted early to control bleeding and pain. Again, the serum lactic acid concentration is monitored; a decrease to less than 2.5 mmol/L is an indication of successful resuscitation (Blow, Magliore, Claridge, Butler, & Young, 1999).

If an extremity is involved, it is elevated to relieve swelling and pressure. To restore neurovascular function, the physician may perform a **fasciotomy** (surgical incision to the level of the fascia). Medications for pain and anxiety are then administered as prescribed, and the patient is quickly transported to the operating suite for wound débridement and fracture repair. Then, a hyperbaric chamber (if one is available) can be used for hyperoxygenation of the crushed tissue, if indicated.

## MULTIPLE INJURIES

Care of the patient with multiple injuries requires a team approach, with one person responsible for coordinating the treatment. Immediately after injury, the body is hypermetabolic, hypercoagulable, and severely stressed. Mortality in patients with multiple injuries is related to the severity of the injuries and the number of systems and organs involved.

Multiple trauma potentially affects every body system. The nursing staff assumes responsibility for assessing and monitoring the patient, ensuring intravenous access, administering prescribed medications, collecting laboratory specimens, and documenting activities and the patient's response.

### Assessment and Diagnostic Findings

Gross evidence of trauma may be slight or absent. The injury regarded as the least significant in appearance may be the most lethal. For example, the pelvis fracture not identified until x-ray may be the injury from which the patient is exsanguinating into the pelvic cavity. Another example is a pneumothorax that is insidiously increasing in size, affecting both the heart and lungs, while the staff are focused on the treatment of external lacerations. An obvious amputation of the arm may have already

stopped bleeding from the body's normal response of vasoconstriction, despite being obvious and a devastating injury; meanwhile, the patient may be dying from an internal, not so visible, injury.

## Management

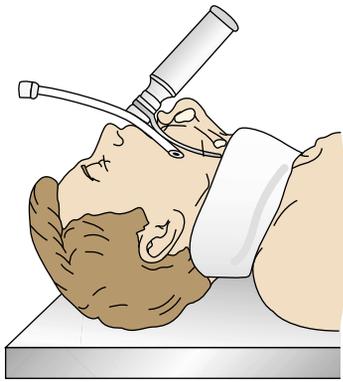

The goals of treatment are to determine the extent of injuries and to establish priorities of treatment. Any injury interfering with a vital physiologic function (eg, airway, breathing, circulation) is an immediate threat to life and has the highest priority for immediate treatment. Essential life-saving procedures are performed simultaneously by the emergency team. As soon as the pa-

tient is resuscitated, clothes are usually cut off, and a rapid physical assessment is performed. Transfer from field management to the ED must be orderly and controlled, with attention given to the verbal report from emergency medical services. Treatment in a level I trauma center is appropriate for patients experiencing major trauma. Treatment priorities are illustrated in Figure 71-3.

## FRACTURES

Immediate management of a fracture may determine the patient's outcome and may mean the difference between recovery and disability. When the patient is being examined for fracture, the body part is handled gently and as little as possible. Clothing is cut off

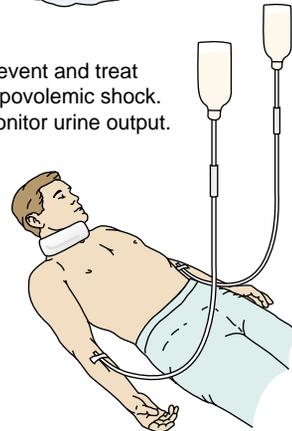

1 Establish airway and ventilation.

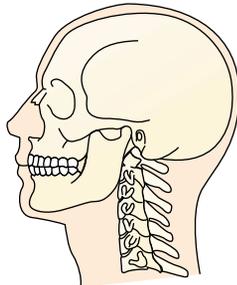

2 Control of hemorrhage

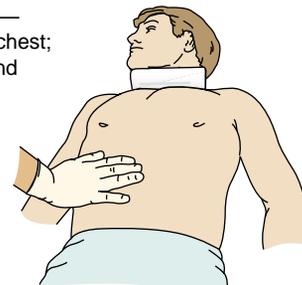

3 Prevent and treat hypovolemic shock. Monitor urine output.

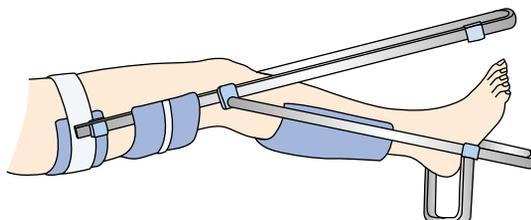

4 Assess for head and neck injuries. Maintain spine immobilization.

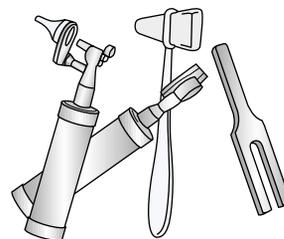

5 Evaluate for other injuries — reassess head and neck, chest; assess abdomen, back, and extremities.

6 Splint fractures

7 Carry out a more thorough and ongoing examination and assessment.

**FIGURE 71-3** Management of the patient with multiple injuries.

to visualize the body. Assessment is conducted for pain over or near a bone, swelling (from blood, lymph, and exudate infiltrating the tissue), and circulatory disturbance. The patient is assessed for ecchymosis, tenderness, and crepitation. The nurse must remember that the patient may have multiple fractures accompanied by head, chest, spine, or abdominal injuries.

## Management

Immediate attention is given to the patient's general condition. Assessment of airway, breathing, and circulation (which includes pulses in the extremities) is conducted. The patient is also evaluated for neurologic or abdominal injuries before the extremity is treated, unless a pulseless extremity is detected.

If a pulseless extremity is identified, repositioning of the extremity to proper alignment is required. If the pulseless extremity involves a fractured hip or femur, **Hare traction** (a portable in-line traction device) may be applied to assist with alignment. If repositioning is ineffective in restoring the pulse, a rapid total-body assessment should be completed, followed by transfer of the patient to the operating room for arteriography and possible arterial repair.

After the initial evaluation has been completed, all injuries identified are evaluated and treated. The fractured body part is inspected. Using a systematic head-to-toe approach, the clinician inspects the entire body, observing for lacerations, swelling, and deformities, including angulation (bending), shortening, rotation, and asymmetry. All peripheral pulses, especially those distal to the fractured extremity, are palpated. The extremity is also assessed for coolness, blanching, and decreased sensation and motor function, which are indicative of injury to the extremity's neurovascular supply.

A splint is applied before the patient is moved. Splinting immobilizes the joint above and below the fracture, relieves pain, restores or improves circulation, prevents further tissue injury, and prevents a closed fracture from becoming an open one. To splint an extremity, one hand is placed distal to the fracture and some traction is applied while the other hand is placed beneath the fracture for support. The splints should extend beyond the joints adjacent to the fracture. Upper extremities must be splinted in a functional position. If the fracture is open, a moist, sterile dressing is applied.

After splinting, the vascular status of the extremity is checked by assessing color, temperature, pulse, and blanching of the nail bed. If there is evidence of neurovascular compromise, the splint is removed and reapplied. In addition, any complaints of pain or pressure are investigated. (See Chap. 69 for a complete description of fracture management.)

## Environmental Emergencies

### HEAT STROKE

Heat stroke is an acute medical emergency caused by failure of the heat-regulating mechanisms of the body. It usually occurs during extended heat waves, especially when they are accompanied by high humidity. People at risk are those not acclimatized to heat, elderly and very young people, those unable to care for themselves, those with chronic and debilitating diseases, and those taking certain medications (eg, major tranquilizers, anticholinergics, diuretics, beta-adrenergic blocking agents). Exertional heat stroke occurs in healthy individuals during sports or work activities (eg, exercising in extreme heat and humidity). Hyperthermia

results because of inadequate heat loss. This type of heat stroke can also cause death. See Chart 71-7 for prevention strategies.

### Gerontologic Considerations

Most heat-related deaths occur in the elderly, because their circulatory systems are unable to compensate for stress imposed by heat. Elderly people have a decreased ability to perspire as well as a decreased thirst mechanism to compensate for heat.

## Assessment and Diagnostic Findings

Heat stroke causes thermal injury at the cellular level, resulting in widespread damage to the heart, liver, kidney, and blood coagulation. Recent patient history reveals exposure to elevated ambient temperature or excessive exercise during extreme heat. When assessing the patient, the nurse notes the following symptoms: profound central nervous system (CNS) dysfunction (manifested by confusion, delirium, bizarre behavior, coma); elevated body temperature (40.6°C [105°F] or higher); hot, dry skin; and usually anhidrosis (absence of sweating), tachypnea, hypotension, and tachycardia.

## Management

The primary goal is to reduce the high temperature as quickly as possible, because mortality is directly related to the duration of hyperthermia. Simultaneous treatment focuses on stabilizing oxygenation using the ABCs of basic life support.

After the patient's clothing is removed, the core (internal) temperature is reduced to 39°C (102°F) as rapidly as possible. One or more of the following methods may be used as directed:

- Cool sheets and towels or continuous sponging with cool water
- Ice applied to the neck, groin, chest, and axillae while spraying with tepid water
- Cooling blankets
- Iced saline lavage of the stomach or colon if the temperature does not decrease
- Immersion of the patient in a cold water bath (if possible)

During cooling, the patient is massaged to promote circulation and maintain cutaneous vasodilation. An electric fan is positioned so that it blows on the patient to augment heat dissipation by convection and evaporation. The patient's temperature is con-

Chart 71-7

### Health Promotion: Preventing Heat Stroke

- Advise the patient to avoid immediate reexposure to high temperatures; hypersensitivity to high temperatures may remain for a considerable time.
- Emphasize the importance of maintaining adequate fluid intake, wearing loose clothing, and reducing activity in hot weather.
- Advise athletes to monitor fluid losses and weight loss during workout activities or exercise and to replace fluids.
- Advise the patient to use a gradual approach to physical conditioning, allowing sufficient time for acclimatization.
- Direct frail elderly patients living in urban settings with high environmental temperatures to places where air conditioning is available (eg, shopping mall, library, church).

stantly monitored with a thermistor placed in the rectum, bladder, or esophagus to evaluate core temperature. Caution is used to avoid hypothermia and to prevent hyperthermia, which may recur spontaneously within 3 to 4 hours.

Throughout treatment, the patient's status is monitored carefully, including vital signs, ECG findings (for possible myocardial ischemia, myocardial infarction, and dysrhythmias), CVP, and level of responsiveness, all of which may change with rapid alterations in body temperature. A seizure may be followed by recurrence of hyperthermia. To meet tissue needs exaggerated by the hypermetabolic condition, 100% oxygen is administered. The patient may require endotracheal intubation and mechanical ventilation to support failing cardiopulmonary systems.

Intravenous infusion therapy of normal saline or lactated Ringer's solution is initiated as directed to replace fluid losses and maintain adequate circulation. Fluids are administered carefully because of the dangers of myocardial injury from high body temperature and poor renal function. Cooling redistributes fluid volume from the periphery to the core.

Urine output is also measured frequently, because acute tubular necrosis is a complication of heat stroke from rhabdomyolysis (myoglobin in the urine). Blood specimens are obtained for serial testing to detect bleeding disorders, such as disseminated intravascular coagulopathy, and for serial enzyme studies to estimate thermal hypoxic injury to the liver, heart, and muscle tissue. Permanent liver, cardiac, and CNS damage may occur.

Additional supportive care may include dialysis for renal failure, antiseizure agents to control seizures, potassium for hypokalemia, and sodium bicarbonate to correct metabolic acidosis. Benzodiazepines or chlorpromazine may be prescribed to suppress seizure activity. Patient education regarding the prevention of heat stroke (ie, adequate fluid intake, staying out of the sun especially between 10 AM and 2 PM) is also important to prevent a recurrence of heat stroke.

## FROSTBITE

Frostbite is trauma from exposure to freezing temperatures and actual freezing of the tissue fluids in the cell and intercellular spaces. It results in cellular and vascular damage. Body parts most frequently affected by frostbite include the feet, hands, nose, and ears. Frostbite ranges from first degree (redness and erythema) to fourth degree (full-depth tissue destruction).

### Assessment and Diagnostic Findings

A frozen extremity may be hard, cold, and insensitive to touch and may appear white or mottled blue-white. The extent of injury from exposure to cold is not always initially known. The history of the patient should include environmental temperature, duration of exposure, humidity, and the presence of wet conditions.

### Management

The goal of management is to restore normal body temperature. Constrictive clothing and jewelry that could impair circulation are removed. If the lower extremities are involved, the patient should not be allowed to ambulate.

**NURSING ALERT** If the patient requires transport, do not initiate rewarming. During transport, rewarming procedures may not be able to be maintained. In addition, any further cooling or freezing experience will cause significant damage to the already frozen body part.

Controlled yet rapid rewarming is instituted. The extremity is usually placed in a 37° to 40°C (98.6° to 104°F) circulating bath for 30- to 40-minute spans. This treatment is repeated until circulation is effectively restored. Early rewarming appears to decrease the amount of ultimate tissue loss. During rewarming, an analgesic for pain is administered as prescribed, because the rewarming process may be very painful. To avoid further mechanical injury, the body part is not handled. Massage is contraindicated.

Once rewarmed, the part is protected from further injury and is elevated to help control swelling. Sterile gauze or cotton is placed between affected fingers or toes to prevent maceration. A foot cradle may be used to prevent contact with bedclothes if the feet are involved. Blisters, which develop 1 hour to a few days after rewarming, are left intact and not ruptured, especially if they are hemorrhagic.

A physical assessment is conducted with rewarming to observe for concomitant injury, such as soft tissue injury, dehydration, alcohol coma, or fat embolism. Problems such as dehydration, hyperkalemia, and hypovolemia, which occur frequently in people with frostbite, are corrected. Risk for infection is also great; therefore, strict aseptic technique is used during dressing changes, and tetanus prophylaxis is administered as indicated. Antiinflammatory medication is also prescribed.

Additional measures that may be carried out when appropriate include the following:

- Whirlpool bath for the affected extremity to aid circulation, debride necrotic tissue, and help prevent infection
- Escharotomy (incision through the eschar) to prevent further tissue damage, allow for normal circulation, and permit joint motion
- Fasciotomy to treat compartment syndrome

After rewarming, hourly active motion of the affected digits is encouraged to promote maximal restoration of function and to prevent contractures. Refreezing is avoided. The patient is also encouraged to avoid tobacco, alcohol, and caffeine because of their vasoconstrictive effects, which further reduce the already deficient blood supply to injured tissues.

## HYPOTHERMIA

Hypothermia is a condition in which the core (internal) temperature is 35°C (95°F) or less as a result of exposure to cold. Hypothermia occurs when a patient loses the ability to maintain body temperature. Urban hypothermia (extreme exposure to cold in an urban setting) is associated with a high mortality rate; elderly people, infants, people with concurrent illnesses, and the homeless are particularly susceptible. Alcohol ingestion increases susceptibility because it causes systemic vasodilation. Trauma victims are also at risk for hypothermia resulting from treatment with cold fluids, unwarmed oxygen, and exposure during examination. The patient may also have frostbite, but the hypothermia takes precedence in treatment.

### Assessment and Diagnostic Findings

Hypothermia leads to physiologic changes in all organ systems. There is progressive deterioration, with apathy, poor judgment, ataxia, dysarthria, drowsiness, pulmonary edema, acid-base abnormalities, coagulopathy, and eventual coma. Shivering may be suppressed below a temperature of 32.2°C (90°F), because the body's self-warming mechanisms become ineffective. The heart-beat and blood pressure may be so weak that peripheral pulses

become undetectable. Cardiac irregularities may also occur. Other physiologic abnormalities include hypoxemia and acidosis.

## Management

Management consists of continuous monitoring, rewarming, removal of wet clothing, insulation, and supportive care.

### MONITORING

The ABCs of basic life support are a priority. The patient's vital signs, CVP, urine output, arterial blood gas levels, blood chemistry determinations (blood urea nitrogen, creatinine, glucose, electrolytes), and chest x-rays are evaluated frequently. Body temperature is monitored with an esophageal, bladder, or rectal thermistor. Continuous ECG monitoring is performed, because cold-induced myocardial irritability leads to conduction disturbances, especially ventricular fibrillation. An arterial line is inserted and maintained to record blood pressure and to facilitate blood sampling.

### REWARMING

Rewarming methods include active core (internal) rewarming, active external rewarming, and passive or spontaneous rewarming.

*Core rewarming* methods include cardiopulmonary bypass, warm fluid administration, warm humidified oxygen by ventilator, and warmed peritoneal lavage. Core rewarming is recommended for severe hypothermia. Monitoring for ventricular fibrillation as the patient passes through 31° to 32°C (88° to 90°F) is essential.

*Passive external rewarming* includes the use of warm blankets or over-the-bed heaters. Passive rewarming of the extremities increases blood flow to the acidotic, anaerobic extremities. The cold blood with high lactic acid levels returning to the core has significant effects on the core temperature and metabolic response, possibly causing cardiac dysrhythmias and electrolyte disturbances.

### SUPPORTIVE CARE

Supportive care during rewarming includes the following as directed:

- External cardiac compression (only as directed in the very cold patient)
- Defibrillation of ventricular fibrillation. Patients whose temperature is less than 32°C (90°F) will experience spontaneous ventricular fibrillation if moved or touched. Defibrillation is ineffective in patients with temperatures lower than 31°C (88°F).
- Mechanical ventilation with positive end-expiratory pressure (PEEP) and heated humidified oxygen to maintain tissue oxygenation
- Administration of warmed intravenous fluids to correct hypotension and maintain urine output and core rewarming, as described previously
- Administration of sodium bicarbonate to correct metabolic acidosis if necessary
- Administration of antiarrhythmic medications
- Insertion of an indwelling urinary catheter to monitor fluid status

### NEAR-DROWNING

Near-drowning is survival for at least 24 hours after submersion. The most common consequence is hypoxemia. Drowning is one of the leading causes of unintentional death in children younger

than 14 years of age. An estimated 7000 drownings and 90,000 near-drownings occur yearly in the United States. There are approximately 1000 deaths by drowning of children every year. Children younger than 4 years of age account for 40% of drownings (Suominen et al., 2002).

Factors associated with drowning and near-drowning include alcohol ingestion, inability to swim, diving injuries, hypothermia, and exhaustion. Efforts to save the victim should not be abandoned prematurely. Successful resuscitation with full neurologic recovery has occurred in near-drowning victims after prolonged submersion in cold water. This is possible because of a decrease in metabolic demands or the diving reflex.

After resuscitation, hypoxia and acidosis, the primary problems of a victim who has nearly drowned, require immediate intervention in the ED. Resultant pathophysiologic changes and pulmonary injury depend on the type of fluid (fresh or salt water) and the volume aspirated. Fresh water aspiration results in a loss of surfactant, hence an inability to expand the lungs. Salt water aspiration leads to pulmonary edema from the osmotic effects of the salt within the lung. After a person survives submersion, acute respiratory distress syndrome resulting in hypoxia, hypercarbia, and respiratory or metabolic acidosis can occur.

## Management

Therapeutic goals include maintaining cerebral perfusion and adequate oxygenation to prevent further damage to vital organs. Immediate cardiopulmonary resuscitation is the factor with the greatest influence on survival. The treatment goal, prevention of hypoxia, is accomplished by ensuring an adequate airway and respiration, thus improving ventilation (which helps to correct respiratory acidosis) and oxygenation. Arterial blood gas analyses are performed to evaluate oxygen, carbon dioxide, and bicarbonate levels and pH. These parameters determine the type of ventilatory support needed. Use of endotracheal intubation with positive-pressure ventilation (with PEEP) improves oxygenation, prevents aspiration, and corrects intrapulmonary shunting and ventilation-perfusion abnormalities (caused by aspiration of water). If the patient is breathing spontaneously, supplemental oxygen may be administered by mask. However, an endotracheal tube is necessary if the patient does not breathe spontaneously.

Because of submersion, the patient is usually hypothermic. A rectal probe is used to determine the degree of hypothermia. Prescribed rewarming procedures (eg, extracorporeal warming, warmed peritoneal dialysis, inhalation of warm aerosolized oxygen, torso warming) are started during resuscitation. The choice is determined by the severity and duration of hypothermia and available resources. Intravascular volume expansion and inotropic agents are used to manage hypotension and impaired tissue perfusion. ECG monitoring is initiated, because dysrhythmias frequently occur. An indwelling urinary catheter is inserted to measure urine output. Hypothermia and accompanying metabolic acidosis may compromise renal function. Nasogastric intubation is used to decompress the stomach and to prevent the patient from aspirating gastric contents.

In case the patient appears deceptively healthy, close monitoring continues with serial vital signs, serial arterial blood gas values, ECG monitoring, intracranial pressure assessments, serum electrolyte levels, intake and output, and serial chest x-rays. After a near-drowning, the patient is at risk for complications, such as hypoxic or ischemic cerebral injury, acute respiratory distress syndrome, pulmonary damage secondary to aspiration, and life-threatening cardiac arrest.

## DECOMPRESSION SICKNESS

Decompression sickness (DCS), also called “the bends,” occurs in patients who have engaged in diving, high-altitude flying, or flying in commercial aircraft within 24 hours after diving. Although DCS occurs in relatively few divers compared with the number of dives worldwide, its effects can be hazardous. Being aware of DCS and assessing the patient properly will ensure proper management and result in the least morbidity possible.

DCS results from nitrogen bubbles trapped in the body. They may occur in joint or muscle spaces, resulting in musculoskeletal pain, numbness, or hypesthesia. More significantly, nitrogen bubbles can become air emboli in the bloodstream and thereby produce stroke, paralysis, or death. Taking a rapid history about the events preceding the symptoms is essential. Recompression is necessary as soon as possible and may necessitate a low-altitude flight to the nearest hyperbaric chamber.

### Assessment and Diagnostic Findings

To identify DCS, a detailed history is obtained from the patient or diving buddy. Evidence of rapid ascent, loss of air in the tank, buddy breathing, recent alcohol intake or lack of sleep, or a flight within 24 hours after diving suggests the potential for DCS. Note that some patients describe a perfect dive yet still have the signs and symptoms of DCS and must be treated as such.

Signs and symptoms include joint or extremity pain, numbness, hypesthesia, and loss of range of motion. Neurologic symptoms mimicking those of a stroke or spinal cord injury could indicate an air embolus. Cardiopulmonary arrest can also occur with severe cases of DCS. Because of hypoxia, these patients seldom survive. Any neurologic symptoms should be rapidly assessed. All patients with DCS need rapid transfer to a hyperbaric chamber.

### Management

A patent airway and adequate ventilation are established as described previously, and 100% oxygen is administered throughout treatment and transport. A chest x-ray is obtained to identify aspiration, and at least one intravenous line is started with lactated Ringer's or normal saline solution.

The cardiopulmonary and neurologic systems are supported as needed. If an air embolus is suspected, the head of the bed should be lowered. The patient's wet clothing is removed, and the patient is kept warm. Transfer to the closest hyperbaric chamber capable of treating DCS is initiated. The Divers Alert Network (DAN) can be contacted by telephone (1-919-684-8111) to locate the nearest chamber. If air transport is necessary, low-altitude flight (below 1000 feet) is required. However, the patient who is awake and alert without central neurologic deficits may be able to travel by ground ambulance or by automobile, depending on the severity of symptoms. Throughout treatment, the patient is continually assessed, and changes are documented. If aspiration is suspected, antibiotics and other treatment may be prescribed.

## ANAPHYLACTIC REACTION

An anaphylactic reaction is an acute systemic hypersensitivity reaction that occurs within seconds or minutes after exposure to certain foreign substances, such as medications (eg, penicillin, iodinated contrast material), and other agents, such as insect

stings (eg, bee, wasp, yellow jacket, hornet) or foods (eg, eggs, peanuts). Repeated administration of parenteral or oral therapeutic agents (eg, repeated exposures to penicillin) may also precipitate an anaphylactic reaction when initially only a mild allergic response occurred. See Chart 71-8 for anaphylaxis prevention strategies.

An anaphylactic reaction is the result of an antigen–antibody interaction in a sensitized individual who, as a consequence of previous exposure, has developed a special type of antibody (immunoglobulin) that is specific for that particular allergen. The antibody immunoglobulin E (IgE) is responsible for most of the immediate type of human allergic responses. The individual becomes sensitive to a particular antigen after production of IgE to that antigen. A second exposure to the same antigen results in a more severe and more rapid response (see Chap. 53).

Anaphylactic reaction produces a wide range of clinical manifestations, especially respiratory symptoms (difficulty breathing and stridor secondary to laryngeal edema), fainting, itching, swelling of mucous membranes, and a sudden drop in blood pressure secondary to massive vasodilation (see Chart 71-9 and Chapters 15 and 53 for additional discussion).

### Management

With an anaphylactic reaction, establishing a patent airway and ventilation is essential. (This is performed while another person administers epinephrine.) Early endotracheal tube intubation is essential to avoid loss of the airway, and oropharyngeal suction may be necessary to remove excessive secretions. Resuscitative

Chart  
71-8

### Preventing Anaphylactic Reactions

- Be aware of the danger of anaphylactic reactions and the early signs of anaphylaxis.
- Ask the patient about previous allergies to medications, foods, stings, latex, pollen, and so on.
- Before giving a foreign serum or other type of antigenic agent, ask the patient or caregiver whether the agent was received at some earlier time.
- Ask about allergies to eggs.
- Avoid giving medications to patients with hay fever, asthma, or other allergic disorders unless absolutely necessary.
- Avoid giving parenteral medications unless absolutely necessary, because anaphylactic reactions are more likely to occur when the agent is given parenterally.
- Perform a skin test before administration of certain materials known to produce anaphylactic reactions (eg, horse serum). Remember that negative skin test results do not always indicate safety and that skin testing can precipitate anaphylaxis in highly sensitive individuals. Have epinephrine, intravenous infusions, and intubation and tracheostomy equipment available as precautionary measures.
- If the patient is an outpatient, keep him or her in the office, hospital, or clinic for at least 30 minutes after injection of any agent. Caution the patient to return if symptoms develop.
- Caution patients who are highly sensitive (eg, to insect bites and stings) to carry kits equipped to treat insect stings (epinephrine). Instruct the patient, family, and significant others in the use of the emergency supplies.
- Encourage patients with allergies to wear medical identification tags or bracelets.

Chart  
71-9

## Signs and Symptoms of Anaphylaxis

**Respiratory Signs**

- Nasal congestion
- Itching
- Sneezing and coughing
- Possible respiratory distress that progresses rapidly (caused by bronchospasm or edema of the larynx)
- Chest tightness
- Other respiratory difficulties, such as wheezing, dyspnea, and cyanosis

**Skin Manifestations**

- Flushing with a sense of warmth and diffuse erythema
- Generalized itching over the entire body (indicates developing general systemic reaction)
- Urticaria (hives)
- Massive facial angioedema possible with accompanying upper respiratory edema

**Cardiovascular Manifestations**

- Tachycardia or bradycardia
- Peripheral vascular collapse as indicated by
  - Pallor
  - Imperceptible pulse
  - Decreasing blood pressure
  - Circulatory failure, leading to coma and death

**Gastrointestinal Problems**

- Nausea
- Vomiting
- Colicky abdominal pains
- Diarrhea

measures are used, especially for patients with stridor and progressive pulmonary edema. If glottal edema occurs, a cricothyroidotomy is used to provide an airway.

Simultaneously with airway management, aqueous epinephrine is administered as prescribed to provide rapid relief of the hypersensitivity reaction. Epinephrine may be administered again, if necessary and as prescribed. Judgment is used in choosing the route of administration, as follows:

- Subcutaneous injection for mild, generalized symptoms
- Intramuscular injection when the reaction is more severe and progressive, and with concern that vascular collapse will inhibit absorption
- Intravenous route (aqueous epinephrine diluted in saline solution and administered *slowly*), used in rare instances in which there is complete loss of consciousness and severe cardiovascular collapse. This method may precipitate cardiac dysrhythmias. ECG monitoring with a readily available defibrillator is necessary. This method is controversial and is not usually recommended because it can lead to more distress than is initially present. An intravenous infusion of saline solution is initiated to provide for emergency access to a vein and to treat hypotension.

Additional treatments may include

- Antihistamines to block further histamine binding at target cells
- Aminophylline by slow intravenous infusion for severe bronchospasm and wheezing refractory to other treatment

- Albuterol inhalers or humidified treatments to decrease bronchoconstriction; crystalloids, colloids, or vasopressors to treat prolonged hypotension
- Isoproterenol or dopamine for reduced cardiac output; oxygen to enhance tissue perfusion
- Intravenous benzodiazepines for control of seizures, and corticosteroids for prolonged reaction with persistent hypotension or bronchospasm

After the acute symptoms have been treated, the patient is usually admitted to the hospital for observation. The patient should be informed about ways to prevent anaphylactic reactions. See Chart 71-10 for strategies to limit exposure to stinging insects.

**LATEX ALLERGY**

Another allergy situation with which emergency nurses are dealing on a daily basis is latex allergy. The number of products that contain latex is staggering. Nurses must be aware of latex allergy (health care providers have died from anaphylaxis related to latex allergy) and the potential for patients to react to latex.

There is an increased awareness among manufacturers of the need for products that are latex free. Latex-free gloves are provided for nurses who have latex allergy or who have signs of allergy, such as itching, redness, or rash associated with use of a latex product. Severe anaphylaxis can occur even on first exposure; therefore, recognition of the signs and symptoms of anaphylaxis is essential. Treatment must be rapid, and the latex product must be removed promptly. See Chapters 19 and 53 for more information about latex allergy.

Chart  
71-10

## Limiting Exposure to Stinging Insects

- Avoid places where stinging insects congregate, such as camp and picnic sites, and insect feeding areas, such as flower beds, ripe fruit orchards, garbage, and fields of clover.
- Wear covering on the feet, and avoid going barefoot outdoors, because yellow jackets nest and pollinate on the ground.
- Avoid perfumes, scented soaps, and bright colors, which attract bees.
- Keep car windows closed.
- Spray garbage cans with quick-acting insecticide.
- Secure a professional exterminator to dispose of wasp and hornet nests or beehives in the home area.
- Remain motionless if an insect is buzzing around. Motion, especially running, increases the likelihood of being stung.
- If allergic, carry a self-treatment kit containing injectable and inhalant forms of epinephrine, an oral antihistamine, and written instructions. Carry it with you at all times.

**If Stung, Do the Following:**

1. Inject self immediately with epinephrine if allergy is known or allergic response occurs.
2. Remove the stinger with one quick scrape of the fingernail. *Do not* squeeze the venom sac because this may cause injection of additional venom.
3. Clean the area with soapy water, and apply ice.
4. Report to the nearest health care facility for further examination if allergic response or allergy is suspected.

## INJECTED POISONS: STINGING INSECTS

A person may have an extreme sensitivity to the venoms of the Hymenoptera (bees, hornets, yellow jackets, fire ants, and wasps). Venom allergy is thought to be an IgE-mediated reaction, and it constitutes an acute emergency. Although stings in any area of the body can trigger anaphylaxis, stings of the head and neck are especially serious.

Clinical manifestations range from generalized urticaria, itching, malaise, and anxiety due to laryngeal edema to severe bronchospasm, shock, and death. Generally, the shorter the time between the sting and the onset of severe symptoms, the worse the prognosis.

### Management

Management includes stinger removal if the bite is from a bee, because the venom is associated with sacs around the barb of the stinger itself. Wound care with soap and water is sufficient for stings. Scratching is avoided because it results in a histamine response. Ice application reduces swelling and also decreases venom absorption. An oral antihistamine and analgesic will decrease the itching and pain.

In the case of an anaphylactic or severe allergic response, epinephrine (aqueous) is injected subcutaneously (*not intravenously*), and the injection site is massaged to hasten absorption. The patient is assessed for signs and symptoms of anaphylactic reaction and treated as necessary (see previous discussion and also Chap. 15). Desensitization therapy should be given to people who have had systemic or significant local reactions.

Patient and family education is an important measure in preventing exposure to stinging insects.

## SNAKE BITES

Venomous (poisonous) snakes cause 7000 to 8000 bites in the United States each year and result in 12 to 15 deaths. Children between the ages of 1 and 9 years are the most likely victims. The greatest number of bites occur through the daylight hours into early evening during summer months. The most frequent poisonous snakebite occurs from pit vipers. The most common site is the upper extremity. Of these bites, only 20% to 25% result in **envenomation** (injection of a poisonous material by sting, spine, bite, or other means). Venomous snake bites are medical emergencies (Moon & Galvan, 2000).

Nineteen different species of venomous snakes are found in every part of the United States, with different parts of the country and the world having different types of snakes. Because snake bites are medical emergencies, nurses should be familiar with the types of snakes that are common to the geographic region in which they practice. Snake venom consists primarily of proteins with a broad range of physiologic effects. Multiple organ systems, especially the neurologic, cardiovascular, and respiratory systems, may be affected.

### Management

Initial first aid at the site of the snake bite includes having the victim lie down, removing constrictive items such as rings, providing warmth, cleansing the wound, covering the wound with a light sterile dressing, and immobilizing the injured body part below the level of the heart. Ice or a tourniquet *is not* applied. Ini-

tial evaluation in the ED is performed quickly and includes information about the following:

- Whether the snake was venomous or nonvenomous; if the snake is dead, it should be transported to the ED with the patient for identification
- Where and when the bite occurred and the circumstances of the bite
- Sequence of events, signs and symptoms (fang punctures, pain, edema, and erythema of the bite and nearby tissues)
- Severity of poisonous effects
- Vital signs
- Circumference of the bitten extremity or area at several points; the circumference of the extremity that was bitten is compared with the circumference of the opposite extremity
- Laboratory data (complete blood count, urinalysis, and clotting studies)

The course and prognosis of snake bite injuries depend on the kind and amount of venom injected, where on the body the bite occurred, and the general health, age, and size of the victim. There is no one specific protocol for treatment of snake bites. Generally, ice, tourniquets, heparin, and corticosteroids are not used during the acute stage. Corticosteroids are contraindicated in the first 6 to 8 hours after the bite, because they may depress antibody production and hinder the action of **antivenin** (antitoxin manufactured from the snake venom and used to treat snake bites).

Parenteral fluids may be used to treat hypotension. If vasopressors are used to treat hypotension, their use should be short-term. Surgical exploration of the bite is rarely indicated. Typically, the patient is observed closely for at least 6 hours. The patient is *never* left unattended.

### ADMINISTRATION OF ANTIVENIN (ANTITOXIN)

Although envenomation is rare, it can occur with snake bites. An assessment of progressive signs and symptoms is essential before considering administration of antivenin, which is most effective if administered within 12 hours after the snake bite. The dosage depends on the type of snake and the estimated severity of the bite. Children may require more antivenin than adults because their smaller bodies are more susceptible to toxic effects of venom. A skin or eye test should be performed before the initial dose to detect allergy to the antivenin. However, because even the skin test can cause an anaphylactic reaction, patients should not be tested unless antivenin is to be given.

Before administering antivenin and every 15 minutes thereafter, the circumference of the affected part is measured proximally. Premedication with diphenhydramine and cimetidine decreases the allergic response to antivenin. Antivenin is administered as an intravenous infusion whenever possible, although intramuscular administration can be used. Depending on the severity of the bite, the antivenin is diluted in 500 to 1000 mL of normal saline solution; the fluid volume may be reduced for children. The infusion is started slowly, and the rate is increased after 10 minutes if there is no reaction. The total dose should be infused during the first 4 to 6 hours after poisoning. The initial dose is repeated until symptoms decrease. After the symptoms decrease, the circumference of the affected part should be measured every 30 to 60 minutes for the next 48 hours to detect symptoms of compartment syndrome (swelling, loss of pulse, increased pain, and paresthesias).

The most common cause of allergic reaction to the antivenin is its too-rapid infusion, although about 3% of patients with neg-

ative skin test results develop reactions not related to infusion rate. Reactions may consist of a feeling of fullness in the face, urticaria, pruritus, malaise, and apprehension. These symptoms may be followed by tachycardia, shortness of breath, hypotension, and shock. In this situation, the infusion should be stopped immediately and intravenous diphenhydramine (Benadryl) administered. Vasopressors are used for patients in shock, and resuscitation equipment must be on standby while antivenin is infusing.

## Poisoning

A poison is any substance that, when ingested, inhaled, absorbed, applied to the skin, or produced within the body in relatively small amounts, injures the body by its chemical action. Poisoning from inhalation and ingestion of toxic materials, both intentional and unintentional, constitutes a major health hazard and an emergency situation. Emergency treatment is initiated with the following goals:

- To remove or inactivate the poison before it is absorbed
- To provide supportive care in maintaining vital organ systems
- To administer a specific antidote to neutralize a specific poison
- To implement treatment that hastens the elimination of the absorbed poison

### INGESTED (SWALLOWED) POISONS

Swallowed poisons may be corrosive. **Corrosive poisons** include alkaline and acid agents that can cause tissue destruction after coming in contact with mucous membranes. Alkaline products include lye, drain cleaners, toilet bowl cleaners, bleach, nonphosphate detergents, oven cleaners, and button batteries (batteries used to power watches, calculators, or cameras). Acid products include toilet bowl cleaners, pool cleaners, metal cleaners, rust removers, battery acid.

### Management

Control of the airway, ventilation, and oxygenation are essential. In the absence of cerebral or renal damage, the patient's prognosis depends largely on successful management of respiration and circulation. Measures are instituted to stabilize cardiovascular and other body functions. ECG, vital signs, and neurologic status are monitored closely for changes. Shock, which may result from the cardiodepressant action of the substance ingested, from venous pooling in lower extremities, or from reduced circulating blood volume resulting from increased capillary permeability, is treated. An indwelling urinary catheter is inserted to monitor renal function. Blood specimens are obtained to test for concentration of drug or poison.

Efforts are initiated to determine what substance was taken; the amount; time since ingestion; signs and symptoms, such as pain or burning sensations, any evidence of redness or burn in the mouth or throat, pain on swallowing or an inability to swallow, vomiting, or drooling; age and weight of the patient; and pertinent health history.

Measures are instituted to remove the toxin or decrease its absorption. The patient who has ingested a corrosive poison is given

water or milk to drink for dilution. However, dilution is not attempted if the patient has acute airway edema or obstruction or if there is clinical evidence of esophageal, gastric, or intestinal burn or perforation. The following gastric emptying procedures may be used as prescribed:

- Syrup of ipecac to induce vomiting in the alert patient.
- Gastric lavage for the obtunded patient (Chart 71-11). Gastric aspirate is saved and sent to the laboratory for testing (toxicology screens)
- Activated charcoal administration if poison is one that is absorbed by charcoal
- Cathartic, when appropriate

**NURSING ALERT** Vomiting is never induced after ingestion of caustic substances (acid or alkaline) or petroleum distillates.

The specific chemical or physiologic antagonist (antidote) is administered as early as possible, to reverse or diminish the effects of the toxin. If these measures are ineffective, procedures are initiated to remove the ingested substance. These procedures include administration of multiple doses of charcoal, diuresis (for substances excreted by the kidneys), dialysis, and hemoperfusion. Hemoperfusion involves detoxification of the blood by processing it through an extracorporeal circuit and an adsorbent cartridge containing charcoal or resin, after which the cleaned blood is returned to the patient.

Throughout detoxification, the patient's vital signs, CVP, and fluid and electrolyte balance are monitored closely. Hypotension and cardiac dysrhythmias are possible. Seizures are also possible because of CNS excitement from the poison or from oxygen deprivation. If the patient complains of pain, analgesics are administered cautiously. Severe pain causes vasomotor collapse and reflex inhibition of normal physiologic functions.

After the patient's condition has stabilized and discharge is imminent, written material indicating the signs and symptoms of potential problems related to the poison ingested and signs or symptoms requiring evaluation by a physician should be given to the patient. If poisoning was determined to be a suicide attempt, a psychiatric consultation should be requested before the patient is discharged. In cases of inadvertent poison ingestion, poison prevention and home poison-proofing instructions should be provided to the patient and family.

### INHALED POISONS: CARBON MONOXIDE POISONING

Carbon monoxide poisoning may occur as a result of industrial or household incidents or attempted suicide. It is implicated in more deaths than any other toxin except alcohol. Carbon monoxide exerts its toxic effect by binding to circulating hemoglobin and thereby reducing the oxygen-carrying capacity of the blood. Hemoglobin absorbs carbon monoxide 200 times more readily than it absorbs oxygen. Carbon monoxide-bound hemoglobin, called **carboxyhemoglobin**, does not transport oxygen.

Because the CNS has a critical need for oxygen, CNS symptoms predominate with carbon monoxide toxicity. A person suffering from carbon monoxide poisoning may appear intoxicated (from cerebral hypoxia). Other signs and symptoms include headache, muscular weakness, palpitation, dizziness, and confusion, which can progress rapidly to coma. Skin color, which can range from pink or cherry-red to cyanotic and pale, is not a reliable sign. Pulse oximetry is also not valid, because the hemoglobin

**NURSING ALERT** The area poison control center should be called if an unknown toxic agent has been taken or if it is necessary to identify an antidote for a known toxic agent.

Chart 71-11

## GUIDELINES FOR Assisting With Gastric Lavage

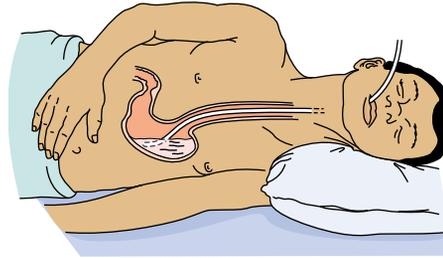

Gastric lavage is the aspiration of stomach contents and washing out of the stomach by means of a large-bore gastric tube. Gastric lavage is contraindicated after acid or alkali ingestion, in the presence of seizures, or after ingestion of hydrocarbons or petroleum distillates. It is particularly dangerous after ingestion of strong corrosive agents.

### Purposes:

- For urgent removal of ingested substance to decrease systemic absorption
- To empty the stomach before endoscopic procedures
- To diagnose gastric hemorrhage and to arrest hemorrhage

### Equipment:

Large-bore Levin tubes or large-bore Ewald tube  
 Large irrigating syringe with adapter  
 Large plastic funnel with adapter to fit tube  
 Water-soluble lubricant  
 Tap water or appropriate antidote (milk, saline solution, sodium bicarbonate solution, fruit juice, activated charcoal)  
 Container for aspirate; suction apparatus  
 Nasotracheal or endotracheal tubes with inflatable cuffs  
 Containers for specimens

During gastric lavage, the patient is positioned on the left side, which allows the gastric contents to pool and decreases the passage of fluid into the duodenum during lavage.

### PROCEDURE

1. Remove dentures and inspect the oral cavity for loose teeth.
2. Measure the distance between the bridge of the nose and the xiphoid process. Mark the tube with indelible pencil or tape.
3. Lubricate the tube with water-soluble lubricant.
4. If comatose, the patient is intubated with a cuffed nasotracheal or endotracheal tube before placement of the nasogastric tube.
5. Place the patient in a left lateral position with the head lowered about 15 degrees.
6. Pass the tube orally while keeping the patient's head in a neutral position. Pass the tube to the adhesive marking or about 50 cm (20 in). Encourage patient to swallow to assist with passage of the tube. Then lower the head of the stretcher or bed. Have standby suction available.
7. Aspirate the stomach contents with the syringe attached to the tube before instilling water or an antidote. Save the specimen for analysis. Ensure correct placement before installation.
8. Remove the syringe. Attach the funnel to the end of the tube, or use a 50-mL syringe to instill solution in the gastric tube. The volume of fluid placed in the stomach should be small.
9. Elevate the funnel above the patient's head and pour 150 to 200 mL of solution into the funnel.
10. Lower the funnel and siphon the gastric contents into the container or connect to suction.
11. Save samples of the first two washings.
12. Repeat the lavage procedure until the returns are relatively clear and no particulate matter is seen.
13. At the completion of lavage:
  - a. The stomach may be left empty.
  - b. An adsorbent (powder form of activated charcoal mixed with water to form a liquid the consistency of thick soup) may be instilled in the tube and allowed to remain in the stomach.
  - c. A saline cathartic may be instilled in the tube.
14. Pinch off the tube during removal or maintain suction while the tube is being withdrawn. Keep the patient's head lower than the body.
15. Warn the patient that his stools will turn black from the charcoal.

### RATIONALE/AMPLIFICATION

1. This will prevent aspiration of teeth.
2. This distance is a rule-of-thumb measurement of the distance the tube must be passed to reach the stomach. This avoids curling and kinking of excess tubing in the stomach.
3. Lubrication eases insertion of the tube.
4. A cuffed nasotracheal or endotracheal tube decreases the risk of aspiration of gastric contents.
5. This position decreases passage of gastric contents into the duodenum during lavage.
6. The depth of insertion of the tube varies according to the size of the patient. If the tube enters the trachea instead of the esophagus, the patient will experience coughing, dyspnea, stridor, and cyanosis. Positive confirmation of tube placement is accomplished by x-ray.
7. Aspiration is carried out to determine that the tube is in the stomach and to remove the stomach contents. Positive confirmation of tube placement is accomplished by x-ray.
8. Overfilling of the stomach may cause regurgitation and aspiration or force the stomach contents through the pylorus.
9. Gravity allows the solution to flow into the tube.
10. The fluid should flow in freely and drain by gravity.
11. Keep the first washing sample isolated from other washings for toxicologic analysis.
12. This usually requires a total volume of at least 2 L; some clinicians advocate the use of 5 to 20 L.
13.
  - a. The stomach is kept empty if no further medications are required.
  - b. Activated charcoal reduces absorption by adsorbing (attaching to its surface) a wide range of substances; it renders the poison inaccessible to the circulation, thereby reducing its toxicity.
  - c. A cathartic may be given to hasten the elimination of remaining ingested material.
14. Pinching off the tube prevents aspiration and the initiation of the gag reflex. Keeping the patient's head lower than the body also helps to prevent initiation of the gag reflex.

is well saturated. It is not saturated with oxygen, but the pulse oximeter reads the saturation as such and presents the false impression that the patient is well oxygenated and in no danger. Exposure to carbon monoxide requires immediate treatment.

## Management

Goals of management are to reverse cerebral and myocardial hypoxia and to hasten elimination of carbon monoxide. Whenever a patient inhales a poison, the following general measures apply:

- Carry the patient to fresh air immediately; open all doors and windows.
- Loosen all tight clothing.
- Initiate cardiopulmonary resuscitation if required; administer oxygen.
- Prevent chilling; wrap the patient in blankets.
- Keep the patient as quiet as possible.
- Do not give alcohol in any form.

In addition, for the patient with carbon monoxide poisoning, carboxyhemoglobin levels are analyzed on arrival at the ED and before treatment with oxygen if possible. Then 100% oxygen is administered at atmospheric or hyperbaric pressures to reverse hypoxia and accelerate the elimination of carbon monoxide. Oxygen is administered until the carboxyhemoglobin level is less than 5%. The patient is monitored continuously. Psychoses, spastic paralysis, ataxia, visual disturbances, and deterioration of mental status and behavior may persist after resuscitation and may be symptoms of permanent brain damage.

When unintentional carbon monoxide poisoning occurs, the health department should be contacted, so that the dwelling or building in question can be inspected. A psychiatric consultation is warranted if poisoning was determined to be a suicide attempt.

## SKIN CONTAMINATION POISONING (CHEMICAL BURNS)

Skin contamination injuries from exposure to chemicals are challenging because of the large number of offending agents with diverse actions and metabolic effects. The severity of a chemical burn is determined by the mechanism of action, the penetrating strength and concentration, and the amount and duration of exposure of the skin to the chemical.

## Management

The skin should be drenched immediately with running water from a shower, hose, or faucet.

**NURSING ALERT** Water should not be applied to burns from lye or white phosphorus because of the potential for an explosion or for deepening of the burn. All evidence of these chemicals should be brushed off the patient before any flushing.

A constant stream of water should continue as the patient's clothing is being removed. The skin of health care personnel assisting the patient should be appropriately protected if the burn is extensive or if the agent is significantly toxic or is still present. Prolonged lavage with generous amounts of tepid water is important.

In the meantime, attempts to determine the identity and characteristics of the chemical agent are necessary for future treat-

ment. The standard burn treatment appropriate for the size and location of the wound (antimicrobial treatment, débridement, tetanus prophylaxis as prescribed) is instituted. The patient may require plastic surgery for further wound management. The patient is instructed to have the affected area reexamined at 24 and 72 hours and in 7 days because of the risk for underestimating the extent and depth of these types of injuries.

## FOOD POISONING

Food poisoning is a sudden illness that occurs after ingestion of contaminated food or drink. Botulism is a serious form of food poisoning that requires continual surveillance. See Chart 71-12 for assessment questions.

## Management

The key to treatment is determining the source and type of food poisoning. If possible, the suspected food should be brought to the medical facility and a history obtained from the patient or family.

Food, gastric contents, vomitus, serum, and feces are collected for examination. The patient's respirations, blood pressure, sensorium, CVP (if indicated), and muscular activity are monitored closely. Measures are instituted to support the respiratory system. Death from respiratory paralysis can occur with botulism, fish poisoning, and other food poisonings.

Because large volumes of electrolytes and water are lost by vomiting and diarrhea, fluid and electrolyte balance is also an important area to assess. Severe vomiting produces alkalosis, and severe diarrhea produces acidosis. Hypovolemic shock may also occur from severe fluid and electrolyte losses. The patient is assessed for signs and symptoms of fluid and electrolyte imbalances, including lethargy, rapid pulse rate, fever, oliguria, anuria, hypotension, and delirium. Weight and serum electrolyte levels are obtained for future comparisons.

Measures to control nausea are also important to prevent vomiting, which could further exacerbate fluid and electrolyte imbalances. An antiemetic medication is administered parenterally as prescribed if the patient cannot tolerate fluids or medications by mouth. For mild nausea, the patient is encouraged to take sips of weak tea, carbonated drinks, or tap water. After nausea and

Chart  
71-12

### Food Poisoning

Use the following questions to elicit information about the circumstances surrounding the possibility of food poisoning:

- How soon after eating did the symptoms occur? (Immediate onset suggests chemical, plant, or animal poisoning.)
- What was eaten in the previous meal? Did the food have an unusual odor or taste? (Most foods causing bacterial poisoning *do not* have unusual odor or taste.)
- Did anyone else become ill from eating the same food?
- Did vomiting occur? What was the appearance of the vomitus?
- Did diarrhea occur? (Diarrhea is usually absent with botulism and with shellfish or other fish poisoning.)
- Are any neurologic symptoms present? (These occur in botulism and in chemical, plant, and animal poisoning.)
- Does the patient have a fever? (Fever is characteristic in salmonella, ingestion of fava beans, and some fish poisoning.)
- What is the patient's appearance?

vomiting subside, clear liquids are usually prescribed for 12 to 24 hours, and the diet is gradually progressed to a low-residue, bland diet.

## Substance Abuse

Substance abuse is the misuse of specific substances to alter mood or behavior; drug and alcohol abuse are two examples of substance abuse. Drug abuse is the use of drugs for other than legitimate medical purposes. People who use drugs often take a variety of drugs simultaneously (such as alcohol, barbiturates, opioids, and tranquilizers), and the combination may have additive and addictive effects. IV/injecting drug users are at increased risk for HIV infection, acquired immunodeficiency syndrome (AIDS), and hepatitis B and are the most frequent victims of tetanus in the United States.

Clinical manifestations vary with the substance used, but the underlying principles of management are essentially the same. Table 71-1 identifies commonly abused drugs, listing their clinical manifestations and therapeutic management. Treatment goals for a patient suffering from drug overdose are to support the respiratory and cardiovascular functions, to enhance clearance of the agent, and to provide for safety of the patient and staff.

### ACUTE ALCOHOL INTOXICATION

Alcohol is a psychotropic drug that affects mood, judgment, behavior, concentration, and consciousness. Many heavy drinkers are young adults or people older than 60 years of age. There is a high prevalence of alcoholism among ED patients. Because patients who abuse alcohol return frequently to the ED, they often frustrate and tax the patience of the health care professionals who care for them. Their management requires patience and thoughtful, accurate, long-term treatment.

Alcohol, or ethanol, is a direct multisystem toxin and CNS depressant that causes drowsiness, incoordination, slurring of speech, sudden mood changes, aggression, belligerence, grandiosity, and uninhibited behavior. In excess, it also can cause stupor, coma, and death. In the ED, the patient is assessed for head injury, hypoglycemia (which mimics intoxication), and other health problems. Possible nursing diagnoses include ineffective breathing pattern related to CNS depression and risk for violence (self-directed or directed at others) related to severe intoxication from alcohol.

### Management

Treatment involves detoxification of the acute poisoning, recovery, and rehabilitation. Commonly, the patient uses mechanisms of denial and defensiveness. The nurse should approach the patient in a nonjudgmental manner, using a firm, consistent, accepting, and reasonable attitude. Speaking in a calm and slow manner is helpful because alcohol interferes with thought processes. If the patient appears intoxicated, hypoxia, hypovolemia, and neurologic impairment must be ruled out before it is assumed that the patient is intoxicated. Typically, a blood specimen is obtained for analysis of the blood alcohol level.

If drowsy, the patient should be allowed to sleep off the state of alcoholic intoxication. During this time, maintenance of a patent airway and observation for symptoms of CNS depression are essential. The patient should be undressed and kept warm with blankets. On the other hand, if the patient is noisy or belligerent, sedation may be necessary. If sedation is used, the patient should

be monitored carefully for hypotension and decreased level of consciousness.

Additionally, the patient is examined for alcohol withdrawal delirium and also for injuries and organic disease, such as head injury, seizures, pulmonary infections, hypoglycemia, and nutritional deficiencies, that may be masked by alcoholic intoxication. People with alcoholism suffer more injuries than the general population. Also, acute alcohol intoxication is the cause of trauma for many nonalcoholic patients. Pulmonary infections are also more common in patients with alcoholism, resulting from respiratory depression, an impaired defense system, and a tendency toward aspiration of gastric contents. The patient may show little increase in temperature or white blood cell count. The patient may be hospitalized or admitted to a detoxification center in an effort to examine problems underlying substance abuse.

### ALCOHOL WITHDRAWAL SYNDROME/DELIRIUM TREMENS

Alcohol withdrawal syndrome (AWS) is an acute toxic state that occurs as a result of sudden cessation of alcohol intake after a bout of heavy drinking or, more usually, after prolonged intake of alcohol. Severity of symptoms depends on how much alcohol was ingested and for how long. Delirium tremens may be precipitated by acute injury or infection (pneumonia, pancreatitis, hepatitis) and is the most severe form of AWS.

Patients with AWS show signs of anxiety, uncontrollable fear, tremor, irritability, agitation, insomnia, and incontinence. They are talkative and preoccupied and experience visual, tactile, olfactory, and auditory hallucinations that often are terrifying. Autonomic overactivity occurs and is evidenced by tachycardia, dilated pupils, and profuse perspiration. Usually, all vital signs are elevated in the alcoholic toxic state. Delirium tremens is a life-threatening condition and carries a high mortality rate.

### Management

The goals of management are to give adequate sedation and support to allow the patient to rest and recover without danger of injury or peripheral vascular collapse. A physical examination is performed to identify preexisting or contributing illnesses or injuries (eg, head injury, pneumonia). A drug history is obtained to elicit information that may facilitate adjustment of any sedative requirements. Baseline blood pressure is determined, because the patient's subsequent treatment may depend on blood pressure changes.

Usually, the patient is sedated as directed with a sufficient dosage of benzodiazepines to establish and maintain sedation, which reduces agitation, prevents exhaustion, prevents seizures, and promotes sleep. The patient should be calm, able to respond, and able to maintain an airway safely on his or her own. A variety of medications and combinations of medications are used (for example, chlordiazepoxide [Librium], lorazepam, and clonidine). Haloperidol or droperidol may be administered for severe acute AWS. Dosages are adjusted according to the patient's symptoms (agitation, anxiety) and blood pressure response.

The patient is placed in a calm, nonstressful environment (usually a private room) and observed closely. The room remains lighted to minimize the potential for illusions and hallucinations. Homicidal or suicidal responses may result from hallucinations. Closet and bathroom doors are closed to eliminate shadows. Someone is designated to stay with the patient as much as possible. The presence of another person has a reassuring and calming effect,

**Table 71-1 • Emergency Management of Drug Abuse Patients and Patients with Drug Overdose**

DRUG	CLINICAL MANIFESTATIONS	THERAPEUTIC MANAGEMENT
<b>Narcotics</b>		
Cocaine	Cocaine is a central nervous system (CNS) stimulant that can increase heart rate and blood pressure and cause hyperpyrexia, seizures, and ventricular dysrhythmias. It produces intense euphoria, then anxiety, sadness, insomnia, and sexual indifference; cocaine hallucinations with delusions; psychosis with extreme paranoia and ideas of persecution; and hypervigilance. Chronic psychotic symptoms may persist.	<ol style="list-style-type: none"> <li>1. Ensure airway and ventilation.</li> <li>2. Control seizures.</li> <li>3. Monitor cardiovascular effects; have lidocaine and defibrillator available.</li> <li>4. Treat for hyperthermia.</li> <li>5. If cocaine was ingested, use charcoal to treat.</li> <li>6. Refer for psychiatric evaluation and treatment in an inpatient unit that eliminates access to the drug. Include drug rehabilitation counseling.</li> </ol>
Intranasally (“snorting”): inhaled into nostrils through straws By smoking (“freebasing”): cocaine hydrochloride dissolved in ether to yield a pure cocaine alkaloid base (called “crack”); smoking in a small pipe delivers large quantities of cocaine to lungs Intravenously		
Heroin Opium or paregoric	Acute intoxication (overdose) Pinpoint pupils (may be dilated with severe hypoxia); decreased blood pressure Marked respiratory depression	<ol style="list-style-type: none"> <li>1. Support respiratory and cardiovascular functions.</li> <li>2. Establish an intravenous (IV) line; obtain blood for chemical and toxicologic analysis. Patient may be given bolus of glucose to eliminate possibility of hypoglycemia.</li> <li>3. Give narcotic antagonist (naloxone hydrochloride [Narcan]) as prescribed to reverse severe respiratory depression and coma.</li> <li>4. Continue to monitor level of responsiveness and respirations, pulse, and blood pressure. Duration of action of naloxone hydrochloride is shorter than that of heroin; repeated dosages may be necessary.</li> <li>5. Send urine for analysis; opiates can be detected in urine.</li> <li>6. Obtain an electrocardiogram.</li> <li>7. Do not leave patient unattended; he or she may lapse back into coma rapidly. Clinical status may change from minute to minute. Hemodialysis may be indicated for severe drug intoxication.</li> <li>8. Monitor for pulmonary edema, which is frequently seen in patients who abuse/overdose on narcotics.</li> <li>9. Refer patient for psychiatric and drug rehabilitation evaluation before discharge.</li> </ol>
Morphine, codeine, OxyContin, synthetic derivatives (methadone, meperidine) Fentanyl (Sublimaze)	Stupor → coma Fresh needle marks along course of any superficial vein; skin abscesses	
<b>Barbiturates</b>		
Pentobarbital (Nembutal) Secobarbital (Seconal) Amobarbital (Amytal)	Acute intoxication (may mimic alcohol intoxication): <ul style="list-style-type: none"> <li>• Respiratory depression</li> <li>• Flushed face</li> <li>• Decreased pulse rate; decreased blood pressure</li> <li>• Increasing nystagmus</li> <li>• Depressed deep tendon reflexes</li> <li>• Decreasing mental alertness</li> <li>• Difficulty in speaking</li> <li>• Poor motor coordination</li> <li>• Coma, death</li> </ul>	<ol style="list-style-type: none"> <li>1. Maintain airway and provide respiratory support.</li> <li>2. Endotracheal intubation or tracheostomy is considered if there is any doubt about the adequacy of airway exchange. <ol style="list-style-type: none"> <li>a. Check airway frequently.</li> <li>b. Perform suctioning as necessary.</li> </ol> </li> <li>3. Support cardiovascular and respiratory functions; most deaths result from respiratory depression or shock.</li> <li>4. Start infusion through large-gauge needle or IV catheter to support blood pressure; coma and dehydration result in hypotension and respond to infusion of intravenous fluids with elevation of blood pressure. Sodium bicarbonate may be prescribed to alkalinize urine; it promotes excretion of barbiturates.</li> <li>5. Evacuate stomach contents or lavage as soon as possible to prevent absorption; repeated doses of activated charcoal may be administered.</li> </ol>

(continued)

**Table 71-1 • Emergency Management of Drug Abuse Patients and Patients with Drug Overdose (Continued)**

DRUG	CLINICAL MANIFESTATIONS	THERAPEUTIC MANAGEMENT
		<ol style="list-style-type: none"> <li>6. Assist with hemodialysis for severely overdosed patient.</li> <li>7. Maintain neurologic and vital sign flow sheet.</li> <li>8. Patient awakening from overdose may demonstrate combative behavior.</li> <li>9. Refer for psychiatric and drug rehabilitation consultation/rehabilitation to evaluate suicide potential and drug abuse.</li> </ol>
<b>Amphetamine-Type Drugs (Pep Pills, "Uppers," "Speed," "Crystal," "Meth")</b>		
Amphetamine (Benzedrine)	Nausea, vomiting, anorexia, palpitations, tachycardia, increased blood pressure, tachypnea,	<ol style="list-style-type: none"> <li>1. Provide airway support, ventilation, cardiac monitoring; insert IV line.</li> <li>2. Employ gastrointestinal (GI) decontamination in cases of oral overdose; activated charcoal, gastric lavage.</li> <li>3. Keep in calm, cool, quiet environment; elevated temperature potentiates amphetamine toxicity.</li> <li>4. Use small doses of diazepam (IV) or haloperidol as prescribed for CNS and muscular hyperactivity.</li> <li>5. Administer appropriate pharmacologic therapy as prescribed for severe hypertension and ventricular dysrhythmias.</li> <li>6. Treat seizures with benzodiazepines.</li> <li>7. Treat sympathetic stimulation with beta-blocker agents.</li> <li>8. Try to communicate with patient if delusions or hallucinations are present.</li> <li>9. Place in a protective environment (preferably psychiatric security room with video monitoring) to observe for suicide attempt.</li> <li>10. Refer for psychiatric and drug rehabilitation evaluation.</li> </ol>
Dextroamphetamine (Dexedrine)	anxiety, nervousness, diaphoresis, mydriasis	
Methamphetamine (Desoxyn)	Repetitive or stereotyped behavior	
MDMA ("Ecstasy," "Adam")	Irritability, insomnia, agitation	
MDEA ("Eve")	Visual misperceptions, auditory hallucinations	
MDA	Fearful anxiety/depression, cold, distant hostility, paranoia Hyperactivity, rapid speech, euphoria Seizures, coma, hyperthermia, cardiovascular collapse, rhabdomyolysis	
<b>Hallucinogens or Psychedelic-Type Drugs</b>		
Lysergic acid diethylamide (LSD)	Nystagmus	<i>Emergency Management</i>
Phencyclidine HCl (PCP, "angel dust")	Mild hypertension Marked confusion bordering on panic	<ol style="list-style-type: none"> <li>1. Evaluate and maintain patient's airway, breathing, and circulation.</li> <li>2. Determine by urine or serum drug screen whether the patient has ingested hallucinogenic drug or has a toxic psychosis.</li> <li>3. Try to communicate with and reassure the patient. <ol style="list-style-type: none"> <li>a. "Talking down" involves understanding the process through which the patient is proceeding and helping him overcome his fears while establishing contact with reality.</li> <li>b. Remind the patient that fear is common with this problem.</li> <li>c. Reassure the patient that he is not losing his mind but is experiencing the effect of drugs and that this will wear off.</li> <li>d. Instruct the patient to keep the eyes open; this reduces the intensity of reaction.</li> <li>e. Reduce sensory stimuli: minimize noise, lights, movement, tactile stimulation.</li> </ol> </li> <li>4. Sedate the patient as prescribed if hyperactivity cannot be controlled; diazepam (Valium) or a barbiturate may be prescribed.</li> </ol>
Mescaline, psilocybin	Incoherence, hyperactivity	
Cannabinoids (marijuana)	Withdrawn Combative behavior; delirium, mania, self-injury Hallucinations, body image distortion Hypertension, hyperthermia, renal failure Flashback: recurrence of LSD-like state without having taken the drug; may occur weeks or months after drug was taken	

(continued)

**Table 71-1 • Emergency Management of Drug Abuse Patients and Patients with Drug Overdose (Continued)**

DRUG	CLINICAL MANIFESTATIONS	THERAPEUTIC MANAGEMENT
		<ol style="list-style-type: none"> <li>5. Search for evidence of trauma; hallucinogen users have a tendency to “act out” their hallucinations.</li> <li>6. Manage seizures.</li> <li>7. Observe patient closely; patient’s behavior may become hazardous. Have safety officers stationed near the patient’s room.</li> <li>8. Monitor for hypertensive crisis if patient has prolonged psychosis due to drug ingestion.</li> <li>9. Place patient in a protected environment under proper medical supervision to prevent self-inflicted bodily harm.</li> </ol> <p><i>Management for Phencyclidine Abusers</i></p> <ol style="list-style-type: none"> <li>1. Place patient in a calm, supportive environment to minimize stimuli; protect from self-injury.</li> <li>2. Avoid talking down.</li> <li>3. Do not leave patient unobserved. Treat symptoms as they occur.               <ol style="list-style-type: none"> <li>a. Drug effects are unpredictable and prolonged.</li> <li>b. Symptoms are likely to exacerbate; patient becomes out of control.</li> </ol> </li> <li>4. Refer all patients in this category for psychiatric and drug evaluation/rehabilitation.</li> </ol>
<p><b><i>Drugs Producing Sedation, Intoxication, or Psychological and Physical Dependence (Nonbarbiturate Sedatives)</i></b></p>		
Diazepam (Valium)	Seizures, coma, circulatory collapse, death	
Chlordiazepoxide (Librium)	Acute intoxication:	<i>Management</i>
Oxazepam (Serax)	• Respiratory depression	1. Endotracheal tube is inserted as a precaution; use assisted ventilation to stabilize and correct respiratory depression. Observe for sudden apnea and laryngeal spasm (especially in patients dependent on glutethimide [Doriden]).
Lorazepam (Ativan)	• Decreasing mental alertness	2. Assess for hypotension
Midazolam (Versed)	• Confusion	a. Insert indwelling urinary catheter for comatose patient; decreased urinary volume is an index of reduced renal flow associated with reduced intravascular volume or vascular collapse.
	• Slurred speech, decreased blood pressure	b. Start volume expansion with saline or dextrose as prescribed.
	• Ataxia	3. Evacuate stomach contents; emesis; lavage; activated charcoal; cathartic.
	• Pulmonary edema	4. Start ECG monitoring. Observe for dysrhythmias.
	• Coma, death	5. Administer flumazenil (Romazicon), the benzodiazepine antagonist (reversal agent)
		6. Refer patient for psychiatric evaluation (potential suicide intent).
<b><i>Salicylate Poisoning</i></b>		
Aspirin (present in compound analgesic tablets)	Restlessness, tinnitus, deafness, blurring of vision	1. Treat respiratory depression.
	Hyperpnea, hyperpyrexia, sweating	2. Induce gastric emptying by lavage.
	Epigastric pain, vomiting, dehydration	3. Give activated charcoal to adsorb aspirin; a cathartic may be administered with charcoal to help ensure intestinal cleansing.
	Respiratory and metabolic acidosis	4. Support patient with IV infusions as prescribed to establish hydration and correct electrolyte imbalances.
	Disorientation, coma, cardiovascular collapse	5. Enhance elimination of salicylates as directed by forced diuresis, alkalization of urine, peritoneal dialysis, or hemodialysis, according to severity of intoxication.

(continued)

**Table 71-1 • Emergency Management of Drug Abuse Patients and Patients with Drug Overdose (Continued)**

DRUG	CLINICAL MANIFESTATIONS	THERAPEUTIC MANAGEMENT
Acetaminophen (present in prescription and nonprescription analgesics, antipyretics, and cold remedies)	Lethargy to encephalopathy and death GI upset, diaphoresis Right upper quadrant pain Abnormal liver function tests, prolonged prothrombin time, increased bilirubin Hepatomegaly leading to liver failure	<ol style="list-style-type: none"> <li>6. Monitor serum salicylate level for efficacy of treatment.</li> <li>7. Administer specific prescribed pharmacologic agent for bleeding and other problems.</li> <li>8. Refer patient for psychiatric evaluation (potential suicide intent).</li> </ol> <ol style="list-style-type: none"> <li>1. Maintain airway</li> <li>2. Obtain acetaminophen level. Levels <math>\geq 140</math> mg/kg are toxic.</li> <li>3. Laboratory studies—liver function tests, prothrombin time/partial thromboplastin time, complete blood count, blood urea nitrogen, creatinine</li> <li>4. Administer syrup of ipecac and follow emesis with activated charcoal.</li> <li>5. Prepare for possible hemodialysis, which clears acetaminophen but does not halt liver damage.</li> <li>6. Administer <i>N</i>-acetylcysteine (NAC, Mucomyst) as soon as possible. NAC replenishes essential liver enzymes and requires a total of 18 doses every 4 hr. Charcoal absorbs NAC; do not administer together. Repeat NAC dose if patient vomits.</li> <li>7. Refer patient for psychiatric evaluation (potential suicide intent).</li> </ol>
<b>Tricyclic Antidepressants (TCA)</b> Amitriptyline Doxepin Nortriptyline Imipramine	Dysrhythmia: ventricular fibrillation/tachycardia, tachycardia Hypotension Pulmonary edema, hypoxemia, acidosis Confusion, agitation, coma Visual hallucinations Clonus, hyperactive reflexes, nystagmus, myoclonic jerking Seizures Blurred vision, flushing, hyperthermia	<ol style="list-style-type: none"> <li>1. Provide airway support, ventilation, cardiac monitoring; insert IV line with normal saline solution.</li> <li>2. If within 1 hr after overdose, insert a nasogastric tube and instill activated charcoal with sorbitol every 4 hr <math>\times 3</math>.</li> <li>3. Administer a sodium bicarbonate drip to decrease dysrhythmias; the alkaline environment increases the protein binding of the metabolite.</li> <li>4. Administer vasopressors</li> <li>5. Use only Class IB antiarrhythmics (eg, lidocaine), as some other types of antiarrhythmics have the same effect as TCA.</li> <li>6. Manage seizure activity</li> <li>7. Refer patient for psychiatric evaluation for potential suicide intent and evaluation of medication regimen for effectiveness.</li> </ol>

which helps the patient maintain contact with reality. Any visual misrepresentations (illusions) are explained, to orient the patient to reality.

**NURSING ALERT** Restraints are used as prescribed, if necessary, if the client is aggressive or violent, but only when other alternatives have been unsuccessful. The least restrictive device that will prevent the patient from injuring self or others is used. Caution is taken to ensure that restraints are applied properly and that they are not impairing circulation to any part of the body or interfering with respirations. Restraints must be released according to protocol. Physical observation (eg, skin integrity, circulatory status, respiratory status) is ongoing, and the patient's response is documented.

Fluid losses may result from gastrointestinal losses (vomiting), profuse perspiration, and respiration (hyperventilation). In addition, the patient may be dehydrated as a result of alcohol's effect of decreasing antidiuretic hormone. The oral or intravenous route is used to restore fluid and electrolyte balance.

Temperature, pulse, respiration, and blood pressure are recorded frequently (every 30 minutes in severe forms of delirium) in anticipation of peripheral circulatory collapse or hyperthermia (the two most lethal complications). Phenytoin (Dilantin) or other antiseizure medications may be prescribed to prevent or control repeated withdrawal seizures.

Frequently seen complications include infections (eg, pneumonia), trauma, hepatic failure, hypoglycemia, and cardiovascular problems. Hypoglycemia may accompany alcohol withdrawal,

because alcohol depletes liver glycogen stores and impairs gluconeogenesis; many patients with alcoholism also are malnourished. Parenteral dextrose may be prescribed if the liver glycogen level is depleted. Orange juice, Gatorade, or other forms of carbohydrates are given to stabilize the blood glucose level and counteract tremulousness. Supplemental vitamin therapy and a high-protein diet are provided as prescribed to counteract vitamin deficiency. The patient should be referred to an alcoholic treatment center for follow-up care and rehabilitation.

## Violence, Abuse, and Neglect

### FAMILY VIOLENCE, ABUSE, AND NEGLECT

EDs are often the first place where victims of family violence, abuse, or neglect go to seek help. Each year in the United States 3 to 4 million women experience domestic violence, and up to one third of all women will be in a domestic violence situation in their lifetime. One million women are severely beaten each year. Approximately 2 to 3 million children are seriously abused, an additional 5 million children are maltreated, and 1 to 2 million elders are abused or neglected (Guth, Pachter, 2000). Among women who are pregnant, 4% to 14% will suffer physical violence from their intimate partner, with 10% to 24% of this population having been abused during the year before they became pregnant. These statistics are startlingly higher for teenagers, of whom 20% are assaulted while pregnant. The severity of the abuse increases and is associated with battering during pregnancy. Domestic violence is the leading cause of death for young African American women (Campbell, 1999; Harrell et al., 2002). On the average, between 6% and 28% of women seen in the ED have suffered abuse, with up to 6% of these patients seeking treatment for a complaint related to a recent event. Between 20% and 35% of all ED visits relate to continuous abuse. Young women are most likely to suffer nonlethal violent acts that result in visits to the ED (Moskowitz, Griffith, DiScala, & Sege, 2001). ED nurses must be aware that men and persons with disabilities are also victims of domestic violence and should include questions to that effect in their evaluations. Elder abuse takes many forms, including physical and psychological abuse, neglect, violation of personal rights, and financial abuse.

### Clinical Manifestations

When victims of abuse seek treatment, they may present with physical injuries or with health problems, such as anxiety, insomnia, or gastrointestinal symptoms, that are related to stress. They usually do not identify their abuser.

The possibility of abuse should be investigated whenever a person presents with multiple injuries that are in various stages of healing, when injuries are unexplained, and when the explanation does not fit the physical picture (Chart 71-13). The possibility of neglect should be investigated whenever a dependent person with adequate resources and a designated care provider shows evidence of inattention to hygiene, to nutrition, or to known medical needs (eg, unfilled medication prescriptions, missed appointments with health care providers). In the ED, the most common physical injuries seen are unexplained bruises, lacerations, abrasions, head injuries, or fractures. The most common clinical manifestations of neglect are malnutrition and dehydration.

### Chart 71-13

### Abuse, Maltreatment, and Neglect

The following questions may be helpful when assessing a patient for abuse, maltreatment, and neglect:

- I noticed that you have a number of bruises. Can you tell me how they happened? Has anyone hurt you?
- You seem frightened. Has anyone ever hurt you?
- Sometimes patients tell me that they have been hurt by someone at home or at work. Could this be happening to you?
- Are you afraid of anyone at home or work? Or of anyone with whom you come in contact?
- Has anyone failed to help you to take care of yourself when you needed help?
- Has anyone prevented you from seeing friends or other people whom you wish to see?
- Have you signed any papers that you did not understand or did not wish to sign?
- Has anyone forced you to sign papers against your will?

### Assessment and Diagnostic Findings

Nurses in EDs are in an ideal position to provide early detection and interventions for victims of domestic violence. This requires an acute awareness of the signs of possible abuse, maltreatment, and neglect. Nurses must be skilled in interviewing techniques that are likely to elicit accurate information. A careful history is crucial in the screening process. Asking questions in private—away from others—may be helpful in eliciting information about abuse, maltreatment, and neglect.

Whenever evidence leads one to suspect abuse or neglect, an evaluation with careful documentation of descriptions of events and drawings or photos of injuries is important, because the medical record may be used as part of a legal document. Assessment of the patient's general appearance and interactions with significant others, an examination of the entire surface area of the body, and a mental status examination are crucial.

### Management

Whenever abuse, maltreatment, or neglect is suspected, the health care worker's primary concern should be the safety and welfare of the patient. Treatment focuses on the consequences of the abuse, violence, or neglect and on prevention of further injury. Protocols of most EDs require that a multidisciplinary approach be used. Nurses, physicians, social workers, and community agencies work collaboratively to develop and implement a plan for meeting the patient's needs.

If in immediate danger, the patient should be separated from the abusing or neglecting person whenever possible. On the basis of this danger, or on the basis of injuries or neglected medical conditions, hospitalization is justified until alternative plans are made. However, it must be remembered that third-party payers may not approve hospitalization that is based solely on abuse or neglect.

When abuse or neglect is considered to be the result of stress experienced by a caregiver who is no longer able to cope with the burden of caring for an elderly person or a person with chronic disease or a disability, respite services may be necessary. Support groups may be helpful to these caregivers. When mental illness of the abuser or neglecter is responsible for the situation, alternative living arrangements may be required.

Nurses must be mindful that competent adults are free to accept or refuse the help that is offered to them. Some patients will insist on remaining in the home environment where the abuse or neglect is occurring. The wishes of patients who are competent and not cognitively impaired should be respected. However, all possible alternatives and available resources should be explored with the patient.

Mandatory reporting laws in most states require health care workers to report *suspected* abuse to an official agency, usually Adult (or Child) Protective Services. All that is required for reporting is the suspicion of abuse. The health care worker is not required to prove anything. Likewise, health care workers who report suspected abuse are immune to civil or criminal liability if the report is made in good faith. Subsequent home visits resulting from the report of suspected abuse are a part of gathering information about the patient in the home environment. In addition, many states have resource hotlines for use by health care workers and by patients who seek answers to questions about abuse and neglect.

## SEXUAL ASSAULT

The definition of *rape* is forced sexual acts, especially vaginal or anal penetration. Perpetrators and victims may be either male or female. The feminist movement has focused on the rights and care of rape victims, and law enforcement agencies are becoming increasingly sensitive and aggressive in managing these crimes. Rape crisis centers offer support, educate victims, and help them through the subsequent courtroom experience.

The manner in which the patient is received and treated in the ED is important to his or her future psychological well-being. Crisis intervention should begin when the patient enters the health care facility. The patient should be seen immediately. Most hospitals have a written protocol that reflects consideration for the victim's physical and emotional needs as well as forensic evidence collection that is required.

### The Sexual Assault Nurse Examiner

In many states, there is the opportunity for emergency nurses to become trained sexual assault nurse examiners (SANEs). The role allows for specific training in forensic evidence collection, history taking, documentation, and ways to approach the patient and family. Specialized training also includes proper photography and the use of colposcopy. Colposcopy increases assessment by examination for microtrauma through magnification. Evidence is collected through photography, videography, and analysis of specimens. Another tool useful to SANEs is the light-staining microscope, which enables the examiner to identify motile and nonmotile sperm and infection. This tool saves time and also enhances assessment. SANEs complement the ED staff and can spend more time with both the patient and police officers investigating the incident.

### Assessment and Diagnostic Findings

The patient's reaction to rape has been termed *rape trauma syndrome* and is seen as an acute stress reaction to a life-threatening situation. The nurse performing the assessment is aware that the patient may go through several phases of psychological reactions (Dole, 1996; Ritchie, 1998):

- An acute disorganization phase, which may manifest as an expressed state in which shock, disbelief, fear, guilt, humilia-

tion, anger, and other such emotions are encountered or as a controlled state in which feelings are masked or hidden and the victim appears composed

- A phase of denial and unwillingness to talk about the incident, followed by a phase of heightened anxiety, fear, flashbacks, sleep disturbances, hyperalertness, and psychosomatic reactions
- A phase of reorganization, in which the incident is put into perspective. Some victims never fully recover and go on to develop chronic stress disorders and phobias.

## Management

The goals of management are to give sympathetic support, to reduce the emotional trauma of the patient, and to gather available evidence for possible legal proceedings. All of the interventions have the ultimate goal of having the patient regain control over his or her life.

Throughout the patient's stay in the ED, the patient's privacy and sensitivity must be respected. The patient may exhibit a wide range of emotional reactions, such as hysteria, stoicism, or feelings of being overwhelmed. Support and caring are crucial. The patient should be reassured that anxiety is natural and asked whether a support person may be called. Appropriate support is available from professional and community resources. The Rape Victim Companion Program, if available in the community, can be contacted, and services of a volunteer can be requested. The patient should never be left alone.

### PHYSICAL EXAMINATION

A written, witnessed informed consent must be obtained from the patient (or parent or guardian if the patient is a minor) for examination, for taking of photographs, and for release of findings to police. A history is obtained only if the patient has not already talked to a police officer, social worker, or crisis intervention worker. The patient should not be asked to repeat the history. Any history of the event that is obtained should be recorded in the patient's own words. The patient is asked whether he or she has bathed, douched, brushed teeth, changed clothes, urinated, or defecated since the attack, because these actions may alter interpretation of subsequent findings. The time of admission, time of examination, date and time of the alleged rape, and the patient's emotional state and general appearance (including any evidence of trauma, such as discoloration, bruises, lacerations, secretions, or torn and bloody clothing) are documented.

For the physical examination, the patient is helped to undress and is draped properly. Each item of clothing is placed in a separate paper bag. Plastic bags are not used because they retain moisture; moisture may promote mold and mildew formation, which can destroy evidence. The bags are labeled and given to appropriate law enforcement authorities.

The patient is examined (from head to toe) for injuries, especially injuries to the head, neck, breast, thighs, back, and buttocks. Body diagrams and photographs aid in documenting the evidence of trauma. The physical examination focuses on the following:

- External evidence of trauma (bruises, contusions, lacerations, stab wounds)
- Dried semen stains (appearing as crusted, flaking areas) on the patient's body or clothes
- Broken fingernails and body tissue and foreign materials under nails (if found, samples are taken)

- Oral examination, including a specimen of saliva and prescribed cultures of gum and tooth areas

Pelvic and rectal examinations are also performed. The perineum and other areas are examined with a Wood lamp or other filtered ultraviolet light. Areas that appear fluorescent may indicate semen stains. The color and consistency of any discharge present is noted. A water-moistened rather than a lubricated vaginal speculum is used for the examination. Lubricant contains chemicals that may interfere with later forensic testing of specimens and acid phosphatase determinations. The rectum is examined for signs of trauma, blood, and semen. During the examination, the patient should be advised of the nature and necessity of each procedure and given the rationale for each question asked.

### SPECIMEN COLLECTION

During the physical examination, numerous laboratory specimens may be collected, including the following:

- Vaginal aspirate, examined for presence or absence of motile and nonmotile sperm
- Secretions (obtained with a sterile swab) from the vaginal pool for acid phosphatase, blood group antigen of semen, and precipitin test against human sperm and blood
- Separate smears from the oral, vaginal, and anal areas
- Culture of body orifices for gonorrhea
- Blood serum for syphilis and HIV testing; a sample of serum for syphilis may be frozen and saved for future testing
- Pregnancy test if there is a possibility that the patient may be pregnant
- Any foreign material (leaves, grass, dirt), which is placed in a clean envelope
- Pubic hair samples obtained by combing or trimming. Several pubic hairs with follicles are placed in separate containers and identified as the patient's hairs.

To preserve the chain of evidence, each specimen is labeled with the name of the patient, the date and time of collection, the body area from which the specimen was obtained, and the names of personnel collecting specimens. Then the specimens are given to a designated person (eg, crime laboratory technician), and an itemized receipt is obtained.

### TREATING POTENTIAL CONSEQUENCES OF RAPE

After the initial physical examination is completed and specimens have been obtained, any associated injuries are treated as indicated. The patient is given the option of prophylaxis against sexually transmitted disease. Ceftriaxone (Rocephin), administered intramuscularly with 1% lidocaine (Xylocaine), may be prescribed as prophylaxis for gonorrhea. Doxycycline (Vibramycin) taken for 10 days may be prescribed as prophylaxis for syphilis and chlamydia.

Antipregnancy measures may be considered if the patient is of childbearing age, is not using contraceptives, and is at high risk in her menstrual cycle. A postcoital contraceptive medication, such as Ovral, which contains estrogen ethinyl estradiol and progestin norgestrel, may be prescribed after a pregnancy test. To promote effectiveness, Ovral should be administered within 12 to 24 hours and no later than 72 hours after intercourse. The 21-day package rather than the 28-day package is prescribed, so that the patient does not take the inert tablets by mistake. An antiemetic may be administered as prescribed to decrease discomfort from

side effects. A cleansing douche, mouthwash, and fresh clothing are usually offered.

### FOLLOW-UP CARE

The patient is informed of counseling services to prevent long-term psychological effects. Counseling services should be made available to both the patient and the family. A referral is made to the Rape Victim Companion Program, if available. Appointments for follow-up surveillance for pregnancy, sexually transmitted disease, and HIV testing also are made.

The patient is encouraged to return to his or her previous level of functioning as soon as possible. When leaving the health care facility, the patient should be accompanied by a family member or friend.

## VIOLENCE IN THE EMERGENCY DEPARTMENT

Not only do ED staff members encounter patients who are violent from substance abuse, injury, or other emergencies, but they may also encounter violent situations in the rest of the environment. Patients and families waiting for assistance are increasingly volatile. Often, waiting rooms are the site for dissatisfaction, fear, and anger to be acted out in violence. Some EDs assign security officers to the area and have installed metal detectors to identify weapons and protect patients, families, and staff. It is not unusual for a patient to come to the ED armed. Nurses and other personnel must be prepared to deal with such circumstances.

### Management

Safety is the first priority. Protecting the ED on a daily basis will prevent any untoward events from occurring. Protection of the department provides protection for the patients, families, and staff. It is essential that all nurses be aware of the environment in which they are working.

Metal detectors, silent alarm systems, and secured entry into the department assist in maintaining safety. Members of gangs and feuding families need to be separated in the ED, in the waiting room, and later in the inpatient nursing unit to avoid angry confrontations. Security officers should be ready to assist at all times. The department should be able to be locked against entry if security is at all in question.

Patients from prison and those who are under guard need to be shackled to the bed with appropriate assessment. The same assessment and care that are provided to patients with hand or ankle restraints are provided to patients with handcuffs. In addition, the following precautions are taken:

- Never release the hand or ankle restraint (handcuff).
- Always have a guard present in the room.
- Place the patient face down on the stretcher to avoid injury from head-butting, spitting, or biting.
- Use restraints on any violent patient as needed.
- Administer medication if necessary to control violent behavior until definitive treatment can be obtained.

In the case of gunfire in the ED, self-protection is a priority. There is no advantage to protecting others if the caregivers are also injured. Security officers and police must gain control of the situation first; then care is provided to the injured.

## Psychiatric Emergencies

A psychiatric emergency is an urgent, serious disturbance of behavior, affect, or thought that makes the patient unable to cope with life situations and interpersonal relationships. A patient presenting with a psychiatric emergency may display overactive or violent, underactive or depressed, or suicidal behaviors.

The most important concern of the ED personnel is determining whether the patient is at risk for injuring self or others. The aim is to try to maintain the patient's self-esteem (and life, if necessary) while providing care. Determining whether the patient is currently under psychiatric treatment is important so that contact can be made with the therapist or physician who works with the patient.

### OVERACTIVE PATIENTS

Patients who display disturbed, uncooperative, and paranoid behavior and those who feel anxious and panicky may be prone to assaultive and destructive impulses and abnormal social behavior. Intense nervousness, depression, and crying are evident in some patients. Disturbed and noisy behavior may be exacerbated or compounded by alcohol or drug intoxication.

### Management

A reliable source is needed to identify events leading to the crisis, and a history is obtained. Past mental illness, hospitalizations, injuries, serious illnesses, use of alcohol or drugs, crises in interpersonal relationships, or intrapsychic conflicts are explored. Because abnormal thoughts and behavior may be manifestations of an underlying physical disorder, such as hypoglycemia, stroke, epilepsy, head injury, or drug or alcohol toxicity, a physical assessment is performed when possible.

The immediate goal is to gain control of the situation. If the patient is potentially violent, security or local police should be nearby. Restraints are used as a *last resort* and as prescribed. Approaching the patient with a calm, confident, and firm manner is therapeutic and has a calming effect. Helpful interventions include the following:

- Introduce yourself by name.
- Tell the patient, "I am here to help you."
- Repeat the patient's name from time to time.
- Speak in one-thought sentences and be consistent.
- Give the patient space and time to slow down.
- Show interest in, listen to, and encourage the patient to talk about personal thoughts and feelings.
- Offer appropriate and honest explanations.

A psychotropic agent (ie, one that exerts an effect on the mind) may be prescribed for emergency management of functional psychosis. However, personality disorders cannot and should not be treated with psychotropic medications; nor are psychotropic medications used if the patient's behavior results from use of hallucinogens (eg, lysergic acid diethylamide [LSD]).

Agents such as chlorpromazine (Thorazine) and haloperidol (Haldol) act specifically against psychotic symptoms of thought fragmentation and perceptual and behavioral aberrations. The initial dosage depends on the patient's body weight and the severity of the symptoms. After administration of the initial dose, the patient is observed closely to determine the degree of change in psychotic behavior. Subsequent dosages depend on the patient's response.

Typically, after stabilization, the patient is transferred to a psychiatric unit or psychiatric outpatient treatment is arranged.

### VIOLENT BEHAVIOR

Violent and aggressive behavior, usually episodic, is a means of expressing feelings of anger, fear, or hopelessness about a situation. Usually, the patient has a history of outbursts of rage, temper tantrums, or impulsive behavior. People with a tendency for violence frequently lose control when intoxicated with alcohol or drugs. Family members are the most frequent victims of their aggression (see earlier discussion). Patients with a propensity for violence include those intoxicated by drugs or alcohol; those going through drug or alcohol withdrawal; and those diagnosed with acute paranoid schizophrenic state, acute organic brain syndrome, acute psychosis, paranoid character, borderline personality, or antisocial personality disorders.

### Management

The goal of treatment is to bring the violence under control. A specially designated room with at least two exits should be used for the interview. The door of the room should be kept open, and the nurse should remain in clear view of the staff, *staying between the patient and the door*. However, the patient's exit to the door must not be blocked, because the patient may feel trapped and threatened. No objects that could be used as weapons should be in sight, in the room, or carried in with health care personnel. If the interviewer feels anxious or uneasy about the patient's response, security staff, a family member, or another health care worker should be asked to remain in the hall nearby in the event that additional help is needed. The patient should never be left alone, because this may be interpreted as rejection or provide an opportunity for self-harm.

To bring the violence under control, it is crucial to use a calm, noncritical approach while remaining in control of the situation. Sudden movements are avoided. External calm and structure in conjunction with providing the patient some space may help the patient gain control. If the patient is carrying a weapon, the emergency health care provider should ask that it be surrendered. If the patient is unwilling to surrender the weapon, the security staff is called. If necessary, the security staff may seek further assistance from the local police department.

The patient's violent behavior is a crisis situation for the patient and the ED. Crisis intervention, achieved by talking and listening to the patient, is best accomplished by expressing an interest in the patient's well-being while attempting to tune in to the patient and remain firm. The patient's agitated state is acknowledged by statements such as, "I want to work with you to relieve your distress."

The patient is allowed the opportunity to ventilate anger verbally. If the patient is delusional, challenging the patient is avoided. Trying to hear what the patient is saying, conveying an expectation of appropriate behavior, and making the patient aware that help is available are key. The patient should be informed that violent behavior may be frightening others and that violence is not acceptable. Help that is available in crisis situations (from a clinic, ED, or mental health facility) should be described and offered. Often, the offer of protection by hospitalization is welcomed by the patient, who fears losing control or harming self or others. If the patient does not calm down, security personnel or police intervention may be necessary.

If these measures fail to alleviate the patient's tension, medication may be prescribed (rapid sedation with haloperidol, diazepam,

or chlorpromazine) to reduce tension, anxiety, and hyperactivity. Restraints must be prescribed by a physician. They are applied with a minimum of force and only when necessary and when other alternatives have been unsuccessful.

**NURSING ALERT** The least restrictive device to prevent the patient from injuring self or others is used. Caution is taken to ensure that restraints are applied properly. Restraints should be used with verbal intervention to calm the patient and promote compliance. Appropriate personnel must be available when applying restraints (in such a way that they do not impair circulation to any part of the body or interfere with breathing). Physical observation (eg, skin integrity, circulatory status, respiratory status) is ongoing, and the patient's response is documented.

After combativeness, agitation, and fear have decreased, the patient is referred for further mental health treatment.

## POSTTRAUMATIC STRESS DISORDER

Posttraumatic stress disorder (PTSD) is the development of characteristic symptoms after a psychologically stressful event that is considered outside the range of normal human experience (eg, rape, combat, motor vehicle crash, natural catastrophe, terrorist attack). Symptoms of this disorder include intrusive thoughts and dreams, phobic avoidance reaction (avoidance of activities that arouse recollection of the traumatic event), heightened vigilance, exaggerated startle reaction, generalized anxiety, and societal withdrawal. PTSD may be acute, chronic, or delayed.

### Assessment and Diagnostic Findings

Assessment includes an evaluation of the patient's pretrauma history, the trauma itself, and posttrauma functioning. PTSD often presents as multiple readmissions to the ED for minor or recurring complaints without evidence of injury. The patient is allowed to discuss the traumatic event and permitted to grieve.

### Management

The patient's goal is to organize and begin to integrate the experience so that he or she can return to the pretrauma level of functioning as soon as possible. Emergency management focuses on the patient's presenting behaviors. A wide range of interventions are carried out, including crisis intervention strategies, establishing a trusting and sharing relationship, and educating the patient and family about stress management and support services available in the community. Psychiatric support may be useful to the patient.

## UNDERACTIVE OR DEPRESSED PATIENTS

In the ED, depression may be seen as the primary condition bringing the patient to the health care facility, or it may be masked by anxiety and somatic complaints. The depressed person has a mood disturbance.

Clinical manifestations may include sadness, apathy, feelings of worthlessness, self-blame, suicidal thoughts, desire to escape, avoidance of simple problems, anorexia and weight loss, decreased interest in sex, sleeplessness, and ceaseless activity or reduction in activity. The agitated depressed individual may exhibit motor restlessness and severe anxiety.

## Management

The depressed patient benefits from ventilating personal feelings and should be provided an opportunity to talk about personal problems while emergency health care personnel listen in a calm, unhurried manner. Information about a perceived or real illness or a sudden worsening of depression is an important clue. Any patient who is depressed may be at risk for suicide.

Attempts are made to find out whether the patient has thought about or attempted suicide. Questions such as, "Have you ever thought about taking your own life?" may be helpful. Generally, the patient is relieved to have an opportunity to discuss personal feelings. If the patient is seriously depressed, relatives should be notified. The patient should never be left alone, because suicide is usually committed in solitude.

The patient needs to understand that depression is treatable. Antidepressant and antianxiety agents may be prescribed. Crisis and supportive services in the community, including mental health centers, telephone counseling and referral, suicide prevention centers, group therapy, and marital and family counseling, should be offered to the patient and family. Usually, the patient is referred for psychiatric consultation or to a psychiatric facility.

## SUICIDAL PATIENTS

Attempted suicide is an act that stems from depression (eg, loss of a loved one, loss of body integrity or status, poor self-image) and can be viewed as a cry for help and intervention. Males are at greater risk than females. Others at risk are elderly people; young adults; people who are enduring unusual loss or stress; those who are unemployed, divorced, widowed, or living alone; those showing signs of significant depression (eg, weight loss, sleep disturbances, somatic complaints, suicidal preoccupation); and those with a history of a previous suicide attempt, suicide in the family, or psychiatric illness.

Being aware of people at risk and assessing for specific factors that predispose a person to suicide are key management strategies. Specific signs and symptoms of potential suicide include the following:

- Communication of *suicidal intent*, such as preoccupation with death or talking of someone else's suicide (eg, "I'm tired of living. I've put my affairs in order. I'm better off dead. I'm a burden to my family")
- History of a previous suicide attempt (the risk is much greater in these cases)
- Family history of suicide
- Loss of a parent at an early age
- Specific plan for suicide
- A means to carry out the plan

### Management

Emergency management focuses on treating the consequences of the suicide attempt (eg, gunshot wound, drug overdose) and preventing further self-injury. A patient who has made a suicidal gesture may do so again. Crisis intervention is employed to determine suicidal potential, to discover areas of depression and conflict, to find out about the patient's support system, and to determine whether hospitalization or psychiatric referral is necessary. Depending on the patient's potential for suicide, the patient may be admitted to the intensive care unit, referred for follow-up care, or admitted to the psychiatric unit.

## Critical Thinking Exercises

1. A young woman arrives at the ED by ambulance after a car crash. She is immobilized on a backboard with a cervical collar. An oxygen mask is in place. You note shallow, slow respirations and no movement of the left chest wall. She complains of pain in her abdomen, and it is tense. Her left leg is angulated. How would you prioritize the patient's needs? Develop an assessment strategy, identify diagnostic studies that will benefit the patient, and describe the patient's treatment needs.
2. A man who was out ice fishing all day, wearing sneakers instead of his boots, comes to the ED for treatment of frostbite of his feet. His friends have been massaging his feet en route to the ED. The patient insists that his feet be placed in a pan of hot water. Describe how you would respond and the explanation you would give to this patient. How would you proceed with managing this patient's care? Describe the treatment dilemmas for this type of injury.
3. A young woman with a toddler in her arms waits her turn in line at the triage desk of the ED. The child is crying and rubbing her eyes and face. You overhear the mother telling another patient that the child has had an allergic reaction to her first soft-cooked egg, which the child smeared on her face. While waiting, the child becomes quiet and pale in color. Analyze this information. What is your immediate response? What action would you take and what is the rationale for your decision?
4. An elderly patient is brought to the ED by her son. She is complaining of pain in her hip, and the son says that she tripped over her oxygen tubing and fell. On initial assessment you notice that the patient has many bruises on her body in varying stages of resolution. What conclusions might you draw from these findings, and how might you proceed to evaluate the situation to determine your course of action?

# ● Terrorism, Mass Casualty, and Disaster Nursing

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Identify the necessary components of an emergency operations plan.
2. Discuss how triage in a disaster differs from triage in an emergency.
3. Develop a plan of care for a patient experiencing short- or long-term psychological effects after a disaster.
4. Evaluate the different levels of personal protection and decontamination procedures that may be necessary during an event involving mass casualties or weapons of mass destruction.
5. Describe isolation precautions necessary for bioterrorism agents.
6. Identify the differences among the various chemical agents used in terrorist events, their effects, and the decontamination and treatment procedures that are necessary.
7. Determine the injuries associated with varying levels of radiation or chemical exposure and the associated decontamination processes.

The possibility and reality of mass casualties associated with disasters, terrorism, and biological warfare are not new to human history; nor is the concept of using **weapons of mass destruction (WMDs)**. In fact, the use of WMDs dates as far back as the 6th century BC for biological weapons and the year 436 BC for chemical weapons (U.S. Army Medical Research Institute of Infectious Disease, 1996; U.S. Army Medical Research Institute of Chemical Defense, 1999). However, geopolitical forces and interests, the “shrinking globe,” and the availability of destructive technology have brought the possibility of more terrorist events to our doorsteps. Examples include the 1995 Oklahoma City bombing of the Murrah building; the 1993 bombing of the World Trade Center in New York City; the total destruction of the World Trade Center towers and the damage to the Pentagon on September 11, 2001; and the anthrax exposures that same year. Terrorism has become increasingly sophisticated, organized, and therefore effective. It is no longer a question of *whether* it will happen, but *when* it will happen again.

In 1999, a government agency called the National Domestic Preparedness Organization was developed to coordinate preparedness in the event of a terrorist attack (Kotzmann, 1999). The Department of Homeland Security was created after the September 11, 2001, attacks to coordinate federal and state efforts to combat terrorist activity. In 2001 and 2002, all acute care facilities across the nation were asked to present detailed plans to their health departments on how they would handle situations involving WMDs.

As distressing as terrorism and warfare are, they are just two of the manmade reasons that health care providers need to plan for mass casualties. Airplane crashes, train crashes, and toxic substance spillages are other manmade disasters that can result in casualties and tax the resources of health care facilities and their communities. In addition to manmade disasters, natural phenomena such as floods, tornadoes, hurricanes, fires, and earthquakes kill and injure hundreds of thousands of people worldwide each year. The acute care facility must be prepared for any and all of these disasters. This chapter focuses on disaster preparedness, especially providing information about possible terrorist-sponsored injuries and illnesses that can occur after biological, chemical, and nuclear or radiation attacks. Information about the process of responding to these emergencies is applicable to other types of mass disasters as well.

## EMERGENCY PREPAREDNESS

### Federal, State, and Local Responses

There are many resources available at the federal, state and local levels to assist in the management of disasters and emergencies. Disasters are often assigned levels, which indicate the anticipated

level of response (Chart 72-1). A list of the local resources with specific instructions about how and when to contact them should be readily available and frequently reviewed for needed updates. The following are a few of the resources that may be of assistance during a **mass casualty incident (MCI)** or a disaster.

### FEDERAL AGENCIES

There are many federal resources that can be accessed through a process of requests. The state authorities must request the federalization of resources through the proper channels. This request for federal resources generally is made when local resources have become or are in the process of becoming depleted.

Federal resources include organizations such as Department of Health and Human Services (DHHS) and the Department of Justice (DOJ). Each of these federal departments oversees hundreds of agencies that may respond to MCIs. For example, the Federal Bureau of Investigations (FBI) (under the DOJ) may be used for scene control and collection of forensic evidence. The Federal Emergency Management Agency (FEMA) can activate teams such as the Urban Search and Rescue Teams (USRTs). The DHSS administers the Centers for Disease Control and Prevention (CDC) and the National Disaster Medical System (NDMS). The NDMS has many medical support teams, such as Disaster Medical Assistance Teams (DMATs), Disaster Mortuary Response Teams (DMORTs), Veterinary Medical Assistance Teams (VMATs), and National Medical Response Teams for Weapons of Mass Destruction (NMRTs).

The DMAT provides medical personnel who can set up and staff a field hospital; there are many DMATs located across the country. There are only four NMRTs: the mobile California, North Carolina, and Colorado teams and the Washington, DC team, which is stationary. These specialty teams were developed to respond to situations involving WMDs. They consist of specially trained medical and technical personnel. The National Guard is also a resource, with some guard units functioning as Civil Strike Teams (CSTs).

Also included in federal resources are the teams from the CDC. This is the lead federal agency for disease prevention and control activities and provides backup support to state and local health departments. An additional support is available from the American Red Cross, which provides many support systems and shelter as needed.

### STATE AND LOCAL AGENCIES

Some of the state and local agencies may be the same agencies already listed (eg, local CDC and FBI agencies). Other state and local resources may include the American Red Cross, poison

## Glossary

**biological warfare:** use of a biological agent, such as anthrax, as a WMD

**chemical warfare:** use of a chemical agent, such as chlorine, as a WMD

**decontamination:** process of removing, or rendering harmless, contaminants that have accumulated on personnel, patients, and equipment

**mass casualty incident (MCI):** situation in which the number of casualties exceeds the number of resources

**material safety data sheet (MSDS):** provides chemical information to employees and health care providers regarding specific agents; includes chemical name, physical data, chemical ingredients, fire and explosive hazard data, health and reactive data, spill or leak procedures, special protection information, and special precautions. Established under the OSHA Hazard Communication Standard, also known as the Worker’s Right to Know.

**nuclear warfare:** use of nuclear contamination as a WMD

**Occupational Safety and Health Association (OSHA):** federal agency established for worker safety and protection

**personal protective equipment (PPE):** equipment beyond standard precautions; may include level A, B, C, and D equipment.

**weapons of mass destruction (WMDs):** weapons used to cause widespread death and destruction

Chart  
72-1**Disaster Levels**

Disasters are often classified by the resultant anticipated necessary response:

**Level I:** Local emergency response personnel and organizations can contain and effectively manage the disaster and its aftermath.

**Level II:** Regional efforts and aid from surrounding communities are sufficient to manage the effects of the disaster.

**Level III:** Local and regional assets are overwhelmed; statewide or federal assistance is required.

control centers, and other local volunteer organizations. The Metro Medical Response Teams Systems (MMRS) are local teams that are located in cities deemed to be possible terrorist targets and are funded for specialty response to WMDs. Many state and federal task forces have been developed to assist in the development and improvement of civilian medical response to chemical and biological terrorism.

Most cities and all states have an Office of Emergency Management (OEM). The OEM coordinates the disaster relief efforts at the state and local levels. The OEM is responsible for providing interagency coordination during an emergency. It maintains a corps of emergency management personnel, including responders, planners, and administrative and support staff.

**THE INCIDENT COMMAND SYSTEM**

The Incident Command System (ICS) is a management tool for organizing personnel, facilities, equipment, and communication for any emergency situation. The federal government mandates that the ICS be used during emergencies. Under this structure, one person is designated as incident commander. This person must be continuously informed of all activities and informed about any deviation from the established plan (Currance & Bronstein, 1999; Lewis & Aghababian, 1996; Londorf, 1995). Whereas the ICS is primarily a field structure and process, aspects of it are used at the level of an individual hospital's emergency response plan as well.

**Hospital Emergency Preparedness Plans**

Every facility is required by the Joint Commission on Accreditation of Healthcare Organizations (JCAHO) to create a plan for emergency preparedness and to practice this plan twice a year (Burgess, Kirk, Burron, & Cisek, 1999; JCAHO, 2000). Generally these plans are developed under the Environment of Care Committee or Safety Committee and are overseen by an administrative liaison.

Before the basic emergency operations plan (EOP) can be developed, the planning committee of the facility first evaluates the community to anticipate the types of natural and manmade disasters that might occur. This is not a difficult task and should be a responsibility of the local facility, safety committee, safety officer, or emergency department (ED) manager. This information can be gathered by questioning local law enforcement and fire departments and assessing the amount of air or train traffic, automobile traffic, and flood, earthquake, tornado, or hurricane activity. Consideration is given to special situations such as proximity to chemical plants, nuclear facilities, or military bases that may enhance the community's potential for manmade disasters. Federal, judicial, or financial buildings, schools, and any places where large groups of people gather can be considered high-risk areas.

The planning committee must have a realistic understanding of its resources. It must determine, for example, whether the facility has a pharmaceutical stockpile available to treat specific chemical or biological agents (Anteau, 1997; Stopford, 2000). Another scenario that might be anticipated, the dispersal of a pulmonary intoxicant or choking agent, requires that emergency operations planners find out how many ventilators would be available in the facility and in the community. The committee might also outline how staff would triage and assign priority to patients when the number of ventilators is limited. Multiple factors influence a facility's ability to respond effectively to a sudden influx of injured patients, and the committee must anticipate various scenarios to improve its preparedness.

**COMPONENTS OF EMERGENCY OPERATIONS PLAN**

Once the initial assessment is complete, the facility develops the EOP. Essential components of the plan are as follows:

- *An activation response:* The EOP activation response of a health care facility should define where, how, and when the response is initiated.
- *An internal/external communication plan:* Communication is critical for all parties involved, including communication to and from the prehospital arena (Heightman, 1999; Lewis & Aghababian, 1996; Mickelson, Burno, & Schario, 1999).
- *A plan for coordinated patient care:* A response is planned for coordinated patient care into and out of the facility, including transfers to other facilities. The site of the disaster can determine where the greater number of patients may self-refer.
- *Security plans:* A coordinated security plan involving facility and community agencies is key to the control of an otherwise chaotic situation.
- *Identification of external resources:* External resources are identified, including local, state, and federal resources and information about how to activate these resources.
- *A plan for people management and traffic flow:* "People management" includes strategies to manage the patients, the public, the media, and personnel. Specific areas are assigned, and a designated person is delegated to manage each of these areas (Anteau, 1997; Lewis & Aghababian, 1996).
- *A data management strategy:* A data management plan for every aspect of the disaster will save time at every step. A backup system for charting, tracking, and staffing is developed if the facility has a computer system.
- *Deactivation response:* Deactivation of the response is as important as activation; resources should not be overused. The person who decides when the facility is able to go from the disaster response back to daily activities is clearly identified. Any possible residual effects of a disaster must be considered before this decision is made (Anteau, 1997).
- *A post-incident response:* Often facilities see increased volumes of patients up to 3 months after an incident. Post-incident response must include a critique and a debriefing for all parties involved, immediately and again at a later date.
- *A plan for practice drills:* Practice drills that include community participation allow for troubleshooting any issues before a real-life incident occurs.
- *Anticipated resources:* Food and water must be available for staff, families, and others who may be at the facility for an extended period.
- *Mass casualty incident planning:* MCI planning includes such issues as mass fatality and morgue readiness.

- *An educational plan for all of the above:* A strong educational plan for all personnel regarding each step of the plan allows for improved readiness and additional input for fine-tuning of the EOP (Howard, 2001; Kotzmann, 1999; Anteau, 1997; Burgess et al., 1999; Lewis & Aghababian, 1996; Heightman, 2000; Levitin & Siegelson, 1996).

The EOP should also include a structure that defines roles for all employees in each emergency situation. The most common structure is the ICS described earlier, but applied at the level of the hospital itself instead of at the site of the disaster. For example, an administrator, possibly the nurse executive, will act as Incident Commander within the hospital and coordinate all aspects of the implementation of the plan. Other personnel will be designated to perform key roles, such as resource manager or patient disposition coordinator. Such a predetermined organization is essential to minimize confusion, ensure that all key operations are directed, and promote a well-coordinated response.

## INITIATING THE EMERGENCY OPERATIONS PLAN

Notification of a disaster situation to a facility varies with each situation. Generally, the notification to the facility comes from outside sources unless the initial incident occurred at the facility. The disaster activation plan should clearly state how the EOP is to be initiated. If communication is functioning, field incident command will give notice of the approximate number of arriving patients, although the number of self-referring patients will not be known.

## Identifying Patients and Documenting Patient Information

Patient tracking is a critical component of casualty management. Disaster tags, which are numbered and include triage priority, name, address, age, location and description of injuries, and treatments or medications given, are used to communicate patient information. The tag should be securely placed on the patient and remain with the patient at all times. The tag number and the patient's name are recorded in a disaster log. The log is used by the command center to track patients, assign beds, and provide families with information.

## Triage of Disaster Victims

Triage is the sorting of casualties to determine priority of health care needs and the proper site for treatment. In nondisaster situations, health care workers assign a high priority and allocate the most resources to those who are the most critically ill. For example, a young man who has a chest injury and is in full cardiac arrest would receive advanced cardiopulmonary resuscitation, including medications, chest tubes, intravenous fluids, blood, possibly even emergency surgery in an effort to restore life. In a disaster, however, when health care providers are faced with a large number of casualties, the fundamental principle guiding resource allocation is to do the greatest good for the greatest number of people. Decisions are based on the likelihood of survival and consumption of available resources. Therefore, this same patient, and others with conditions associated with a high mortality rate, would be assigned a low triage priority in a disaster situation, even if the person is conscious. Although this may sound uncaring, from an ethical standpoint the expenditure of limited resources

on individuals with a low chance of survival, and denial of those resources to others with serious but treatable conditions, cannot be justified.

The triage officer rapidly assesses those injured at the disaster scene. Victims are immediately tagged and transported or given life-saving interventions. One person performs the initial triage while other emergency services personnel perform life-saving measures (eg, intubation) and transport patients. Although emergency medical services personnel carry out initial field triage, secondary and continuous triage at all subsequent levels of care is essential.

Staff should control all entrances to the acute care facility so that incoming patients are directed to the triage area first. The triage area may be outside the entry or just at the door of the ED. This allows all patients, including those arriving by medical transport and those who walk in, to be triaged. Some patients already seen in the field will be reclassified in the triage area, based on their current presentation.

## TRIAGE CATEGORIES

Triage categories separate patients according to severity of injury and use a color-coded tagging system so that the triage category is immediately obvious. There are several triage systems in use across the country, and every nurse should be aware of the system used by his or her facility and community. The North Atlantic Treaty Organization (NATO) triage system is one that is widely used and is presented here. It consists of four colors—red, yellow, green, and black. Each color signifies a different level of priority. Table 72-1 describes each category and gives examples of how different injuries would be classified.

## Managing Internal Problems

Each facility must determine its supply lists based on its own needs assessment. The Red Cross has developed a basic survival/shelter resource kit. The EOP committee should determine the top 10 critical medications used during normal day-to-day operations and then anticipate which other medications may be required in a disaster or an MCI. For example, the hospital might plan to have available a stockpile of cyanide kits or antibiotics used in treating biological agents. Information should be available about local resources for stocking or restocking any of the basic and special supplies, how those supplies are requested, and the time required to receive those supplies.

## Communicating With the Media and Family

Communication is a key component of disaster management. Communication within the vast team of disaster responders is paramount; however, effective, informative communication with the media and worried family members is also crucial.

## MANAGING MEDIA REQUESTS FOR INFORMATION

Although the media have an obligation to report the news and can play a significant positive role in communication, the number of reporters, newscasters, and their support teams can be overwhelming, possibly compromising operations and patient confidentiality. A clearly defined process for managing the media, which includes a designated spokesperson, a site for the dissemination of information (away from patient care areas), and a regular schedule for providing updates should be part of the disaster plan.

Such a plan helps to prevent the release of contradictory or inaccurate information. Initial statements should focus on current efforts and what is being done to better understand the scope and

Table 72-1 • Triage Categories

TRIAGE CATEGORY	PRIORITY	COLOR	TYPICAL CONDITIONS
<b>Immediate:</b> Injuries are life-threatening but survivable with minimal intervention. Individuals in this group can progress rapidly to expectant if treatment is delayed.	1	Red	Sucking chest wound, airway obstruction secondary to mechanical cause, shock, hemothorax, tension pneumothorax, asphyxia, unstable chest and abdominal wounds, incomplete amputations, open fractures of long bones, and 2nd/3rd degree burns of 15–40% total body surface area.
<b>Delayed:</b> Injuries are significant and require medical care, but can wait hours without threat to life or limb. Individuals in this group receive treatment only after immediate casualties are treated.	2	Yellow	Stable abdominal wounds without evidence of significant hemorrhage; soft tissue injuries; maxillofacial wounds without airway compromise; vascular injuries with adequate collateral circulation; genitourinary tract disruption; fractures requiring open reduction, débridement, and external fixation; most eye and CNS injuries.
<b>Minimal:</b> Injuries are minor and treatment can be delayed hours to days. Individuals in this group should be moved away from the main triage area.	3	Green	Upper extremity fractures, minor burns, sprains, small lacerations without significant bleeding, behavioral disorders or psychological disturbances.
<b>Expectant:</b> Injuries are extensive and chances of survival are unlikely even with definitive care. Persons in this group should be separated from other casualties, but not abandoned. Comfort measures should be provided when possible	4	Black	Unresponsive patients with penetrating head wounds, high spinal cord injuries, wounds involving multiple anatomical sites and organs, 2nd/3rd degree burns in excess of 60% of body surface area, seizures or vomiting within 24 hr after radiation exposure, profound shock with multiple injuries, agonal respirations; no pulse, no BP, pupils fixed and dilated.

impact of the situation. Information about casualties should not be released. Security staff should not allow media personnel access to patient care areas.

### CARING FOR FAMILIES

Friends and family members converging on the scene must be cared for by the facility. They may be feeling intense anxiety, shock, or grief and should be provided with information and updates about their loved ones as soon as possible and regularly thereafter. They should not be in the triage or treatment areas, but in a designated area staffed by available social service workers, counselors, therapists, or clergy. Access to this area should be controlled to prevent families from being disturbed. See Chart 72-2 for a discussion of cultural variables to consider when coping with disaster-related injuries and death.

Chart  
72-2

### Cultural Considerations

Any disaster or mass casualty incident can be expected to involve members of diverse religious and ethnic groups or may be targeted at and predominately affect a specific religious or ethnic group. Health care providers likewise include members of all religious and ethnic backgrounds and should bear in mind that victims may have

- Language difficulties that increase fears and frustrations
- Specific religious practices related to medical treatment, hygiene, or diet
- Specific places/times for prayer
- Rituals about handling the dead
- Timing of funeral services

Some religious communities have plans for emergencies and disasters, and local hospitals should integrate these plans to the extent possible into their emergency operations plans.

### The Role of Nursing in Disaster Response Plans

The role of the nurse during a disaster varies. The nurse may be asked to perform outside his or her area of expertise and may take on responsibilities normally held by physicians or advanced practice nurses. For example, a critical care nurse may intubate a patient or even insert chest tubes. Wound débridement or suturing may be performed by staff registered nurses. A nurse may serve as the triage officer.

Although the exact role of a nurse in disaster management depends on the specific needs of the facility at the time, it should be clear which nurse or physician is in charge of a given patient care area and which procedures each individual nurse may or may not perform. Assistance can be obtained through the incident command center, and nonmedical personnel can provide services where possible. For example, family members can provide nonskilled interventions for their loved ones. Nurses should remember that nursing care in a disaster focuses on essential care from a perspective of what is best for all patients.

New settings and atypical roles for nurses arise during a disaster: the nurse may provide shelter care in a temporary housing area, or bereavement support and assistance with identification of deceased loved ones. Individuals may require crisis intervention, or the nurse may participate in counseling other staff members and in critical incident stress management (CISM). At-risk populations may also require special considerations during a disaster (Chart 72-3).

### CONSIDERING ETHICAL CONFLICTS

Disasters represent a disparity between the resources of the health care agency and the needs of the victims. This generates ethical

Chart  
72-3

### Caring for Persons with Disabilities During a Disaster

When disaster occurs, the multiple agencies involved attempt to provide food, water, and shelter to all of those affected. People with disabilities have specific needs that require attention. It is recommended that persons with disabilities have a personal support network to check on them after a disaster and to assist them with any needs. Agencies need to be aware that service animals are also affected during a disaster and may be brought to shelters with their companions.

Evacuation assistance is imperative for those with disabilities. Directions to personal equipment (eg, communication devices, medications, oxygen) should be available to rescue personnel. In a rapid evacuation, mobility devices, oxygen, suction, and medications will be needed at the shelters. Persons skilled in sign language are also valuable resources during a disaster. On their website, the American Red Cross provides a handbook for disaster preparedness for people with disabilities: <http://www.redcross.org/services/disaster/beprepared/disability.html>.

dilemmas for the nurses and other providers of care. Issues include conflicts related to

- Rationing care
- Futile therapy
- Consent
- Duty
- Confidentiality
- Resuscitation
- Assisted suicide

Nurses may find it difficult to not provide medical care to the dying, or to withhold information to avoid spreading fear and panic. Clinical scenarios that are unimaginable in normal circumstances, confront the nurse in extreme instances. Other ethical dilemmas may arise out of health care providers' instinct for self-protection and protection of their families. For example, what should a pregnant nurse do when incoming disaster victims have been exposed to radiation, yet too few nurses are available?

Nurses can plan for the ethical dilemmas they will face during disasters by establishing a framework for evaluating ethical questions before they arise and by identifying and exploring possible responses to difficult clinical situations. They can consider how the fundamental ethical principles of utilitarianism, beneficence, and justice will influence their decisions and care in disaster response.

#### MANAGING BEHAVIORAL ISSUES

Although most people pull together and function during a disaster, both individuals and communities suffer immediate and sometimes long-term psychological trauma. Common responses to disaster include

- Depression
- Anxiety
- Somatization (fatigue, general malaise, headaches, gastrointestinal disturbances, skin rashes)
- Posttraumatic stress disorder
- Substance abuse
- Interpersonal conflicts
- Impaired performance

Factors that influence an individual's response to disaster include the degree and nature of the exposure to the disaster, loss of friends and loved ones, existing coping strategies, available resources and support, and the personal meaning attached to the event. Other factors, such as loss of home and valued possessions, extended exposure to danger, and exposure to toxic contamination, also influence response and increase the risk of adjustment problems. Those exposed to the dead and injured, eyewitnesses and those endangered by the event, the elderly, children, emergency first-responders, and medical personnel caring for victims are considered to be at higher risk for emotional sequelae.

Nurses can assist disaster victims by providing active listening and emotional support, giving information, and referring patients to a therapist or social worker. Health care workers must refer individuals to mental health care services, because experience has shown that few disaster victims seek these services and early intervention minimizes psychological consequences. Nurses can also discourage victims from subjecting themselves to repeated exposure to the event through media replays and news articles, and encourage them to return to normal activities and social roles when appropriate.

#### Critical Incident Stress Management (CISM)

CISM is an approach to preventing and treating the emotional trauma that can affect emergency responders as a consequence of their jobs and that can also occur to anyone involved in a disaster or MCI. Critical incident stress management is handled by CISM teams that are available to the OEM. There are 350 such teams in the United States. All branches of emergency services have CISM teams, as do the military and many industries (eg, airline industry).

Components of a management plan include education before an incident about critical incident stress and coping strategies; field support (ensuring that staff get adequate rest, food and fluids, and rotating work loads) during an incident; and defusing, debriefings, demobilization, and follow-up care after the incident.

Defusing is a process by which the individual receives education about recognition of stress reactions and management strategies for handling stress. Debriefing is a more complicated intervention; it involves a 2- to 3- hour process during which participants are asked about their emotional reactions to the incident, what symptoms they may be experiencing (eg, flashbacks, difficulty sleeping, intrusive thoughts), and other psychological ramifications. In follow-up, members of the CISM team contact the participants of a debriefing and schedule a follow-up meeting if necessary. People with ongoing stress reactions are referred to mental health specialists.

#### PREPARING FOR TERRORISM

##### Recognition and Awareness

Being prepared for terrorism as a health care provider includes awareness of the potential for covert use of WMDs, self-protection, and early detection, containment, or decontamination of substances and agents that may affect others by secondary exposure. The strength of many toxins, today's mobile society, and long incubation periods for some substances can result in an epidemic that can quickly and silently spread across the entire country. For example, there must be awareness that the healthy person with a

rapid onset of flu-like symptoms can have an ominous illness, as occurred with the anthrax exposures in 2001.

Health care personnel should have a heightened awareness for trends that may suggest deliberate dispersal of toxic or infectious agents (Howard, 2001). The following are some general principles of awareness that should raise suspicion:

- Beware of an unusual increase in the number of people seeking care for fever or respiratory or gastrointestinal complaints.
- Take note of an unusual illness for the time of year. Clusters of patients from a single location should raise suspicion. Clusters can be from a specific geographical location, such as a city, or from a single sporting or entertainment event.
- A large number of rapidly fatal cases should raise suspicion, especially when death occurs within 72 hours after hospital admission.
- Any increase in disease incidence in a normally healthy population should also raise suspicion. These cases should be reported to the state health department and to the CDC (Chettle, 2001).

An extensive patient history is taken in an attempt to identify the agent involved. This history includes an occupational, work, and environmental assessment in addition to the regular admission history. An exposure history contains, at a minimum, information about current and past exposures to possible hazards and an assessment of the patient's typical day and any deviations in routines. The work history includes, at a minimum, a description of all previous jobs, including short-term, seasonal, and part-time employment and any military service. The environmental history includes assessment of present and previous home locations, water supply, and any hobbies, to name a few factors. The admission history should include such information as recent travel and contact with others who have been ill or have recently died of a fatal illness. This is just a brief review of the extensive history that may need to be obtained to identify an exposure agent. This type of history should become a universal part of admission processes at all health care facilities (Agency for Toxic Substances and Disease Registry, 2000).

Suspicions or findings are reported to the appropriate resources in the facility and to proper authorities in the community. Resources can include the Infection Control Department, **material safety data sheets (MSDS)**, the state Health Department, the Centers for Disease Control and Prevention, the local poison control center, and many Internet sites (Chettle, 2001). Reporting furnishes data elements to those agencies responsible for epidemiology and response. Reporting also allows for sharing of information among facilities and jurisdictions and can help determine the source of infections or exposure and prevent further exposures and even deaths.

## Personal Protective Equipment

Another component of preparedness and response involves the protection of the health care provider by additional **personal protective equipment (PPE)**. Chemical or biological agents and radiation are silent killers and are generally colorless and odorless. The purpose of PPE is to shield individuals from the chemical, physical, and biological hazards that may exist when caring for contaminated patients. The U.S. Environmental Protection Agency (EPA) has divided protective clothing and respiratory protection into four categories, level A through level D:

- Level A protection is worn when the highest level of respiratory, skin, eye, and mucous membrane protection is required. Briefly, this includes a self-contained breathing apparatus (SCBA) available in the prehospital arena. This also includes a fully encapsulating, vapor-tight, chemical-resistant suit with chemical-resistant gloves and boots.
- Level B is similar to level A and is selected when the situation requires the highest level of respiratory protection but a lesser level of skin and eye protection. This level of protection includes the SCBA and a chemical-resistant suit (Currance & Bronstein, 1999).
- Level C protection requires the air-purified respirator (APR), which uses filters or sorbent materials to remove harmful substances from the air. A chemical-resistant coverall with splash hood, chemical-resistant gloves, and boots are included in level C protection.
- Level D protection is basically the work uniform.

Level C and Level D PPE are the levels most often used in hospital facilities (Currance & Bronstein, 1999).

Protective equipment must be donned before contact with a contaminated patient. The acute care facility's standard precaution PPE (levels D or C) generally is not adequate for protection from a contaminated patient. The health care provider must use equipment that is capable of providing protection against the agent involved. This may mean using a splash suit along with a full-face positive- or negative-pressure respirator (a filter-type gas mask) or even an SCBA for medical personnel in the field (Burgess et al., 1999; Currance & Bronstein, 1999; JCAHO, 2000).

No single combination of PPE is capable of protecting against all hazards. Under no circumstances should responders wear any PPE without proper training, practice, and fit testing of respirator masks as necessary.

## Decontamination

**Decontamination**, the process of removing accumulated contaminants, is critical to the health and safety of health care providers by preventing secondary contamination. The decontamination plan should establish procedures and educate employees about decontamination procedures, identify the equipment needed and methods to be used, and establish methods for disposal of contaminated materials (Currance & Bronstein, 1999).

Although many principles and theories surround decontamination of a patient, authorities agree that, to be effective, decontamination must include a minimum of two steps. The first step is removal of the patient's clothing and jewelry and then rinsing the patient with water. Depending on the type of exposure, this step alone can remove a large amount of the contamination and decrease secondary contamination (Burgess et al., 1999). The second step consists of a thorough soap-and-water wash and rinse. When patients arrive at the facility from a prehospital provider, it should not be assumed that they have been thoroughly decontaminated.

## WEAPONS OF TERROR

### Biological Weapons

Biological weapons are weapons that spread disease among the general population or the military. Use of biological weapons dates far back into history, but improved production techniques and genetic engineering have expanded the potential for widespread casualties as a result of biological weaponry.

## EFFECTS OF BIOLOGICAL WEAPONS

**Biological warfare** is a covert method of severely affecting the target. Overall, biological weapons are easily obtained and easily disseminated, and they result in significant mortality and morbidity. The potential use of biological agents calls for continuous increased surveillance by health departments and an increased index of suspicion by clinicians. Many biological weapons result in signs and symptoms similar to those of common disease processes.

Biological agents are delivered in either a liquid or dry state, applied to foods or water, or vaporized for inhalation or direct contact. Vaporization may be accomplished through spray or explosives loaded with the agent. With increased travel, an agent could be released in one city and affect people in other cities thousands of miles away. The vector can be an insect, animal, or person, or there may be direct contact with the agent itself.

The following is a discussion of two of the agents most likely to be used or weaponized. Table 72-2 describes other easily weaponized biological agents.

### ANTHRAX

*Bacillus anthracis* is a naturally occurring gram-positive, encapsulated rod that lives in the soil in the spore state throughout the world. The bacterium sporulates (is liberated) when exposed to air and is infective only in the spore form. Contact with infected animal products (raw meat) or inhalation of the spores results in infection. Cattle and other herbivores are vaccinated against anthrax to prevent transmission through contaminated meat.

It is believed that approximately 8000 to 50,000 spores must be inhaled to put a person at risk. As an aerosol, anthrax is odorless and invisible and can travel a great distance before disseminating; hence, the site of release and the site of infection can be miles apart.

Anthrax is recognized as the most likely weaponized biological agent available. Anthrax has been known as a highly debilitating agent for centuries. It is believed that the plague in 1500 BC Egypt was caused by anthrax (Spencer, Whitman & Morton, 2001). In 1979, Sverdlosk, Russia, experienced the intentional release of anthrax, with widespread mortality and morbidity. Anthrax was released with the sarin gas attack in Tokyo, Japan, in 1995; however, the method of release chosen was poorly designed for effect.

Anthrax is caused by replicating bacteria that release toxin resulting in hemorrhage, edema, and necrosis. The incubation period is from 1 to 6 days. There are three primary methods of infection: skin contact, inhalation, and gastrointestinal ingestion. Skin lesions (the most common infection) cause edema with pruritis and macule or papule formation resulting in ulceration with 1- to 3-mm vesicles. A painless eschar develops, which falls off in 1 to 2 weeks.

Ingestion of anthrax results in fever, nausea and vomiting, abdominal pain, bloody diarrhea, and occasionally ascites. If massive diarrhea develops, decreased intravascular volume becomes the primary treatment concern. The bacterium affects the terminal ileum and cecum. Sepsis can occur. Treatment is fluorquinolones or tetracycline.

The inhalation form of anthrax is the most severe. Its symptoms mimic those of the flu, and usually treatment is sought only when the second stage of severe respiratory distress occurs. At this point, even antibiotic therapy will not halt the progress of the disease. The inhalation form can have an incubation period of up to 60 days, making it difficult to identify the source of the bacterium. Initial signs and symptoms include cough, headache, fever, vomiting, chills, weakness, mild chest discomfort, dyspnea, and syncope, without rhinorrhea or nasal congestion.

Most patients have a brief recovery period followed by the second stage within 1 to 3 days, characterized by fever, severe respiratory distress, stridor, hypoxia, cyanosis, diaphoresis, hypotension, and shock. These patients require optimization of oxygenation, correction of electrolyte imbalances, and ventilatory and hemodynamic support. More than 50% of these patients have hemorrhagic mediastinitis on chest x-ray (a hallmark sign) (Spencer, Whitman, & Morton 2001; Altman, 2002; Inglesby et al., 1999). The disease can also progress to include meningitis with subarachnoid hemorrhage. Death results in approximately 24 to 36 hours after the onset of severe respiratory distress. The mortality rate nears 100%.

**Treatment.** Presently anthrax is penicillin sensitive; however, the Russian government has been involved in the production of penicillin-resistant anthrax. Recommended treatment includes penicillin, erythromycin, chloramphenicol, gentamicin, or doxycycline. If antibiotic treatment begins within 24 hours after exposure, death can be prevented (Franz & Zajtchuk, 2000). In a mass casualty situation, ciprofloxacin or doxycycline is recommended. Treatment is continued for 60 days. For patients who have been directly exposed to anthrax but have no signs and symptoms of disease, ciprofloxacin or doxycycline is used for prophylaxis for 60 days.

When caring for a patient infected with anthrax, standard precautions are all that are necessary. The patient is not contagious, and the disease cannot be spread from person to person. Equipment should be cleaned using standard hospital disinfectant. After death, cremation is recommended because the spores can survive for decades and represent a threat to morticians and forensic medicine personnel.

### SMALLPOX

Variola is classified as a DNA virus. It has an incubation period of approximately 12 days. It is extremely contagious and is spread by direct contact, contact with clothing or linens, or by droplets from person to person only after the fever has decreased and the rash phase has begun (Inglesby et al., 1999). There is an associated 30% case-fatality rate. Aerosolization of the virus would result in widespread dissemination. The World Health Organization (WHO) declared smallpox eradicated in 1977 and stopped worldwide vaccination in 1980. In the United States, the last child was vaccinated in 1972. Therefore, a large portion of the current population has no immunity to the virus. Recently, plans have been instituted in the U.S. for smallpox vaccination, with health care personnel being the first to receive the vaccine.

Smallpox was used as biowarfare during the French and Indian War in 1754–1767, when blankets from smallpox patients were sent into the Indian camps, resulting in greater than 50% fatality rates (Inglesby et al., 1999). Smallpox virus survives for up to 24 hours in cool temperatures and low humidity.

Signs and symptoms include high fever, malaise, headache, backache, and prostration. After 1 to 2 days, a maculopapular rash appears, evolving at the same rate and beginning on the face, mouth and pharynx, and forearms (Fig 72-1). Only then does the rash progress to the trunk and also become vesicular to pustular (Inglesby et al., 1999; Hagstad, 2000; Franz & Zajtchuk, 2000). There is a large amount of the virus in the saliva and pustules. Smallpox (variola) is contagious only after the appearance of the rash. Variola major has a 30% case fatality rate. Hemorrhagic smallpox includes all of the above signs and symptoms with the addition of a dusky erythema and petechiae to frank hemorrhage of the skin and mucous membranes, resulting in death by day 5 or 6. Variola minor produces fewer constitutional symptoms and a sparse rash.

**Table 72-2 • Examples of Biological Agents That Can Be Used as Weapons**

AGENT/ORGANISM	CONTAGION	DECONTAMINATION AND PROTECTIVE EQUIPMENT	SIGNS AND SYMPTOMS	TREATMENT (MORTALITY RATE)
Tularemia— <i>Francisella tularensis</i> : gram-negative coccobacillus, one of the most infectious bacteria known	Direct contact with infected animals or aerosolized as a bioterror weapon; bites  Not contagious through human-to-human contact	Standard barrier precautions Clothing and linens should be laundered under the usual hospital protocol	<i>Initial</i> : Abrupt onset of fever, fatigue, chills, headache, lower backache, malaise, rigor, coryza, dry cough, and sore throat without adenopathy. Nausea and vomiting or diarrhea possible. <i>As disease progresses</i> : Sweating, fever, progressive weakness, anorexia, and weight loss demonstrate continued illness. <i>Mortality secondary to</i> : pneumonitis (if inhalation is the source) with copious watery or purulent sputum, hemoptysis, respiratory insufficiency, sepsis, and shock.	Streptomycin or gentamicin/aminoglycoside for 10–14 days. Inhalation tularemia must be treated within 48 hours of onset. In mass casualty situations, doxycycline or ciprofloxacin is recommended. For persons exposed to tularemia, tetracycline or doxycycline is recommended for 14 days. (Mortality rate = 2%)
Botulism— <i>Clostridium botulinum</i> : Botulinum blocks acetylcholine-containing vesicles from fusing with the terminal membranes of the motor-neuron end-plate, resulting in a flaccid paralysis.	Direct contact Not contagious through human-to-human contact	Any exposure to the botulism toxin can be treated with soap and water or a 0.1% hypochlorite solution. Standard precautions are used when treating patients with botulism.	<i>Gastrointestinal botulism</i> : abdominal cramps, nausea, vomiting, and diarrhea. <i>Inhalation botulism</i> : fever; symmetric descending flaccid paralysis with multiple cranial nerve palsies. Classic signs and symptoms include diplopia, dysphagia, dry mouth, lack of fever, and alert mental status. Other possible symptoms include ptosis of the eyelids, blurred vision, enlarged sluggish pupils, dysarthria, and dysphonia. <i>Mortality secondary to</i> : airway obstruction and inadequate tidal volume.	Supportive ventilatory therapy is necessary if respiratory infection occurs. Aminoglycosides and clindamycin are contraindicated because they exacerbate neuromuscular blockage. Equine antitoxin is used to minimize subsequent nerve damage. There is a 2% rate of anaphylaxis to the antitoxin; therefore, diphenhydramine (Benadryl) and epinephrine must be immediately available for use. Supportive care—mechanical ventilation, nutrition, fluids, prevention of complications (Mortality rate = 5%)
Plague— <i>Yersinia pestis</i> : nonsporulating gram-negative coccobacillus. The bacterium causes destruction and necrosis of the lymph nodes.	Contagious <i>Bubonic plague</i> : transmitted through flea bites with no person-to-person transmission <i>Pneumonic plague</i> : transmitted through respiratory droplet contact	Isolation barrier precautions with full face respirators. The patient should wear a mask. Rooms should receive a terminal cleaning. Clothing and linens with body fluids on them should be cleaned with the usual disinfectant. Routine precautions should be used in the case of death.	<i>Bubonic plague</i> : Sudden fever and chills, weakness, a swollen and tender lymph node (bubo) in the groin, axilla, or cervical area. The resultant bacteremia progresses to septicemia from the endotoxin and, finally, shock and death. <i>Primary septicemic plague</i> : Disseminated intravascular coagulopathy (DIC), necrosis of small vessels, purpura, and gangrene of the digits and nose (black death). <i>Pneumonic plague</i> : Severe bronchospasm, chest pain, dyspnea, cough, and hemoptysis. There is a 100% mortality associated with pneumonic plague if not treated within the first 24 hours.	Streptomycin or gentamicin for 10–14 days. Tetracycline or doxycycline is an acceptable alternative if an aminoglycoside cannot be given. People with close contact exposure (<2 meters) require prophylaxis with doxycycline for 7 days. (Mortality rate = 50%)

**Treatment.** Treatment includes supportive care with antibiotics for any additional infection. The patient must be isolated with the use of transmission precautions. Laundry and biological wastes should be autoclaved before being washed with hot water and bleach. Standard decontamination of the room is effective. All persons who have household or face-to-face contact with the patient after the fever begins should be vaccinated within 4 days to prevent infection and death (Franz & Zajtchuk, 2000; Inglesby et al., 1999). A patient with a temperature of 38°C (101°F) or higher within 17 days after exposure requires isolation. Postvaccination encephalitis occurs in approximately 1 of every 300,000 patients and has a 25% fatality rate. Cremation is preferred for all deaths, because the virus can survive in scabs for up to 13 years.

## Chemical Weapons

Agents that may potentially be used in **chemical warfare** are overt agents in that the effects are more apparent and occur more quickly than those caused by biological weapons. Agents are available and well-known, result in major mortality and morbidity,

and cause panic and social disruption. There are many agents, including those that affect nerves (sarin, soman), those that affect blood (cyanide), those that are vesicants (lewisite, nitrogen and sulfur mustard, phosgene), heavy metals (arsenic, lead), volatile toxins (benzene, chloroform), pulmonary agents (chlorine), and corrosive acids (nitric acid, sulfuric acid) (Table 72-3). Chlorine, phosgene, and cyanide are widely used in industry and therefore are readily available.

## CHARACTERISTICS OF CHEMICALS

**Volatility.** Volatility is the tendency for a chemical to become a vapor. The most volatile agents are phosgene and cyanide. Most chemicals are heavier than air, except for hydrogen cyanide. Therefore, in the presence of most chemicals, the victim should stand up to avoid heavy exposure (because the chemical will sink toward the floor or ground).

**Persistence.** Persistence means that the chemical is less likely to vaporize and disperse. More volatile chemicals do not evaporate very quickly. Most industrial chemicals are not very persistent.

**FIGURE 72-1** Comparison of progression of smallpox rash and chicken pox rash. From World Health Organization. (2001). WHO slide set on the diagnosis of smallpox. Reproduced by permission of the World Health Organization. Available at: <http://www.who.int/emc/diseases/smallpox/slides/index.htm>.

**Table 72-3 • Common Chemical Agents**

AGENT	ACTION	SIGNS AND SYMPTOMS	DECONTAMINATION AND TREATMENT
<b><i>Nerve Agents</i></b> Sarin Soman organophosphates	Inhibition of cholinesterase	Increased secretions, gastrointestinal motility, diarrhea, bronchospasm	Soap and water Supportive care Benzodiazepine Pralidoxime Atropine
<b><i>Blood Agent</i></b> Cyanide	Inhibition of aerobic metabolism	Inhalation—tachypnea, tachycardia, coma, seizures. Can progress to respiratory arrest, respiratory failure, cardiac arrest, death.	Sodium nitrite Sodium thiocyanate Amyl nitrate Hydroxycobalamin
<b><i>Vesicant Agents</i></b> Lewisite Sulfur mustard Nitrogen mustard Phosgene	Blistering agents	Superficial to partial-thickness burn with vesicles that coalesce	Soap and water Blot; do not rub dry
<b><i>Pulmonary Agents</i></b> Phosgene Chlorine	Separation of alveoli from capillary bed	Pulmonary edema, bronchospasm	Airway management Ventilatory support Bronchoscopy

Weaponized agents (chemicals developed as weapons by the military) are more likely than industrial chemicals to penetrate and cause secondary exposure as well.

**Toxicity.** Toxicity is the potential of an agent to cause injury to the body. The median lethal dose (LD50) is the amount of the chemical that will cause death in 50% of those who are exposed. The median effective dose (ED50) is the amount of the chemical that will cause signs and symptoms in 50% of those who are exposed. The concentration time (CT) is the concentration released multiplied by the time exposed (mg/min). For example, if 1000 mg of a chemical were released and the time of exposure to this amount of chemical was 10 minutes, then the concentration time would be 10,000 mg/min.

**Latency.** Latency is the time from absorption to the appearance of symptoms. Sulfur mustards and pulmonary agents have the longest latency, whereas vesicants, nerve agents, and cyanide produce symptoms within seconds.

### LIMITING EXPOSURE

Evacuation is essential, as are removal of clothing and decontamination as close to the scene as possible and before transport of the person exposed. Soap and water are effective means of decontamination in most cases. Staff involved in decontamination efforts must wear PPE and contain the runoff after decontamination procedures.

### VESICANTS

Vesicants are chemicals that cause blistering and result in burning, conjunctivitis, bronchitis, pneumonia, hematopoietic suppression, and death. Examples of vesicants include lewisite, phosgene, nitrogen mustard, and sulfur mustard. In World War I and in the Iran–Iraq conflict of 1980–1988, vesicants were used to disable the opponent. Vesicants were the primary incapacitating agents, resulting in minimal (less than 5%) death but large numbers of injured (Brennan, Waeckerle, Sharp, & Lillibridge, 1999). Liquid sulfur mustard was the most frequently used vesicant in these conflicts. It is an oily liquid with a garlic odor, has a long latent period, and penetrates the skin if not rapidly removed. The skin damage is irreversible but is seldom fatal (2% to 3% mortality).

The initial presentation after exposure to a vesicant is similar to that of a large superficial to partial-thickness burn in the warm and moist areas of the body (ie, perineum, axillae, antecubital spaces). There is stinging and erythema for approximately 24 hours, followed by pruritus, painful burning, and small vesicle formation after 2 to 18 hours. These vesicles can coalesce into large, fluid-filled bullae. Lewisite and phosgene result in immediate pain after exposure. Tissue damage occurs within minutes.

If the eye is exposed, there is pain, photophobia, lacrimation, and decreased vision. This progresses to conjunctivitis, blepharospasm, corneal ulcer, and corneal edema.

Respiratory effects are more serious and often are the cause of mortality with vesicant exposure. Purulent fibrinous pseudo-membrane discharge leads to obstruction of the airways. Gastrointestinal exposure includes nausea and vomiting, leukopenia, and upper gastrointestinal bleeding.

Appropriate decontamination includes soap and water. Scrubbing and the use of hypochlorite solutions should be avoided, because they increase penetration. Once the substance has penetrated, it cannot be removed. Eye exposure requires copious irrigation. For respiratory exposure, intubation and bronchoscopy to remove necrotic tissue are essential. With lewisite exposure, dimercaprol (BAL in oil) is administered intravenously for sys-

temic toxicity and topically for skin lesions. All persons with sulfur mustard exposures should be monitored for 24 hours for delayed (latent) effects.

### NERVE AGENTS

The most toxic agents in existence are the nerve agents such as sarin, soman, tabun, VX, and organophosphates (pesticides). They are inexpensive, effective in small quantities, and easily dispersed. In the liquid form, nerve agents evaporate into a colorless, odorless vapor. Organophosphates are similar in nature to the nerve agents used in warfare and are readily available. Nerve agents can be inhaled or absorbed percutaneously or subcutaneously. These agents bond with acetylcholinesterase, so that acetylcholine is not removed; the adverse result is continuous stimulation (hyperstimulation) of the nerve endings. Carbamates, which are insecticides originally extracted from the Calabar bean, are derivatives of carbamic acid; they are nerve agents that specifically inhibit acetylcholinesterase for several hours and then spontaneously become unbound from the acetylcholinesterase. Organophosphates, however, require the formation of new enzyme (acetylcholinesterase) before function can be restored.

A very small drop of agent is enough to result in sweating and twitching at the site of exposure. A larger amount results in more systemic symptoms. Effects can begin anywhere from 30 minutes up to 18 hours after exposure. The more common organophosphates and carbamates that are used in agriculture (sevin and malathion) result in less severe symptoms than do those used in warfare.

Signs and symptoms of nerve gas exposure are those of cholinergic crisis and include bilateral miosis, visual disturbances, increased gastrointestinal motility, nausea and vomiting, diarrhea, substernal spasm, indigestion, bradycardia and atrioventricular block, bronchoconstriction, laryngeal spasm, weakness, fasciculations, and incontinence. The patient must be examined in a dark area to truly identify miosis. Neurologic responses include insomnia, forgetfulness, impaired judgment, depression, and irritability. A lethal dose results in loss of consciousness, seizures, copious secretions, fasciculations, flaccid muscles, and apnea.

Decontamination with copious amounts of soap and water or saline solution for 8 to 20 minutes is essential. The water is blotted, not wiped, off. Fresh 0.5% hypochlorite solution can also be used. The airway is maintained, and suctioning is frequently required. One must be aware that plastic airway equipment will absorb sarin gas, resulting in continued exposure to the agent.

**Treatment.** Intravenous atropine 2 to 4 mg is administered, followed by 2 mg every 3 to 8 minutes for up to 24 hours of treatment. Alternatively, intravenous atropine 1 to 2 mg/hr may be administered until clear signs of anticholinergic activity have returned (decreased secretions, tachycardia, and decreased gastrointestinal motility). Another medication is pralidoxime; which allows cholinesterase to become active against acetylcholine. Pralidoxime 1 to 2 g in 100 to 150 mL of normal saline solution should be administered over 15 to 30 minutes. Pralidoxime has no effect on secretions and may have any of the following side effects: hypertension, tachycardia, weakness, dizziness, blurred vision, and diplopia.

Diazepam (Valium) or other benzodiazepines should be administered for seizures, to decrease fasciculations, and to alleviate apprehension and agitation. The military provides all military personnel with Mark I autoinjectors, which contain 2 mg atropine and 600 mg pralidoxime chloride. Diazepam is administered by a partner.

## BLOOD AGENTS

Blood agents have a direct effect on cellular metabolism, resulting in asphyxiation through alterations in hemoglobin. Examples include hydrogen cyanide and cyanogen chloride. Cyanide is an agent that has profound systemic effects. It is commonly used in the mining of gold and silver and in the plastics and dye industries. In 1984, the Union Carbide pesticide plant in Bhopal, India, released large amounts of cyanide in an industrial disaster, and hundreds of deaths occurred.

A cyanide release is often associated with the odor of bitter almonds. In house fires, cyanide is released during the combustion of plastics, rugs, silk, furniture, and other construction materials. There is a significant correlation between blood cyanide and carbon monoxide levels in fire victims, and most often the cause of death is cyanide.

Cyanide can be ingested, inhaled, or absorbed through the skin and mucous membranes.

Cyanide is protein bound and inhibits aerobic metabolism, leading to respiratory muscle failure, respiratory arrest, cardiac arrest, and death. Inhalation of cyanide results in flushing, tachypnea, tachycardia, nonspecific neurologic symptoms, stupor, coma, and seizure preceding respiratory arrest.

**Emergency Treatment.** Rapid administration of the following medications is essential to the successful management of cyanide exposure: amyl nitrate, sodium nitrite, and sodium thiosulfate. First, the patient is intubated and placed on a ventilator. Next, amyl nitrate pearls are crushed and placed in the ventilator reservoir to induce methemoglobinemia. Cyanide has a 20% to 25% higher affinity for methemoglobin than it does for hemoglobin; it binds methemoglobin to form either cyanomethemoglobin or sulfmethemoglobin. The cyanomethemoglobin is then detoxified in the liver by the enzyme rhodanase. Next, sodium nitrite is administered intravenously, also to induce the rapid formation of methemoglobin. Sodium thiosulfate is then administered intravenously; it has a higher affinity for cyanide than methemoglobin does and stimulates the conversion of cyanide to sodium thiocyanate, which can be renally excreted. There are side effects of these emergency medications: sodium nitrite can result in severe hypotension, and thiocyanate can cause vomiting, psychosis, arthralgia, and myalgia.

The production of methemoglobin is contraindicated in patients with smoke inhalation, because they already have decreased oxygen-carrying capacity secondary to the carboxyhemoglobin produced by smoke inhalation. An alternative suggested treatment for cyanide poisoning is hydroxycobalamin (vitamin B<sub>12a</sub>). Hydroxycobalamin binds cyanide to form cyanocobalamin (vitamin B<sub>12</sub>). It must be administered intravenously in large doses. Administration of vitamin B<sub>12a</sub> can result in transient pink discoloration of mucous membranes, skin, and urine. In high doses, tachycardia and hypertension can occur, but they usually resolve within 48 hours.

## PULMONARY AGENTS

Pulmonary agents such as phosgene and chlorine destroy the pulmonary membrane that separates the alveolus from the capillary bed. Hence, the person exposed cannot release carbon dioxide or acquire oxygen. Capillary leak results in fluid-filled alveoli. Phosgene and chlorine both vaporize, rapidly causing this pulmonary injury. Phosgene has the odor of fresh-mown hay.

Signs and symptoms include pulmonary edema with shortness of breath, especially during exertion. Cough starts as a hacking

cough followed by frothy sputum production. A mask is the only protection required. Phosgene does not injure the eyes.

## Nuclear Radiation Exposure

The threat of **nuclear warfare** or radiation exposure is very real with the availability of nuclear material and easily concealed simple devices, such as the so-called dirty bomb, for dispersal. A dirty bomb is a conventional explosive (eg, dynamite) that is packaged with radioactive material that scatters when the bomb is detonated. It disperses radioactive material and may be called a radiologic weapon, but is not a nuclear weapon, which is a complex nuclear fission reaction that is thousands of times more devastating than the dirty bomb.

Sources of radioactive material include not only nuclear weapons but reactors and simple radioactive samples, such as weapons-grade plutonium or uranium, freshly spent nuclear fuel, or medical supplies (eg, radium, certain cesium isotopes) used in cancer treatments and radiography machines. Exposure of a large number of people can be accomplished by placing a radioactive sample in a public place. Thousands may be exposed this way; some may be immediately affected, and others may require health monitoring for many years to assess long-term effects.

History has demonstrated the effectiveness of these weapons in the devastating results of the bombings of Hiroshima and Nagasaki in World War II. The effects of radiation exposure also were felt by the inhabitants of a small town in Brazil, who in 1987 found and opened a small canister of cesium 137 and rubbed the blue powder on themselves; 249 people were sickened, and 4 died (Jagminas & Suner, 2001). In 1983, a hospital sample was stolen in Mexico, resulting in the release of radioactive material among some scrap metal. A year later, the radiation contamination was detected when the scrap metal was inadvertently transported into the Los Alamos National Laboratory and triggered a Geiger counter.

On a larger scale, nuclear reactor incidents have occurred in the Chernobyl (1986) and Three Mile Island (1979) nuclear facilities. There were 31 official deaths on the day of the Chernobyl incident, which involved a core meltdown and explosion, releasing radiation throughout the community. The long-term effects of this incident, including increased incidence of thyroid cancers and leukemia, continue to be evaluated. Reactors, however, follow very strict security measures and protocols for prevention of core meltdown. These measures decrease the possibility of a radiation incident from a reactor.

## TYPES OF RADIATION

Atoms consist of protons, neutrons, and electrons. The protons and neutrons are in balance in the nucleus. The protons repel each other, because they are all positively charged. The number of protons is specific for each element in the periodic table. There is a specific ratio of protons and neutrons for each different atom, and the result is element stability. When an element is radioactive, there is an imbalance in the nucleus resulting from an excess of neutrons.

To achieve stability, a radioactive nuclide can eject particles until the most stable number (an even number) of protons and neutrons exists. A proton can become a neutron by ejecting a positron; conversely, a neutron can become a proton by ejecting a negative electron. An alpha particle is released when two protons and two electrons are ejected.

Alpha particles cannot penetrate the skin. A thin layer of paper or clothing is all that is necessary to protect the skin from alpha-radiation. However, this low-level radiation can enter the

body through inhalation, ingestion, or injection (open wound). Only localized damage will occur.

Beta particles have the ability to moderately penetrate the skin to the layer in which skin cells are being produced. This high-energy radiation can cause skin damage if the skin is exposed for a prolonged period and can cause injury if beta particles become internal by penetrating the skin.

Gamma-radiation is a short-wavelength electromagnetic energy that is emitted when there is excess core nucleus energy. Gamma particles are penetrating. It is difficult to shield against gamma-radiation. X-rays are an example of gamma-radiation. Gamma-radiation often accompanies both alpha- and beta-particle emission.

### MEASUREMENT AND DETECTION

Radiation is measured in several different units. The *rad* is the basic unit of measurement. A rad is equivalent to 0.01 joule of energy per kilogram of tissue. To determine the damaging effect of the rad, a conversion to the *rem* (Roentgen equivalent man) is necessary. The rem reflects the type of radiation absorbed and the potential for damage. For example, 200,000 mrem will result in mild radiation sickness (1 rem = 1000 millirem) (Jagminas & Suner, 2001). Typical natural yearly exposure for an individual is 360 mrem. Another important concept is *half-life*. The half-life of a radioactive product is the time it takes to lose one half of its radioactivity.

Radiation is invisible. The only means of detection is through a device that determines the exposure per minute. There are various devices for this purpose. The Geiger counter (or Geiger-Mueller survey meter) can measure background radiation quickly through detection of gamma- and some beta-radiation. With high-level radiation, the Geiger counter may underestimate exposure. Other devices include the ionization chamber survey meter, alpha monitors, and dose-rate meters. Personal dosimeters are simple tools to identify radiation exposure and are worn by radiology personnel.

### EXPOSURE

Exposure is affected by time, distance, and shielding. The longer a person is within the radiation area, the higher the exposure. Also, the larger the amount of radioactive material in the area, the greater the exposure. The farther away the person is from the radiation source, the lower the exposure. Shielding from the radiation source also decreases exposure. One should never touch radioactive materials directly.

Three types of radiation-induced injury can occur: external irradiation, contamination with radioactive materials, and incorporation of radioactive material into body cells, tissues, or organs.

*External irradiation* exposure occurs when all or part of the body is exposed to radiation that penetrates or passes completely through the body. In this type of exposure, the patient is not radioactive and does not require special isolation or decontamination measures. Irradiation does not necessarily constitute a medical emergency.

*Contamination* occurs when the body is exposed to radioactive gases, liquids, or solids either externally or internally. If internal, the contaminant can be deposited within the body. Contamination requires immediate medical management to prevent incorporation.

*Incorporation* is the actual uptake of radioactive material into the cells, tissues, and susceptible organs. The organs involved are usually the kidneys, bone, liver, and thyroid.

Sequelae of contamination and incorporation can occur days to years later. The thyroid gland can be largely protected from ra-

diation exposure by administration of stable iodine (potassium iodide, or KI) before or promptly after the intake of radioactive iodine (WHO, 1999).

Priorities in the treatment of any type of radiation exposure are always treatment of life-threatening injuries and illnesses first, followed by measures to limit exposure, contamination control, and finally decontamination.

### DECONTAMINATION

Hospital and countywide disaster plans should be in effect when managing a radiation disaster. Access restriction is essential to prevent contamination of other areas of the hospital. Triage outside the hospital is the most effective means of preventing contamination of the facility itself. Floors are covered to prevent tracking of contaminants throughout the treatment areas. Strict isolation precautions should be in effect. Waste is controlled through double-bagging and the use of plastic-lined containers outside of the facility.

Staff are required to wear protective clothing, such as water-resistant gowns, two pairs of gloves, masks, caps, goggles, and booties. Dosimetry devices should be worn by all staff members participating in patient care. The radiation safety officer in the hospital should be notified immediately to assist with surveys (using a radiation survey meter) of the incoming patients and to provide dosimeters to all staff personnel involved with patient care of exposed victims. There is minimal risk to staff if the patients are properly surveyed and decontaminated. The majority of patients can be safely decontaminated with soap and water.

Each patient arriving at the hospital should be first surveyed with the radiation survey meter for external contamination and then directed toward the decontamination area as needed. Decontamination occurs outside of the ED with a shower, collection pool, tarp, and collection containers for patient belongings, as well as soap, towels, and disposable paper gowns for patients. Water runoff needs to be contained. Patients who are uninjured can perform self-decontamination with the use of handheld showers. After the patient has showered, a resurvey should be conducted to determine whether the radioactive contaminants have been removed. Additional washings should occur until the patient is free of contamination. It is important to ensure during showers that previously clean areas are not contaminated with runoff from the washed contaminated areas (eg, hair should be washed in the bent-over position to protect the body from contamination).

Biologic samples should be taken through nasal and throat swabs, and a complete blood count with differential should be obtained. Wounds should be irrigated and then covered with a water-resistant dressing prior to total body decontamination.

Internal contamination or incorporation requires decontamination through catharsis and/or gastric lavage with chelating agents (agents that bind with radioactive substances and are then excreted). Samples of urine, feces, and vomitus are surveyed to determine internal contamination levels.

### ACUTE RADIATION SYNDROME

Acute radiation syndrome (ARS) can occur after exposure to radiation. It is the dose rather than the source that determines whether ARS develops. Factors that determine whether the patient's response to exposure will result in ARS include a high dose (minimum 100 rad) and rate of radiation with total body exposure and penetrating-type radiation. Age, medical history, and genetics also affect the outcome after exposure. The effects follow a predictable course. Table 72-4 identifies the phases of ARS.

**Table 72-4 • Phases of Effects of Radiation Exposure**

PHASE	TIME OF OCCURRENCE	SIGNS AND SYMPTOMS
Prodromal phase (presenting symptoms)	48–72 hr after exposure	Nausea, vomiting, loss of appetite, diarrhea, fatigue High-dose radiation—fever, respiratory distress, and increased excitability
Latent phase (a symptom-free period)	After resolution of prodromal phase; can last up to 3 wk With high-dose radiation—latent period is shorter	Decreasing lymphocytes, leukocytes, thrombocytes, red blood cells
Illness phase	After latent period phase	Infection, fluid and electrolyte imbalance, bleeding, diarrhea, shock, and altered level of consciousness
Recovery phase OR	After illness phase	Can take weeks to months for full recovery
Death	After illness phase	Increased intracranial pressure is a sign of impending death

Each body system is affected differently in ARS. Systems with cells that rapidly reproduce are the most affected. The effects on the hematopoietic system include decreased numbers of lymphocytes, granulocytes, thrombocytes, and reticulocytes. It is the first system affected and serves as an indicator of the severity of radiation exposure (Jarrett, 2001; Jagminas & Suner, 2001). A marker of outcome is the absolute lymphocyte count at 48 hours after exposure. A significant exposure would be indicated by lymphocyte counts of 300 to 1200 per cubic millimeter of blood (the normal lymphocyte count is 1500 to 3000/mm<sup>3</sup>). Barrier precautions should be implemented to protect the patient from infection. Neutrophils decrease within 1 week, platelets decrease within 2 weeks, and red blood cells decrease within 3 weeks. Hemorrhagic complications, fever, and sepsis are common.

The gastrointestinal system, with its rapidly producing cells, is also readily affected by radiation. Doses of radiation required to produce symptoms are approximately 600 rad or higher (Jagminas & Suner, 2001). The gastrointestinal symptoms usually occur at the same time as the changes in the hematopoietic system. Nausea and vomiting occur within 2 hours after exposure. Sepsis, fluid and electrolyte imbalance, and opportunistic infections can occur as complications. An ominous sign is the presence of high fever and bloody diarrhea; these typically appear on day 10 after exposure.

The central nervous system is affected with doses greater than 1000 rad (Jagminas & Suner, 2001). The symptoms occur when damage to the blood vessels of the brain results in fluid leakage. Signs and symptoms include cerebral edema, nausea, vomiting, headache, and increased intracranial pressure. Increased intracranial pressure heralds a poor outcome and imminent death. Central nervous system injury with this amount of exposure is irreversible and occurs before hematopoietic or gastrointestinal system symptoms appear. Cardiovascular collapse is usually seen in conjunction with these injuries.

Depending on the dose, skin effects can also occur. With exposure of 600 to 1000 rad, erythema occurs; it can disappear within hours, and then reappear. The exposed patient must be evaluated hourly for the presence of erythema. With exposures greater than 1000 rad, desquamation (radiation dermatitis) of the skin occurs. Necrosis becomes evident within a few days to months at doses greater than 5000 rad. Skin signs are an indication of the dose of radiation exposure.

Secondary injury can occur when the radiation exposure occurs during a traumatic event such as a blast or burn. Trauma in addition to radiation exposure increases patient mortality. Attention must first be directed toward the primary assessment for trauma. Airway, breathing, circulation, and fracture reduction require immediate attention. All definitive treatments must occur within the first 48 hours. Thereafter, all surgical procedures should be delayed for 2 to 3 months because of the potential for delayed wound healing and the possible development of opportunistic infections several weeks after exposure.

### SURVIVAL

There are three categories of predicted survival after radiation exposure: probable, possible, and improbable. Triage of victims at the scene, after decontamination, is conducted with the routine system for disaster triage. Presenting signs and symptoms determine the potential for survival and therefore the category of predicted survival during triage.

Probable survival victims have either no initial symptoms or only minimal symptoms (eg, nausea and vomiting), or these symptoms resolve within a few hours. These patients should receive a complete blood count and may be discharged with instructions to return if any symptoms recur.

Possible survivors are those who present with nausea and vomiting that persists for 24 to 48 hours. They will experience a latent period, during which leukopenia, thrombocytopenia, and lymphocytopenia occur. Barrier precautions and protective isolation are implemented if the patient's lymphocyte count is less than 1200/mm<sup>3</sup>. Supportive treatment includes administration of blood products, prevention of infection, and provision of enhanced nutrition.

The improbable survival group is composed of those who have received more than 800 rad of total body penetrating irradiation. Acutely, people in this group demonstrate vomiting, diarrhea, and shock. Any neurologic symptoms suggest a lethal dose of radiation (Jarrett, 2001). These patients still require decontamination, to prevent contamination of the area. Personal protection is essential, because it is virtually impossible to fully decontaminate these patients since all of their internal organs have been irradiated. The survival time is variable; however, death usually ensues swiftly due to shock. If there are no neurologic symptoms, the patient may be alert and oriented, similar to a patient with

extensive burns. In a mass casualty situation, the nurse should expect to triage these patients into the black category, where they will receive comfort measures and emotional support. If it is not a mass casualty situation, aggressive fluid and electrolyte therapy are essential.

Although radiation, biological, and chemical events are not everyday events, when they do occur every facility and every nurse will need to know the basics of caring for affected patients.

Any terrorist-sponsored or unintentional radiation release can be sizeable and may require the entire hospital and prehospital staff to be prepared, recognize signs and symptoms of exposure, and rapidly treat victims without contamination of personnel, visitors, patients, or the facility itself.

### Critical Thinking Exercises

**1.** You are the triage nurse at the receiving facility for casualties after a tornado. Five patients arrive at the same time. Together with the surgeon on duty, you must identify the patients' needs. You are presented with an elderly man with a respiratory rate of 8 breaths per minute, color ashen, tense abdomen, and only carotid pulses present; a 7-year-old child with a bleeding scalp laceration who has a Glasgow Coma Score of 8 and needs intubation; the 30-year-old mother of the child, who is crying hysterically, is walking, and appears to have no pain or visible injuries; a 15-year-old girl who complains of pain in her left leg, with obvious deformity at the calf but good pulses in the foot; and a 65-year-old woman who arrives in a police car holding her right wrist, which is cool, ecchymotic, and painful with good pulses. How would you classify these patients?

Family members, members of the press, and city officials begin arriving at the hospital in large numbers. How would you expect these people to be managed? How will the family members be cared for?

**2.** A patient arrives at the triage desk complaining of sudden onset of high fever and respiratory flu-like symptoms. What are the signs and symptoms that you should identify if considering a biological warfare agent? Which agents cause pneumonia-like signs and symptoms? What precautions would be taken to protect staff?

**3.** Multiple patients begin arriving at the ED complaining of burning eyes and difficulty breathing. All of these persons work at the railroad, where there are often tanker trucks transporting chemical agents. What should you do first? Where do you find information about chemical agents and their treatment?

**4.** You are a member of the disaster committee at your hospital. What are the elements of the disaster plan that you will be sure to include? How will you plan for triage? What types of PPE will you purchase?

# ● Understanding Clinical Pathways

**C**linical pathways (also called critical pathways) are care plans developed collaboratively by physicians, nurses, physical therapists, technicians, pharmacists, speech therapists, case managers, and other staff members involved in patient care. Nurses are instrumental in ensuring the successful use of clinical pathways and can best contribute by gaining a thorough understanding of why and how pathways are used.

## **UNDERSTANDING AND USING CLINICAL PATHWAYS IN PATIENT CARE**

Clinical pathways grew out of financial upheaval in the health care industry. They represent a significant change in how patient care is managed. In the past (and currently for many patients), each health care discipline developed its own plan of care and used the patient's chart (medical record) as the primary communication tool. Each care provider needed to read the notes written by other care providers of other disciplines to get a complete picture of the plan of care and the patient's progress. Although there was probably general agreement about how patient progress would be facilitated and measured, individual steps in the processes of care and outcomes to be achieved were not usually specifically articulated. The physician managed the case and most patients remained in the hospital until they required very little care or could be transferred to a convalescent center. The length of hospital stay was not an issue; 2 to 3 weeks in an acute care facility was not unusual.

## **COST AND EFFECTS**

Although this system worked for decades, it was expensive. Not including charges for diagnostic tests or treatments, each day in the hospital could easily cost \$800 or more. The federal government and, later, insurance companies balked at paying these costs when highly skilled care was no longer needed. So they determined how many days of hospitalization a patient with a specific diagnosis required and decided to reimburse the insured parties only for that number of days. At the same time, hospitals tried to obtain meaningful financial data about the costs of hospital-based patient care—where the greatest costs were generated and how they could be reduced. Decreasing the length of stay was seen as one way to save money. As hospital stays became shorter and shorter, nurses and physicians began to express concerns about the quality of care. Patients were discharged to home or rehabilitation centers much sooner than before. They were weaker, had relatively fresh incisions, or often could not perform even minimal self-care independently. Regulatory agencies and consumers shared these concerns and demands arose for hard data demonstrating that patients were not being harmed.

This scenario compelled hospital administrators and clinicians to develop a new way to measure and manage costs, quality, and outcomes. Thoughtful examination of how patient care was provided exposed inefficiencies and highlighted the lack of face-to-face communication among disciplines. It became apparent that patient care could be managed more cost-effectively, possibly saving hundreds of thousands of dollars yearly. Hospitals adopted a system known as case management to address these issues.

## CASE MANAGEMENT

Under case management, care is planned collaboratively so that important events, such as initiation of physical therapy, home care consultation, or discontinuation of invasive treatments, occur on a schedule that clinicians, through experience or research, have identified as optimum for enhancing recovery. Care is mapped out by day or by other pivotal time intervals and goals or desired outcomes are specified for each time frame. When the patient has met all the goals, he or she is ready for discharge to home or to the next level of care. Responsibility for monitoring an individual patient's progress and tracking variance or deviation from the pathway is given to the case manager who usually but not always is a nurse. The tool on which all this information is contained is the clinical pathway. The purposes of a clinical pathway are to

- Promote quality care and improve clinical outcomes
- Standardize important aspects of care
- Reduce unnecessary delays in care
- Reduce costs

## ELEMENTS OF A CLINICAL PATHWAY

Clinical pathways are now used in a variety of settings and cover diverse diagnoses and conditions. They are often developed by individual organizations and, although the format varies from institution to institution, clinical pathways have major features in common.

### Patient Population

The first important element of the clinical pathway is the patient population (Fig. AP-1A). Each pathway clearly specifies the patients appropriate for inclusion on the pathway. Pathways tend to cover patient groups in which the treatment and recovery are relatively predictable. Institutions typically use a diagnosis-related group (DRG) to identify patients, but qualifiers may be added. For example, a pathway for community-acquired pneumonia may exclude patients with *Pneumocystis carinii* pneumonia or underlying obstructive pulmonary disease because those patients require highly individualized treatment plans and may not respond as quickly to intervention as patients without these underlying disorders.

### Time Frames

All pathways are divided into useful time frames (Fig. AP-1B). The identified time frame may be minutes, hours, days, weeks, or phases. Conditions requiring emergency treatment (myocardial infarction, head injury, stroke) might be divided into 15-minute intervals, whereas conditions requiring chronic care (chronic pain, spinal cord injury rehabilitation) may be divided into

weekly or monthly intervals. An example of interventions by phases might be seen in postanesthesia care pathways.

## Interventional Categories

Interventional categories consist of the groups of activities that make up a comprehensive treatment plan and are shown in the left-hand column of the pathway (Fig. AP-1C). Although the order in which they are listed varies, these categories typically include

- Tests
- Treatments and nursing interventions
- Consultations
- Medications
- Diet
- Activity
- Patient and family education
- Discharge planning

Clinical pathway teams begin working with a blank grid and fill in the appropriate interventions. The discipline responsible for the intervention recommends the optimal timing.

## Outcomes

Defined outcomes provide the focus for patient care activities and unify the various disciplines. All well-written pathways include outcomes identified for each time interval (Fig. AP-1D). They should be realistic, reflect incremental progress, and be achievable by 90% of the population. Pathway outcomes are similar in content and language to the goals or expected outcomes written into nursing plans of care; physiologic, psychological, social, and educational outcomes are included to capture all elements of complete recovery.

## Variance Record

The variance record (Fig. AP-2) is an extremely important part of the pathway and represents the mechanism through which improvements in patient care can be accomplished. Variance is defined as any deviation from the pathway. Because all events on the pathway are critical to recovery, deviations can have a negative impact on outcomes. If the pathway calls for a specific test or treatment on day 2 and it is not carried out on day 2, a variance has occurred. If the patient is to ambulate 3 times a day and ambulates only once, a variance has occurred. The variance and the causes are recorded. Some variance records require a written note and others use code numbers (see Fig. AP-2). Many hospitals have developed or purchased software so that variance can be recorded electronically.

Case managers collect and analyze the variance data to identify trends in patient care and outcomes. For example, a pneumonia pathway may specify that the first dose of antibiotics be given within 3 hours of admission to the hospital (delays in administration of the first dose of an antibiotic are associated with increased morbidity and mortality). The case manager reviews the variance records and determines that only 40% of pneumonia patients are receiving the antibiotic in that time frame. Assessment of the problem reveals that delays are a result of the length of time it takes for the medication order to be taken off the chart and delivered to the pharmacy, and the length of time it takes for the medication to be delivered. The pneumonia pathway team discusses this problem and determines that the first

dose of medication should be given in the emergency department since the emergency department stocks these medications. The pathway is revised to reflect this change in care. At the next review, the case manager reports that 92% of pneumonia patients on the clinical pathway received their antibiotics within 1 to 2 hours of admission. This scenario illustrates how pathway use and variance data collection provide the forum for assessing a problem, determining a plan of action, implementing the plan, and evaluating the effectiveness of the plan.

### THE NURSE'S ROLE

Nurses have a key role in all aspects of clinical pathway use. Participating in the development of the pathway is the first step. Because they begin and end the chain of staff involved in delivering care, nurses possess a unique perspective in how health care systems work to enhance or impede the delivery of care. In the above example about antibiotic administration, staff nurses were able to identify the problem quickly and suggest solutions. Other staff

from other disciplines, being single links in the chain, cannot supply this global view of the problem.

Nurses are also responsible for initiating the pathway on appropriate patients and ensuring that the various events occur as planned. In some care settings or conditions, case managers who are advanced practice nurses closely follow pathway patients; in others,

staff nurses or community-based nurses function as case managers. In any environment, enhancing and monitoring outcome achievement is a nursing activity. Patients are often given a printed patient pathway for reference. The pathway describes the care plan in simple language and pictures. The nurse discusses the pathway with the patient and focuses on achieving specific outcomes.

Nurses are also responsible for completing required documentation. Practices vary, but well-designed pathways strive for simplicity and should not duplicate documentation required elsewhere. For example, a separate nursing plan of care is not necessary when using a clinical pathway. The outcome section of the pathway usually requires documentation; other areas may need to be checked off or initialed so that other providers can readily see what has been accomplished. Documenting variance and initiating steps to address the variance are equally important as is participating in redesigning care practices to promote the highest quality of cost-effective care.

## PATHWAYS IN PRACTICE

Several pathways are provided in the following pages to demonstrate the variety of formats the nurse may encounter. Figure AP-3 is a pathway used at Medical College of Ohio for patients with

acute ischemic stroke. The time frame (3 to 5 days) is identified at the top of the pathway and in the Expected Outcomes portion. The pathway provides clear expected outcomes as well as a variety of checklists identifying all significant and sequential aspects of patient care. Figure AP-4 is a pathway used at the Wilmer Eye Institute of the Johns Hopkins Hospital for a patient having eye surgery. Figure AP-5 appears to be different from typical pathways, although it contains all the elements of a pathway and also functions as a physician order sheet. (Note: Days 2 and 3 have been omitted.)

Whatever format is used or condition treated, clinical pathways are documents in transition; they will change as research suggests better treatment strategies and as variance data are analyzed. Nurses' participation in these processes is essential for the successful implementation of clinical pathways and, ultimately, the opportunity to improve patient care.

## CRITICAL PATHWAY HIV WITH DIARRHEA

Doctor: Draw a line through any items you do not wish to order and fill in any blank orders. Use a separate order sheet for additional orders.

**Goals:** By the end of this pathway, the patient/family will be able to:

1. Discuss disease process
2. State action(s) to take to maintain intact skin at peri-anal area
3. Plan diet within restrictions
4. Describe ordered GI-related diagnostic test including rationale for use, preparation, and patient participation, if applicable
5. Describe discharge drug regimen including drug name, dose, time, major side effects, if applicable

Date initiated: \_\_\_\_\_ Allergies: \_\_\_\_\_ Ht: \_\_\_\_\_ Wt: lb: \_\_\_\_\_ Kg: \_\_\_\_\_

DAY 1	SHIFT			DAY 1	SHIFT		
	N	D	E		N	D	E
<b>Admission</b> Admit to: _____				<b>8. Labs</b> CBC w/differential Renal profile Stool for: leukocytes guaiac culture for <i>Salmonella</i> , <i>Shigella</i> , & <i>Campylobacter</i> Ova & parasites <i>Cryptosporidia</i> <i>Clostridium difficile</i> (toxin)			
<b>Pathway Criteria</b> Diarrhea = stool output $\geq 1,500$ cc/24° and/or $\geq$ BM's/24°							
<b>1. Vital Signs</b> BP/P/RR: q4° Temp: q4° (tympanic) Blood cultures q15' X 2 if T > 100.5°F							
<b>2. Weight</b> On admission & QD							
<b>3. Nutrition</b> NPO OR: if no nausea/vomiting, clear liquids Nutrition consult within 24° for diarrhea							
<b>4. IVs</b> _____ @ _____ cc/hr Start peripheral IV OR: use existing indwelling venous access device							
<b>5. I &amp; O</b> q8° Use Stool Flow Sheet							
<b>6. Stool Collection</b> Use Bed Side Commode (BSC) or Specipan Avoid urine contamination of stool specimen Diaper, if needed-weigh after each change							
<b>7. Infection Control</b> Contact isolation Private room							
				<b>9. Medications</b> Patient may self-administer Imodium 2 mg cap PO after each BM; up to 16 mg/day Anusol HC Cream to rectum PRN Tuck's pads to rectum PRN			
				<b>10. Activity</b> Bed Rest (BR) with Bed Side Commode (BSC) or BRP			
				<b>11. Psychological/Cultural</b> Provide emotional support re: illness, altered body image, isolation Orient to unit, if applicable Orient family/significant other to unit, visiting hours, call-in times if applicable Assess, attend to & document specific cultural needs PRN			
	<b>12. Patient Teaching &amp; Discharge Planning</b> Begin to teach HIV with Diarrhea Patient Teaching Standard (PTS) Begin Generic PTS, if applicable

## TEST VALUE STUDIED

Reference Ranges—Hematology  
 Reference Ranges—Serum, Plasma, and Whole Blood Chemistries  
 Reference Ranges—Immunodiagnostic Tests  
 Reference Ranges—Urine Chemistry  
 Reference Ranges—Cerebrospinal Fluid (CSF)  
 Miscellaneous Values

## SELECTED ABBREVIATIONS USED IN REFERENCE RANGES

### Conventional Units

kg = kilogram  
 gm = gram  
 mg = milligram  
 µg = microgram  
 µµg = micromicrogram  
 ng = nanogram  
 pg = picogram  
 dL = 100 milliliters  
 mL = milliliter  
 mm<sup>3</sup> = cubic millimeter  
 fL = femtoliter  
 mM = millimole  
 nM = nanomole  
 mOsm = milliosmole  
 mm = millimeter  
 µm = micron or micrometer  
 mm Hg = millimeters of mercury  
 U = unit

mU = milliunit  
 µU = microunit  
 mEq = milliequivalent  
 IU = International Unit  
 mIU = milliInternational Unit

### SI Units

g = gram  
 L = liter  
 d = day  
 h = hour  
 mol = mole  
 mmol = millimole  
 µmol = micromole  
 nmol = nanomole  
 pmol = picomole

Table B-1 • Reference Ranges—Hematology\*

DETERMINATION	REFERENCE RANGE		CLINICAL SIGNIFICANCE
	Conventional Units	SI Units	
A <sub>2</sub> hemoglobin	2.0%–3.2% of total hemoglobin	Mass fraction: 0.015–0.035 of total hemoglobin	Increased in certain types of thalassemia
Bleeding time	1.5–9.5 min	1.5–9.5 min	Prolonged in thrombocytopenia, defective platelet function, and aspirin therapy
Factor V assay (proaccelerin factor)	60%–140%		
Factor VIII assay (antihemophilic factor)	60%–140%		Deficient in classical hemophilia
Factor IX assay (plasma thromboplastin component)	60%–140%		Deficient in Christmas disease (pseudohemophilia)
Factor X (Stuart factor)	60%–140%		Deficient in Stuart clotting defect
Fibrinogen	200–400 mg/dL	2–4 g/dL	Increased in pregnancy, infections accompanied by leukocytosis, nephrosis Decreased in severe liver disease, abruptio placentae
Fibrin split (degradation) products	<5 µg/mL	<5 µg/mL	Increased in disseminated intravascular coagulation
Fibrinolysins (whole blood clot lysis time)	No lysis in 24 h		Increased activity associated with massive hemorrhage, extensive surgery, transfusion reactions
Partial thromboplastin time (activated)	Lower limit of normal: 20–25 sec; Upper limit of normal: 32–39 sec		Prolonged in deficiency of fibrinogen, factors II, V, VIII, IX, X, XI, and XII, and in heparin therapy
Prothrombin consumption	Lower limit of normal: 10 sec		Impaired in deficiency of factors VIII, IX, and X
Prothrombin time	9.5–12 sec		Prolonged by deficiency of factors I, II, V, VII, and X, fat malabsorption, severe liver disease, coumarin anticoagulant therapy.
INR	1.0		INR used to standardize the prothrombin time and anticoagulation therapy
	2–3 for therapy in atrial fibrillation, deep vein thrombosis, and pulmonary embolism 2.5–3.5 for therapy in prosthetic heart valves		
Erythrocyte count	Males: 4,600,000–6,200,000/cu mm Females: 4,200,000–5,400,000/cu mm	4.6–6.2 × 10 <sup>12</sup> /L 4.2–5.4 × 10 <sup>12</sup> /L	Increased in severe diarrhea and dehydration, polycythemia, acute poisoning, pulmonary fibrosis Decreased in all anemias in leukemia, and after hemorrhage, when blood volume has been restored
Erythrocyte indices			
Mean corpuscular volume (MCV)	84–96 cu µm	84–96 fL	Increased in macrocytic anemias; decreased in microcytic anemia
Mean corpuscular hemoglobin (MCH)	28–33 µg/cell	28–33 pg	Increased in macrocytic anemias; decreased in microcytic anemia
Mean corpuscular hemoglobin concentration (MCHC)	33%–35%	Concentration fraction: 0.33–0.35	Decreased in severe hypochromic anemia
Reticulocytes	0.5%–1.5% of red cells	Number fraction: 0.005–0.015	Increased with any condition stimulating increase in bone marrow activity (ie, infection, blood loss [acute and chronically following iron therapy in iron deficiency anemia], polycythemia rubra vera) Decreased with any condition depressing bone marrow activity, acute leukemia, late stage of severe anemias

(continued)

**Table B-1 • Reference Ranges—Hematology\*** (Continued)

DETERMINATION	REFERENCE RANGE		CLINICAL SIGNIFICANCE
	Conventional Units	SI Units	
Erythrocyte sedimentation rate (ESR)—Westergren method	Males under 50 yr: <15 mm/h Males over 50 yr: <20 mm/h Females under 50 yr: <25 mm/h Females over 50 yr: <30 mm/h	<15 mm/h <20 mm/h <25 mm/h <30 mm/h	Increased in tissue destruction, whether inflammatory or degenerative; during menstruation and pregnancy; and in acute febrile diseases
Erythrocyte sedimentation ratio—Zeta centrifuge	<50 years: <55% 50–80 years: 40%–60%	Volume fraction: <0.55 0.40–0.60	Significance similar to ESR
Hematocrit	Males: 42%–52% Females: 35%–47%	Volume fraction: 0.42–0.52 Volume fraction: 0.35–0.47	Decreased in severe anemias, anemia of pregnancy, acute massive blood loss Increased in erythrocytosis of any cause, and in dehydration or hemoconcentration associated with shock
Hemoglobin	Males: 13–18 gm/dL Females: 12–16 gm/dL	2.02–2.79 mmol/L 1.86–2.48 mmol/L	Decreased in various anemias, pregnancy, severe or prolonged hemorrhage, and with excessive fluid intake Increased in polycythemia, chronic obstructive pulmonary disease, failure of oxygenation because of congestive heart failure, and normally in people living at high altitudes
Hemoglobin F	Less than 2% of total hemoglobin	Mass fraction: <0.02	Increased in infants and children, and in thalassemia and many anemias
Leukocyte alkaline phosphatase	Score of 15–130 (varies among labs)		Increased in polycythemia vera, myelofibrosis, and infections Decreased in chronic granulocytic leukemia, paroxysmal nocturnal hemoglobinuria, hypoplastic marrow, and viral infections, particularly infectious mononucleosis
Leukocyte count	Total: 4,500–11,000/cu mm	4.5–11 × 10 <sup>9</sup> /L	Neutrophils increased with acute infections, trauma or surgery, leukemia
Neutrophils	45%–73%	Number fraction: 0.45–0.73	malignant disease, necrosis; decreased with viral infections, bone marrow suppression, primary bone marrow disease
Eosinophils	0%–4%	Number fraction: 0.00–0.04	Eosinophils increased in allergy, parasitic disease, collagen disease, subacute infections; decreased with stress, use of some medications (ACTH, epinephrine, thyroxine)
Basophils	0%–1%	Number fraction: 0.00–0.01	Basophils increased with acute leukemia and following surgery or trauma; decreased with allergic reactions, stress, allergy, parasitic disease, use of corticosteroids
Lymphocytes	20%–40%	Number fraction: 0.2–0.4	Lymphocytes increased with infectious mononucleosis, viral and some bacterial infections, hepatitis; decreased with aplastic anemia, SLE, immunodeficiency including AIDS
Monocytes	2%–8%	Number fraction: 0.02–0.08	Monocytes increased with viral infections, parasitic disease, collagen and hemolytic disorders; decreased with use of corticosteroids, RA, HIV infection
Platelet count	150,000–450,000/cu mm	0.15–0.45 × 10 <sup>12</sup> /L	Increased in malignancy, myeloproliferative disease, rheumatoid arthritis, and postoperatively; about 50% of patients with unexpected increase of platelet count will be found to have a malignancy Decreased in thrombocytopenic purpura, acute leukemia, aplastic anemia, and during cancer chemotherapy.

\*Laboratory values may vary according to the techniques used in different laboratories.

Table B-2 • Reference Ranges—Serum, Plasma, and Whole Blood Chemistries

DETERMINATION	NORMAL ADULT REFERENCE RANGE		CLINICAL SIGNIFICANCE	
	Conventional Units	SI Units	Increased	Decreased
Acetoacetate	0.2–1.0 mg/dL	19.6–98 μmol/L	Diabetic acidosis	
Acetone	0.3–2.0 mg/dL	51.6–344.0/μmol/L	Fasting Diabetic ketoacidosis Toxemia of pregnancy Carbohydrate-free diet High-fat diet	
Acid, total phosphatase	Males: 2–12 UL Females: 0.3–9.2 UL	Males: 2–12 UL Females: 0.3–9.2 UL	Carcinoma of prostate Advanced Paget's disease Hyperparathyroidism Gaucher's disease	
Acid, phosphatase, prostatic—RIA	2.5–3.37 ng/mL	2.5–3.37 μg/L	Carcinoma of prostate	
Alkaline phosphatase	Adults: 50–120 UL	50–120 UL	Conditions reflecting increased osteoblastic activity of bone Rickets Hyperparathyroidism Hepatic disease Bone disease	
Alkaline phosphatase, thermostable fraction	Hepatic: >25% Combined: 10%–25% Skeletal: <10%			
Adrenocorticotrophic hormone (ACTH) (plasma)—RIA*	<50 pg/mL	<50 ng/L	Pituitary-dependent Cushing's syndrome Ectopic ACTH syndrome Primary adrenal atrophy	Adrenocortical tumor Adrenal insufficiency secondary to hypopituitarism
Aldolase	3–8 Sibley-Lehninger U/dL at 37°C	22–59 mU/L at 37°C	Hepatic necrosis Granulocytic leukemia Myocardial infarction Skeletal muscle disease	
Aldosterone (plasma)—RIA	Supine: 3–10 ng/dL Upright: 5–30 ng/dL Adrenal vein: 200–800 ng/dL	0.08–0.30 nmol/L 0.14–0.90 nmol/L 5.54–22.16 nmol/L	Primary aldosteronism Secondary aldosteronism	Addison's disease
Alpha-1-antitrypsin	110–140 mg/dL	1.1–1.4 g/L		Certain forms of chronic lung and liver disease in young adults
Alpha-1-fetoprotein	<15 ng/mL	<15 μg/L	Hepatocarcinoma Metastatic carcinoma of liver Germinal cell carcinoma of the testicle or ovary Fetal neural tube defects—elevation in maternal serum	
Alpha-hydroxybutyric dehydrogenase	<140 U/L	<140 U/L	Myocardial infarction Granulocytic leukemia Hemolytic anemias Muscular dystrophy	
Ammonia (plasma)	15–45, μg/dL (varies with method)	11–32/μmol/L	Severe liver disease Hepatic decompensation	
Amylase	60–160 Somogyi U/dL	111–296U/L	Acute pancreatitis Mumps Duodenal ulcer Carcinoma of head of pancreas Prolonged elevation with pseudocyst of pancreas Increased by medications that constrict pancreatic duct sphincters: morphine, codeine, cholinergics	Chronic pancreatitis Pancreatic fibrosis and atrophy Cirrhosis of liver Pregnancy (2nd and 3rd trimesters)

(continued)

Table B-2 • Reference Ranges—Serum, Plasma, and Whole Blood Chemistries (Continued)

DETERMINATION	NORMAL ADULT REFERENCE RANGE		CLINICAL SIGNIFICANCE	
	Conventional Units	SI Units	Increased	Decreased
Arsenic	<70 µg/dL; poisoning: 100–150 µg/dL	<0.93–2.6 µmol/L; poisoning: 133–6.65 µmol/L	Intentional or unintentional poisoning Excessive occupational exposure	
Ascorbic acid (vitamin C)	0.4–1.5 mg/dL	23–85 µmol/L	Large doses of ascorbic acid as a prophylactic against the common cold	
ALT (alanine aminotransferase), formerly SGPT	Males: 10–40 U/mL Females: 8–35 U/mL	Males: 0.17–0.68 µkat/L Females: 0.14–0.60 µkat/L	Same conditions as AST (SGOT), but increase is more marked in liver disease than AST (SGOT)	
AST (aspartate aminotransferase), formerly SGOT	Males: 10–40 U/L Females: 15–30 U/L	Males: 0.34–0.68 µkat/L Females: 0.25–0.51 µkat/L	Myocardial infarction Skeletal muscle disease Liver disease	
Bilirubin	Total: 0.3–1.0 mg/dL Direct: 0.1–0.4 mg/dL Indirect: 0.1–0.4 mg/dL	5–17 µmol/L 1.7–3.7 µmol/L 3.4–11.2 µmol/L	Hemolytic anemia (indirect) Biliary obstruction and disease Hepatocellular damage (hepatitis) Pernicious anemia Hemolytic disease of newborn	
Blood gases				
Oxygen, arterial (whole blood): Partial pressure (PaO <sub>2</sub> )	85–95 mm Hg	10.64–12.64 kPa	Polycythemia	Anemia Cardiac or pulmonary disease
Saturation (SaO <sub>2</sub> )	95%–99%	Volume fraction: 0.95–0.99		Cardiac decompensation Chronic obstructive lung disease
Carbon dioxide, arterial (whole blood) partial pressure (PaCO <sub>2</sub> )	35–45 mm Hg	4.66–5.99 kPa	Respiratory acidosis Metabolic alkalosis	Respiratory alkalosis Metabolic acidosis
pH (whole blood, arterial)	7.35–7.45	7.35–7.45	Vomiting Hyperventilation Fever Intestinal obstruction	Uremia Diabetic acidosis Hemorrhage Nephritis
Calcitonin	Basal: <19 pg/mL Stimulation test Males: <350 pg/mL Females: <100 pg/mL	19 ng/L <350 ng/L <100 ng/L	Medullary carcinoma of the thyroid Some nonthyroid tumors Zollinger-Ellison syndrome	
Calcium	8.6–10.2 mg/dL	2.15–2.55 mmol/L	Tumor or hyperplasia of parathyroid Hypervitaminosis D Multiple myeloma Nephritis with uremia Malignant tumors Sarcoidosis Hyperthyroidism Skeletal immobilization Excess calcium intake:milk alkali syndrome	Hypoparathyroidism Diarrhea Celiac disease Vitamin D deficiency Acute pancreatitis Nephrosis After parathyroidectomy
CO <sub>2</sub> , venous	Adults 24–32 mEq/L Infants: 18–24 mEq/L	24–32 mmol/L 18–24 mmol/L	Tetany Respiratory disease Intestinal obstruction Vomiting	Acidosis Nephritis Eclampsia Diarrhea Anesthesia

(continued)

Table B-2 • Reference Ranges—Serum, Plasma, and Whole Blood Chemistries (Continued)

DETERMINATION	NORMAL ADULT REFERENCE RANGE		CLINICAL SIGNIFICANCE	
	Conventional Units	SI Units	Increased	Decreased
Catecholamines (plasma)—RIA	Epinephrine: <100 pg/mL Norepinephrine: <400 pg/mL	<540 pmol/L <2360 pmol/L	Pheochromocytoma	
Ceruloplasmin	Dopamine: <143 pg/mL 20–40 mg/dL	<935 pmol/L 1.26–2.52 μmol/L		Wilson's disease (hepatolenticular degeneration)
Chloride	97–107 mEq/L	97–107 mmol/L	Nephrosis Nephritis Urinary obstruction Cardiac decompensation Anemia	Diabetes mellitus Diarrhea Vomiting Pneumonia Heavy metal poisoning Cushing's syndrome Intestinal obstruction Febrile conditions
Cholesterol	150–200 mg/dL	3.9–5.2 mmol/L	Lipemia Obstructive jaundice Diabetes Hypothyroidism	Pernicious anemia Hemolytic anemia Hyperthyroidism Severe infection Terminal states of debilitating disease
Cholesterol esters	60%–70% of total	Fraction of total cholesterol 0.6–0.7		The esterified fraction decreases in liver diseases
Cholinesterase	Serum: 0.6–1.6 delta pH Red cells: 0.6–1 delta pH	0.6–1.6 U 0.6–1 U	Nephrosis Exercise	Nerve gas exposure (greater effect on red cell activity) Insecticide poisoning Threatened abortion Ectopic pregnancy
Chorionic gonadotropin, beta subunit	0–5 IU/L	0–5 IU/L	Pregnancy Hydatidiform mole Choriocarcinoma	
Complement, C <sub>3</sub>	80–170 mg/dL	0.8–1.7 g/L	Some inflammatory diseases, acute myocardial infarction, cancer	Acute glomerulonephritis Disseminated lupus erythematosus with renal involvement
Complement C <sub>4</sub>	18–51 mg/dL	180–510 mg/L	Some inflammatory diseases, acute myocardial infarction, cancer	Often decreased in immunologic disease, especially with active systemic lupus erythematosus Hereditary angioneurotic edema
Complement, total (hemolytic)	90%–94% complement	25–70 U/mL	Some inflammatory diseases	Acute glomerulonephritis Epidemic meningitis Subacute bacterial endocarditis
Copper	70–150 μg/dL	11–24 μmol/L	Cirrhosis of liver Pregnancy	Wilson's disease
Cortisol-RIA	8 AM: 5–25 μg/dL 4 PM: 3–16 μg/dL	138–690 nmol/L 83–442 nmol/L	Stress: infectious disease, surgery, burns, etc. Pregnancy Cushing's syndrome Pancreatitis Eclampsia	Addison's disease Anterior pituitary hypofunction
C-peptide reactivity	0.9–4.0 ng/mL	0.9–4.0 μg/L	Insulinoma	Diabetes mellitus

(continued)

Table B-2 • Reference Ranges—Serum, Plasma, and Whole Blood Chemistries (Continued)

DETERMINATION	NORMAL ADULT REFERENCE RANGE		CLINICAL SIGNIFICANCE	
	Conventional Units	SI Units	Increased	Decreased
Creatine	0.2–0.8 mg/mL	15.3–61 $\mu$ mol/L	Pregnancy Skeletal muscle necrosis or atrophy Starvation	
Creatine phosphokinase (CPK)	Males: 50–325 mU/mL Females: 50–250 mU/mL	50–325 U/L 50–250 U/L	Hyperthyroidism Myocardial infarction Skeletal muscle diseases Intramuscular injections Crush syndrome Hypothyroidism Alcohol withdrawal delirium Alcoholic myopathy Cerebrovascular disease	
Creatine phosphokinase isoenzymes	MM band present (skeletal muscle)-MB band absent (heart muscle)		MB band increased in myocardial infarction, ischemia	
Creatinine	0.7–1.4 mg/dL	62–124 $\mu$ mol/L	Nephritis Chronic renal disease	
Creatinine clearance	Males: 85–125 mL/min Females: 75–115 mL/min	1.42–2.08 mL/s 1.25–1.92 mL/s		Kidney diseases
Cryoglobulins, qualitative	Negative		Multiple myeloma Chronic lymphocytic leukemia Lymphosarcoma Systemic lupus erythematosus Rheumatoid arthritis Infective subacute endocarditis Some malignancies Scleroderma	
11-Deoxycortisol	1/ $\mu$ g/dL	<0.029 $\mu$ mol/L	Hypertensive form of virilizing adrenal hyperplasia due to an 11- $\beta$ -hydroxylase defect	
Dibucaine number	Normal: 70%–85% inhibition Heterozygote: 50%–65% inhibition Homozygote: 16%–25% inhibition			Important in detecting carriers of abnormal cholinesterase activity who are susceptible to succinylcholine anesthetic shock
Dihydrotestosterone	Males: 50–210 ng/dL Females: none detectable	1.72–7.22 nmol/L		Testicular feminization syndrome
Estradiol—RIA	Females: Follicular: 10–90 pg/mL Midcycle: 100–500 pg/mL Luteal: 50–240 pg/mL Follicular phase: 2–20 ng/dL Midcycle: 12–40 ng/dL Luteal phase: 10–30 ng/dL Postmenopausal: 1–5 ng/dL	37–370 pmol/L 367–1835 pmol/L 184–881 pmol/L	Pregnancy	Depressed or failure to peak—ovarian failure
Estriol—RIA	Males: 0.5–5 ng/dL Nonpregnant females: <0.5 ng/mL Pregnant females: 1st trimester: up to 1 ng/mL 2nd trimester: 0.8–7 ng/mL 3rd trimester: 5–25 ng/mL	<1.75 nmol/L Up to 3.5 nmol/L 2.8–24.3 nmol/L 17.4–86.8 nmol/L	Pregnancy	Depressed or failure to peak—ovarian failure

(continued)

Table B-2 • Reference Ranges—Serum, Plasma, and Whole Blood Chemistries (Continued)

DETERMINATION	NORMAL ADULT REFERENCE RANGE		CLINICAL SIGNIFICANCE	
	Conventional Units	SI Units	Increased	Decreased
Estrogens, total— RIA	Females: cycle days: Day 1–10: 61–394 pg/mL Day 11–20: 122–437 pg/mL Day 21–30: 156–350 pg/mL Males: 40–115 pg/mL	61–394 ng/L 122–437 ng/L 156–350 ng/L 40–115 ng/L	Pregnancy Measured on a daily basis, can be used to evaluate response of hypogonadotrophic, hypogonadotropic women to human menopausal or pituitary gonadotropin	Fetal distress Ovarian failure
Estrone—RIA	Females: Day 1–10: 4.3–18 ng/dL Day 11–20: 7.5–19.6 ng/dL Day 21–30: 13–20 ng/dL Males: 2.5–7.5 ng/dL	15.9–66.6 pmol/L 27.8–72.5 pmol/L 48.1–74 pmol/L 9.3–27.8 pmol/L		Depressed or failure to peak—ovarian failure
Ferritin—RIA	Males: 20–250 ng/mL Females: 12–250 ng/mL	20–250 µg/L 12–250 µg/L	Nephritis Hemochromatosis Certain neoplastic diseases Acute myelogenous leukemia Multiple myeloma	Iron deficiency
Folic acid—RIA	2.5–20 ng/mL	6–46 nmol/L		Megaloblastic anemias of infancy and pregnancy Inadequate diet Liver disease Malabsorption syndrome Severe hemolytic anemia Pituitary failure
Follicle stimulating hormone (FSH)— RIA	Males: 2–10 mIU/mL Females: Follicular phase: 5–20 mIU/mL Peak of middle cycle: 12–30 mIU/mL Luteinic phase: 5–15 mIU/mL Menopausal females: 40–200 mIU/mL	5–20 IU/L 12–30 IU/L 5–15 IU/L 40–200 IU/L	Menopause and primary ovarian failure	
Galactose	<5 mg/dL	<0.28 mmol/L		Galactosemia
Gamma glutamyl transpeptidase	Males: 20–30 U/L Females: 1–24 U/L	0.03–0.5 µkat/L 0.02–0.4 µkat/L	Hepatobiliary disease Drug toxicity Myocardial infarction Renal infarction Zollinger-Ellison syndrome Peptic ulceration of the duodenum Pernicious anemia	
Gastrin—RIA	Fasting: 50–155 pg/mL Postprandial: 80–170 pg/mL	50–155 ng/L 80–170 ng/L		
Glucose	Fasting: 60–110 mg/dL Postprandial (2 h): 65–140 mg/dL	3.3–6.05 mmol/L 3.58–7.7 mmol/L	Diabetes mellitus Nephritis Hyperthyroidism Early hyperpituitarism Cerebral lesions Infections Pregnancy Uremia	Hyperinsulinism Hypothyroidism Late hyperpituitarism Pernicious vomiting Addison's disease Extensive hepatic damage

(continued)

Table B-2 • Reference Ranges—Serum, Plasma, and Whole Blood Chemistries (Continued)

DETERMINATION	NORMAL ADULT REFERENCE RANGE		CLINICAL SIGNIFICANCE	
	Conventional Units	SI Units	Increased	Decreased
Glucose tolerance (oral)	Features of a normal response: 1. Normal fasting between 60–110 mg/dL 2. No sugar in urine 3. Upper limits of normal: Fasting = 125 1 hour = 190 2 hours = 140 3 hours = 125	3.3–6.05 mmol/L	Two-hour value >200 mg/dL (11.1 mmol/L) is diagnostic for diabetes mellitus	Decreased 2 and 3 hour values may occur with hypoglycemia mellitus
Glucose-6-phosphate dehydrogenase (red cells)	Screening: Decolorization in 20–100 min Quantitative: 1.86–2.5 IU/mL RBC	1860–2500 U/L		Drug-induced hemolytic anemia Hemolytic disease of newborn
Glycoprotein (alpha-1-acid)	50–120 mg/dL	0.5–1.2 g/L	Neoplasm Tuberculosis Diabetes complicated by degenerative vascular disease Pregnancy Rheumatoid arthritis Rheumatic fever Infectious liver disease Lupus erythematosus Acromegaly	
Growth hormone—RIA	Males: 0–4 ng/mL Females: 0–18 ng/mL	0.4 µg/L 0–18 µg/L		Failure to stimulate with arginine or insulin—hypopituitarism
Haptoglobin	30–200 mg/dL	0.3–2.0 g/L	Pregnancy Estrogen therapy Chronic infections Various inflammatory conditions	Hemolytic anemia Hemolytic blood transfusion reaction
Hemoglobin (plasma)	0.5–5 mg/dL	5–50 mg/L	Transfusion reactions Paroxysmal nocturnal hemoglobinuria Intravascular hemolysis Suboptimal glucose control	Anemia, pregnancy, chronic renal failure
Glycohemoglobin (GHB, hemoglobin A <sub>1c</sub> , hemoglobin A1)	Nondiabetics and diabetics with good control: 4.4%–6.4%			
Hexosaminidase, total	Controls: 333–375 nM/mL/h	333–375 µmol/L/h	Sandhoff's disease	Tay-Sachs disease and heterozygotes
Hexosaminidase A	Controls: 49%–68% of total Heterozygotes: 26%–45% of total Tay-Sachs disease: 0%–4% of total Diabetics: 39%–59% of total	Fraction of total: 0.49–0.68 0.26–0.45 0–0.04 0.39–0.59		
High-density lipoprotein cholesterol (HDL cholesterol)	Males: 35–70 mg/dL Females: 35–85 mg/dL	0.91–1.81 mmol/L 0.91–2.20 mmol/L		HDL cholesterol is lower in patients with increased risk for coronary heart disease
17 Hydroxy-progesterone—RIA	Males: 0.5–2.0 ng/mL Females: 0.2–3.0 ng/mL Children: <1.0 ng/mL	1.5–6.0 nmol/L 0.6–9.0 nmol/L <3.0 nmol/L	Congenital adrenal hyperplasia Pregnancy Some cases of adrenal or ovarian adenomas	

(continued)

Table B-2 • Reference Ranges—Serum, Plasma, and Whole Blood Chemistries (Continued)

DETERMINATION	NORMAL ADULT REFERENCE RANGE		CLINICAL SIGNIFICANCE	
	Conventional Units	SI Units	Increased	Decreased
Immunoglobulin A	Adults: 85–385 mg/dL (in children the normals are lower and vary with age)	0.85–3.85 g/L	Gamma A myeloma Wiskott-Aldrich syndrome Autoimmune disease Hepatic cirrhosis	Ataxia telangiectasis Agammaglobulinemia Hypogammaglobulinemia, transient Dysgammaglobulinemia Protein-losing enteropathies
Immunoglobulin D	0–14 mg/dL	0–140 mg/L	IgD multiple myeloma Some patients with chronic infectious diseases	
Immunoglobulin E	100–700 ng/mL	100–700 µg/L	Allergic patients and those with parasitic infections	
Immunoglobulin G	Adults: 565–1765 mg/dL	6.35–14 g/L	IgG myeloma Following hyperimmunization Autoimmune disease states Chronic infections	Congenital and acquired hypogammaglobulinemia IgA myelomas, Waldenström's (IgM) macroglobulinemia Some malabsorption syndromes Extensive protein loss
Immunoglobulin M	Adults: 55–375 mg/dL	0.4–2.8 g/L	Waldenström's macroglobulinemia Parasitic infections Hepatitis	Agammaglobulinemias Some IgG and IgA myelomas Chronic lymphatic leukemia Diabetes mellitus
Insulin—RIA	5–25 µU/mL	0.2–1 µg/L	Insulinoma Acromegaly	
Iron	50–160 µg/dL	9–29 µmol/L	Pernicious anemia Aplastic anemia Hemolytic anemia Hepatitis Hemochromatosis	Iron deficiency anemia
Iron-binding capacity	IBC: 250–350 µg/dL TIBC: 250–475 µg/dL % Saturation: 20–50	45–63 µmol/L 45–85 µmol/L Fraction of total iron-binding capacity: 0.2–0.5	Iron deficiency anemia Acute and chronic blood loss Hepatitis	Chronic infectious diseases Cirrhosis
Isocitric dehydrogenase	50–180 U	0.83–3 UIL	Hepatitis, cirrhosis Obstructive jaundice Metastatic carcinoma of the liver Megaloblastic anemia	
Lactic acid (whole blood)	Venous: 5–15 mg/dL Arterial: 3–11 mg/dL	0.5–1.7 mmol/L 0.36–1.25 mmol/L	Increased muscular activity Congestive heart failure Hemorrhage Shock Lactic acidosis Some febrile infections May be increased in severe liver disease	
Lactic dehydrogenase (LDH)	90–176 mU/mL	90–176 U/L	Untreated pernicious anemia Myocardial infarction Pulmonary infarction Liver disease	
*Lactic dehydrogenase isoenzymes Total lactic dehydrogenase	90–176 mU/mL	90–176 U/L	LDH-1 and LDH-2 are increased in myocardial infarction, megaloblastic anemia, and hemolytic anemia LDH-4 and LDH-5 are increased in pulmonary infarction, congestive heart failure, and liver disease	
LDH-1	22%–36%	Fraction of total LDH: 0.2–0.36		
LDH-2	35%–46%	0.35–0.46		
LDH-3	13%–26%	0.13–0.26		
LDH-4	3%–10%	0.03–0.10		
LDH-5	2%–12%	0.02–0.12		

(continued)

Table B-2 • Reference Ranges—Serum, Plasma, and Whole Blood Chemistries (Continued)

DETERMINATION	NORMAL ADULT REFERENCE RANGE		CLINICAL SIGNIFICANCE	
	Conventional Units	SI Units	Increased	Decreased
Lead (whole blood)	Up to 40 µg/dL	Up to 2 µmol/L	Lead poisoning	
Leucine amino-peptidase	80–200 U/mL	19.2–48 U/L	Liver or biliary tract diseases Pancreatic disease Metastatic carcinoma of liver and pancreas Biliary obstruction	
<sup>†</sup> Lipase	<200 U/mL	<200 U/L	Acute and chronic pancreatitis Biliary obstruction Cirrhosis Hepatitis Peptic ulcer	
Lipids, total	400–800 mg/dL	4–8 g/L	Hypothyroidism Diabetes mellitus Nephrosis Glomerulonephritis Hyperlipoproteinemias	Hyperthyroidism
Low-density lipoprotein cholesterol (LDL cholesterol)	mg/dL desirable levels: <160 if no coronary artery disease (CAD) and <2 risk factors <130 if no CAD and 2 or more risk factors <100 if CAD present		LDL cholesterol is higher in patients with increased risk for coronary heart disease	
Luteinizing hormone—RIA	Males: 1.5–9.3 mU/mL Females: Follicular phase: 1.9–12.5 mU/mL Midcycle: 8.7–76.3 mU/mL	1.5–9.3 U/L  1.9–12.5 U/L  8.7–76.3 U/L	Pituitary tumor Ovarian failure	Depressed or failure to peak—pituitary failure
Lysozyme (muramidase)	4.0–15.6 µg/mL	0.28–1.10 µmol/L	Certain types of leukemia (acute monocytic leukemia) Inflammatory states and infections	Acute lymphocytic leukemia
Magnesium	1.3–2.3 mg/dL	0.62–0.95 mmol/L	Excess ingestion of magnesium-containing antacids	Chronic alcoholism Severe renal disease Diarrhea Defective growth
Mercury	<10 µg/L	<50 µmol/L	Mercury poisoning	
Myoglobin—RIA	5–70 ng/mL	5–70 µg/mL	Myocardial infarction Muscle necrosis	
5' Nucleotidase	3.2–11.6 IU/L	3.2–11.6 U/L	Hepatobiliary disease	
Osmolality	275–300 mOsm/kg	275–300 mmol/L	Diabetes insipidus, osmotic diuresis	
Parathyroid hormone	10–65 pg/mL	10–65 ng/L	Hyperparathyroidism	Inappropriate secretion of ADH Addison's disease
Phenylalanine	1.2–3.5 mg/dL 1st week 0.7–3.5 mg/dL thereafter	0.07–0.21 mmol/L 0.04–0.21 mmol/L	Phenylketonuria	Chronic renal failure Hypoparathyroidism
Phosphohexose isomerase	20–90 IU/L	20–90 U/L	Malignancy Disease of heart, liver, and skeletal muscles	
Phospholipids	125–300 mg/dL	1.25–3 g/L	Diabetes mellitus Nephritis	
Phosphorus, inorganic	2.5–4.5 mg/dL	0.8–1.45 mmol/L	Chronic nephritis Hypoparathyroidism	
Potassium	3.5–5 mEq/L	3.5–5 mmol/L	Renal Failure Acidosis Cell lysis Tissue breakdown or hemolysis	Hyperparathyroidism Vitamin D deficiency GI losses Diuretic administration

(continued)

Table B-2 • Reference Ranges—Serum, Plasma, and Whole Blood Chemistries (Continued)

DETERMINATION	NORMAL ADULT REFERENCE RANGE		CLINICAL SIGNIFICANCE	
	Conventional Units	SI Units	Increased	Decreased
Progesterone—RIA	Follicular phase: up to 0.8 ng/mL Luteal phase: 10–20 ng/mL End of cycle: <1 ng/mL Pregnant: up to 50 ng/mL in 20th week	2.5 nmol/L 31.8–63.6 nmol/L <3 nmol/L Up to 160 nmol/L	Useful in evaluation of menstrual disorders and infertility and in the evaluation of placental function during pregnancies complicated by toxemia, diabetes mellitus, or threatened miscarriage	
Prolactin—RIA	4–30 ng/mL	4–30 µg/L	Pregnancy Functional or structural disorders of the hypothalamus Pituitary stalk section Pituitary tumors	
Prostate-specific antigen	<4 ng/mL		Prostatic cancer, benign prostatic hyperplasia, prostatitis	
Protein, total	6–8 gm/dL	60–80 g/L	Hemoconcentration	Malnutrition
Albumin	4–5.5 g/dL	40–55 g/L	Shock	Hemorrhage
Globulin	1.7–3.3 g/dL	17–33 g/L	Globulin fraction increased in multiple myeloma, chronic infection, liver disease	Loss of plasma from burns Proteinuria
Protein Electrophoresis		35–50 g/L		
Albumin	4.0–5.5 g/dL	40–55 g/L		
Alpha-1 globulin	0.15–0.25 g/dL	1.5–2.5 g/L		
Alpha-2 globulin	0.43–0.75 g/dL	4.3–7.5 g/L		
Beta globulin	0.5–1.0 g/dL	5–10 g/L		
Gamma globulin	0.6–1.3 g/dL	6–13 g/L		
Protoporphyrin erythrocyte (whole blood)	Males: 11–45 µg/dL Females: 19–52 µg/dL	0.20–0.80 µmol/L 0.34–0.92 µmol/L	Lead toxicity Erythropoietic porphyria	
Pyridoxine	5–30 ng/mL	20–1.21 nmol/L		A wide spectrum of clinical conditions, such as mental depression, peripheral neuropathy, anemia, neonatal seizures, and reactions to certain drug therapies
Pyruvic acid (whole blood)	0.3–0.9 mg/dL	34–102 µmol/L	Diabetes mellitus Severe thiamine deficiency Acute phase of some infections, possibly secondary to increased glycogenolysis and glycolysis	
Renin (plasma)—RLA	Normal diet: Supine: 0.3–1.9 ng/mL/h Upright: 0.6–3.6 ng/mL/h Low salt diet: Supine: 0.9–4.5 ng/mL/h Upright: 4.1–9.1 ng/mL/h	0.08–0.52 ng/L/S 0.16–1.00 µg/L/S 0.25–1.25 µg/L/S 1.13–2.53 µg/L/S	Renovascular hypertension Malignant hypertension Untreated Addison's disease Primary salt-losing nephropathy Low-salt diet Diuretic therapy Hemorrhage	Frank primary aldosteronism Increased salt intake Salt-retaining steroid therapy Antidiuretic hormone therapy Blood transfusion
Sodium	135–145 mEq/L	135–145 mmol/L	Hemoconcentration Nephritis Pyloric obstruction	Alkali deficit Addison's disease Myxedema
Sulfate (inorganic)	0.5–1.5 mg/dL	0.05–0.15 mmol/L	Nephritis Nitrogen retention	

(continued)

Table B-2 • Reference Ranges—Serum, Plasma, and Whole Blood Chemistries (Continued)

DETERMINATION	NORMAL ADULT REFERENCE RANGE		CLINICAL SIGNIFICANCE	
	Conventional Units	SI Units	Increased	Decreased
Testosterone—RIA	Females: 20–80 ng/dL Males: 240–1200 ng/dL	0.7–2.8 nmol/L 18.3–41.8 nmol/L	Females: Polycystic ovary Virilizing tumors	Males Orchidectomy for neoplastic disease of the prostate or breast Estrogen therapy Klinefelter's syndrome Hypopituitarism Hypogonadism Hepatic cirrhosis Hypothyroidism
T <sub>3</sub> (triiodothyronine) uptake	24%–34%	Relative uptake fraction: 0.24–0.34	Hyperthyroidism Thyroxine-binding globulin (TBG) deficiency Androgens and anabolic steroids	Pregnancy TBG excess Estrogens and anti-ovulatory drugs Hypothyroidism
T <sub>3</sub> total circulating—RIA	70–204 ng/dL	1.08–3.14 nmol/L	Pregnancy Hyperthyroidism	
T <sub>4</sub> (thyroxine)—RIA	5–11 µg/dL	65–138 nmol/L	Hyperthyroidism Thyroiditis Elevated thyroxine-binding proteins caused by oral contraceptives Pregnancy	Primary and pituitary hypothyroidism Idiopathic involvement Cases of diminished thyroxine-binding proteins caused by androgenic and anabolic steroids Hypoproteinemia Nephrotic syndrome
T <sub>4</sub> , free	0.8–2.7 ng/dL	10.3–35 pmol/L	Euthyroid patients with normal free thyroxine levels may have abnormal T <sub>3</sub> and T <sub>4</sub> levels caused by drug preparations Hypothyroidism	
Thyroid-stimulating hormone (TSH)—RIA		0.4–4.2 mIU/L		Hyperthyroidism
Thyroid-binding globulin	10–26 µg/dL	100–260/µg/L	Hypothyroidism Pregnancy Estrogen therapy Oral contraceptive use Genetic and idiopathic liver disease	Use of androgens and anabolic steroids Nephrotic syndrome Marked hypoproteinemia
Transferrin	200–380 mg/dL	2.3–3.2 g/L	Pregnancy Iron deficiency anemia due to hemorrhaging Acute hepatitis Polycythemia Oral contraceptive use	Pernicious anemia in relapse Thalassemic and sickle cell anemia Chromatosis Neoplastic and hepatic diseases
Triglycerides	100–200 mg/dL	1.13–3.8 mmol/L		
Tryptophan	1.4–3 mg/dL	68.6–147 nmol/L		Tryptophan-specific malabsorption syndrome
Tyrosine	0.5–4 mg/dL	27.6–220.8 mmol/L	Tyrosinosis	
Urea nitrogen (BUN)	10–20 mg/dL	3.6–7.2 mmol/L	Acute glomerulonephritis Obstructive uropathy Mercury poisoning Nephrotic syndrome	Severe hepatic failure Pregnancy
Uric acid	2.5–8 mg/dL	0.15–0 mmol/L	Gouty arthritis Acute leukemia Lymphomas treated by chemotherapy Toxemia of pregnancy	Defective tubular reabsorption

(continued)

Table B-2 • Reference Ranges—Serum, Plasma, and Whole Blood Chemistries (Continued)

DETERMINATION	NORMAL ADULT REFERENCE RANGE		CLINICAL SIGNIFICANCE	
	Conventional Units	SI Units	Increased	Decreased
Viscosity	1.4–1.8 relative to water at 37°C (98.6°F)		Patients with marked increases of the gamma globulins	
Vitamin A	30–120 µg/dL	1.05–4.20 µmol/L	Hypervitaminosis A	Vitamin A deficiency Celiac disease Sprue Obstructive jaundice Giardiasis Parenchymal hepatic disease
Vitamin B <sub>1</sub> (thiamine)	1.6–4 µg/dL	47.4–135.7 nmol/L		Anorexia Beriberi Polyneuropathy Cardiomyopathies Chronic alcoholism
Vitamin B <sub>6</sub> (pyridoxal phosphate)	5–30 ng/mL	20–121 nmol/L		Malnutrition Uremia Neonatal seizures Malabsorption, such as celiac syndrome
Vitamin B <sub>12</sub> —RIA	200–900 pg/mL	148–666 pmol/L	Hepatic cell damage and in association with the myeloproliferative disorders (the highest levels are encountered in myeloid leukemia)	Strict vegetarianism Alcoholism Pernicious anemia Total or partial gastrectomy Ileal resection Sprue and celiac disease Fish tapeworm infestation
Vitamin E	0.5–1.8 mg/dL	12–42 µmol/L		Vitamin E deficiency
Xylose absorption test	2 hr, 30–50 mg/dL	2–3.35 mmol/L		Malabsorption syndrome
Zinc	55–150 µg/dL	7.65–22.95 µmol/L	Coronary artery disease Arteriosclerosis Industrial exposure	Metastatic liver disease Tuberculosis Sprue

\*By radioimmunoassay.

†Varies among methods.

Table B-3 • Reference Ranges—Immunodiagnostic Test

DETERMINATION	NORMAL VALUE	CLINICAL SIGNIFICANCE
Acetylcholine receptor binding antibody	Negative or <0.03 nmol/L	Considered to be diagnostic for myasthenia gravis in patients with symptoms.
Anti-ds-DNA antibody	<70 U by enzyme-linked immunosorbent assay (ELISA) <1:20 by indirect fluorescence	Valuable in supporting diagnosis or monitoring disease activity and prognosis of systemic lupus erythematosus (SLE).
Antiglomerular basement membrane antibody	Negative or less than 5εUL	Primarily used in the differential diagnosis of glomerular nephritis induced by antiglomerular basement membrane antibodies from other types of glomerular nephritis.
Anti-insulin antibody	<3% binding of labeled beef and pork insulin by patient's serum; or <9 mIU/L	Helpful in determining the best therapeutic agent in diabetics and the cause of allergic manifestations. Also used to identify insulin resistance.
Antinuclear antibody	Negative, <1:40	Increased in SLE, chronic hepatitis, scleroderma, leukemia, and mononucleosis.
Anti-parietal cell antibody	Negative	Helpful in diagnosing chronic gastric disease and differentiating autoimmune pernicious anemia from other megaloblastic anemias.
Antiribonucleoprotein antibody	Negative	Helpful in differential diagnosis of systemic rheumatic disease.
Antiscleroderma antibody	Negative	Highly diagnostic for scleroderma.
Anti-Smith antibody	Negative	Highly diagnostic of SLE.
Anti-SS-A/anti-SS-B antibody	Negative	SS-A antibodies are found in Sjögren's syndrome alone or associated with lupus. SS-B antibodies are associated with primary Sjögren's syndrome.
Antithyroglobulin and antimicrosomal antibodies	<1:100 titer by gelatin or hemagglutination	Presence and concentration is important in evaluation and treatment of various thyroid disorders, such as Hashimoto's thyroiditis and Graves' disease. May indicate previous autoimmune disorders.
CA 15-3 tumor marker	<30 IU/mL	Increased in metastatic breast cancer.
CA 19-9 tumor marker	<37 IU/mL	Increased in pancreatic, hepatobiliary, gastric, and colorectal cancer, gallstones.
CA 125	0–35 IU/mL	Increased in colon, upper gastrointestinal (GI), ovarian, and other gynecologic cancers: pregnancy, peritonitis.
Carcinoembryonic antigen (CEA)—RLK	0–2.5 µg/L (nonsmoker) 0–5/µg/L (smoker)	The repeatedly high incidence of this antigen in cancers of the colon, rectum, pancreas, and stomach suggests that CEA levels may be useful in the therapeutic monitoring of these conditions, but it is not a screening test.
Cold agglutinins	Negative or <1:32	Increased in mycoplasma pneumonia, viral illness, mononucleosis, multiple myeloma, scleroderma.
C-reactive protein	<0.8 mg/dL	Increase indicates active inflammation.
Cytomegalovirus antibodies (CMV IgG)	Negative: <0.9 units/mL	Positive >1:0 unit/mL if exposed to CMV at anytime. Acute and convalescent specimens can help identify acute infection.
Cytomegalovirus antibodies (CMV IgM)	Negative: <0:79 Equivocal: 0:80–1.20	Positive >1:20 usually indicates acute infection. Repeat specimen in 1–2 weeks for equivocal result.
Epstein-Barr virus serology (viral capsid antigen IgG and IgM, early antigen IgG, and nuclear antigen IgG)	Negative: <1:20 or <1:20 for each individual test	Differentiation of acute from chronic or old infection by interpretation of table below.
Hepatitis A virus antibodies, IgM (HAV-Ab/IgM)	Negative	Positive in acute-stage hepatitis A; develops early in disease.

## EBV INTERPRETATION

	VCA-IgG	VCA-IgM	EA-IgG	EBV-NA
Susceptible	–	–	–	–
Acute infection	+	+	±	–
Convalescent phase	+	±	±	+
Chronic or reactivated	+	–	+	±
Old infection	±	–	–	+

Antibody present: +

Antibody absent: –

VCA, viral capsid antigen; EA, early antigen; EBV-NA, Epstein Barr virus-nuclear antigen

(continued)

Table B-3 • Reference Ranges—Immunodiagnostic Test (Continued)

DETERMINATION	NORMAL VALUE	CLINICAL SIGNIFICANCE
Hepatitis A virus antibodies, IgG (HAV-Ab/IgG)	Negative	Positive if previous exposure and immunity to hepatitis A.
Hepatitis B surface antigen (HBsAg)	Negative	Positive in acute-stage hepatitis B.
Hepatitis B surface antibody (HBsAb)	Negative	Positive if previous exposure and immunity to hepatitis B.
Hepatitis C virus antibodies	Negative	Positive in exposure to hepatitis C virus; may indicate acute, chronic, or cleared infection.
Hepatitis C virus RNA	Negative	Positive in hepatitis C infection, can be quantitative
Infectious mononucleosis tests (monospot, monostest, heterophile antigen test, Epstein-Barr virus (EBV), antiviral capsid antigen IgM and IgG)	Negative	Positive monospot and monostest are presumptive, positive EBV IgM and IgG indicate acute and recent or past infection, respectively.
Lyme disease titer	Negative, <1:256 by indirect fluorescent antibody method; nonreactive by ELISA	Positive results help diagnose Lyme disease. False positive may occur with high rheumatoid factor titers or syphilis. Positive ELISA confirmed by Western blot test.
Pyroglobulin test	Negative	These abnormal proteins may be associated with myeloma, lymphoma, polycythemia vera, and SLE.
Rheumatoid factor	Negative or less than 40 IU/mL	Elevated in rheumatoid arthritis, lupus endocarditis, tuberculosis, syphilis, sarcoidosis, cancer.
T and B cell lymphocyte surface markers T-helper/T-suppressor ratio	T and B cell lymphocyte surface markers: Percent T cells (CD2) 60–88% Percent helper cells (CD4) 34–67% Percent suppressor cells (CD8) 10–42% Percent B cells (CD19) 3–21% Absolute counts: Lymphocytes 0.66–4.60 thou/mL T cells 644–2201 cells/mL Helper cells 493–1191 cells/mL Suppressor T cells 182–785 cells/mL B cells 92–392 cells/mL Lymphocyte ratio: T <sub>H</sub> /T <sub>S</sub> ratio > 1	Used to evaluate immune system by identifying the specific cells involved in the immune response. Valuable in diagnosis of lymphocytic leukemia, lymphoma, and immunodeficiency diseases including acquired immunodeficiency syndrome, and in the assessment of patient response to chemotherapy and radiation.

Table B-4 • Reference Ranges—Urine Chemistry

DETERMINATION	NORMAL ADULT REFERENCE RANGE		CLINICAL SIGNIFICANCE	
	Conventional Units	SI Units	Increased	Decreased
Acetone and acetoacetate	Zero		Diabetic ketoacidosis Starvation	
Aldosterone	With normal salt diet: Normal: 4–20 µg/24 h Renovascular: 10–40 µg/24 h Tumor: 20–100 µg/24 h	11.1–55.5 nmol/24h 27.7–111 nmol/24 h 55.4–277 nmol/24 h	Primary aldosteronism (adrenocortical tumor) Secondary aldosteronism Salt depletion Potassium loading ACTH in large doses Cardiac failure Cirrhosis with ascites formation Nephrosis Pregnancy	
Alpha amino nitrogen	50–200 mg/24 h	3.6–14.3 nmol/24 h	Leukemia Phenylketonuria Other metabolic diseases	
Amylase	35–260 units excreted per h	6.5–48.1 U/h	Acute pancreatitis	
Arylsulfatase A	>2.4 U/mL			
Bence-Jones protein	None detected		Myeloma	Metachromatic leukodystrophy
Calcium	100–250 mg/24 h	2.5–6.2 mmol/24 h	Hyperparathyroidism Vitamin D intoxication Fanconi's syndrome Pheochromocytoma Neuroblastoma	Hypoparathyroidism Vitamin D deficiency
Catecholamines	Total: 0–275 µg/24 h Epinephrine: 10%–40% Norepinephrine: 60%–90%	0–275 µg/24 h Fraction total: 0.10–8.4 Fraction total: 0.60–0.90		
Chorionic gonadotrophin, qualitative (pregnancy test)	Negative		Pregnancy Chorionepithelioma Hydatidiform mole	
Copper	15–60 µg/24 h	0.22–0.9 µmol/24 h	Wilson's diseases Cirrhosis Nephrosis	
Coproporphyrin	50–300 µg/24 h	0.075–0.45 µmol/24 h	Poliomyelitis Lead poisoning Porphyria	
Cortisol, free	20–90 µg/24 h	55.2–248.4 nmol/d	Cushing's syndrome	
Creatinine	Males: 1–2 g/24 h Females: 0.8–1.8 g/24 h	8.8–17.7 mmol/24 h 7.1–15.9 mmol/24 h	Muscular dystrophy Fever Carcinoma of liver Pregnancy Hyperthyroidism Myositis	
Creatine	0–270 mg/24 h	0–2.05 mmol/24 h	Typhoid fever Salmonella infections Tetanus	Muscular atrophy Anemia Advanced degeneration of kidneys Leukemia Renal diseases
Creatinine clearance	Males: 85–125 mL/min Females: 75–115 mL/min	1.42–2.08 mL/s 1.25–1.92 mL/s		
Cystine and cysteine	10–100 mg/24 h	0.08–0.83 mmol/24 h	Cystinuria	
Delta aminolevulinic acid	0–0.54 mg/dL	0–40 µmol/L	Lead poisoning Porphyria hepatica Hepatitis Hepatic carcinoma	
11-Desoxycortisol	20–100 µg/24 h	0.6–2.9 µmol/d	Hypertensive form of virilizing adrenal hyperplasia due to an 11-beta hydroxylase defect	

(continued)

Table B-4 • Reference Ranges—Urine Chemistry (Continued)

DETERMINATION	NORMAL ADULT REFERENCE RANGE		CLINICAL SIGNIFICANCE	
	Conventional Units	SI Units	Increased	Decreased
Estriol (placental)	Weeks of pregnancy	$\mu\text{m}/24\text{ h}$	$\text{mmol}/24\text{ h}$	Decreased values occur with fetal distress of many conditions, including preeclampsia, placental insufficiency, and poorly controlled diabetes mellitus
	12	<1	<3.5	
	16	2–7	7–24.5	
	20	4–9	14–32	
	24	6–13	21–45.5	
	28	8–22	28–77	
	32	12–43	42–150	
	36	14–45	49–158	
Estrogens, total (fluorometric)	40	19–46	66.5–160	Hyperestrogenism due to gonadal or adrenal neoplasm  Primary or secondary amenorrhea
	Females:			
	Onset of menstruation:			
	4–25 $\mu\text{g}/24\text{ h}$	4–25 $\mu\text{g}/24\text{ h}$		
	Ovulation peak:			
	28–100 $\mu\text{g}/24\text{ h}$	28–100 $\mu\text{g}/24\text{ h}$		
	Luteal peak: 22–105 $\mu\text{g}/24\text{ h}$	22–105 $\mu\text{g}/24\text{ h}$		
	Menopausal: 1.4–19.6 $\mu\text{g}/24\text{ h}$	1.4–19.6 $\mu\text{g}/24\text{ h}$		
Etiocholanolone	Males: 5–18 $\mu\text{g}/24\text{ h}$	5–18 $\mu\text{g}/24\text{ h}$		Adrenogenital syndrome Idiopathic hirsutism Menopause and primary ovarian failure
	Males: 1.9–6 $\text{mg}/24\text{ h}$	6.5–20.6 $\mu\text{mol}/24\text{ h}$		
Follicle-stimulating hormone—RIA	Females:			Pituitary failure
	Follicular: 5–20 IU/24 h	5–20 IU/d		
	Luteal: 5–15 IU/24 h	5–15 IU/d		
	Midcycle: 15–60 IU/24 h	15–60 IU/d		
	Menopausal: 50–100 IU/24 h	50–100 IU/d		
Glucose	Males: 5–25 IU/24 h	5–25 IU/d		Diabetes mellitus Pituitary disorders Increased ICP Lesion in floor of 4th ventricle Extensive burns Transfusion of incompatible blood Myoglobin increased in severe crushing injuries to muscles
	Negative			
Hemoglobin and myoglobin	Negative			Neuroblastoma Cushing's disease
Homovanillic acid		<44 $\mu\text{mol}/24\text{ h}$		Addison's disease
17-hydroxycorticosteroids	8 $\text{mg}/24\text{ h}$ 2–10 $\text{mg}/24\text{ h}$	5.5–27.5 $\mu\text{mol}/\text{d}$		Anterior pituitary hypofunction
5-Hydroxyindoleacetic acid, qualitative	Negative			Malignant carcinoid tumors
17-ketosteroids, total	Males: 10–22 $\text{mg}/24\text{ h}$	35–76 $\mu\text{mol}/24\text{ h}$		Interstitial cell tumor of testes Simple hirsutism, occasionally Adrenal hyperplasia Cushing's syndrome Adrenal cancer, virilism Adrenoblastoma
	Females: 6–16 $\text{mg}/24\text{ h}$	21–55 $\mu\text{mol}/24\text{ h}$		
Lead	<125 $\mu\text{g}/24\text{ h}$	<60 $\mu\text{mol}/24\text{ h}$		Thyrototoxicosis Female hypogonadism Diabetes mellitus Hypertension Debilitating disease of mild to moderate severity Eunuchoidism Addison's disease Panhypopituitarism Myxedema Nephrosis
Luteinizing hormone	Males: 5–18 IU/24 h			Lead poisoning Pituitary tumor Ovarian failure  Depressed or failure to peak—pituitary failure

(continued)

Table B-4 • Reference Ranges—Urine Chemistry (Continued)

DETERMINATION	NORMAL ADULT REFERENCE RANGE		CLINICAL SIGNIFICANCE	
	Conventional Units	SI Units	Increased	Decreased
Metanephrines, total	Females:			
	Follicular phase: 2–25 IU/24 h	2–25 IU/d		
	Ovulatory peak: 30–95 IU/24 h	30–95 IU/d		
	Luteal phase: 2–20 IU/24 h	2–20 IU/d		
	Postmenopausal: 40–110 IU/24 h	40–110 IU/d		
	<1.4 mg/24 h	<7 μmol/24h	Pheochromocytoma; a few patients with pheochromocytoma may have elevated urinary metanephrines but normal catecholamines and vanillylmandelic acid (VMA)	
Osmolality	250–900 mOsm/kg	250–900 mmol/kg	Useful in the study of electrolyte and water balance	
Oxalate	Up to 45 mg/24 h	Up to 500/μmol/24 h	Primary hyperoxaluria	
Phenylpyruvic acid qualitative	Negative		Phenylketonuria	
Phosphorus, inorganic	0.9–1.3 g/24 h	29–42 mmol/24 h	Hypoparathyroidism Vitamin D intoxication Paget's disease Metastatic neoplasm to bone	Hypoparathyroidism Vitamin D deficiency
Porphobilinogen, qualitative	Negative		Chronic lead poisoning Acute porphyria Liver disease	
Porphobilinogen quantitative	0–1 mg/24 h	0–4.4 μmol/24 h	Acute porphyria Liver disease	
Porphyryns, qualitative	Negative		See porphyryns, quantitative	
Porphyryns, quantitative (coproporphyrin and uroporphyrin)	Coproporphyrin: 50–160 μg/24 h	0.075–0.24 μmol/24h	Porphyria	
	Uroporphyrin: up to 50 μg/24 h	Up to 0.06 μmol/24 h	Lead poisoning (only coproporphyrin increased)	
Potassium	26–123 mEq/24 h	26–123 mmol/24 h	Hemolysis Chronic renal failure Acidosis Cushing's disease Corpus luteum cysts	Diarrhea Adrenocortical insufficiency
Pregnanediol	Females:			
	Proliferative phase: 0.5–1.5 mg/24 h	1.6–4.8 μmol/24 h	When placental tissue remains in the uterus following parturition	Placental dysfunction Threatened abortion Intrauterine death
	Luteal phase: 2–7 mg/24 h	6–22 μmol/24 h	Some cases of adrenocortical tumors	
	Menopause: 0.2–1 mg/24 h	0.6–3.1 μmol/24 h		
Pregnancy: Weeks of gestation				
	10–12	mg/24 h	μmol/24 h	
	12–18	5–15	15.6–47	
	18–24	5–25	15.6–78.0	
	24–28	15–33	47.0–103.0	
	28–32	20–42	62.4–131.0	
		27–47	84.2–146.6	

(continued)

Table B-4 • Reference Ranges—Urine Chemistry (Continued)

DETERMINATION	NORMAL ADULT REFERENCE RANGE		CLINICAL SIGNIFICANCE	
	Conventional Units	SI Units	Increased	Decreased
Pregnanetriol	Females: 0.1–2.2 mg/24 h Males: 0.4–2.5 mg/24 h	0.3–6.5 $\mu$ mol/24 h 1.2–7.5 $\mu$ mol/24 h	Congenital adrenal androgenic hyperplasia	
Protein	<150 mg/24 h	<150 mg/24 h	Nephritis Cardiac failure Mercury poisoning Bence-Jones protein in multiple myeloma Febrile states Hematuria	
Sodium	75–200 mEq/24 h	75–200 mmol/24 h	Useful in detecting gross changes in water and salt balance	Metabolic alkalosis
Titrateable acidity	20–40 mEq/24 h	20–40 mmol/24 h	Metabolic acidosis	Impaired kidney function
Urea nitrogen	9–16 gm/24 h	0.32–0.57 mol/L	Excessive protein catabolism	Nephritis
Uric acid	250–750 mg/24 h	1.48–4.43 mmol/24 h	Gout	Complete or nearly complete biliary obstruction
Urobilinogen	Random urine: <0.25 mg/dL 24-hour urine: up to 4 mg/24 h	<0.42 mol/24 h Up to 6.76 $\mu$ mol/24 h	Liver and biliary tract disease Hemolytic anemias	Diarrhea Renal insufficiency
Vanillylmandelic acid (VMA)	0.7–6.8 mg/24 h	3.5–34.3 $\mu$ mol/24 h	Pheochromocytoma Neuroblastoma Ingestion of coffee, tea, aspirin, bananas, and several different drugs	
Xylose absorption test (5-hour)	16%–33% of ingested xylose	Fraction absorbed: 0.16–0.33		
Zinc	0.15–1.2 mg/24 h	2.3–18.4 $\mu$ mol/24h		Malabsorption syndromes

Table B-5 • Reference Ranges—Cerebrospinal Fluid (CSF)

DETERMINATION	NORMAL ADULT REFERENCE RANGE		CLINICAL SIGNIFICANCE	
	Conventional Units	SI Units	Increased	Decreased
Albumin	15–30 mg/dL	150–300 mg/L	Certain neurologic disorders Lesion in the choroid plexus or blockage of the flow of CSF Damage to the blood–brain barrier	
Cell count (white blood cells)	0–5 cells per cu mm	0–5 × 10 <sup>6</sup> /L	Bacterial meningitis Neurosyphilis Anterior poliomyelitis Encephalitis lethargica	
Chloride	120–130 mEq/L	120–130 mmol/L	Uremia	Acute generalized meningitis Tuberculous meningitis
Glucose	50–75 mg/dL; 50%–80% of blood glucose value	2.75–4.13 mmol/L	Diabetes mellitus Diabetic coma Epidemic encephalitis Uremia	Acute meningitis Tuberculous meningitis Insulin shock Subarachnoid hemorrhage
Glutamine	6–15 mg/dL	0.41–1 mmol/L	Hepatic encephalopathies, including Reye’s syndrome Hepatic coma Cirrhosis	
IgG	<5 mg/dL	<50 mg/L	Damage to the blood–brain barrier Multiple sclerosis Neurosyphilis Subacute sclerosing panencephalitis Chronic phases of CNS infections	
Lactic acid	4.5–28.8 mg/dL	0.5–3.2 mmol/L	Bacterial meningitis Hypocapnia Hydrocephalus Brain abscesses Cerebral ischemia Fungal meningitis	
Lactate dehydrogenase	% that of serum level	Activity fraction: 0.1 of serum	CNS disease Acute meningitis	
Protein	15–45 mg/dL	150–450 mg/L	Tubercular meningitis Neurosyphilis Poliomyelitis Guillain-Barré syndrome Subdural hematoma Brain tumor Multiple sclerosis	

Table B-6 • Miscellaneous Values

DETERMINATIONS	NORMAL VALUE	CLINICAL SIGNIFICANCE	
		Conventional Units	SI Units
Acetaminophen	Zero	Therapeutic level = 10–30 µg/mL	10–30 mg/L
Aminophylline (theophylline)	Zero	Therapeutic level = 10–20 µg/mL	10–20 mg/L
Bromide	Zero	Therapeutic level = 5–50 mg/dL	50–500 mg/L
Carbamazepine	Zero	Therapeutic level = 8–12 µg/mL	34–51 µmol/L
Carbon monoxide	0%–2%	Symptoms with 10%–30% saturation	
Chlordiazepoxide	Zero	Therapeutic level = 0.7–1.0 µg/mL	0.7–1.0 mg/L
Diazepam	Zero	Therapeutic level = 0.2–1.0 µg/mL	0.2–1.0 mg/L
Digitoxin	Zero	Therapeutic level = 18–35 ng/mL	18–35 µg/L
Digoxin	Zero	Therapeutic level = 0.8–2 ng/mL	0.8–2 µg/L
Ethanol	0%–0.01%	Legal intoxication level = 0.10% or above 0.3%–0.4% = marked intoxication 0.4%–0.5% = alcoholic stupor	
Gentamicin	Zero	Therapeutic level = 4–10 µg/mL	4–10 mg/L
Lithium	Zero	Therapeutic level = 0.6–1.2 mEq/L	0.6–1.2 mmol/L
Methanol	Zero	May be fatal in concentration as low as 10 mg/dL	100 mg/L
Phenobarbital	Zero	Therapeutic level = 20–40 µg/mL	20–40 mg/L
Phenytoin	Zero	Therapeutic level = 10–20 µg/mL	10–20 mg/L
Primidone	Zero	Therapeutic level = 5–12 µg/mL	5–12 mg/L
Quinidine	Zero	Therapeutic level = 0.2–0.5 mg/dL	2–5 mg/L
Salicylate	Zero	Therapeutic level = 2–25 mg/dL Toxic level = >30 mg/dL	20–250 mg/L 300 mg/L
Vancomycin	Zero	Therapeutic peak 20–40 µg/mL Therapeutic trough 5–10 µg/mL	
Amitriptyline	Zero	Therapeutic level 80–200 ng/mL	289–722 nmol/L
Doxepin	Zero	Therapeutic level 150–250 ng/mL (includes metabolites)	540–900 nmol/L
Imipramine	Zero	Therapeutic level 100–300 ng/mL (includes metabolites)	360–1070 nmol/L
Lidocaine	Zero	Therapeutic level 1.5–5 µg/mL	6.4–21.4 µmol/L
Methotrexate	Zero	Toxic (48 hr. after high dose) 454 mg/mL	1000 mmol/L
Propranolol	Zero	Therapeutic level 50–100 ng/mL	193–386 nmol/L
Valproic acid	Zero	Therapeutic level 50–100 µg/mL	347–693 µmol/L
