During ambulation, the patient usually protects the surgical incision by splinting. Gradually, she will achieve a more upright position. The patient is instructed to avoid tight and underwire bras until the surgeon indicates that no injury will result. Elevating the arms above the shoulder and lifting more than 5 pounds of weight are avoided for 1 month after surgery to avoid stress on the incision.

### Nipple–Areola Reconstruction

After the breast mound has been created and the site has healed, some women choose to have a nipple–areola reconstruction. This consists of minor surgical procedures carried out either in the physician's office or as outpatient surgery. A nipple is created using a skin graft from the inner thigh or labia because this skin has darker pigmentation than the skin on the reconstructed breast. After the nipple graft has healed, the areolar complex is usually completed with micropigmentation (tattooing). The surgeon can usually match the reconstructed nipple–areola complex with that of the contralateral breast for an acceptable cosmetic result.

**FIGURE 48-9** Breast reconstruction: latissimus dorsi flap. (A) Tissue taken from the back is tunneled to the front of the chest wall to support the reconstructed breast. (B) The transported tissue forms a flap that can hold a breast implant if there is not enough tissue to form a breast mound, or (C) tissue may be taken from the abdomen and tunneled to the breast or surgically transplanted to form a new breast mound. Adapted from “Breast Reconstruction,” American Society of Plastic and Reconstructive Surgeons, Arlington Heights, IL.

## Diseases of the Male Breast

### GYNECOMASTIA

Gynecomastia, or overdeveloped breast tissue, is the most common breast condition in the male. Adolescent boys can be affected by this condition because of hormones secreted by the testes. Gynecomastia usually subsides in 1 or 2 years, but it can occur before or after puberty and in elderly men. It is usually unilateral and presents as a firm, tender mass underneath the areola. In adult men, gynecomastia may be diffuse and related to medications (ie, digitalis, reserpine, ergotamine, ranitidine, and phenytoin). Pain and tenderness are initial symptoms. Treatment depends on the man’s feelings and preference. Observation is acceptable because it may resolve on its own; surgical removal of the tissue through an incision around the areola is another option. Liposuction of the tissue done by a plastic surgeon, another option, yields a positive cosmetic result.

### MALE BREAST CANCER

Cancer of the male breast accounts for 1% of all breast cancers; about 1,500 new cases of breast cancer and 400 deaths due to breast cancer occur annually (ACS, 2002b). Symptoms can include a painless lump beneath the areola, nipple retraction, nipple discharge, or skin ulceration. Diagnostic tests and treatment modalities are similar to those used for women. The average age of the patient at the time of diagnosis is 60 years, but it can occur in younger men, especially if there is a genetic link to the disease, because there may be a relationship to BRCA-2 in men with breast cancer. Risk factors may include a history of mumps orchitis, radiation exposure, and Klinefelter’s syndrome (a chromosomal condition reflecting decreased testosterone levels).

Detection usually occurs well into the disease because cancer of the breast is not a common concern among men. Therefore, treatment generally consists of a modified radical mastectomy. If the pectoralis muscles are involved, a radical mastectomy is indicated. Radiation therapy may be used postoperatively. Prognosis varies depending on the stage of disease at diagnosis. Bone and soft tissue are the most common sites of advanced disease and metastasis. Orchiectomy (removal of the testes), adrenalectomy (removal of the adrenal gland), and hypophysectomy (removal of

the pituitary gland) may be used in advanced disease, but anti-hormonal agents are preferable because they are less invasive and disfiguring.

### Critical Thinking Exercises

1. You are caring for a patient who had breast augmentation surgery 10 years ago. When you ask her how often she examines her breasts, she states that she does not do so because she would be unable to detect masses because of her previous surgery. She also states that she does not think it is appropriate to touch her own breasts and that her physician performs a clinical breast examination each year when she has a Pap smear. How would you address the issues she has raised? Describe the teaching approach you would use.
2. Your 40-year-old patient has been diagnosed with breast cancer. Her mother, aunt, and one of her sisters have all had breast cancer. She is very worried about her two daughters’ risks for breast cancer and asks if they should undergo genetic testing. She also asks about the need for her daughters to have mammograms performed. What guidelines would you give to this patient about mammography and genetic testing that might be considered for her daughters? What issues must be taken into account when someone is considering genetic testing for breast cancer?
3. A 46-year-old woman reports to you that she wants to undergo mastectomy and oophorectomy because she has a positive family history of breast cancer and is terrified of developing breast or ovarian cancer. Describe the benefits and risks of these surgeries for prophylactic management in women at risk for breast cancer. What postoperative care and teaching are indicated if she has both mastectomy and oophorectomy performed to reduce her risks for breast and ovarian cancer?
4. Two weeks after having a mastectomy to treat breast cancer, a 37-year-old patient calls you. She is distraught because her husband, who moved out of their bedroom

immediately after her discharge so that he did not disturb her, has refused to sleep in the same bed or same room with her. How would you address this issue? What resources would you use to address the problem, and what resources would you provide to the patient and her spouse?

**5.** A 59-year-old woman with a history of cardiac disease is scheduled for a modified radical mastectomy and breast reconstruction surgery. Describe the preoperative and postoperative care of this patient, including discharge planning.

# ● Assessment and Management of Problems Related to Male Reproductive Processes

## **LEARNING OBJECTIVES** ●

*On completion of this chapter, the learner will be able to:*

1. Describe structures and function of the male reproductive system.
2. Discuss nursing assessment of the male reproductive system and identify diagnostic tests that complement assessment.
3. Discuss the causes and management of male sexual dysfunction.
4. Compare the types of prostatectomy with regard to advantages and disadvantages.
5. Use the nursing process as a framework for care of the patient undergoing prostatectomy.
6. Describe the nursing management of patients with testicular cancer.
7. Describe the various conditions affecting the penis, including pathophysiology, clinical manifestations, and management.

Disorders of the male reproductive system include a wide variety of conditions that usually affect both the urinary and reproductive systems. Because these disorders focus on the genitalia and in some instances sexuality, the patient may experience anxiety and embarrassment. Nurses must recognize the patient's need for privacy as well as his need for education. This requires an openness to discuss critical and sensitive issues with the patient as well as effective assessment, management, and communication on the part of the nurse.

## Anatomic and Physiologic Overview

In the male, several organs serve as parts of both the urinary tract and the reproductive system. Disorders in the male reproductive organs may interfere with the functions of one or both of these systems. As a result, diseases of the male reproductive system are usually treated by a urologist. The structures in the male reproductive system are the testes, the vas deferens (ductus deferens) and the seminal vesicles, the penis, and certain accessory glands, such as the prostate gland and Cowper's gland (bulbourethral gland) (Fig. 49-1).

## TESTICULAR DEVELOPMENT

The **testes** are formed in the embryo within the abdominal cavity near the kidney. During the last month of fetal life, they descend posterior to the peritoneum and pierce the abdominal wall in the groin. Later, they progress along the inguinal canal into the scrotum. In this descent, they are accompanied by blood vessels, lymphatics, nerves, and ducts, which support the tissue and make up the spermatic cord. This cord extends from the internal inguinal ring through the abdominal wall and the inguinal canal to the scrotum. As the testes descend into the scrotum, a tubular extension of peritoneum accompanies them. Normally, this tissue is obliterated during fetal development, the only remaining portion being that which covers the testes, the tunica vaginalis. (When this peritoneal process is not obliterated but remains open into the abdominal cavity, a potential sac remains into which abdominal contents may enter to form an indirect inguinal hernia.)

The testes are encased in the scrotum, which keeps them at a slightly lower temperature than the rest of the body to facilitate **spermatogenesis** (production of sperm). The testes consist of numerous seminiferous tubules in which the spermatozoa form. Collecting tubules transmit the spermatozoa into the epididymis,

## Glossary

**benign prostatic hyperplasia (BPH):** non-cancerous enlargement or hypertrophy of the prostate. BPH is the most common pathologic condition in older men and the second most common cause of surgical intervention in men older than age 60 years.

**Bowen's disease:** form of squamous cell carcinoma in situ of the penile shaft

**circumcision:** excision of the foreskin, or prepuce, of the glans penis

**cryosurgery of the prostate:** localized treatment of the prostate by application of freezing temperatures

**cryptorchidism:** most common congenital defect, characterized by failure of one or both of the testes to descend into the scrotum

**epididymitis:** infection of the epididymis that usually descends from an infected prostate or urinary tract; also may develop as a complication of gonorrhea

**erectile dysfunction:** also called impotence; the inability to either achieve or maintain an erection sufficient to accomplish sexual intercourse

**hydrocele:** a collection of fluid, generally in the tunica vaginalis of the testis, although it also may collect within the spermatic cord

**nocturia:** urination during the night

**orchietomy:** surgical removal of one or both of the testes

**orchitis:** inflammation of the testes (testicular congestion) caused by pyogenic, viral, spirochetal, parasitic, traumatic, chemical, or unknown factors

**penile cancer:** represents about 0.5% of malignancies in men in the United States; can involve the glans, the body of the

penis, the urethra, and regional or distant lymph nodes

**penis:** male organ for copulation and urination; consists of glans penis, body, and root

**Peyronie's disease:** buildup of fibrous plaques in the sheath of the corpus cavernosum, causing curvature of the penis when it is erect

**phimosis:** condition in which the foreskin is constricted so that it cannot be retracted over the glans; can occur congenitally or from inflammation and edema

**priapism:** an uncontrolled, persistent erection of the penis occurring from either neural or vascular causes, including medications, sickle cell thrombosis, leukemic cell infiltration, spinal cord tumors, and tumor invasion of the penis or its vessels

**prostate cancer:** the most common cancer in men; risk factors include increasing age, African American race, and possibly a higher-fat diet; the genetic association of prostate cancer and the increased incidence within certain families is being investigated

**prostate gland:** gland that lies just below the neck of the bladder, surrounds the urethra, and is traversed by the ejaculatory duct, a continuation of the vas deferens; produces a secretion that is chemically and physiologically suitable to the needs of the spermatozoa in their passage from the testes

**prostate-specific antigen (PSA):** substance that is produced by the prostate gland and measured in a blood specimen; PSA levels are increased with prostate cancer; the PSA test is used in combination with digital rectal examination to detect prostate cancer

**prostatism:** obstructive and irritative symptom complex that includes increased frequency and hesitancy in starting urination, a decrease in the volume and force of the urinary stream, acute urinary retention, and recurrent urinary tract infections

**prostatitis:** inflammation of the prostate gland caused by infectious agents (bacteria, fungi, mycoplasma) or various other problems (eg, urethral stricture, prostatic hyperplasia)

**spermatogenesis:** production of sperm in the testes

**testes:** the ovoid sex glands encased in the scrotum; the testes produce sperm

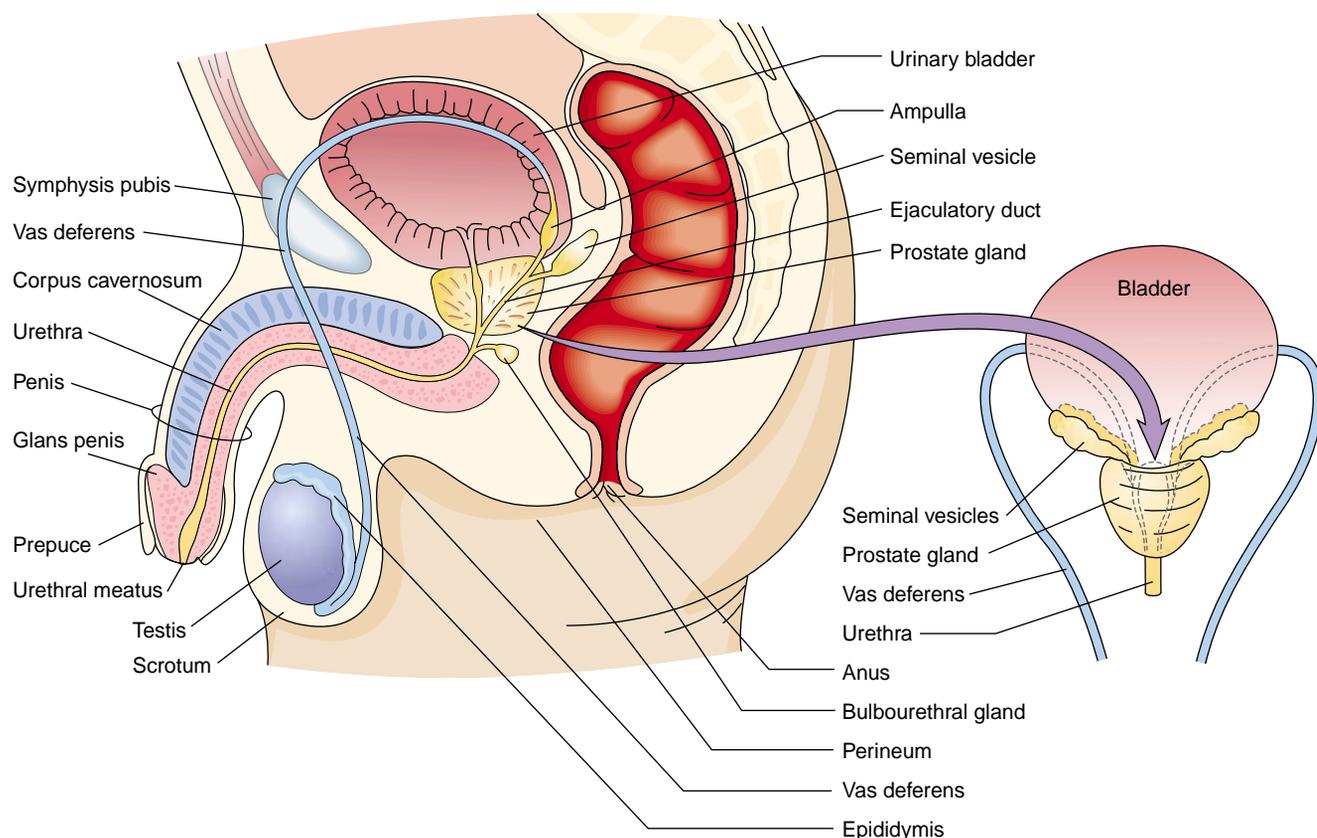

**testicular cancer:** the most common cancer in men 15 to 35 years of age and the second most common malignancy in those 35 to 39 years of age; its cause is unknown

**testosterone:** male sex hormone secreted by the testes; induces and preserves the male sex characteristics

**transurethral resection of the prostate (TUR or TURP):** resection of the prostate through endoscopy; the surgical and optical instrument is introduced directly through the urethra to the prostate, and the gland is then removed in small chips with an electrical cutting loop

**varicocele:** an abnormal dilation of the veins of the pampiniform venous plexus in the scrotum (the network of veins from the testis and the epididymis, which constitute part of the spermatic cord)

**vasectomy:** also called male sterilization; ligation and transection of part of the vas deferens, with or without removal of a segment of the vas to prevent the passage of the sperm from the testes

**FIGURE 49-1** Structures of the male reproductive system. Adapted from Willis, M. C. (1996). *Medical terminology: The language of health care*. Baltimore: Williams & Wilkins.

a hoodlike structure lying on the testes and containing winding ducts that lead into the vas deferens. This firm, tubular structure passes upward through the inguinal canal to enter the abdominal cavity behind the peritoneum. It then extends downward toward the base of the bladder. An outpouching from this structure is the seminal vesicle, which acts as a reservoir for testicular secretions. The tract is continued as the ejaculatory duct, which passes through the prostate gland to enter the urethra. Testicular secretions take this pathway when they exit the penis during ejaculation.

## GLANDULAR FUNCTION

The testes have a dual function: the formation of spermatozoa from the germinal cells of the seminiferous tubules and the secretion of the male sex hormone **testosterone**, which induces and preserves the male sex characteristics.

The **prostate gland** lies just below the neck of the bladder. It surrounds the urethra and is traversed by the ejaculatory duct, a continuation of the vas deferens. This gland produces a secretion that is chemically and physiologically suitable to the needs of the spermatozoa in their passage from the testes.

Cowper's gland lies below the prostate within the posterior aspect of the urethra. This gland empties its secretions into the urethra during ejaculation, providing lubrication. The **penis** has a dual function: it is the organ for copulation and for urination. Anatomically, it consists of the glans penis, body, and root. The glans penis is the soft, rounded portion at the distal end of the penis. The urethra, the tube that carries urine, opens at the tip of the glans. The glans is naturally covered or protected by elongated

penile skin—the foreskin—which may be retracted to expose the glans. However, many men have had the foreskin removed (circumcision) as newborns. The body of the penis is composed of erectile tissues containing numerous blood vessels that become distended, leading to an erection during sexual excitement. The urethra, which passes through the penis, extends from the bladder through the prostate to the distal end of the penis.

## Assessment

### HEALTH HISTORY AND CLINICAL MANIFESTATIONS

Assessment of male reproductive function begins with an evaluation of urinary function and symptoms. This assessment also includes a focus on sexual function as well as manifestations of sexual dysfunction. The patient is asked about his usual state of health and any recent change in general physical and sexual activity. Any symptoms or changes in function are explored fully and described in detail. These symptoms may include those associated with an obstruction caused by an enlarged prostate gland: increased urinary frequency, decreased force of urine stream, “double” or “triple” voiding (the patient needs to urinate two or three times over a period of several minutes to completely empty his bladder). The patient is also assessed for dysuria, hematuria, and hematospermia (blood in the ejaculate).

Assessment of sexual function and dysfunction is an essential part of every health history. The extent of the history will depend on the patient's presenting symptoms and the presence of factors that may affect sexual function: chronic illnesses (eg, diabetes,

multiple sclerosis, stroke, cardiac disease), use of medications that affect sexual function (eg, many antihypertensive and anti-cholesterolemic medications, psychotropic agents), stress, and alcohol use.

Discussing sexuality with patients with an illness or disability can be uncomfortable for nurses and other health care providers. Health care professionals may unconsciously have stereotypes related to sexuality about people who are ill or disabled (eg, ill or disabled persons are asexual or should remain sexually inactive). In addition, patients are often embarrassed to initiate a discussion about these issues with their health care providers (Hughes, 2000). Because changes in sexual functioning are a common concern of patients, it is important to address these issues when obtaining the health history. By initiating an assessment about sexual concerns, the nurse demonstrates that changes in sexual functioning are valid topics for discussion and provides a safe environment for discussing these sensitive topics. The PLISSIT (permission, limited information, specific suggestions, intensive therapy) model of sexual assessment and intervention may be used to provide a framework for nursing interventions (Annon, 1976). This model begins by asking the patient's permission to discuss sexual functioning. Limited information about sexual function may then be provided to the patient. As the discussion progresses, the nurse may offer specific suggestions for interventions. For some individuals, a professional who specializes in sex therapy may provide more intensive therapy as needed.

## PHYSICAL ASSESSMENT

In addition to the customary aspects of the physical examination, two essential components address disorders of the male genital or reproductive system: the digital rectal examination and the testicular examination.

### Digital Rectal Examination

The digital rectal examination (DRE) is recommended as part of the regular health checkup for every man older than 40 years of age; it is invaluable in screening for cancer of the prostate gland. The DRE enables the examiner to assess the size, shape, and consistency of the prostate gland (Fig. 49-2). Tenderness of the prostate gland on palpation and the presence and consistency

of any nodules are noted. Although having this examination may be embarrassing for the patient, it is an important screening tool.

### Testicular Examination

The male genitalia are inspected for abnormalities and palpated for masses. The scrotum is palpated carefully for nodules, masses, or inflammation. Examining the scrotum can reveal such disorders as hydrocele, hernia, or tumor of the testis. The penis is inspected and palpated for ulcerations, nodules, inflammation, and discharge. The testicular examination provides an excellent opportunity to instruct the patient about techniques for testicular self-examination and its importance in early detection of testicular cancer (discussed later in this chapter). This self-examination should begin during adolescence.

### Gerontologic Considerations

As men age, the prostate gland enlarges, prostate secretion decreases, the scrotum hangs lower, the testes become smaller and more firm, and pubic hair becomes sparser and stiffer. Changes in gonadal function include a decline in plasma testosterone levels and reduced production of progesterone (Table 49-1). Other changes include decreasing sexual function, slower sexual responses, an increased incidence of genitourinary tract cancer, and urinary incontinence for various reasons.

Male reproductive capability is maintained with advancing age. Although degenerative changes occur in the seminiferous tubules, spermatogenesis (production of sperm) continues. Sexual function, however, involving libido (desire) and potency, decreases. Vascular problems cause about half of the cases of impotence in men older than 50 years of age.

Hypogonadism occurs in up to one fourth of older men. The relationship of hypogonadism to impotence is uncertain. This decline is more evident in men older than 70 years but is also noted in men in their 60s. In older men, the sexual response slows. Erection takes longer in men older than 50 years of age, and full erections may not be attained until orgasm. Sexual function is affected by several factors, such as psychological problems, illnesses, and medications. In general, the sexual act takes longer. In older men, ejaculatory control increases; however, if the erection is partially

A

B

**FIGURE 49-2** (A) Palpation of the prostate gland during digital rectal examination (DRE) enables the examiner to assess the size, shape, and texture of the gland. (B) The prostate is round, with a palpable median sulcus or groove separating the two lobes. It should feel rubbery and free of nodules and masses.

**Table 49-1 • Age-Related Changes in Male Reproductive System**

AGE-RELATED CHANGES	PHYSIOLOGIC CHANGES	MANIFESTATIONS
Decrease in sex hormone secretion, especially testosterone	Decreased muscle strength and sexual energy	Changes in sexual response: prolonged time to reach full erection, rapid penile detumescence and prolonged refractory period Decrease in number of viable sperm
	Shrinkage and loss of firmness of testes; thickening of seminiferous tubules	Smaller testes
	Fibrotic changes of corpora cavernosa	Erectile dysfunction
	Enlargement of prostate gland	Weakening of prostatic contractions Hyperplasia of prostate gland Signs and symptoms of obstruction of lower urinary tract (urgency, frequency, nocturia)

lost, there may be difficulty in attaining a full erection again, and resolution may occur without orgasm. Sexual activity is closely correlated with the man's sexual activity of his earlier years; if he was more active than average as a young man, he will most likely continue to be more active than average in his later years.

Cancers of the kidney, bladder, prostate, and penis all have increased incidence in men older than 50 years of age. DRE and screening tests for hematuria may uncover a higher percentage of malignancies at earlier stages.

Urinary incontinence in the elderly man may have many causes, including medications and age-related conditions, such as neurologic diseases or **benign prostatic hyperplasia** (BPH; also referred to as hypertrophy and called an enlarged prostate by the lay public). Diagnostic tests are performed to exclude reversible causes of urinary incontinence. For some patients with severe incontinence, augmentation cystoplasty (repair of the bladder) with placement of an artificial urinary sphincter may help alleviate this problem.

## Diagnostic Evaluation

Diagnostic studies that relate to the male reproductive organs and the ability to participate in sexual activity include the following.

### PROSTATE-SPECIFIC ANTIGEN TEST

The prostate gland produces a substance known as **prostate-specific antigen (PSA)**. It can be measured in a blood specimen, and levels increase with prostate cancer. Many factors can increase PSA levels, including BPH, prostate cancer, and infections of the prostate and urinary tract. PSA levels are measured in nanograms per milliliter (ng/mL). The PSA test and DRE are used to detect prostate cancer (Smith, Cokkinides, von Eschenbach, et al., 2002).

The range of values considered normal is 0.2 to 4.0 ng/mL. Values over 4.0 are considered elevated. An elevated PSA level is not a specific indicator of prostate cancer. A number of conditions (eg, BPH, transurethral resection of the prostate, acute urinary retention, and acute prostatitis) can also cause an elevated PSA level in the absence of prostate cancer. Despite these limitations, in combination with other procedures, PSA is useful in identifying men at risk and in monitoring patients following treatment for cancer of the prostate (Barry, 2001). A PSA test, along with DRE, is recommended by the American Cancer Society annually for men at high risk, specifically those with a family history of prostate cancer and for African American men.

## ULTRASONOGRAPHY

Transrectal ultrasound (TRUS) studies may be performed in patients with abnormalities detected by DRE or those with elevated PSA levels. After DRE, a lubricated, condom-covered, rectal probe transducer is inserted into the rectum along the anterior wall. Water may be introduced to the condom to help transmit sound waves to the prostate. TRUS may be used in detecting nonpalpable prostate cancers and in staging localized prostate cancer. Needle biopsies of the prostate are commonly guided by TRUS.

## PROSTATE FLUID OR TISSUE ANALYSIS

Specimens of prostate fluid or tissue may be obtained for culture when disease or inflammation of the prostate gland is suspected. A biopsy of the prostate gland may be necessary to obtain tissue for histologic examination. This may be performed at the time of prostatectomy or by means of a perineal or transrectal needle biopsy.

## TESTS OF MALE SEXUAL FUNCTION

If the patient cannot engage in sexual intercourse to his satisfaction, a detailed history is obtained. Nocturnal penile tumescence tests may be conducted in a sleep laboratory to monitor changes in penile circumference during sleep (using a mercury strain gauge placed around the penis); the results help to identify the cause of erectile dysfunction. Arterial blood flow to the penis is measured with the Doppler probe. Nerve conduction tests and psychological evaluations are also part of the diagnostic workup and are usually conducted by a specialized team of health care providers.

## Disorders of Male Sexual Function

### ERECTILE DYSFUNCTION

**Erectile dysfunction**, also called impotence, is the inability to achieve or maintain an erection sufficient to accomplish intercourse. The man may report decreased frequency of erections, inability to achieve a firm erection, or rapid detumescence (subsiding of erection). Incidence ranges from 25% to 50% in men older than 65 years of age. The physiology of erection and ejaculation is complex and involves sympathetic and parasympathetic components. At the time of erection, pelvic nerves carry parasympathetic impulses that dilate the smaller blood vessels of the region and increase blood flow to the penis, expanding the corpora cavernosa.

Erectile dysfunction has both psychogenic and organic causes. Psychogenic causes include anxiety, fatigue, depression, and pressure to perform sexually. Organic impotence, however, may account for more impotence than previously realized. Organic causes include occlusive vascular disease, endocrine disease (diabetes, pituitary tumors, hypogonadism with testosterone deficiency, hyperthyroidism, and hypothyroidism), cirrhosis, chronic renal failure, genitourinary conditions (radical pelvic surgery), hematologic conditions (Hodgkin's disease, leukemia), neurologic disorders (neuropathies, parkinsonism, spinal cord injury, multiple sclerosis), trauma to the pelvic or genital area, alcohol, medications (Chart 49-1), and drug abuse.

## Assessment and Diagnostic Findings

The diagnosis of erectile dysfunction requires a sexual and medical history; an analysis of presenting symptoms; a physical examination, including a neurologic examination; a detailed assessment of all medications, alcohol, and drugs used; and various laboratory studies. Nocturnal penile tumescence tests are conducted in sleep laboratories to monitor changes in penile circumference. In healthy men, nocturnal penile erections closely parallel rapid eye movement (REM) sleep in occurrence and duration. Organically impotent men show inadequate sleep-related erections that correspond to their waking performance. The nocturnal penile tumescence test can help to determine whether erectile impotence has an organic or psychological cause. Arterial blood flow to the penis is measured using a Doppler probe. In addition, nerve conduction tests and extensive psychological evaluations are carried out. Figure 49-3 describes the evaluation and treatment of men with erectile dysfunction.

### Chart 49-1 • PHARMACOLOGY Classes of Medications Associated With Erectile Dysfunction

Antiadrenergics and antihypertensives: guanethidine (Ismelin), clonidine (Catapres), hydralazine (Apresoline), metoprolol (Lopressor)  
 Anticholinergics and phenothiazines: prochlorperazine (Compazine), trihexyphenidyl (Artane)  
 Anti-seizure agents: carbamazepine (Tegretol)  
 Antifungals: ketoconazole (Nizoral)  
 Antihormone (prostate cancer treatment): flutamide (Eulexin), leuprolide (Lupron)  
 Antipsychotics: haloperidol (Haldol), chlorpromazine (Thorazine)  
 Antispasmodics: oxybutynin (Ditropan)  
 Anxiolytics, sedative-hypnotics, tranquilizers: lorazepam (Ativan), triazolam (Halcion)  
 Beta-blockers: nadolol (Corgard)  
 Calcium channel blockers: nifedipine (Adalat, Procardia)  
 Carbonic anhydrase inhibitors: acetazolamide (Diamox)  
 H<sub>2</sub> antagonists: nizatidine (Axid)  
 Nonsteroidal anti-inflammatory drugs: naproxen (Naprosyn)  
 Thiazide diuretics: hydrochlorothiazide (HydroDIURIL)  
 Tricyclic antidepressants: amitriptyline (Elavil), desipramine (Norpramin)

**FIGURE 49-3** Evaluation and treatment of men with erectile dysfunction. From Lue, T. F. (2000). Erectile dysfunction. *New England Journal of Medicine*, 342(24), 1807. © 2000 Massachusetts Medical Society. All rights reserved. Used with permission.

## Medical Management

Treatment, which depends on the cause, can be medical, surgical, or both (Table 49-2). Nonsurgical therapy includes treating associated conditions, such as alcoholism, and readjusting hypertensive agents or other medications. Endocrine therapy may be instituted for erectile dysfunction secondary to hypothalamic-pituitary-gonadal dysfunction and may reverse the condition. Insufficient penile blood flow may be treated with vascular surgery. Patients with erectile dysfunction from psychogenic causes are referred to a health care provider or therapist specializing in sexual dysfunction. Patients with erectile dysfunction secondary to organic causes may be candidates for penile implants.

### PHARMACOLOGIC THERAPY

Sildenafil (Viagra) is an oral medication for erectile dysfunction (Eid, 2000). When it is taken about 1 hour before sex, an erection can occur with stimulation; the erection can last about 60 to 120 minutes. Despite the effectiveness of this medication, it does have side effects: headache, flushing, and dyspepsia. Sildenafil is contraindicated in patients who take organic nitrates and should be used with caution in patients with retinopathy, especially those with diabetic retinopathy (Chart 49-2).

Other pharmacologic measures to induce erections include injecting vasoactive agents, such as alprostadil, papaverine, and phenolamine, directly into the penis. Complications include **priapism** (a persistent abnormal erection) and development of fibrotic plaques at the injection sites. Alprostadil is also formulated in a gel pellet that can be inserted into the urethra to create an erection.

### PENILE IMPLANTS

Penile implants are available in two types: the semirigid rod and the inflatable prosthesis. The semirigid rod (eg, the Small-Carrion prosthesis) leaves the man with a permanent semierrection. The inflatable prosthesis simulates natural erections and natural flaccidity. Complications after implantation include infection, erosion of the prosthesis through the skin (more common with the semirigid rod than with the inflatable prosthesis), and persistent pain, which may require removal of the implant. Cystoscopic surgery, such as **transurethral resection of the prostate** (TUR or TURP), is more difficult with a semirigid rod than with the inflatable prosthesis. Factors to consider in choosing a prosthesis are the patient's activities of daily living and social activities and the expectations of the patient and his partner. Ongoing counseling for the patient and his partner is usually necessary to help them in adapting to the prosthesis.

### NEGATIVE-PRESSURE DEVICES

Negative-pressure (vacuum) devices may also be used to induce an erection. A plastic cylinder is placed over the flaccid penis, and negative pressure is applied. When an erection is attained, a constriction band is placed around the base of the penis to maintain the erection. Although many men find this method satisfactory, others experience premature loss of penile rigidity or pain when applying suction or during intercourse.

## Nursing Management

Personal satisfaction and the ability to sexually satisfy a partner are common concerns of patients. Men with illnesses and disabilities may need the assistance of a sex therapist to find, implement, and integrate their sexual beliefs and behaviors into a healthy and sat-

isfying lifestyle. The nurse can inform patients that support groups for men with erectile dysfunction and their partners have been established. Information about Impotence Anonymous for patients and I-Anon for their partners can be found at the end of this chapter.

## EJACULATION PROBLEMS

Premature ejaculation occurs when a man cannot control the ejaculatory reflex and, once aroused, reaches orgasm before or shortly after intromission. It is the most common dysfunction in men. Inhibited or retarded ejaculation is the involuntary inhibition of the ejaculatory reflex. The spectrum of responses includes occasional ejaculation through intercourse or self-stimulation or the complete inability to ejaculate under any circumstances.

Treatment modalities depend on the nature and severity of the ejaculation problem. Behavioral therapies may be indicated for people with premature ejaculation; these therapies often involve the man and his sexual partner. "Homework" assignments are often given to the couple to encourage them to identify their sexual needs and to communicate those needs to each other. In some cases, pharmacologic and behavioral therapy together may be effective.

Neurologic disorders (eg, spinal cord injury, multiple sclerosis, neuropathy secondary to diabetes), surgery (prostatectomy), and medications are the most common causes of inhibited ejaculation. Chemical, vibratory, and electrical stimulation have been used with some success. Treatment is usually multidisciplinary and addresses the physical and psychological factors that are often involved in inhibited ejaculation (Lue, 2000).

For men with retrograde ejaculation, the urine may be collected after ejaculation; sperm is then collected from the urine for use in artificial insemination. In men with spinal cord injury, electroejaculation may be used to obtain sperm for artificial insemination.

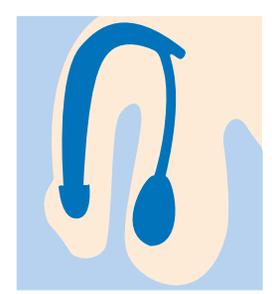

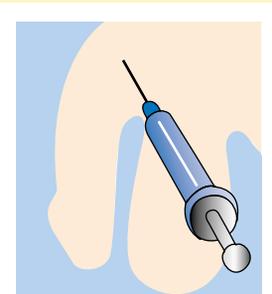

The effects of trauma, chronic illness, and physical disability on sexual function can be profound. In addition to psychogenic factors, the physical changes associated with illness and injury can impair sexual function.

## Infections of the Male Genitourinary Tract

Acute uncomplicated cystitis in adult men is uncommon but occasionally occurs in men whose sexual partners have vaginal infections with *Escherichia coli*. Asymptomatic bacteriuria may also occur from genitourinary manipulation, catheterization, or instrumentation. Urinary tract infections in the male are discussed in Chapter 45.

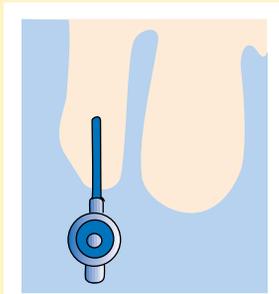

The incidence of sexually transmitted diseases (STDs) is increasing in men and women. STDs are most common in young, sexually active people, with the incidence higher in men than women (U.S. Surgeon General, 2001). STDs affect people from all walks of life—from all social, educational, economic, and racial backgrounds. Several diseases are classified as STDs: urethritis (gonococcal and nongonococcal), genital ulcers (genital herpes infections, primary syphilis, chancroid, granuloma inguinale, and lymphogranuloma venereum), genital warts (human papillomavirus [HPV]), scabies, pediculosis pubis, molluscum contagiosum, hepatitis and enteric infections, proctitis, and acquired immunodeficiency syndrome (AIDS). Trichomoniasis and STDs characterized by genital ulcers are thought to increase susceptibility to human immunodeficiency virus (HIV) infection. Trichomoniasis is associated with nonchlamydial, nongonococcal urethritis.

**Table 49-2 • Treatments for Erectile Dysfunction**

METHOD	DESCRIPTION	ADVANTAGES AND DISADVANTAGES	DURATION
Penile implants <ul style="list-style-type: none"> <li>• Semirigid rod</li> <li>• Inflatable</li> </ul>  <p>Penile implant</p>	Surgically implanted into corpus cavernosum	Reliable Requires surgery Healing takes up to 3 weeks Subsequent cystoscopic surgery is difficult Semirigid rod results in permanent semierection	Indefinite Inflatable prosthesis: saline returns from penile receptacle to reservoir
Negative-pressure (vacuum) devices  <p>Penile vacuum pump</p>	Induction of erection with vacuum; maintained with constriction band around base of penis	Few side effects Cumbersome to use before intercourse Vasocongestion of penis can cause pain or numbness	To prevent penile injury, constriction band must not be left in place for longer than 1 hour
Pharmacologic therapy <ul style="list-style-type: none"> <li>• Oral medication (sildenafil [Viagra])</li> </ul>  <p>Oral medication</p>	Smooth muscle relaxant causing blood to flow into penis	Can cause headache and diarrhea Contraindicated for men taking organic nitrates Used with caution in patients with retinopathy, especially diabetic retinopathy	Taken orally 1 hour before intercourse Stimulation is required to achieve erection Erection can last 1 hour
<ul style="list-style-type: none"> <li>• Injection (alprostadil, papaverine, phentolamine)</li> </ul>  <p>Penile injection</p>	Smooth muscle relaxant causing blood to flow into penis	Firm erections are achievable in more than 50% of cases Pain at injection site; plaque formation, risk of priapism	Injection 20 minutes before intercourse Erection can last up to 1 hour

Table 49-2 • Treatments for Erectile Dysfunction (Continued)

METHOD	DESCRIPTION	ADVANTAGES AND DISADVANTAGES	DURATION
<ul style="list-style-type: none"> <li>• Urethral suppository (alprostadil)</li> </ul>  <p data-bbox="175 703 454 735">Penile suppository</p>	Smooth muscle relaxant causing blood to flow into penis	May be used twice a day Not recommended with pregnant partners	Inserted 10 minutes before intercourse Erection can last up to 1 hour

Treatment of STDs must be targeted at the patient as well as his or her sexual partners and sometimes the unborn child. A thorough history that includes a sexual history is crucial to identify patients at risk and to direct care and teaching. Partners of men with STDs must also be examined, treated, and counseled to prevent reinfection and complications in both partners and to

limit the spread of the disease. Sexual abstinence during treatment and recovery is advised to prevent the transmission of STDs (CDC, 2002). Using latex condoms for at least 6 months after completion of treatment is recommended to decrease transmission of HPV infections as well as other STDs. Because patients with one STD may also have another STD, it is important to

examine and test for other STDs. Use of spermicides with nonoxynol 9 (“N-9”) is discouraged as they do not protect against HIV infection and may increase the risk for transmission of the virus (van Damme, 2000; CDC, 2002). See Chapters 52 and 70 for more detailed discussions of HIV infection and AIDS and other STDs.

## Conditions of the Prostate

### PROSTATITIS

**Prostatitis** is an inflammation of the prostate gland caused by infectious agents (bacteria, fungi, mycoplasma) or other conditions (eg, urethral stricture, prostatic hyperplasia). *E. coli* is the most commonly isolated organism. Microorganisms are usually carried to the prostate from the urethra. Prostatitis may be classified as bacterial or abacterial, depending on the presence or absence of microorganisms in the prostatic fluid.

### Clinical Manifestations

Symptoms of prostatitis may include perineal discomfort, burning, urgency, frequency, and pain with or after ejaculation. Prostatodynia (pain in the prostate) is manifested by pain on voiding or perineal pain without evidence of inflammation or bacterial growth in the prostate fluid.

Acute bacterial prostatitis may produce sudden fever and chills and perineal, rectal, or low back pain. Urinary symptoms, such as dysuria, frequency, urgency, and **nocturia** (urination during the night), may occur. Some patients do not have symptoms. Chronic bacterial prostatitis is a major cause of relapsing urinary tract infection in men. Symptoms are usually mild, consisting of frequency, dysuria, and occasionally urethral discharge. High temperature and chills are uncommon.

Complications of prostatitis may include swelling of the prostate gland and urinary retention. Other complications include epididymitis, bacteremia, and pyelonephritis.

### Assessment and Diagnostic Findings

The diagnosis of prostatitis requires a careful history, culture of prostate fluid or tissue, and occasionally a histologic examination of the tissue. To locate the source of a lower genitourinary infection (bladder neck, urethra, prostate), it is necessary to collect a divided urinary specimen for segmental urine culture. After cleaning the glans penis and retracting the foreskin (if present), the patient voids 10 to 15 mL of urine into a container. This represents urethral urine. Without interrupting the urinary stream, he collects 50 to 75 mL of urine in a second container; this represents bladder urine.

If the patient does not have acute prostatitis, the physician immediately performs a prostatic massage and collects any prostatic fluid that is expressed into a third container. If it is not possible to collect prostatic fluid, the patient voids a small quantity of urine. The specimen may contain the bacteria present in the prostatic fluid. Urinalysis after prostate examination commonly reveals many white blood cells.

### Medical Management

The goal of therapy for acute bacterial prostatitis is to avoid the complications of abscess formation and septicemia. A broad-spectrum antibiotic agent (to which the causative organism is sen-

sitive) is administered for 10 to 14 days. Intravenous administration of the agent may be necessary to achieve high serum and tissue levels; the agent may be administered at home. The patient is encouraged to remain on bed rest to alleviate symptoms quickly. Comfort is promoted with analgesic agents (to relieve pain), antispasmodic medications and bladder sedatives (to relieve bladder irritability), sitz baths (to relieve pain and spasm), and stool softeners (to prevent pain from straining).

Chronic bacterial prostatitis is difficult to treat because most antibiotics diffuse poorly from the plasma into the prostatic fluid. Nevertheless, antibiotics may be prescribed, including trimethoprim-sulfamethoxazole (TMP-SMZ) or a fluoroquinolone. Continuous therapy with low-dose antibiotics to suppress the infection may also be indicated. The patient is advised that the urinary tract infection may recur and is taught to recognize its symptoms. In addition, treatment for chronic prostatitis may include reducing the retention of prostatic fluid by ejaculation through sexual intercourse or masturbation. Other treatments include antispasmodics, sitz baths, stool softeners, and evaluation of sexual partners to reduce the possibility of cross-infection. The treatment of nonbacterial prostatitis is directed toward relieving symptoms.

### Nursing Management

If the patient experiences symptoms of acute prostatitis (fever, severe pain and discomfort, inability to urinate, malaise), he may be hospitalized for intravenous antibiotic therapy. Nursing management includes administration of prescribed antibiotics and provision of comfort measures, including prescribed analgesic agents and sitz baths.

The patient with chronic prostatitis is usually treated on an outpatient basis and needs to be instructed about the importance of continuing antibiotic therapy.

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** The nurse instructs the patient to complete the prescribed course of antibiotics. If intravenous antibiotics are to be administered at home, the nurse instructs the patient and family about correct and safe administration. Arrangements for home care to oversee administration may be needed. Hot sitz baths (10 to 20 minutes) may be taken several times daily. Fluids are encouraged to satisfy thirst but are not “forced” because an effective medication level must be maintained in the urine. Foods and liquids that have diuretic action or that increase prostatic secretions, such as alcohol, coffee, tea, chocolate, cola, and spices, should be avoided. During periods of acute inflammation, sexual arousal and intercourse should be avoided.

To minimize discomfort, the patient should avoid sitting for long periods. Medical follow-up is necessary for at least 6 months to 1 year because prostatitis caused by the same or different organisms can recur.

### BENIGN PROSTATIC HYPERPLASIA (ENLARGED PROSTATE)

In many patients older than 50 years, the prostate gland enlarges, extending upward into the bladder and obstructing the outflow of urine by encroaching on the vesical orifice. This condition is known as benign prostatic hyperplasia (BPH), the enlargement, or hypertrophy, of the prostate. BPH is one of the most common pathologic conditions in older men (McConnell, 1998).

## Clinical Manifestations

Examination reveals a prostate gland that is large, rubbery, and nontender. The cause is uncertain, but evidence suggests that hormones initiate hyperplasia of the supporting stromal tissue and the glandular elements in the prostate (McConnell, 1998). The hypertrophied lobes may obstruct the vesical neck or prostatic urethra, causing incomplete emptying of the bladder and urinary retention. As a result, a gradual dilation of the ureters (hydronephrosis) and kidneys (hydronephrosis) can occur. Urinary tract infections may result from urinary stasis, because some urine remains in the urinary tract and serves as a medium for infective organisms.

## Assessment and Diagnostic Findings

The obstructive and irritative symptom complex (referred to as **prostatism**) includes increased frequency of urination, nocturia, urgency, hesitancy in starting urination, abdominal straining with urination, a decrease in the volume and force of the urinary stream, interruption of the urinary stream, dribbling (urine dribbles out after urination), a sensation that the bladder has not been completely emptied, acute urinary retention (when more than 60 mL of urine remains in the bladder after urination), and recurrent urinary tract infections. Ultimately, azotemia (accumulation of nitrogenous waste products) and renal failure can occur with chronic urinary retention and large residual volumes. Generalized symptoms may also be noted, including fatigue, anorexia, nausea, vomiting, and epigastric discomfort. Other disorders producing similar symptoms include urethral stricture, prostate cancer, neurogenic bladder, and urinary bladder stones.

A physical examination with DRE and diagnostic studies may be performed to determine the degree to which the prostate is enlarged, the presence of any changes in the bladder wall, and the efficiency of renal function. These tests may include urinalysis and urodynamic studies to assess urine flow. Renal function tests, including serum creatinine levels, may be performed to determine if there is renal impairment from prostatic back-pressure and to evaluate renal reserve. Complete blood studies are performed. Because hemorrhage is a major complication of prostate surgery, all clotting defects must be corrected. A high percentage of patients with BPH have cardiac or respiratory complications, or both, because of their age; therefore, cardiac and respiratory function is also assessed.

## Medical Management

The treatment plan depends on the cause of BPH, the severity of the obstruction, and the patient's condition. If the patient is admitted on an emergency basis because he cannot void, he is immediately catheterized. The ordinary catheter may be too soft and pliable to advance through the urethra into the bladder. In such cases, a thin wire called a stylet is introduced (by a urologist) into the catheter to prevent the catheter from collapsing when it encounters resistance. In severe cases, metal catheters with a pronounced prostatic curve may be used. Sometimes an incision is made into the bladder (a suprapubic cystostomy) to provide drainage.

Although prostatectomy (described later in the chapter) to remove the hyperplastic prostatic tissue is frequently performed, other treatment options are available. These include "watchful waiting," transurethral incision of the prostate (TUIP), balloon dilation, alpha-blockers, 5-alpha-reductase inhibitors, transurethral

laser resection, transurethral needle ablation, and microwave thermotherapy (Lepor, 1998; Mebust, 1998; McCullough, 1998). Watchful waiting is the appropriate treatment for many patients because the likelihood of progression of the disease or the development of complications is unknown. Patients are monitored periodically for severity of symptoms, physical findings, laboratory tests, and diagnostic urologic tests.

Alpha-adrenergic receptor blockers (eg, terazosin [Hytrin]) relax the smooth muscle of the bladder neck and prostate. These agents help to reduce obstructive symptoms in many patients.

Because the hormonal component of BPH has been identified, one method of treatment involves hormonal manipulation with antiandrogen agents, such as finasteride (Proscar). In clinical studies, 5-alpha-reductase inhibitors such as finasteride have been effective in preventing the conversion of testosterone to dihydrotestosterone (DHT). With decreased levels of DHT, suppression of glandular cell activity and decreases in prostate size have been demonstrated. Side effects of these medications include gynecomastia (breast enlargement), erectile dysfunction, and flushing.

With ultrasound guidance, resection of the prostate can be accomplished with lasers. The treated tissue either vaporizes or becomes necrotic and sloughs. This treatment is delivered in the outpatient setting and generally results in less postoperative bleeding than a traditional surgical prostatectomy.

Transurethral needle ablation uses low-level radiofrequencies to produce localized heat to destroy prostate tissue while sparing the urethra, nerves, muscles, and membranes. The radiofrequencies are delivered by thin needles placed into the prostate gland from a catheter. The body then resorbs the dead tissue.

In microwave thermotherapy, heat is applied to the hypertrophied prostatic tissue. A transurethral probe is inserted into the urethra, and microwaves are carefully directed to the prostate tissue. A water-cooling system helps to minimize damage to the urethra and decreases the discomfort from the procedure. The tissue becomes necrotic and sloughs.

Saw palmetto is a botanical remedy used for symptoms of mild to moderate BPH such as urinary frequency and decreased force of urine stream (Gerber, 2000; Marks, Partin, Epstein et al., 2000; Wilt, Ishani, Stark et al., 1998). It is theorized that saw palmetto works by interfering with the conversion of testosterone to DHT. In addition, saw palmetto may directly block the ability of DHT to stimulate prostate cell growth. It should not be used with finasteride or medications containing estrogen.

## CANCER OF THE PROSTATE

**Prostate cancer** is the most common cancer in men other than nonmelanoma skin cancer and the second most common cause of cancer deaths in American men older than 55 years of age (Greenlee et al., 2001). About one in five men in the United States develop prostate cancer. It is estimated that 189,000 new cases of prostate cancer and 30,200 deaths occur annually (American Cancer Society, 2002). Prostate cancer rates are twice as high in African American men than in Caucasian men, and African American men are more likely to die of prostate cancer than men in any other racial or ethnic group. To address this issue, Agho and Lewis (2001) assessed knowledge of prostate cancer and the use of prostate cancer screening services among 108 African American men. The men were unable to answer most of the 21 questions on the test with more than 70% accuracy, although individuals younger than 40 years of age were

more knowledgeable than older men. Despite their increased risk for prostate cancer, only 47% of the men in the sample who were 40 years or older had prostate cancer screening as part of their annual physical examination. Knowledge about prostate cancer was found to be negatively correlated with education, age, and income. A culturally sensitive promotional campaign has been identified as an important strategy to increase awareness of the racial disparities in the incidence of prostate cancer and mortality rates. Nurses are in an ideal position to use these research findings to improve the health of African American men by teaching and counseling them about prostate cancer, screening, and treatment.

Risk factors for prostate cancer include increasing age: the incidence of prostate cancer increases rapidly after the age of 50 years, and more than 70% of cases occur in men over 65 years of age. African American men have the highest incidence of prostate cancer in the world. Prostate cancer is common in the United States and northwestern Europe but is rare in Asia, Africa, Central America, and South America. A familial predisposition may occur in 5% to 10% of cases of prostate cancer. Having a father or brother with prostate cancer doubles the risk; the risk increases further if several relatives have had prostate cancer and if the relatives were young at diagnosis. A diet high in red meat and fat increases the risk for prostate cancer (American Cancer Society, 2002). Large-scale studies are in progress to determine if prostate cancer can be prevented by use of selected supplements or finasteride (Proscar).

## Clinical Manifestations

Cancer of the prostate in its early stages rarely produces symptoms. The symptoms that develop from urinary obstruction occur late in the disease. This cancer tends to vary in its course. If the neoplasm is large enough to encroach on the bladder neck, signs and symptoms of urinary obstruction occur: difficulty and frequency of urination, urinary retention, and decreased size and force of the urinary stream. Other symptoms may include blood in the urine or semen and painful ejaculation. Hematuria may result if the cancer invades the urethra or bladder, or both. Prostate cancer can metastasize to bone and lymph nodes. Symptoms related to metastases include backache, hip pain, perineal and rectal discomfort, anemia, weight loss, weakness, nausea, and oliguria (decreased urine output). Unfortunately, these symptoms may be the first indications of prostate cancer.

## Assessment and Diagnostic Findings

When prostate cancer is detected early, the likelihood of cure is high. Every man older than 40 years of age should have a DRE as part of his regular health checkup. Routine repeated rectal palpation of the gland (preferably by the same examiner) is important because early cancer may be detected as a nodule within the substance of the gland or as an extensive hardening in the posterior lobe. The more advanced lesion is “stony hard” and fixed. DRE also provides useful clinical information about the rectum, anal sphincter, and quality of stool.

### NURSING RESEARCH PROFILE 49-1

#### Impact of Prostate Cancer

Fitch, M. I., Gray, R., Franssen, E., & Johnson, B. (2000). Men's perspectives on the impact of prostate cancer: Implications for oncology nurses. *Oncology Nursing Forum*, 27(8), 1255–1263.

#### Purpose

This study was conducted to describe the experience of and support used by men with prostate cancer and to compare those with recurrent prostate cancer and those without recurrent disease.

#### Study Sample and Design

This was a descriptive study of men with prostate cancer: 120 men with recurrent prostate cancer and 845 men without recurrent prostate cancer living in Canada. Consecutive subjects were recruited through urology offices and self-help groups. A 52-item survey developed by the researchers was used to obtain information from the subjects.

Descriptive data analysis addressed demographic characteristics, problems experienced, assistance received for problems, factors surrounding emotional support (eg, satisfaction with communication, satisfaction with information received, benefits of self-help groups), and impact of illness and treatment on lifestyle (including relationships with partners, children, and friends; employment opportunities and work life; financial status; leisure time activities; mental health; and household responsibilities). The two groups were compared on relevant variables.

#### Findings

Men in both groups reported physical and psychological problems, although the incidence of these problems was higher in men with recurrent disease. Sexual dysfunction was the most frequently identified problem in both groups, but among those with recurrent disease, a significantly higher percentage reported problems with side effects, pain, and anger. Although few men reported having difficulty talking with their health care providers, 10% of men with recurrent disease

had trouble doing so compared to 2% of those without recurrent disease ( $p < 0.025$ ). The percentage of men with recurrent disease who reported dissatisfaction with the information that was provided was higher in the areas of possible side effects or symptoms (31% vs. 14%,  $p < 0.005$ ) and medical condition (25% vs. 10%,  $p < 0.005$ ) than that of men without recurrent disease. Men in both groups indicated that they received inadequate help with problems such as side effects, incontinence, sexual dysfunction, and pain.

Overall, family and friends were the most frequent sources of support when men needed to talk, followed by medical professionals and self-help groups. The subjects also identified the need for more information about possible emotional reactions to the disease, how to arrange to speak to another man with prostate cancer, alternative therapies, diet and nutrition.

#### Nursing Implications

Nurses should conduct early and ongoing comprehensive patient assessments, including physical as well as psychosocial components, to determine patient needs so that they can provide timely and effective interventions. Patients at high risk of experiencing psychosocial difficulties include those who do not have the social networks available to discuss their experiences. To enhance coping with the consequences of prostate cancer and its treatment, particularly in those with recurrent disease, nurses need to teach patients about the disease and provide an opportunity for them to discuss their concerns. In addition, assessment findings will help guide the creation and provision of effective interventions. Referral to self-help groups may be indicated, particularly in the absence of social support from family and friends.

The diagnosis of prostate cancer is confirmed by a histologic examination of tissue removed surgically by transurethral resection, open prostatectomy, or transrectal needle biopsy. Fine-needle aspiration is a quick, painless method of obtaining prostate cells for cytologic examination. The procedure is helpful for determining the stage of disease as well.

Most prostate cancers are diagnosed when a man seeks medical attention for symptoms of urinary obstruction or after abnormalities are found by DRE. Incidentally detected cancer with transurethral resection of the prostate for clinically benign disease and prostatism occurs in 10% to 20% of patients. Rarely do patients have other signs and symptoms, such as azotemia (nitrogen compounds in the blood), weakness, anemia, or bone pain.

PSA, a neutral serine protease, is produced by the normal and neoplastic ductal epithelium of the prostate and secreted into the glandular lumen (Brawer, Cheli, Neaman et al., 2000; Kalish & McKinlay, 1999). A simple blood test can be used to measure PSA levels. The concentration of PSA in the blood is proportional to the total prostatic mass. Although the PSA level indicates the presence of prostate tissue, it does not necessarily indicate malignancy. PSA testing is routinely used to monitor the patient's response to cancer therapy and to detect local progression and early recurrence of prostate cancer. The combination of DRE and PSA testing appears to be a cost-effective method for detecting prostate cancer. The American Cancer Society recommends that, beginning at age 50, an annual DRE and PSA measurement be offered to men who have a life expectancy of at least 10 years and to younger men (age 45 years or older) who are at high risk. Risk factors include strong familial predisposition (two or more affected primary relatives) and African American race (Smith et al., 2000).

Transrectal ultrasound (TRUS) studies are indicated for men who have elevated PSA levels and abnormal DRE findings. TRUS studies help in detecting nonpalpable prostate cancers and assist with staging localized prostate cancer. Needle biopsies of the prostate are commonly guided by TRUS.

Other tests include bone scans to detect metastatic bone disease, skeletal x-rays to identify bone metastases, excretory urography to detect changes caused by ureteral obstruction, renal function tests, and computed tomography (CT) scans or lymphangiography to identify metastases in the pelvic lymph nodes.

The radiolabeled monoclonal antibody Capromab Penderide with Indium-111 (ProstaScint) is an antibody that is attracted to the prostate-specific membrane antigen found on prostate cancer cells (Narayan et al., 2000). The radioactive element attached to the antibody is then visible with scanning, allowing detection of disease spread. This study is used to detect spread of prostate cancer in the lymph nodes or other parts of the body in newly diagnosed men who have apparently localized prostate cancer and who are thought to be at high risk for metastasis. In addition, men who have undergone a prostatectomy and who develop a rising PSA level may also be evaluated with this study.

## Sexual Complications

Men with prostate cancer commonly experience sexual dysfunction before the diagnosis is made. Each treatment (see discussion that follows) for prostate cancer further increases the incidence of sexual problems. With nerve-sparing radical prostatectomy, the chance of recovering erections is better for men who are younger and in whom both neurovascular bundles are spared. Hormonal therapy also affects the central nervous system mechanisms that mediate sexual desire and arousability.

Sildenafil (Viagra) has been found to be effective for treating erectile dysfunction in younger men after radical retropubic pros-

tatectomy, especially if the neurovascular bundles were preserved (Zagaja, Mhoon, Aikens et al., 2000). In addition, sildenafil can improve erectile function in men with partial or moderate erectile dysfunction following radiation therapy for localized prostate cancer (Zelevsky, 1999).

## Medical Management

Treatment is based on the stage of the disease and the patient's age and symptoms. Partin and associates (1997) combined PSA level with the clinical stage and pathologic grade of the tumor to create a nomogram to predict the pathologic stage of localized prostate cancer. This nomogram can be useful in making treatment decisions and predicting treatment outcomes. Nursing care of the patient with cancer of the prostate is summarized in the Plan of Nursing Care.

## SURGICAL MANAGEMENT

A radical prostatectomy (removal of the prostate and seminal vesicles) remains the standard surgical procedure for patients who have early-stage, potentially curable disease and a life expectancy of 10 years or more (Carroll et al., 2001). Sexual impotence follows radical prostatectomy, and 5% to 10% of patients have various degrees of urinary incontinence (Bishoff, Motley, Optenberg et al., 1998).

## RADIATION THERAPY

If prostate cancer is detected in its early stage, the treatment may be curative radiation therapy: either teletherapy with a linear accelerator or interstitial irradiation (implantation of radioactive seeds of iodine or palladium), also referred to as brachytherapy (Carroll et al., 2001). Teletherapy involves about 6 to 7 weeks of daily (5 days/week) radiation treatments. Interstitial seed implantation is performed under anesthesia. About 80 to 100 seeds are placed with ultrasound guidance, and the patient returns home after the procedure. Exposure of others to radiation is minimal, but close contact with pregnant women and infants should be avoided for up to 2 months. Radiation safety guidelines include straining urine for seeds and using a condom during sexual intercourse for 2 weeks after implantation to catch seeds that may pass through the urethra.

Side effects, which usually are transitory, include inflammation of the rectum, bowel, and bladder (proctitis, enteritis, and cystitis) due to their proximity to the prostate and the radiation doses (Horwitz & Hanks, 2000; Krumholz et al., 2000; Ragde, Grado, Nadir et al., 2000). Irritation of the bladder and urethra from radiation therapy can cause pain with urination and during ejaculation until the irritation subsides. There is a greater preservation of sexual potency, however, with radiation therapy than with surgery. For locally advanced prostate cancer, hormonal treatments before and during radiation therapy are frequently used to improve local control and disease-free survival (Lue, 2000).

## HORMONAL THERAPY

Hormonal therapy is one method used to control rather than cure prostate cancer (Carroll et al., 2001). In the early 1940s, it was determined that most prostate cancers were androgen-dependent and could be controlled by androgen withdrawal. Hormonal therapy for advanced prostate cancer suppresses androgenic stimuli to the prostate by decreasing the circulating plasma testosterone levels or interrupting the conversion to or

(continued)

## Plan of Nursing Care

### The Patient With Prostate Cancer (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Deficient knowledge related to the diagnosis of: cancer, urinary difficulties, and treatment modalities

**Goal:** Understanding of the diagnosis and ability to care for self

1. Encourage communication with the patient.	1. This is designed to establish rapport and trust.	• Discusses his concerns and problems freely
2. Review the anatomy of the involved area.	2. Orientation to one's anatomy is basic to understanding its function.	• Asks questions and shows interest in his condition
3. Be specific in selecting information that is relevant to the patient's particular treatment plan.	3. This is based on the treatment plan; as it varies with each patient, individualization is desirable.	• Describes activities that help or hinder recovery
4. Identify ways to reduce pressure on the operative area after prostatectomy:	4. This is to prevent bleeding; such precautions are in order for 6 to 8 weeks post-operatively.	• Identifies ways of attaining/maintaining bladder control
a. Avoid prolonged sitting (in a chair, long automobile rides), standing, walking.		• Demonstrates satisfactory technique and understanding of catheter care
b. Avoid straining, such as during exercises, bowel movement, lifting, and sexual intercourse.		• Lists signs and symptoms that must be reported should they occur
5. Familiarize patient with ways of attaining/maintaining bladder control.	5. These measures will help control frequency and dribbling and aid in preventing retention.	
a. Encourage urination every 2 to 3 hours; discourage voiding when supine.	a. By sitting or standing, patient is more likely to empty his bladder.	
b. Avoid drinking cola and caffeine beverages; urge a cutoff time in the evening for drinking fluids to minimize frequent voiding during the night.	b. Spacing the kind and amount of liquid intake will help to prevent frequency.	
c. Describe perineal exercises to be performed every hour.	c. Exercises will assist him in starting and stopping the urinary stream.	
d. Develop a schedule with patient that will fit into his routine.	d. A schedule will assist in developing a workable pattern of normal activities.	
6. Demonstrate catheter care; encourage his questions; stress the importance of position of urinary receptacle.	6. By requiring a return demonstration of care, collection, and emptying of the device, he will become more independent and also can prevent backflow of urine, which can lead to infection.	

**Nursing Diagnosis:** Imbalanced nutrition: less than body requirements related to decreased oral intake because of anorexia, nausea, and vomiting caused by cancer or its treatment

**Goal:** Maintain optimal nutritional status

1. Assess the amount of food eaten.	1. This assessment will help determine nutrient intake.	• Responds positively to his favorite foods
2. Routinely weigh patient.	2. Weighing the patient on the same scale under similar conditions can help monitor changes in weight.	• Assumes responsibility for his oral hygiene
3. Elicit patient's explanation of why he is unable to eat more.	3. His explanation may present easily corrected practices.	• Notes increase in weight after improved appetite
4. Cater to his individual food preferences (eg, avoiding foods that are too spicy or too cold).	4. He will be more likely to consume larger servings if food is palatable and appealing.	
5. Recognize effect of medication or radiation therapy on appetite.	5. Many chemotherapeutic agents and radiation therapy promote anorexia.	

(continued)

## Plan of Nursing Care

### The Patient With Prostate Cancer (Continued)

Nursing Interventions	Rationale	Expected Outcomes
6. Inform patient that alterations in taste can occur.  7. Use measures to control nausea and vomiting: a. Administer prescribed antiemetics, around the clock if necessary. b. Provide oral hygiene after vomiting episodes. c. Provide rest periods after meals. 8. Provide frequent small meals and a comfortable and pleasant environment. 9. Assess patient's ability to obtain and prepare foods.	6. Aging and the disease process can reduce taste sensitivity. In addition, smell and taste can be altered as a result of the body's absorption of byproducts of cellular destruction (brought on by malignancy and its treatment).  7. Prevention of nausea and vomiting can stimulate appetite.  8. Smaller portions of food are less overwhelming to the patient. 9. Disability or lack of social support can hinder the patient's ability to obtain and prepare foods.	

**Nursing Diagnosis:** Sexual dysfunction related to effects of therapy: chemotherapy, hormonal therapy, radiation therapy, surgery

**Goal:** Ability to resume/enjoy modified sexual functioning

1. Determine from nursing history what effect patient's medical condition is having on his sexual functioning. 2. Inform patient of the effects of prostate surgery, orchiectomy (when applicable), chemotherapy, irradiation, and hormonal therapy on sexual function. 3. Include his partner in developing understanding and in discovering alternative, satisfying close relations with each other.	1. Usually decreased libido and, later, impotence may be experienced. 2. Treatment modalities may alter sexual function, but each is evaluated separately with regard to its effect on a particular patient. 3. Often the bonds between a couple are strengthened with new appreciation and support that had not been evident before the current illness.	<ul style="list-style-type: none"> <li>• Describes the reasons for changes in sexual functioning</li> <li>• Discusses with appropriate health care personnel alternative approaches and methods of sexual expression</li> <li>• Includes partner in discussions related to changes in sexual function</li> </ul>
--	---	--

**Nursing Diagnosis:** Pain related to progression of disease and treatment modalities

**Goal:** Relief of pain

1. Evaluate nature of patient's pain, its location and intensity using pain rating scale.  2. Avoid activities that aggravate or worsen pain. 3. Because pain is usually related to bone metastasis, ensure that patient's bed has a bed board on a firm mattress. Also, protect the patient from falls/injuries. 4. Provide support for affected extremities.  5. Prepare patient for radiation therapy if prescribed. 6. Administer analgesics or opioids at regularly scheduled intervals as prescribed.  7. Initiate bowel program to prevent constipation.	1. Determining nature and causes of pain and its intensity helps to select proper relief modality and provide baseline for later comparison. 2. Bumping the bed is an example of an action that can intensify the patient's pain. 3. This will provide added support and is more comfortable. Protecting the patient from injury protects him from additional pain. 4. More support, coupled with reduced movement of the part, helps in pain control. 5. Radiation therapy may be effective in controlling pain. 6. Analgesics alter perception of pain and provide comfort. Regularly scheduled analgesics around the clock rather than PRN provide more consistent pain relief. 7. Opioid analgesics and inactivity contribute to constipation.	<ul style="list-style-type: none"> <li>• Reports relief of pain</li> <li>• Expects exacerbations, reports their quality and intensity, and obtains relief</li> <li>• Uses pain relief strategies appropriately and effectively</li> <li>• Identifies strategies to avoid complications of analgesic use</li> </ul>

## Plan of Nursing Care

### The Patient With Prostate Cancer (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Impaired physical mobility and activity intolerance related to tissue hypoxia, malnutrition, and exhaustion and to spinal cord or nerve compression from metastases

**Goal:** Improved physical mobility

- |  |   |  |
|--|---|--|
| <ol style="list-style-type: none"> <li>1. Assess for factors causing limited mobility (eg, pain, hypercalcemia, limited exercise tolerance).</li> <li>2. Provide pain relief by administering prescribed medications.</li> <li>3. Encourage use of assistive devices: cane, walker.</li> <li>4. Involve significant others in helping patient with range-of-motion exercises, positioning, and walking.</li> <li>5. Provide positive reinforcement for achievement of small gains.</li> <li>6. Assess nutritional status.</li> </ol> | <ol style="list-style-type: none"> <li>1. This information offers clues to the cause; if possible, cause is treated.</li> <li>2. Analgesics/opioids allow the patient to increase his activity more comfortably.</li> <li>3. Support may offer the security needed to become mobile.</li> <li>4. Assistance from partner or others encourages patient to repeat activities and achieve goals.</li> <li>5. Encouragement stimulates improvement of performance.</li> <li>6. See Nursing Diagnosis: Imbalanced nutrition: less than body requirements.</li> </ol> | <ul style="list-style-type: none"> <li>• Achieves improved physical mobility</li> <li>• Relates that short-term goals are encouraging him because they are attainable</li> </ul> |
|--|---|--|

**Collaborative Problems:** Hemorrhage, infection, bladder neck obstruction

**Goal:** Absence of complications

- |  |   |   |
|--|---|---|
| <ol style="list-style-type: none"> <li>1. Alert the patient to changes that may occur (after discharge) and that need to be reported:               <ol style="list-style-type: none"> <li>a. Continued bloody urine; passing blood clots</li> <li>b. Pain; burning around the catheter</li> <li>c. Frequency of urination</li> <li>d. Diminished urinary output</li> <li>e. Increasing loss of bladder control</li> </ol> </li> </ol> | <ol style="list-style-type: none"> <li>1. Certain changes signal beginning complications, which call for nursing and medical interventions.               <ol style="list-style-type: none"> <li>a. Hematuria with or without blood clot formation may occur postoperatively.</li> <li>b. Indwelling urinary catheters may be a source of infections.</li> <li>c. Urinary frequency may be caused by urinary tract infections or by bladder neck obstruction, resulting in incomplete voiding.</li> <li>d. Bladder neck obstruction decreases the amount of urine that is voided.</li> <li>e. Urinary incontinence may be a result of urinary retention.</li> </ol> </li> </ol> | <ul style="list-style-type: none"> <li>• Experiences no bleeding or passage of blood clots</li> <li>• Reports no pain around the catheter</li> <li>• Experiences normal frequency or urination</li> <li>• Reports normal urinary output</li> <li>• Maintains bladder control</li> </ul> |
|--|---|---|

binding of dihydrotestosterone. As a result, the prostatic epithelium atrophies (decreases). This effect is accomplished either by **orchiectomy** (removal of the testes) or by the administration of medications.

Orchiectomy lowers plasma testosterone levels because about 93% of circulating testosterone is of testicular origin (7% is from the adrenal glands). As a result, the testicular stimulus required for continued prostatic growth is removed, resulting prostatic atrophy. Although orchiectomy does not cause the side effects associated with other hormonal therapies, it carries a significant emotional impact.

Estrogen therapy, usually in the form of diethylstilbestrol (DES), has long been used to inhibit the gonadotropins responsible for testicular androgenic activity, thereby removing the androgenic hormone that promotes the growth of the malignancy. DES relieves symptoms of advanced prostate cancer, reduces tumor size, decreases pain from metastatic nodules, and pro-

motes well-being. However, DES significantly increases the risk for thromboembolism, pulmonary embolism, myocardial infarction, and stroke. Other side effects of estrogen therapy include impotence, decreased libido, difficulty in achieving orgasm, decreased sperm production, and gynecomastia (enlargement of breasts in men).

Newer hormonal therapies include the luteinizing hormone-releasing hormone (LH-RH) agonists (leuprolide [Lupron] and goserelin [Zoladex]) and antiandrogen agents, such as flutamide (Eulexin). LH-RH suppresses testicular androgen, whereas flutamide causes adrenal androgen suppression (Carroll et al., 2001). Cyproterone acetate is a synthetic progesterone derivative that provides effective, competitive inhibition of androgens at the target cells. In contrast to estrogen, the newer hormonal agents are associated with a lower incidence of cardiovascular side effects, gynecomastia, and decreased sexual function. Hot flushing can occur with orchiectomy or LH-RH agonist therapy because these

agents increase hypothalamic activity, which stimulates the thermoregulatory centers of the body.

### OTHER THERAPIES

**Cryosurgery of the prostate** is used to ablate prostate cancer in patients who could not physically tolerate surgery or in those with recurrent prostate cancer. Transperineal probes are inserted into the prostate under ultrasound guidance to freeze the tissue directly. Chemotherapy, such as doxorubicin, cisplatin, and cyclophosphamide, may also be used.

Keeping the urethral passage patent may require repeated transurethral resections. When this is impractical, catheter drainage is instituted by way of the suprapubic or transurethral route.

For men with advanced prostate cancer, palliative measures are indicated. Although cure is unlikely with advanced prostate cancer, many men survive for long intervals apparently free of metastatic disease. If prostate cancer metastasizes to the bones, these bone lesions can be very painful. Opioid and nonopioid medications are used to control the pain. In addition, external-beam radiation therapy can be delivered to skeletal lesions to relieve pain. Radiopharmaceuticals, such as strontium-89 and samarium-153, can also be intravenously injected to treat multiple sites of bone metastases (Cherney, 2000). Antiandrogen therapies are used in an effort to reduce the circulating androgens. If antiandrogen therapies are not effective, medications such as prednisone and mitoxantrone have been effective in reducing pain and improving quality of life. With advanced prostate cancer, blood transfusions are administered to maintain adequate hemoglobin levels when bone marrow is replaced by tumor.

## THE PATIENT UNDERGOING PROSTATE SURGERY

Prostate surgery may be indicated for the patient with BPH or prostate cancer. The objectives before prostate surgery are to assess the patient's general health status and to establish optimal renal function. Prostate surgery should be performed before acute urinary retention develops and damages the upper urinary tract and collecting system or, in the case of prostate cancer, before cancer progresses.

### Surgical Procedures

Several approaches can be used to remove the hypertrophied portion of the prostate gland: transurethral resection of the prostate (TURP), suprapubic prostatectomy, perineal prostatectomy, retropubic prostatectomy, and transurethral incision of the prostate (TUIP) (Table 49-3). In these approaches, the surgeon removes all hyperplastic tissue, leaving behind only the capsule of the prostate. The transurethral approaches (TURP, TUIP) are closed procedures; the other three are open procedures (ie, a surgical incision is required). The procedure chosen depends on the underlying disorder, the patient's age and physical status, and patient preference.

#### TRANSURETHRAL RESECTION OF THE PROSTATE

TURP, the most common procedure used, can be carried out through endoscopy. The surgical and optical instrument is introduced directly through the urethra to the prostate, which can then be viewed directly. The gland is removed in small chips with an electrical cutting loop (Fig. 49-4A). This procedure, which requires no incision, may be used for glands of varying size and is

ideal for patients who have small glands and those who are considered poor surgical risks.

This approach usually requires an overnight hospital stay. Strictures are more frequent, and repeated procedures may be necessary because the residual prostatic tissue can grow back. TURP rarely causes erectile dysfunction, but it may cause retrograde ejaculation because removing the prostatic tissue at the bladder neck can cause the seminal fluid to flow backward into the bladder rather than forward through the urethra during ejaculation.

#### SUPRAPUBIC PROSTATECTOMY

Suprapubic prostatectomy is one method of removing the gland through an abdominal incision. An incision is made into the bladder, and the prostate gland is removed from above (see Fig. 49-4B). Such an approach can be used for a gland of any size, and few complications occur, although blood loss may be greater than with the other methods. Another disadvantage is the need for an abdominal incision, with the concomitant hazards of any major abdominal surgical procedure.

#### PERINEAL PROSTATECTOMY

Perineal prostatectomy involves removing the gland through an incision in the perineum (see Fig. 49-4C). This approach is practical when other approaches are not possible and is useful for an open biopsy. Postoperatively, the wound may easily become contaminated because the incision is near the rectum. Incontinence, impotence, and rectal injury are more likely with this approach.

#### RETROPUBIC PROSTATECTOMY

Retropubic prostatectomy, another technique, is more common than the suprapubic approach. The surgeon makes a low abdominal incision and approaches the prostate gland between the pubic arch and the bladder without entering the bladder (see Fig. 49-4D). This procedure is suitable for large glands located high in the pelvis. Although blood loss can be better controlled and the surgical site is easier to visualize, infections can readily start in the retropubic space.

#### TRANSURETHRAL INCISION OF THE PROSTATE

Transurethral incision of the prostate (TUIP) is another procedure used in treating BPH. An instrument is passed through the urethra (see Fig. 49-4E). One or two incisions are made in the prostate and prostate capsule to reduce the prostate's pressure on the urethra and to reduce urethral constriction. TUIP is indicated when the prostate gland is small (30 g or less) and is an effective treatment for many cases of BPH. TUIP can be performed on an outpatient basis and has a lower complication rate than other invasive prostate procedures (Mebust, 1998).

#### LAPAROSCOPIC RADICAL PROSTATECTOMY

Laparoscopic radical prostatectomy is a method recently developed in France. Although not yet widespread in the United States, it is anticipated that this procedure will be widely used in place of more extensive surgery for patients with localized prostate cancer. The laparoscopic approach provides better visualization of the surgical site and surrounding areas. Preliminary data suggest that patients who undergo this procedure have less bleeding and reduced need for blood transfusion, a shorter hospital stay, less postoperative pain, and more rapid return to normal activity compared to open radical prostatectomy (Rassweiler, Sentker, Seemann et al., 2001). Further research is needed to assess long-term outcomes.

## Complications

Complications depend on the type of prostatectomy performed and may include hemorrhage, clot formation, catheter obstruction, and sexual dysfunction. All prostatectomies carry a risk of impotence because of potential damage to the pudendal nerves. In most instances, sexual activity may be resumed in 6 to 8 weeks, the time required for the prostatic fossa to heal. During ejaculation, the seminal fluid goes into the bladder and is excreted with the urine. (The anatomic changes in the posterior urethra lead to retrograde ejaculation.) A vasectomy may be performed during surgery to prevent infection from spreading from the prostatic urethra through the vas and into the epididymis.

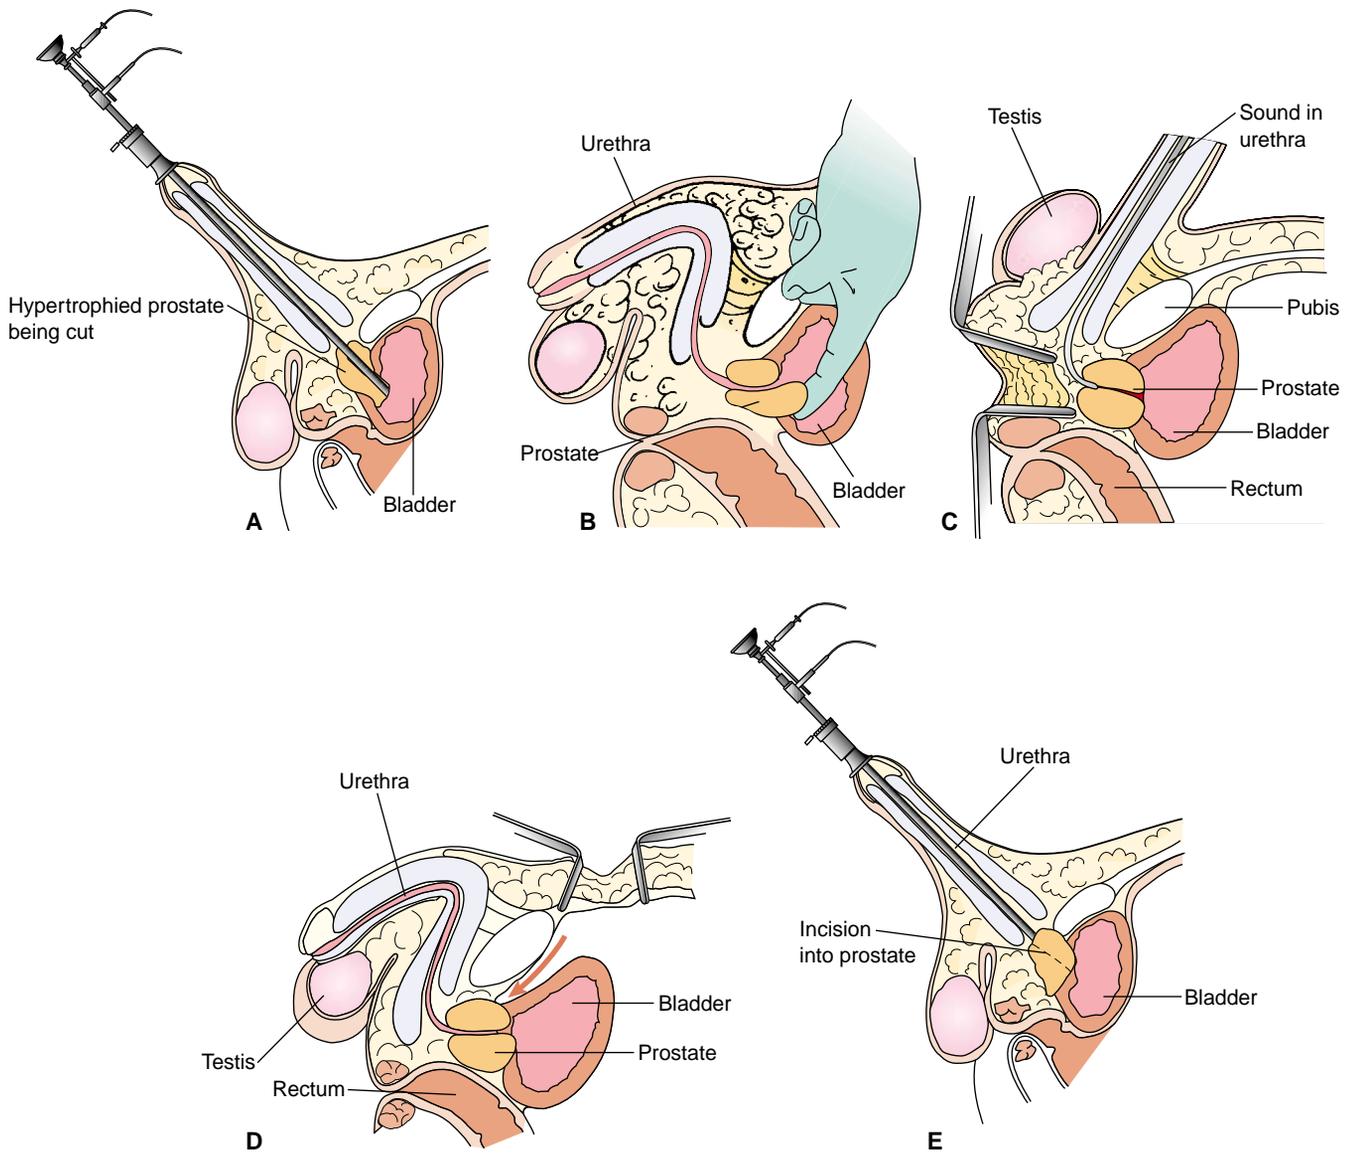

After total prostatectomy (usually for cancer), impotence almost always results. For the patient who does not want to give up sexual activity, options are available to produce erections sufficient for sexual intercourse: prosthetic penile implants, negative-pressure (vacuum) devices, and pharmacologic interventions (see earlier discussion in this chapter).

## NURSING PROCESS: THE PATIENT UNDERGOING PROSTATECTOMY

### Assessment

The nurse assesses how the underlying disorder (BPH or prostate cancer) has affected the patient's lifestyle. Has he been reasonably active for his age? What is his presenting urinary problem (described in his own words)? Has he experienced decreased force of urinary flow, decreased ability to initiate voiding, urgency, frequency, nocturia, dysuria, urinary retention, hematuria? Does the patient report associated problems, such as back pain, flank pain, and lower abdominal or suprapubic discomfort? If he reports such discomfort, possible causes include infection, retention, and renal colic. Has he experienced erectile dysfunction or changes in frequency or enjoyment of sexual activity?

The nurse obtains further information about the patient's family history of cancer and heart or kidney disease, including

**FIGURE 49-4** Prostate surgery procedures. (A) Transurethral resection (TUR). A loop of wire connected with a cutting current is rotated in the cystoscope to remove shavings of prostate at the bladder orifice. (B) Suprapubic prostatectomy. With an abdominal approach, the prostate is shelled out of its bed. (C) Perineal prostatectomy. Two retractors on the left spread the perineal incision to provide a view of the prostate. (D) Retropubic prostatectomy is performed through a low abdominal incision. Note two abdominal retractors and *arrow* pointing to the prostate gland. (E) Transurethral incision of prostate (TUIP) involves one or two incisions into the prostate to reduce pressure on the urethra.

hypertension. Has he lost weight? Does he appear pale? Can he raise himself out of bed and return to bed without assistance? Can he perform usual activities of daily living? This information will help in determining how soon he will return to normal activities after prostatectomy.

## Diagnosis

Based on the assessment data, the patient's major nursing diagnoses may include the following.

### PREOPERATIVE NURSING DIAGNOSES

- Anxiety about surgery and its outcome
- Acute pain related to bladder distention
- Deficient knowledge about factors related to the disorder and the treatment protocol

### POSTOPERATIVE NURSING DIAGNOSES

- Acute pain related to the surgical incision, catheter placement, and bladder spasms
- Deficient knowledge about postoperative care and management

### COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Based on the assessment data, the potential complications may include the following:

- Hemorrhage and shock
- Infection
- Deep vein thrombosis
- Catheter obstruction
- Sexual dysfunction

## Planning and Goals

The major preoperative goals for the patient may include reduced anxiety and learning about his prostate disorder and the perioperative experience. The major postoperative goals may include maintenance of fluid volume balance, relief of pain and discomfort, ability to perform self-care activities, and absence of complications.

## Preoperative Nursing Interventions

### REDUCING ANXIETY

The patient is frequently admitted to the hospital on the morning of surgery. Because contact with the patient may be limited before surgery, the nurse must establish communication with the patient to assess his understanding of the diagnosis and of the planned surgical procedure. The nurse clarifies the nature of the surgery and expected postoperative outcomes. In addition, the nurse familiarizes the patient with the pre- and postoperative routines and initiates measures to reduce anxiety. Because the patient may be sensitive and embarrassed discussing problems related to the genitalia and sexuality, the nurse provides privacy and establishes a trusting and professional relationship. Guilt feelings often surface if the patient falsely assumes a cause-and-effect relationship between sexual practices and his current problems. He is encouraged to verbalize his feelings and concerns.

### RELIEVING DISCOMFORT

If discomfort is present before the day of surgery, the patient is placed on bed rest, analgesic agents are administered, and measures to relieve anxiety are initiated. If the patient is hospitalized, the nurse monitors the patient's voiding patterns, watches for bladder distention, and assists with catheterization if indicated. An indwelling catheter is inserted if the patient has continuing urinary retention or if laboratory test results indicate azotemia (accumulation of nitrogenous waste products in the blood). The catheter can help to decompress the bladder gradually over several days, especially if the patient is elderly and hypertensive and has diminished renal function or an excessive amount of urinary retention that has existed for many weeks. For a few days after the bladder begins draining, the blood pressure may fluctuate and renal function may decline. If the patient cannot tolerate a urinary catheter, he is prepared for a cystostomy (see Chaps. 44 and 45).

### PROVIDING INSTRUCTION

Before surgery, the nurse reviews with the patient the anatomy of the affected parts and their function in relation to the urinary and reproductive system, using diagrams and other teaching aids if indicated. This is often done either during the preadmission testing visit or in the urologist's office. The nurse explains what will take place as the patient is prepared for diagnostic tests and then for surgery (depending on the kind of prostatectomy planned). The nurse describes the type of incision, which varies with the type of surgical approach (directly over the bladder, low on the abdomen, or in the perineal area; in the case of a transurethral procedure, no incision will be made). The patient is informed about the type of urinary drainage system that is expected, the type of anesthesia, and the recovery room procedure. The amount of information given is based on the patient's needs and questions. Procedures expected during the immediate perioperative period are explained, questions are answered, and support is provided. In addition, the patient is instructed about postoperative use of medications for pain management.

## PREPARING THE PATIENT

When the patient is scheduled for a prostatectomy, the preoperative preparation described in Chapter 18 is provided. Elastic compression stockings are applied before surgery and are particularly important for prevention of deep vein thrombosis if the patient is placed in a lithotomy position during surgery. An enema is usually administered at home the evening before surgery or the morning of surgery to prevent postoperative straining, which can induce bleeding.

## Postoperative Nursing Interventions

### MAINTAINING FLUID BALANCE

During the postoperative period, the patient is at risk for imbalanced fluid volume because of the irrigation of the surgical site during and after surgery. With irrigation of the urinary catheter to prevent its obstruction by blood clots, fluid may be absorbed through the open surgical site and retained, increasing the risk for excessive fluid retention, fluid imbalance, and water intoxication. The urine output and the amount of fluid used for irrigation must be closely monitored to determine if irrigation fluid is being retained and to ensure an adequate urine output. The patient also is monitored for electrolyte imbalances (ie, hyponatremia), rising blood pressure, confusion, and respiratory distress. The risk for fluid and electrolyte imbalance is increased in elderly patients with preexisting cardiovascular or respiratory disease. These signs and symptoms are documented and reported to the surgeon.

### RELIEVING PAIN

After a prostatectomy, the patient is assisted to sit and dangle his legs over the side of the bed on the day of surgery. The next morning, he is assisted to ambulate. If pain occurs, the cause and location are determined. It may be related to the incision or may be the result of excoriation of the skin at the catheter site. It may be in the flank area, indicating a kidney problem, or it may be due to bladder spasms. Bladder irritability can initiate bleeding and result in clot formation, leading to urinary retention.

Patients experiencing bladder spasms may note an urgency to void, a feeling of pressure or fullness in the bladder, and bleeding from the urethra around the catheter. Medications that relax the smooth muscles can help to ease the spasms, which can be intermittent and severe; these medications include flavoxate (Urispas) and oxybutynin (Ditropan). Warm compresses to the pubis or sitz baths may also relieve the spasms.

The nurse monitors the drainage tubing and irrigates the system as prescribed to relieve any obstruction that may cause discomfort. Usually, the catheter is irrigated with 50 mL of irrigating fluid at a time. It is important to make sure that the same amount is recovered in the drainage receptacle. Securing the catheter drainage tubing to the leg or abdomen can help to decrease tension on the catheter and prevent bladder irritation. Discomfort may be caused by dressings that are too snug, saturated with drainage, or improperly placed. Analgesic agents are administered as prescribed.

When ambulatory, the patient is encouraged to walk but not to sit for prolonged periods because this increases intra-abdominal pressure and the possibility of discomfort and bleeding. Prune juice and stool softeners are provided to ease bowel movements and to prevent excessive straining. An enema, if prescribed, is administered with caution to avoid rectal perforation.

## MONITORING AND MANAGING POTENTIAL COMPLICATIONS

After prostatectomy, the patient is monitored for major complications such as hemorrhage, infection, deep vein thrombosis, catheter obstruction, and sexual dysfunction.

### Hemorrhage

The immediate dangers after a prostatectomy are bleeding and hemorrhagic shock. This risk is increased with BPH because a hyperplastic prostate gland is very vascular. Bleeding may occur from the prostatic bed. Bleeding may also result in the formation of clots, which then obstruct urine flow. The drainage normally begins as reddish-pink and then clears to a light pink within 24 hours after surgery. Bright-red bleeding with increased viscosity and numerous clots usually indicates arterial bleeding. Venous blood appears darker and less viscous. Arterial hemorrhage usually requires surgical intervention (eg, suturing of bleeders or transurethral coagulation of bleeding vessels), whereas venous bleeding may be controlled by applying prescribed traction to the catheter so that the balloon holding the catheter in place applies pressure to the prostatic fossa. The surgeon applies traction by securely taping the catheter to the patient's thigh.

Nursing management includes strategies to stop the bleeding and to prevent or reverse hemorrhagic shock. If blood loss is extensive, fluids and blood component therapy may be administered. If hemorrhagic shock occurs, treatments described in Chapter 15 are initiated.

Nursing interventions include close monitoring of vital signs; administering medications, intravenous fluids, and blood component therapy as prescribed; maintaining an accurate record of intake and output; and careful monitoring of drainage to ensure adequate urine flow and patency of the drainage system. The patient who experiences hemorrhage and his family are often anxious and benefit from explanations and reassurance about the event and the procedures that are performed.

### Infection

After perineal prostatectomy, the surgeon usually changes the dressing on the first postoperative day. Further dressing changes may become the nurse's responsibility. Careful aseptic technique is used because the possibility for infection is great. Dressings can be held in place by a double-tailed, T-binder bandage or a padded athletic supporter. The tails cross over the incision to give double thickness, and then each tail is drawn up on either side of the scrotum to the waistline and fastened.

Rectal thermometers, rectal tubes, and enemas are avoided because of the risk for injury to and bleeding in the prostatic fossa. After the perineal sutures are removed, the perineum is cleansed as indicated. A heat lamp may be directed to the perineal area to promote healing. The scrotum is protected with a towel while the heat lamp is in use. Sitz baths are also used to promote healing.

Urinary tract infections and epididymitis are possible complications after prostatectomy. The patient is assessed for their occurrence; if they occur, the nurse administers antibiotics as prescribed.

Because the risk for infection continues after discharge from the hospital, the patient and family need to be instructed to monitor for signs and symptoms of infection (fever, chills, sweats, myalgias, dysuria, urinary frequency, and urgency). The patient and family are instructed to contact the urologist if these symptoms occur.

### Deep Vein Thrombosis

Because patients undergoing prostatectomy have a high incidence of deep vein thrombosis (DVT) and pulmonary embolism, the

physician may prescribe prophylactic (preventive) low-dose heparin therapy. The nurse assesses the patient frequently after surgery for manifestations of DVT and applies elastic compression stockings to reduce the risk for DVT and pulmonary embolism. Nursing and medical management of DVT and pulmonary embolism are detailed in Chapters 31 and 23, respectively. The patient who is receiving heparin must be closely monitored for excessive bleeding.

### Obstructed Catheter

After a TUR, the catheter must drain well; an obstructed catheter produces distention of the prostatic capsule and resultant hemorrhage. Furosemide (Lasix) may be prescribed to promote urination and initiate postoperative diuresis, thereby helping to keep the catheter patent.

The nurse observes the lower abdomen to ensure that the catheter has not become blocked. An overdistended bladder presents a distinct, rounded swelling above the pubis.

The drainage bag, dressings, and incisional site are examined for bleeding. The color of the urine is noted and documented; a change in color from pink to amber indicates reduced bleeding. Blood pressure, pulse, and respirations are monitored and compared with baseline preoperative vital signs to detect hypotension. The nurse also observes the patient for restlessness, cold sweats, pallor, any drop in blood pressure, and an increasing pulse rate.

Drainage of the bladder may be accomplished by gravity through a closed sterile drainage system. A three-way drainage system is useful in irrigating the bladder and preventing clot formation (Fig. 49-5). Continuous irrigation may be used with TUR. Some urologists leave an indwelling catheter attached to a dependent drainage system. Gentle irrigation of the catheter may be prescribed to remove any obstructing clots.

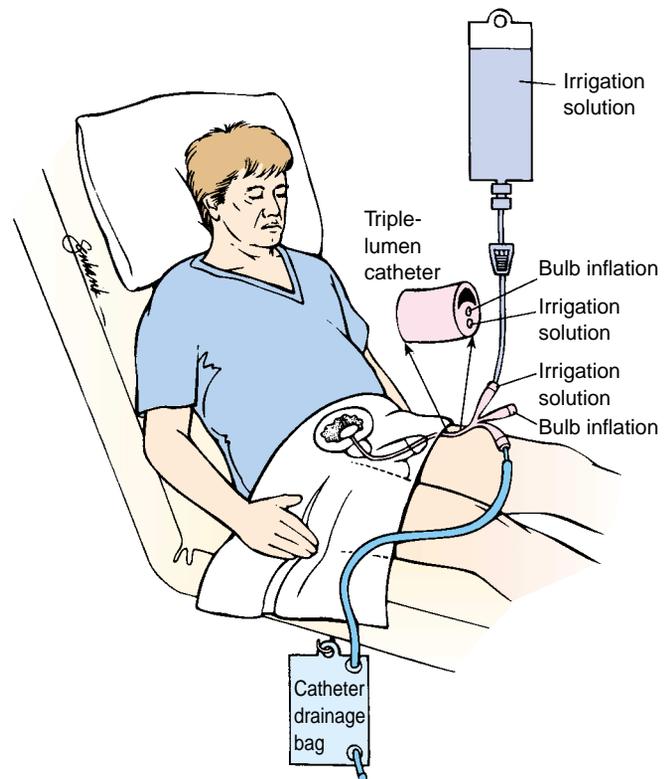

FIGURE 49-5 A three-way system for bladder irrigation.

If the patient complains of pain, the tubing is examined. The drainage system is irrigated, if indicated and prescribed, to clear any obstruction. Usually, the catheter is irrigated with 50 mL of irrigating fluid at a time. The amount of fluid recovered in the drainage bag must equal the amount of fluid injected. Overdistention of the bladder is avoided because it can induce secondary hemorrhage by stretching the coagulated blood vessels in the prostatic capsule.

The nurse maintains an intake and output record, including the amount of fluid used for irrigation.

The drainage tube (not the catheter) is taped to the shaved inner thigh to prevent traction on the bladder. If a cystostomy catheter is in place, it is taped to the abdomen. The nurse explains the purpose of the catheter to the patient and assures him that the urge to void results from the presence of the catheter and from bladder spasms. He is cautioned not to pull on the catheter because this causes bleeding and subsequent catheter blockage, which leads to urinary retention.

### Complications With Catheter Removal

After the catheter is removed (usually when the urine appears clear), urine may leak around the wound for several days in patients who have undergone perineal, suprapubic, and retropubic surgery. The cystostomy tube may be removed before or after the urethral catheter is removed. Some urinary incontinence may occur after catheter removal, and the patient is informed that this is likely to subside in time.

### Sexual Dysfunction

Depending on the type of surgery, the patient may experience sexual dysfunction related to erectile dysfunction, decreased libido, and fatigue. These issues may become a concern of the patient soon after surgery or in the weeks to months during rehabilitation. Erectile dysfunction may occur following prostate surgery. Several options to restore erectile function are discussed with the patient by the surgeon or urologist. These options may include medications, surgically placed implants, or negative-pressure devices. A decrease in libido may also occur following surgery and is usually related to the impact of the surgery on the man's body. Reassurance that the usual level of libido will return following recuperation from surgery is often helpful to the patient and his partner. The patient may also experience fatigue during rehabilitation from surgery. This fatigue may also decrease his libido and alter his enjoyment of usual activities.

Nursing interventions include assessing for the presence of sexual dysfunction following surgery. Providing a private and confidential environment to discuss issues of sexuality is important. The emotional challenges of prostate surgery and its consequences need to be carefully explored with the patient and his partner. Providing the opportunity to discuss these issues can be very beneficial to the patient. For patients who demonstrate significant problems adjusting to their sexual dysfunction, a referral to a sex therapist may be indicated.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

The patient undergoing prostatectomy may be discharged within several days. The length of the hospital stay depends on the type of prostatectomy performed. Patients undergoing a perineal prostatectomy are hospitalized for 3 to 5 days. If a retropubic or suprapubic prostatectomy is performed, the hospital stay is 5 to 7 days. The patient and family require instructions about how to

manage the drainage system, how to assess for complications, and how to promote recovery. Verbal and written instructions are provided about the need to maintain the drainage system and to monitor urinary output, about wound care, and about strategies to prevent complications, such as infection, bleeding, and thrombosis. They are informed about signs and symptoms that should be reported to the physician (eg, blood in urine, decreased urine output, fever, change in wound drainage, calf tenderness).

As the patient recovers and drainage tubes are removed, he may become discouraged and depressed because he cannot regain bladder control immediately. Moreover, urinary frequency and burning may occur after the catheter is removed. Teaching the following exercises may help the patient regain urinary control:

- Tense the perineal muscles by pressing the buttocks together; hold this position; relax. This exercise can be performed 10 to 20 times each hour while sitting or standing.
- Try to interrupt the urinary stream after starting to void; wait a few seconds and then continue to void.

Perineal exercises should continue until the patient gains full urinary control. The patient is instructed to urinate as soon as he feels the first urge to do so. It is important for the patient to know that regaining urinary control is a gradual process; he may continue to “dribble” after being discharged from the hospital, but the dribbling should gradually diminish (within up to 1 year). Lining underwear with absorbent pads can help to minimize embarrassing stains on clothing. The urine may be cloudy for several weeks after surgery but should clear as the prostate area heals.

While the prostatic fossa heals (6 to 8 weeks), the patient should avoid activities that produce Valsalva effects (straining at stool, heavy lifting) because this increases venous pressure and may produce hematuria. He should avoid long motor trips and strenuous exercise, which increase the tendency to bleed. He should also know that spicy foods, alcohol, and coffee may cause bladder discomfort. The patient is cautioned to drink enough fluids to avoid dehydration, which increases the tendency for a blood clot to form and obstruct the flow of urine. Signs of complications, such as bleeding, passage of blood clots, a decrease in the urinary stream, urinary retention, or urinary tract infection symptoms, should be reported to the physician (Chart 49-3).

### Continuing Care

Referral for home care may be indicated if the patient is elderly or has other health problems, if the patient and family cannot provide care in the home, or if the patient lives alone without available supports. The home care nurse assesses the patient's physical status (cardiovascular and respiratory status, fluid and nutritional status), patency of the urinary drainage system, wound and nutritional status) and provides catheter and wound care, if indicated. The nurse reinforces previous teaching and assesses the ability of the patient and family to manage required care. The home care nurse encourages the patient to ambulate and to carry out perineal exercises as prescribed. The patient may need to be reminded that return of bladder control may take time.

The patient is reminded about the importance of participating in routine health screening and other health promotion activities. If the prostatectomy was performed to treat prostate cancer, the patient and family are also instructed about the importance of follow-up and monitoring with the physician.

Chart 49-3

## Home Care Checklist • Postprostatectomy Care

At the completion of the home care instruction, the patient or caregiver will be able to:

- Demonstrate appropriate measures to control postoperative pain and discomfort
- Demonstrate appropriate care of urinary catheter and collection receptacle
- Demonstrate appropriate wound care
- Demonstrate performance of perineal muscle exercises to facilitate bladder control
- Demonstrate increased activity and ambulation
- Identify activities to avoid, such as lifting heavy objects
- Identify signs and symptoms of complications that should be reported to surgeon

	Patient	Caregiver
• Demonstrate appropriate measures to control postoperative pain and discomfort	✓	✓
• Demonstrate appropriate care of urinary catheter and collection receptacle	✓	✓
• Demonstrate appropriate wound care	✓	✓
• Demonstrate performance of perineal muscle exercises to facilitate bladder control	✓	
• Demonstrate increased activity and ambulation	✓	
• Identify activities to avoid, such as lifting heavy objects	✓	✓
• Identify signs and symptoms of complications that should be reported to surgeon	✓	✓

## Evaluation

### EXPECTED PREOPERATIVE PATIENT OUTCOMES

Expected preoperative patient outcomes may include:

1. Demonstrates reduced anxiety
2. States that pain and discomfort are decreased
3. Relates understanding of the surgical procedure and postoperative course and practices perineal muscle exercises and other techniques useful in facilitating bladder control

### EXPECTED POSTOPERATIVE PATIENT OUTCOMES

Expected postoperative patient outcomes may include:

1. Relates relief of discomfort
2. Exhibits fluid and electrolyte balance
  - a. Irrigation fluid and urinary output are within parameters determined by surgeon.
  - b. Experiences no signs or symptoms of fluid retention
3. Participates in self-care measures
  - a. Increases activity and ambulation daily
  - b. Produces urine output within normal ranges and consistent with intake
  - c. Performs perineal exercises and interrupts urinary stream to promote bladder control
  - d. Avoids straining and lifting heavy objects
4. Is free of complications
  - a. Maintains vital signs within normal limits
  - b. Exhibits wound healing, without signs of inflammation or hemorrhage
  - c. Maintains acceptable level of urinary elimination
  - d. Maintains optimal drainage of catheter and other drainage tubes
  - e. Reports understanding of changes in sexual function

## Conditions Affecting the Testes and Adjacent Structures

### UNDESCENDED TESTIS (CRYPTORCHIDISM)

**Cryptorchidism** is a congenital condition characterized by failure of one or both of the testes to descend into the scrotum. One or both testes may be absent. The testis may be located in the abdominal cavity or inguinal canal. If the testis does not descend as the boy matures, a surgical procedure known as orchiopexy is performed to position it properly. An incision is made over the in-

guinal canal, and the testis is brought down and anchored in the scrotum.

### ORCHITIS

**Orchitis** is an inflammation of the testes (testicular congestion) caused by pyogenic, viral, spirochetal, parasitic, traumatic, chemical, or unknown factors. Mumps is one such factor. Mumps vaccination is recommended for postpubertal men who have not been infected. When postpubertal men contract mumps, about one in five develops some form of orchitis 4 to 7 days after the jaw and neck swell. The testis may show some atrophy. In the past, sterility and impotence often resulted. Today, a man who has never had mumps and who is exposed to the disease receives gamma-globulin immediately; the disease is likely to be less severe, with minimal or no complications.

### Medical Management

If the cause of orchitis is bacterial, viral, or fungal, therapy is directed at the specific infecting organism. Rest, elevation of the scrotum, ice packs to reduce scrotal edema, antibiotics, analgesic agents, and anti-inflammatory medications are recommended.

### EPIDIDYMITIS

**Epididymitis** is an infection of the epididymis that usually descends from an infected prostate or urinary tract. It may also develop as a complication of gonorrhea. In men younger than age 35, the major cause of epididymitis is *Chlamydia trachomatis*. The infection passes upward through the urethra and the ejaculatory duct and then along the vas deferens to the epididymis.

The patient complains of unilateral pain and soreness in the inguinal canal along the course of the vas deferens and then develops pain and swelling in the scrotum and the groin. The epididymis becomes swollen and extremely painful; the patient's temperature is elevated. The urine may contain pus (pyuria) and bacteria (bacteriuria), and the patient may experience chills and fever.

### Medical Management

If the patient is seen within the first 24 hours after onset of pain, the spermatic cord may be infiltrated with a local anesthetic agent to relieve pain. If the epididymitis is from a chlamydial infection, the patient and his sexual partner must be treated with antibiotics. The patient is observed for abscess formation as well. If no

improvement occurs within 2 weeks, an underlying testicular tumor should be considered. An epididymectomy (excision of the epididymis from the testis) may be performed for patients with recurrent, incapacitating episodes of epididymitis or for those with chronic, painful conditions. With long-term epididymitis, the passage of sperm may be obstructed. If the obstruction is bilateral, infertility may result.

### Nursing Management

The patient is placed on bed rest, and the scrotum is elevated with a scrotal bridge or folded towel to prevent traction on the spermatic cord and to promote venous drainage and relieve pain. Anti-microbial agents are administered as prescribed until the acute inflammation subsides. Intermittent cold compresses to the scrotum may help ease the pain. Later, local heat or sitz baths may help resolve the inflammation. Analgesic medications are administered for pain relief as prescribed.

The nurse instructs the patient to avoid straining, lifting, and sexual stimulation until the infection is under control. He should continue taking analgesic agents and antibiotics as prescribed and using ice packs if necessary to relieve discomfort. He needs to know that it may take 4 weeks or longer for the epididymis to return to normal.

## TESTICULAR CANCER

**Testicular cancer** is the most common cancer in men 15 to 35 years of age. Although testicular cancer occurs most often between the ages of 15 and 40, it can occur in males of any age. It is a highly treatable and usually curable form of cancer. An estimated 7,500 men are diagnosed with testicular cancer each year, and approximately 400 die from testicular cancer annually (American Cancer Society, 2002).

The testicles contain several types of cells, each of which may develop into one or more types of cancer. The type of cancer determines the appropriate treatment and affects the prognosis. Testicular cancers are classified as germinal or nongerminal (stromal); secondary testicular cancers may also occur.

### Germinal Tumors

Over 90% of all cancers of the testicle are germinal; geminal tumors may be further classified as seminomas or nonseminomas. About half of all geminal tumors are seminomas, or tumors that develop from the sperm-producing cells of the testes. Nonseminoma germinal cell tumors tend to develop earlier in life than seminomas, usually occurring in men in their 20s. Examples of nonseminomas include teratocarcinomas, choriocarcinomas, yolk sac carcinomas, and embryonal carcinomas. Seminomas tend to remain localized, whereas nonseminomatous tumors grow quickly.

### Nongerminal Tumors

Testicular cancer may also develop in the supportive and hormone-producing tissues, or stroma, of the testicles. These tumors account for about 4% of testicular tumors in adults and 20% of testicular tumors in children. The two main types of stromal tumors are Leydig cell tumors and Sertoli cell tumors. Although these tumors infrequently spread beyond the testicle, a small number of these tumors metastasize and tend to be resistant to chemotherapy and radiation therapy.

## Secondary Testicular Tumors

Secondary testicular tumors are those that have metastasized to the testicle from other organs. Lymphoma is the most common cause of secondary testicular cancer. Cancers may also spread to the testicles from the prostate gland, lung, skin (melanoma), kidney, and other organs. The prognosis for these cancers is usually poor because these cancers generally also spread to other organs. Treatment depends on the specific type of cancer (American Cancer Society, 2002).

### Risk Factors

The risk for testicular cancer is several times greater in men with any type of undescended testis than in the general population (Bosl, Bajorin, Scheinfeld et al., 2001). Risk factors include a family history of testicular cancer and cancer of one testicle, which increases the risk for the other testicle. Race and ethnicity have been identified as risk factors: Caucasian American men have a five times greater risk than that of African American men and more than double the risk of Asian American men. Occupational hazards, including exposure to chemicals encountered in mining, oil and gas production, and leather processing, have been suggested as possible risk factors. Prenatal exposure to DES may also be a risk factor, but evidence is not strong (American Cancer Society, 2002). Vasectomy, once considered a possible risk factor, has been shown in recent studies not to be a risk factor (Cox, Sneyd, Paul et al., 2002).

### Clinical Manifestations

The symptoms appear gradually, with a mass or lump on the testicle and generally painless enlargement of the testis. The patient may complain of heaviness in the scrotum, inguinal area, or lower abdomen. Backache (from retroperitoneal node extension), abdominal pain, weight loss, and general weakness may result from metastasis. Enlargement of the testis without pain is a significant diagnostic finding. Testicular tumors tend to metastasize early, spreading from the testis to the lymph nodes in the retroperitoneum and to the lungs.

### Assessment and Diagnostic Findings

Monthly testicular self-examinations (TSEs) are effective in detecting testicular cancer (Chart 49-4). Teaching men of all ages to perform TSE is an important health promotion intervention for early detection of testicular cancer. Since testicular cancer occurs most often in young adults, testicular self-examination should begin during adolescence.

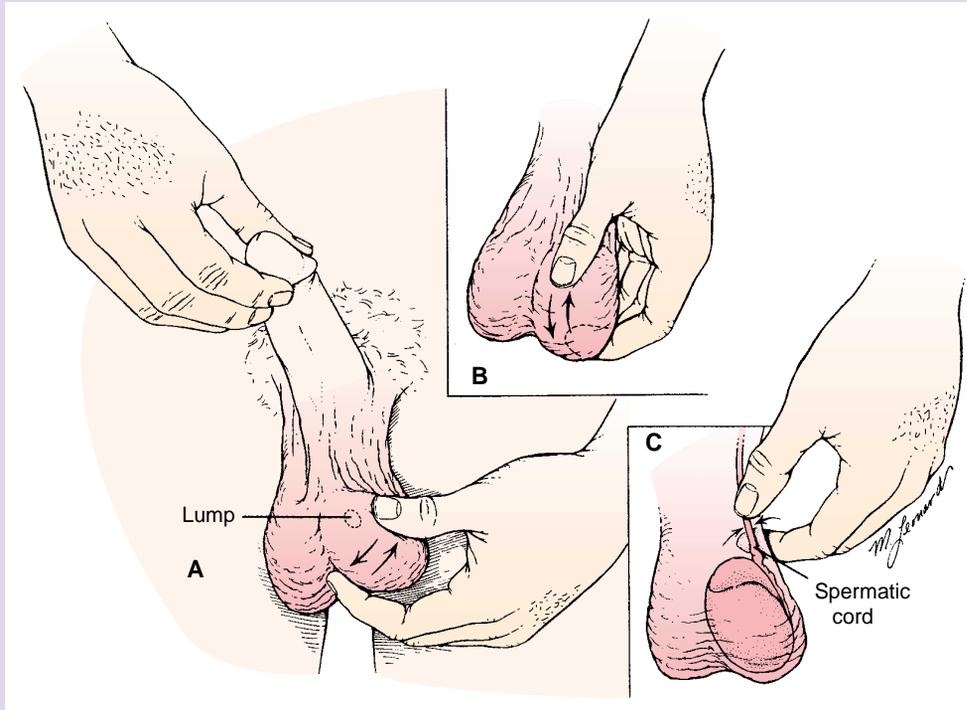

Human chorionic gonadotropin and alpha-fetoprotein are tumor markers that may be elevated in patients with testicular cancer. (Tumor markers are substances synthesized by the tumor cells and released into the circulation in abnormal amounts.) Tumor marker levels in the blood are used for diagnosis, staging, and monitoring the response to treatment. Other diagnostic tests include intravenous urography to detect any ureteral deviation caused by a tumor mass; lymphangiography to assess the extent of tumor spread to the lymphatic system; ultrasound to determine the presence and size of the testicular mass; and CT scan of the chest, abdomen, and pelvis to determine the extent of the disease in the lungs, retroperitoneum, and pelvis. Microscopic analysis of tissue is the only definitive way to determine if

### Chart 49-4 • PATIENT EDUCATION

#### Testicular Self-Examination

Testicular self-examination (TSE) is to be performed once a month. The test is neither difficult nor time-consuming. A convenient time is usually after a warm bath or shower when the scrotum is more relaxed.

1. Use both hands to palpate the testis. The normal testicle is smooth and uniform in consistency.
2. With the index and middle fingers under the testis and the thumb on top, roll the testis gently in a horizontal plane between the thumb and fingers (A).
3. Feel for any evidence of a small lump or abnormality.
4. Follow the same procedure and palpate upward along the testis (B).
5. Locate and palpate the epididymis (C), a cord-like structure on the top and back of the testicle that stores and transports sperm. Also locate and palpate the spermatic cord.
6. Repeat the examination for the other testis, epididymis, and spermatic cord. It is normal to find that one testis is larger than the other.
7. If you find any evidence of a small, pea-like lump or if the testis is swollen (possibly from an infection or tumor), consult your physician.

cancer is present but is usually performed at the time of surgery rather than as a part of the diagnostic workup to reduce the risk of promoting spread of the cancer (American Cancer Society, 2000).

### Medical Management

Testicular cancer is one of the most curable solid tumors. The goals of management are to eradicate the disease and achieve a cure. Treatment selection is based on the cell type and the anatomic extent of the disease. The testis is removed by orchiectomy through an inguinal incision with a high ligation of the spermatic cord. A gel-filled prosthesis can be implanted. After unilateral orchiectomy for testicular cancer, most patients experience no impairment of endocrine function. Other patients, however, have decreased hormonal levels, suggesting that the unaffected testis is not functioning at normal levels. Retroperitoneal lymph node dissection to prevent lymphatic spread of the cancer may be performed after orchiectomy. Although libido and orgasm are usually unimpaired after retroperitoneal lymph node

dissection, the patient may develop ejaculatory dysfunction with resultant infertility. Thus, sperm banking before surgery may be considered (Agarwa, 2000; Zapzalka et al., 1999).

Postoperative irradiation of the lymph nodes from the diaphragm to the iliac region is used in treating seminomas. Radiation is delivered only to the affected side; the other testis is shielded from radiation to preserve fertility. Radiation is also used for patients whose disease does not respond to chemotherapy or for whom lymph node surgery is not recommended. Lymphangiograms and CT scans are used to determine spread of the disease to the lymph nodes.

Testicular carcinomas are highly responsive to chemotherapy. (Bosl et al., 2001) Chemotherapy with cisplatin-based regimens results in a high percentage of complete remissions. Good results may be obtained by combining different types of treatment, including surgery, radiation therapy, and chemotherapy. Even with disseminated testicular cancer, the prognosis is favorable, and the disease is probably curable because of advances in diagnosis and treatment.

A patient with a history of one testicular tumor has a greater chance of developing subsequent tumors. Follow-up studies include chest x-rays, excretory urography, radioimmunoassay of human chorionic gonadotropins and alpha-fetoprotein levels, and examination of lymph nodes to detect recurrent malignancy.

Long-term side effects associated with treatments for testicular cancer include kidney damage, hearing problems, gonadal damage, neurological changes, and rarely secondary cancers (Kollmannsberger, Kuzcyk, Mayer et al., 1999). Research on treatment regimens with less toxicity and the use of cytoprotectants is ongoing.

### Nursing Management

Nursing management includes assessment of the patient's physical and psychological status and monitoring the patient for response to and possible effects of surgery, chemotherapy, and radiation therapy (see Chap. 16). Pre- and postoperative care is described in Chapters 18 and 19, respectively. In addition, because the patient may have difficulty coping with his condition, issues related to body image and sexuality are addressed. He needs encouragement to maintain a positive attitude during what may be a long course of therapy. He also needs to know that radiation therapy will not necessarily prevent him from fathering children, nor does unilateral excision of a testis necessarily decrease virility. The nurse reminds the patient about the importance of performing TSE and keeping follow-up appointments with the physician. The patient is also encouraged to participate in health promotion and health screening activities.

### HYDROCELE

A **hydrocele** is a collection of fluid, generally in the tunica vaginalis of the testis, although it may also collect within the spermatic cord. The tunica vaginalis becomes widely distended with fluid. Hydrocele can be differentiated from a hernia by transillumination; a hydrocele transmits light, whereas a hernia does not. Hydrocele may be acute or chronic. Acute hydrocele may occur in association with acute infectious diseases of the epididymis or as a result of local injury or systemic infectious diseases, such as mumps. The cause of chronic hydrocele is unknown.

Usually, therapy is not required. Treatment is necessary only if the hydrocele becomes tense and compromises testicular circulation or if the scrotal mass becomes large, uncomfortable, or embarrassing. In the surgical treatment of hydrocele, an incision is made through the wall of the scrotum down to the distended tunica vaginalis. The sac is resected or, after being opened, is sutured together to collapse the wall. Postoperatively, the patient wears an athletic supporter for comfort and support. The major complication is hematoma in the loose scrotal tissues.

### VARICOCELE

A **varicocele** is an abnormal dilation of the veins of the pampiniform venous plexus in the scrotum (the network of veins from the testis and the epididymis that constitute part of the spermatic cord). Varicoceles usually occur in the veins on the upper portion of the left testicle in adults. In some men, a varicocele has been associated with infertility. Few, if any, subjective symptoms may be produced by the enlarged spermatic vein, and no treatment is required unless fertility is a concern. Symptomatic varicocele (pain, tenderness, and discomfort in the inguinal region) is corrected surgically by ligating the external spermatic vein at the inguinal area. An ice pack

may be applied to the scrotum for the first few hours after surgery to relieve edema. The patient then wears a scrotal supporter.

### VASECTOMY

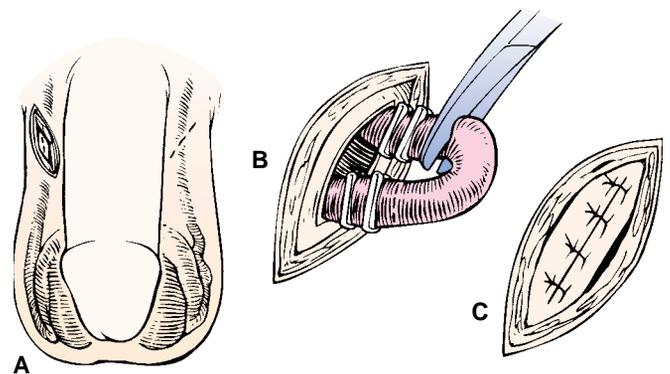

**Vasectomy**, or male sterilization, is the ligation and transection of part of the vas deferens, with or without removal of a segment of the vas deferens. To prevent the passage of the sperm from the testes, the vas deferens is exposed through a surgical opening in the scrotum or a puncture using a sharp, curved hemostat (Fig. 49-6). The severed ends are occluded with ligatures or clips, or the lumen of each vas deferens is sealed by cautery. The spermatozoa, which are manufactured in the testes, cannot travel up the vas deferens after this surgery.

Because seminal fluid is manufactured predominantly in the seminal vesicles and prostate gland, which are unaffected by vasectomy, no noticeable decrease occurs in the amount of ejaculate even though it contains no spermatozoa. Because the sperm cells have no exit, they are resorbed into the body. This procedure has no effect on sexual potency, erection, ejaculation, or production of male hormones and provides no protection against sexually transmitted diseases.

Couples who were worried about pregnancy resulting from contraceptive failure often report a decrease in concern and an increase in spontaneous sexual arousal after vasectomy. Concise and factual preoperative explanations may minimize or relieve the patient's concerns related to masculinity. Although a relationship between vasectomy and autoimmune disorders and prostatic cancer has been suggested, there is no clinical evidence of either.

The patient is advised that he will be sterile but that potency will not be altered after a bilateral vasectomy. As with any surgical procedure, a surgical consent form must be signed. On rare occasions, a spontaneous reanastomosis of the vas deferens occurs, making it possible to impregnate a partner.

Complications of vasectomy include scrotal ecchymoses and swelling, superficial wound infection, vasitis (inflammation of the vas deferens), epididymitis or epididymo-orchitis, hematomas, and spermatic granuloma. A spermatic granuloma is an inflammatory response to the collection of sperm leaking into the scrotum from the severed end of the proximal vas deferens. This can initiate recanalization of the vas deferens, making pregnancy possible.

**FIGURE 49-6** A vasectomy is a resection of the vas deferens to prevent passage of sperm from the testes to the urethra during ejaculation. (A) An incision or small puncture is made to expose the vas deferens. (B) The vas deferens is isolated and severed. (C) The severed ends are occluded with ligatures or clips, or the lumen of each vas is sealed by electrocautery and the incision is sutured closed. (Suturing may not be required if a puncture approach has been used.)

## Nursing Management

Ice bags are applied intermittently to the scrotum for several hours after surgery to reduce swelling and to relieve discomfort. The nurse advises the patient to wear cotton, Jockey-type briefs for added comfort and support. He may become greatly concerned about the discoloration of the scrotal skin and superficial swelling. These are temporary conditions that occur frequently after vasectomy and may be relieved by sitz baths.

Sexual intercourse may be resumed as desired, although fertility remains for a varying time after vasectomy until the spermatozoa stored distal to the severed vas deferens have been evacuated. Other methods of contraception should be used until infertility is confirmed by an examination of ejaculate. Some physicians examine a specimen 4 weeks after the vasectomy to determine sterility; others examine two consecutive specimens 1 month apart; and still others consider a patient sterile after 36 ejaculations.

## Vasovasostomy (Sterilization Reversal)

Microsurgical techniques are used to reverse a vasectomy (vasovasostomy), thus restoring patency to the vas deferens. Many men have sperm in their ejaculate after a reversal, and 40% to 75% can impregnate a partner.

## Banking Sperm

Storing fertile semen in a sperm bank before a vasectomy is an option for men who face an unforeseen life event that may cause them to want to father a child at a later time. In addition, if a man is about to undergo a procedure or treatment (eg, radiation therapy to the pelvis or chemotherapy) that may affect his fertility, sperm banking may be considered. This procedure usually requires several visits to the facility where the sperm is stored under hypothermic conditions. The semen is produced by masturbation and collected in a sterile container for storage.

## Conditions Affecting the Penis

### HYPOSPADIAS AND EPISPADIAS

Hypospadias and epispadias are congenital anomalies of the urethral opening. In hypospadias, the urethral opening is a groove on the underside of the penis. In epispadias, the urethral opening is on the dorsum. These anatomic abnormalities may be repaired by various types of plastic surgery, usually when the boy is very young.

### PHIMOSIS

**Phimosis**, a condition in which the foreskin is constricted so that it cannot be retracted over the glans, can occur congenitally or from inflammation and edema. With the trend away from routine circumcision of newborns, early instruction should be given about cleansing the prepuce. If the preputial area is not cleaned, normal secretions accumulate, causing inflammation (balanitis), which can lead to adhesions and fibrosis. The thickened secretions become encrusted with urinary salts and calcify, forming calculi in the prepuce. In elderly men, penile carcinoma may develop. Phimosis is corrected by circumcision (see later discussion).

Paraphimosis is a condition in which the foreskin is retracted behind the glans and, because of narrowness and subsequent

edema, cannot be returned to its usual position (covering the glans). Paraphimosis is treated by firmly compressing the glans to reduce its size and then pushing the glans back while simultaneously moving the prepuce forward (manual reduction). Circumcision is usually indicated after the inflammation and edema subside.

## CANCER OF THE PENIS

**Penile cancer** occurs in men older than age 60 and represents about 0.5% of malignancies in men in the United States (Stadler, Vogelzang, Elwell & Jones, 2000). In some countries, however, the incidence is 10% to 12%. Since most penile cancers occur in uncircumcised men, it has been suggested that the etiology of this cancer may be the irritative effect of smegma and poor hygiene. However, the “protective” effect of circumcision is seen only in males who are circumcised in the neonatal period; circumcision that occurs at puberty or after does not confer the same benefit (Herr et al., 2001). Cancer of the penis appears on the skin of the penis as a painless, wartlike growth or ulcer. Cancer of the penis can involve the glans, the coronal sulcus under the prepuce, the corporal bodies, the urethra, and regional or distant lymph nodes. **Bowen’s disease** is a form of squamous cell carcinoma in situ of the penile shaft. Typically, a man delays seeking treatment for more than a year, probably because of guilt, embarrassment, or ignorance.

## Prevention

Circumcision in infancy almost eliminates the possibility of penile cancer because chronic irritation and inflammation of the glans penis predispose to penile tumors (Herr et al., 2001; Pettaway & Dinney, 2001; Schoen et al., 2000). In uncircumcised men, personal hygiene is an important preventive measure.

## Medical Management

Smaller lesions involving only the skin may be controlled by excision (Herr et al., 2001). Topical chemotherapy with 5-fluorouracil cream is an option in selected patients. Radiation therapy is used to treat small squamous cell carcinomas of the penis or for palliation in advanced tumors or lymph node metastasis. Partial penectomy (removal of the penis) is preferred to total penectomy if possible; about 40% of patients can then participate in sexual intercourse and stand for urination. The shaft of the penis can still respond to sexual arousal with an erection and has the sensory capacity for orgasm and ejaculation. Total penectomy is indicated when the tumor is not amenable to conservative treatment. After a total penectomy, the patient may still experience orgasm with stimulation of the perineum and scrotal area.

## PRIAPISM

Priapism is an uncontrolled, persistent erection of the penis that causes the penis to become large, hard, and painful. It occurs from either neural or vascular causes, including sickle cell thrombosis, leukemic cell infiltration, spinal cord tumors or injury, and tumor invasion of the penis or its vessels. It may also occur with use of medications that affect the central nervous system, antihypertensive agents, antidepressant medications, and substances injected into the penis to treat erectile dysfunction. This condition may result in gangrene and often results in impotence, whether treated or not.

Priapism is a urologic emergency. The goal of therapy is to improve venous drainage of the corpora cavernosa to prevent is-

chemia, fibrosis, and impotence. The initial treatment is directed at relieving the erection and includes bed rest and sedation. The corpora may be irrigated with an anticoagulant, which allows stagnant blood to be aspirated. Shunting procedures to divert the blood from the turgid corpora cavernosa to the venous system (corpora cavernosa–saphenous vein shunt) or into the corpus spongiosum–glans penis compartment may be attempted.

## PEYRONIE'S DISEASE

**Peyronie's disease** involves the buildup of fibrous plaques in the sheath of the corpus cavernosum. These plaques are not visible when the penis is relaxed. When erect, however, curvature of the penis occurs that can be painful and can make sexual intercourse difficult or impossible. Peyronie's disease primarily occurs in middle-aged and older men. Although the plaques may shrink over time, surgical removal of the plaques may be necessary.

## URETHRAL STRICTURE

Urethral stricture is a condition in which a section of the urethra is narrowed. It can occur congenitally or from a scar along the urethra. Traumatic injury to the urethra (for example, from instrumentation or infections) can result in strictures. Treatment involves dilation of the urethra or, in severe cases, urethrotomy (surgical removal of the stricture).

## CIRCUMCISION

**Circumcision** is the excision of the foreskin, or prepuce, of the glans penis. It is usually performed in infancy. In adults, it is part of the treatment for phimosis, paraphimosis, and recurrent infections of the glans and foreskin and may be performed at the personal desire of the patient.

Postoperatively, a petrolatum (Vaseline) gauze dressing is applied and changed as indicated. The patient is observed for bleeding. Because considerable pain may occur after circumcision, analgesic agents are administered as needed.

### Critical Thinking Exercises

1. During a community health fair, you are approached by a 49-year-old African American man who asks you about his risks for prostate cancer. Develop a plan to address this issue with him at the health fair and provide the rationale for your plan. How would your responses differ if you saw the patient during an office visit to follow up an elevated PSA test result?
2. One of your patients, a 44-year-old man with multiple sclerosis, asks you about Viagra. What information would you give him about Viagra, and what teaching approach would you use? How would your approach differ if your patient were a 56-year-old man with long-standing diabetes? If your patient were a 68-year-old man with coronary artery disease?
3. You are caring for two patients who have undergone prostatectomy. One has had surgery to treat BPH and the other to treat prostate cancer. How would your care differ for these two patients? How would the patient's underlying disorder alter your hospital care and your discharge planning?

4. A 34-year-old man is seeking treatment for an STD. When you are obtaining the health history, he reports that this is his fifth or sixth episode of STD. In addition to assisting with medical management and follow-up, what other interventions would you consider for this patient? What strategies would you suggest to him to reduce his risk for subsequent STDs and the risk of transmitting an STD to his sexual partner? How would your teaching differ if the patient revealed that he had sex with men only?

5. During a routine pre-employment physical examination, a 23-year-old man is found to have a mass in the left testicle. He dismisses its significance, saying that it is nothing to be concerned about and that he cannot interrupt his plans to have it evaluated, as he will be getting married in a month and beginning a new job. What information would you provide to the patient at this time? What explanation would you give to him about the evaluation of the testicular mass and possible outcomes?

# ● Assessment of Immune Function

## **LEARNING OBJECTIVES** ●

*On completion of this chapter, the learner will be able to:*

1. Describe the body's general immune responses.
2. Discuss the stages of the immune response.
3. Differentiate between cellular and humoral immune responses.
4. Describe the effects of the following variables on function of the immune system: age, gender, nutrition, psychoneuroimmunology, concurrent illness, cancer, medications, and radiation.
5. Use assessment parameters for determining the status of immune function.

The immune system functions as the body's defense mechanism against invasion. The term **immunity** refers to the body's specific protective response to an invading foreign agent or organism. Immune function is affected by age and by a variety of other factors, such as central nervous system function, emotional status, medications, the stress of illness, trauma, and surgery. Dysfunctions involving the immune system occur across the life span. Many are genetically based; others are acquired. The term **immunopathology** refers to the study of diseases resulting from dysfunctions within the immune system. Disorders of the immune system may stem from excesses or deficiencies of immunocompetent cells, alterations in the function of these cells, immunologic attack on self-antigens, or inappropriate or exaggerated responses to specific antigens (Table 50-1).

To gain insight into immunopathology and the growing number of immunologic-based disorders and to assess and care for people with immunologic disorders, the nurse needs a sound knowledge base of the immune system and how it functions.

## Anatomic and Physiologic Overview

### ANATOMY OF THE IMMUNE SYSTEM

The immune system comprises cells and molecules with specialized roles in defending against infection and invasion by other organisms. Its major components include the bone marrow, the white blood cells (WBCs) produced by the bone marrow, and the lymphoid tissues. Lymphoid tissues include the thymus gland, the spleen, the lymph nodes, the tonsils and adenoids, and similar tissues in the gastrointestinal, respiratory, and reproductive systems (Fig. 50-1).

#### Bone Marrow

The bone marrow is the production site of the WBCs involved in immunity (Fig. 50-2). Like other blood cells, lymphocytes are generated from stem cells, which are undifferentiated cells. De-

Table 50-1 • Immune System Disorders

DISORDER	DESCRIPTION
Autoimmunity	Normal protective immune response paradoxically turns against or attacks the body, leading to tissue damage
Hypersensitivity	Body produces inappropriate or exaggerated responses to specific antigens
Gammopathies	Immunoglobulins are overproduced
Immune deficiencies	
Primary	Deficiency results from improper development of immune cells or tissues, usually with a genetic basis
Secondary	Deficiency results from some interference with an already developed immune system

scendants of **stem cells** become lymphocytes, the B lymphocytes (**B cells**), and the T lymphocytes (T cells) (Fig. 50-3). B lymphocytes mature in the bone marrow and then enter the circulation. T lymphocytes move from the bone marrow to the thymus, where they mature into several kinds of cells capable of different functions.

### Lymphoid Tissues

The spleen, composed of red and white pulp, acts somewhat like a filter. The red pulp is the site where old and injured red blood cells are destroyed. The white pulp contains concentrations of lymphocytes. The lymph nodes are distributed throughout the body. They are connected by lymph channels and capillaries, which remove foreign material from the lymph before it enters the bloodstream. The lymph nodes also serve as centers for immune cell proliferation. The remaining lymphoid tissues, such as the tonsils and adenoids and other mucoid lymphatic tissues,

## Glossary

**agglutination:** clumping effect occurring when an antibody acts as a cross-link between two antigens

**antibody:** a protein substance developed by the body in response to and interacting with a specific antigen

**antigen:** substance that induces the production of antibodies

**apoptosis:** programmed cell death that results from the digestion of DNA by endonucleases

**B cells:** cells that are important in producing circulating antibodies

**cellular immune response:** the immune system's third line of defense, involving the attack of pathogens by T cells

**complement:** series of enzymatic proteins in the serum that, when activated, destroy bacteria and other cells

**cytokines:** generic term for non-antibody proteins that act as intercellular mediators, as in the generation of immune response

**cytotoxic T cells:** lymphocytes that lyse cells infected with virus; also play a role in graft rejection

**genetic engineering:** emerging technology designed to enable replacement of missing or defective genes

**helper T cells:** lymphocytes that attack foreign invaders (antigens) directly

**humoral immune response:** the immune system's second line of defense; often termed the antibody response

**immunity:** the body's specific protective response to an invading foreign agent or organism

**immunopathology:** study of diseases resulting in dysfunctions within the immune system

**immunoregulation:** complex system of checks and balances that regulates or controls immune responses

**interferons:** proteins formed when cells are exposed to viral or foreign agents; capable of activating other components of the immune system

**lymphokines:** substances released by sensitized lymphocytes when they contact specific antigens

**memory cells:** cells that are responsible for recognizing antigens from previous exposure and mounting an immune response

**natural killer cells (NK cells):** lymphocytes that defend against microorganisms and malignant cells

**null lymphocytes:** lymphocytes that destroy antigens already coated with the antibody

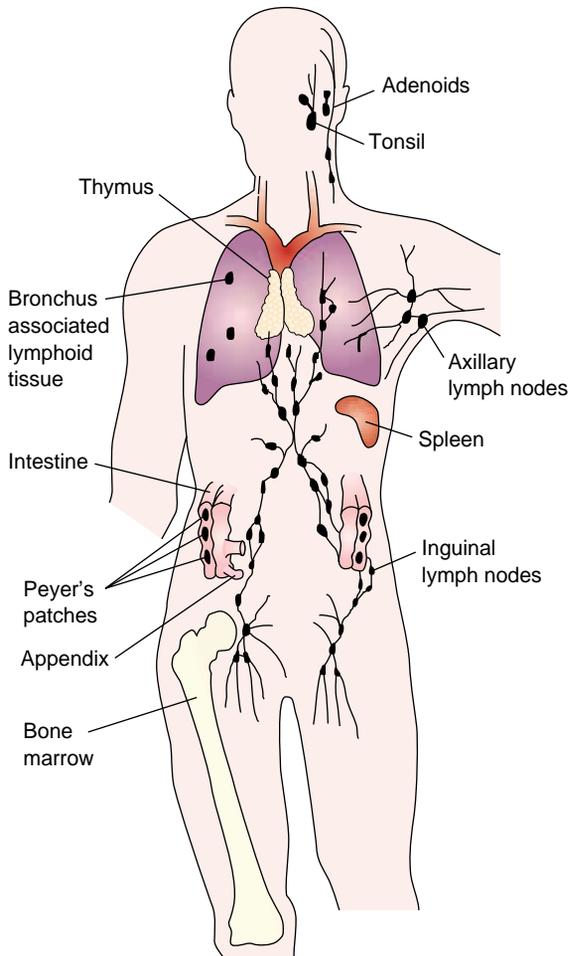

**opsonization:** the coating of antigen—antibody molecules with a sticky substance to facilitate phagocytosis

**phagocytic cells:** cells that engulf, ingest, and destroy foreign bodies or toxins

**phagocytic immune response:** the immune system's first line of defense, involving white blood cells that have the ability to ingest foreign particles

**stem cells:** precursors of all blood cells; reside primarily in bone marrow

**suppressor T cells:** lymphocytes that decrease B-cell activity to a level at which the immune system is compatible with life

**FIGURE 50-1** Central and peripheral lymphoid organs and tissues. From Porth, C. M. (2002). *Pathophysiology: Concepts of altered health states* (6th ed.). Philadelphia: Lippincott Williams & Wilkins.

contain immune cells that defend the body's mucosal surfaces against microorganisms.

## IMMUNE FUNCTION: DEFENSES AND RESPONSES

There are two general types of immunity: natural (innate) and acquired (adaptive). Natural immunity is a nonspecific immunity present at birth. Acquired or specific immunity develops after birth. Natural immune responses to a foreign invader are very similar from one encounter to the next regardless of the number of times the invader is encountered; in contrast, acquired responses increase in intensity with repeated exposure to the invading agent (Delves & Roitt, 2000a). Although each type of immunity plays a distinct role in defending the body against harmful invaders, the various components usually act in an interdependent manner.

### Natural Immunity

Natural (innate) immunity provides a nonspecific response to any foreign invader, regardless of the invader's composition. The basis of natural defense mechanisms is the ability to distinguish between friend and foe or "self" and "nonself." Such natural mechanisms

include physical and chemical barriers, the action of WBCs, and inflammatory responses.

### PHYSICAL AND CHEMICAL BARRIERS

Physical surface barriers include intact skin and mucous membranes, which prevent pathogens from gaining access to the body, and the cilia of the respiratory tract along with coughing and sneezing responses, which act to filter and clear pathogens from the upper respiratory tract before they can invade the body further. Chemical barriers, such as acidic gastric secretions, mucus, enzymes in tears and saliva, and substances in sebaceous and sweat secretions, act in a nonspecific way to destroy invading bacteria and fungi. Viruses are countered by other means, such as interferon. **Interferon**, one type of biologic response modifier, is a nonspecific viricidal protein naturally produced by the body that is capable of activating other components of the immune system.

### WHITE BLOOD CELL ACTION

WBCs, or leukocytes, participate in both the natural and the acquired immune responses. Granular leukocytes, or granulocytes (so called because of granules in their cytoplasm), fight invasion by foreign bodies or toxins by releasing cell mediators, such as histamine, bradykinin, and prostaglandins, and engulfing the foreign bodies or toxins. Granulocytes include neutrophils, eosinophils, and basophils.

Neutrophils (also called polymorphonuclear leukocytes, or PMNs, because their nuclei have multiple lobes) are the first cells to arrive at the site where inflammation occurs. Eosinophils and basophils, other types of granulocytes, increase in number during allergic reactions and stress responses. Nongranular leukocytes include monocytes or macrophages (referred to as histiocytes when they enter tissue spaces) and lymphocytes. Monocytes also function as **phagocytic cells**, engulfing, ingesting, and destroying greater numbers and quantities of foreign bodies or toxins than granulocytes. Lymphocytes, consisting of B cells and T cells, play major roles in humoral and cell-mediated immune responses. About 60% to 70% of lymphocytes in the blood are T cells, and about 10% to 20% are B cells (Porth, 2002).

### INFLAMMATORY RESPONSE

The inflammatory response is a major function of the natural (nonspecific or innate) immune system elicited in response to tissue injury or invading organisms. Chemical mediators assist this response by minimizing blood loss, walling off the invading organism, activating phagocytes, and promoting formation of fibrous scar tissue and regeneration of injured tissue. (The inflammatory response is discussed further in Chap. 6.)

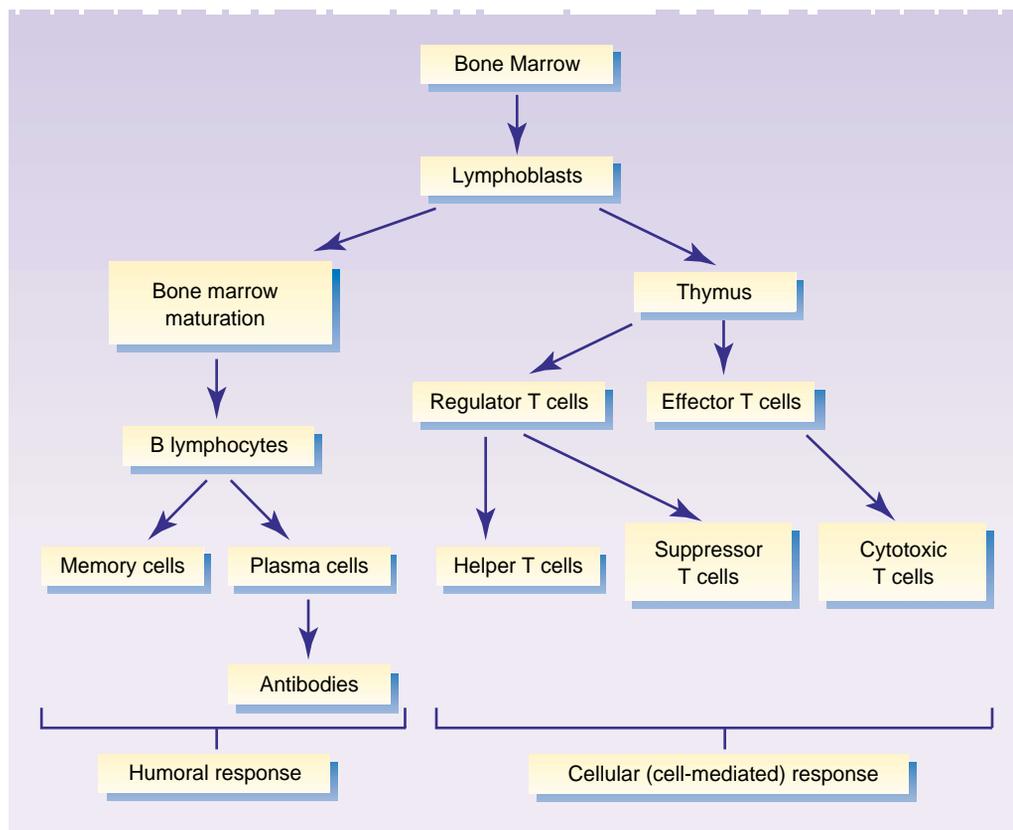

Dysfunction of the natural immune system can occur when the immune components are inactivated or when they remain active long after their effects are beneficial. Immunodeficiencies are characterized by inactivation or impairment of immune components, and disorders with an inflammatory component (eg, asthma, allergy, arthritis) are characterized by persistent inflammatory responses (Medahitov & Janeway, 2000). The immune system's recognition of one's own tissues as "foreign" rather than as self is the basis for many autoimmune disorders.

### Acquired Immunity

Acquired (adaptive) immunity—immunologic responses acquired during life but not present at birth—usually develops as a result of prior exposure to an antigen through immunization (vaccination) or by contracting a disease, both of which generate a protective

## Physiology/Pathophysiology

**FIGURE 50-2** Development of cells of the immune system.

immune response. Weeks or months after exposure to the disease or vaccine, the body produces an immune response that is sufficient to defend against the disease upon re-exposure to it.

The two types of acquired immunity are known as active and passive. In active acquired immunity, the immunologic defenses are developed by the person's own body. This immunity generally lasts many years or even a lifetime.

Passive acquired immunity is temporary immunity transmitted from another source that has developed immunity through previous disease or immunization. For example, immune globulin and antiserum, obtained from the blood plasma of people with acquired immunity, are used in emergencies to provide immunity to diseases when the risk for contracting a specific disease is great and there is not enough time for a person to develop adequate active immunity. For example, immune globulin may be administered to those exposed to hepatitis. Immunity resulting from the transfer of antibodies from the mother to an infant in utero or through breastfeeding is another example of passive immunity. Active and passive acquired immunity involve humoral and cellular (cell-mediated) immunologic responses (described later in this chapter) (Ada, 2001).

### Response to Invasion

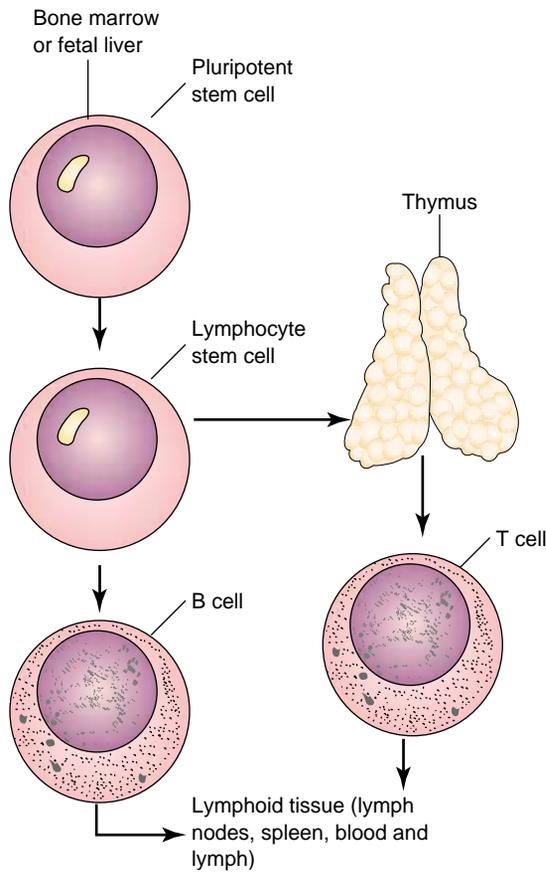

When the body is invaded or attacked by bacteria, viruses, or other pathogens, it has three means of defending itself:

- The phagocytic immune response
- The humoral or antibody immune response
- The cellular immune response

The first line of defense, the **phagocytic immune response**, involves the WBCs (granulocytes and macrophages), which have the ability to ingest foreign particles. These cells move to the point of attack, where they engulf and destroy the invading agents. Phagocytes also remove the body's own dying or dead cells. Cells in necrotic tissue that are dying release substances that trigger an inflammatory response. **Apoptosis**, or programmed cell death, is the body's way of destroying unwanted cells such as cancer cells or cells that die a natural death. Apoptosis involves the digestion of DNA by endonucleases, resulting in the cells being targeted for phagocytosis (Delves & Roitt, 2000a).

Unlike macrophages, eosinophils are only weakly phagocytic. On activation, eosinophils probably kill parasites by releasing specific chemical mediators into the extracellular fluid. Additionally, they secrete leukotrienes, prostaglandins, and various cytokines (Delves & Roitt, 2000a).

A second protective response, the **humoral immune response** (sometimes called the **antibody response**), begins with the B lymphocytes, which can transform themselves into plasma cells that manufacture antibodies. These antibodies, highly specific proteins, are transported in the bloodstream and attempt to disable

**FIGURE 50-3** Lymphocytes originate from stem cells in the bone marrow. B-lymphocytes mature in the bone marrow before entering the bloodstream, whereas T lymphocytes mature in the thymus, where they also differentiate into cells with various functions. From Porth, C. M. (2002). *Pathophysiology: Concepts of altered health states* (6th ed.). Philadelphia: Lippincott Williams & Wilkins.

the invaders. The third mechanism of defense, the **cellular immune response**, also involves the T lymphocytes, which can turn into special cytotoxic (or killer) T cells that can attack the pathogens themselves.

The part of the invading or attacking organism that is responsible for stimulating antibody production is called an **antigen** (or an immunogen). For example, an antigen can be a small patch of proteins on the outer surface of the microorganism. Not all antigens are naturally immunogenic and must be coupled to other molecules to stimulate the immune response. A single bacterium, even a single large molecule, such as a toxin (diphtheria or tetanus toxin), may have several such antigens, or markers, on its surface, thus inducing the body to produce a number of different antibodies. Once produced, an antibody is released into the bloodstream and carried to the attacking organism. There it combines with the antigen, binding with it like an interlocking piece of a jigsaw puzzle (Fig. 50-4). There are four well-defined stages in an immune response: recognition, proliferation, response, and effector.

### RECOGNITION STAGE

Recognition of antigens as foreign, or nonself, by the immune system is the initiating event in any immune response. The body

### NURSING RESEARCH PROFILE 50-1

#### *Epidural Anesthesia and Immune Response in Postpartum Women*

Fehder, W. P., & Gennaro, S. G. (1998). Immune alterations associated with epidural anesthesia for labor and delivery. *Maternal Child Health Nursing, 23*(6), 292–299

#### Purpose

Epidural anesthesia is a common form of analgesia and anesthesia used for women in labor. Although epidural anesthesia is regarded as safe, the results of studies have suggested that epidural anesthesia may be associated with alterations in white blood cell counts. The purpose of this study was to determine if epidural anesthesia is associated with alterations in immune profile or immune function in healthy postpartum women.

#### Study Sample and Design

In this prospective study, the convenience sample included two groups of healthy postpartum women. They were assessed for differences in immune profile and immune function based upon whether they received epidural anesthesia during labor and delivery. Twenty-one subjects had received no epidural anesthesia. Forty-seven subjects had received epidural anesthesia for their deliveries.

Sixty-eight women who agreed to participate in the study and met inclusion criteria underwent laboratory testing for immune profile and immune function studies. This was done within 24 hours after delivery. The data collected included measures that specifically assessed immune phenotypic profile, lymphocyte proliferative response, and NK lysis assays.

#### Findings

No differences were noted in immune profile or immune function in women who received epidural anesthesia in labor versus those who did not.

#### Nursing Implications

This study demonstrated that white blood cell count and other phenotypic measures of leukocytes are not affected by epidural anesthesia. It is suggested that the epidural anesthesia technique does not alter immune response in postpartum women, although studies with larger samples are warranted. Efforts to support the immune response in women who receive epidural anesthesia should be comparable to women who do not receive epidural anesthesia.

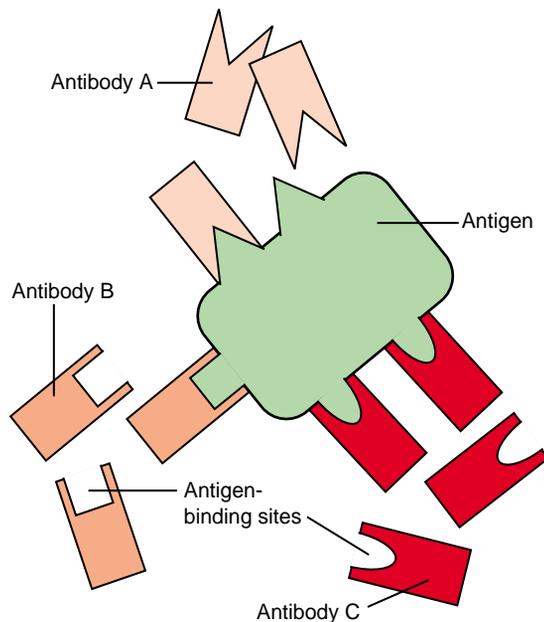

must first recognize invaders as foreign before it can react to them. The body accomplishes recognition using lymph nodes and lymphocytes for surveillance. Lymph nodes are widely distributed internally throughout the body and in the circulating blood, and externally near the body's surfaces. They continuously discharge small lymphocytes into the bloodstream. These lymphocytes patrol the tissues and vessels that drain the areas served by that node.

Lymphocytes recirculate from the blood to lymph nodes and from the lymph nodes back into the bloodstream, in a never-ending series of patrols. Some circulating lymphocytes can survive for decades. Some of these small, hardy cells maintain their solitary circuits for the person's lifetime.

The exact way in which circulating lymphocytes recognize antigens on foreign surfaces is not known; however, recognition is thought to depend on specific receptor sites on the surface of the lymphocytes. Macrophages play an important role

## Physiology/Pathophysiology

**FIGURE 50-4** Antibody specificity. Antibodies are produced by B-cell lymphocytes to bind with specific antigens.

in helping the circulating lymphocytes process the antigens. Both macrophages and neutrophils have receptors for antibodies and complement; as a result, the coating of microorganisms with antibodies, complement, or both enhances phagocytosis. The engulfed microorganisms are then subjected to a wide range of toxic intracellular molecules. When foreign materials enter the body, a circulating lymphocyte comes into physical contact with the surfaces of these materials. Upon contact, the lymphocyte, with the help of macrophages, either removes the antigen from the surface or in some way picks up an imprint of its structure, which comes into play with subsequent re-exposure to the antigen.

In a streptococcal throat infection, for example, the streptococcal organism gains access to the mucous membranes of the throat. A circulating lymphocyte moving through the tissues of the neck comes in contact with the organism. The lymphocyte, familiar with the surface markers on the cells of its own body, recognizes the antigens on the microbe as different (nonself) and the streptococcal organism as antigenic (foreign). This triggers the second stage of the immune response—proliferation.

### PROLIFERATION STAGE

The circulating lymphocyte containing the antigenic message returns to the nearest lymph node. Once in the node, the sensitized lymphocyte stimulates some of the resident dormant T and B lymphocytes to enlarge, divide, and proliferate. T lymphocytes differentiate into cytotoxic (or killer) T cells, whereas B lymphocytes produce and release antibodies. Enlargement of the lymph nodes in the neck in conjunction with a sore throat is one example of the immune response.

### RESPONSE STAGE

In the response stage, the changed lymphocytes function either in a humoral or a cellular fashion. The production of antibodies by the B lymphocytes in response to a specific antigen begins the humoral response. Humoral refers to the fact that the antibodies are released into the bloodstream and so reside in the plasma (fluid fraction of the blood).

With the initial cellular response, the returning sensitized lymphocytes migrate to areas of the lymph node (other than those areas containing lymphocytes programmed to become plasma cells). Here, they stimulate the residing lymphocytes to become cells that will attack microbes directly rather than through the action of antibodies. These transformed lymphocytes are known as cytotoxic (killer) T cells. The T stands for thymus, signifying that during embryologic development of the immune system, these T lymphocytes spent time in the thymus of the developing fetus, where they were genetically programmed to become T lymphocytes rather than the antibody-producing B lymphocytes. Viral rather than bacterial antigens induce a cellular response. This response is manifested by the increasing number of T lymphocytes (lymphocytosis) seen in the blood smears of people with viral illnesses, such as infectious mononucleosis. (Cellular immunity is discussed in further detail later in this chapter.)

Most immune responses to antigens involve both humoral and cellular responses, although one usually predominates. For example, during transplantation rejection, the cellular response predominates, whereas in the bacterial pneumonias and sepsis, the humoral response plays the dominant protective role (Chart 50-1).

### EFFECTOR STAGE

In the effector stage, either the antibody of the humoral response or the cytotoxic (killer) T cell of the cellular response reaches and couples with the antigen on the surface of the foreign invader. The coupling initiates a series of events that in most instances results in the total destruction of the invading microbes or the complete neutralization of the toxin. The events involve an interplay of antibodies (humoral immunity), complement, and action by the cytotoxic T cells (cellular immunity). Figure 50-5 summarizes the stages of the immune response.

Chart  
50-1

### Role of Cellular and Humoral Immune Responses

Whereas B-cell antibodies are distinctive components of the humoral immune response, cytotoxic T cells are distinguishing components of the cellular immune response. Some specific roles of B cells and T cells are as follows:

#### Humoral Responses (B Cells)

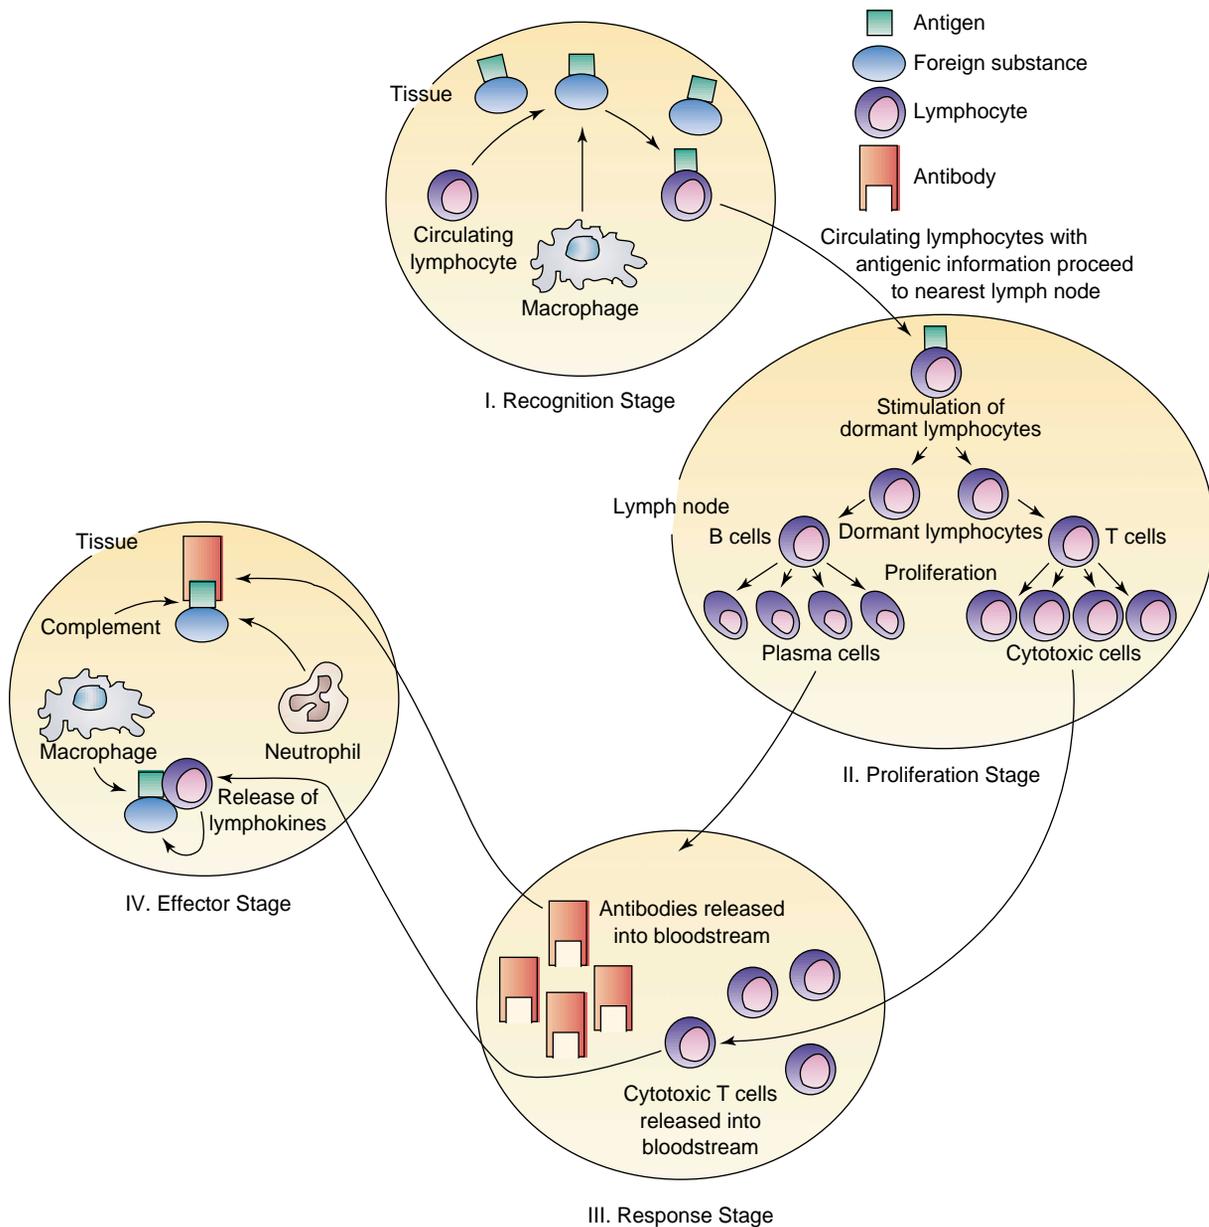

- Bacterial phagocytosis and lysis
- Anaphylaxis
- Allergic hay fever and asthma
- Immune complex disease
- Bacterial and some viral infections

#### Cellular Responses (T Cells)

- Transplant rejection
- Delayed hypersensitivity (tuberculin reaction)
- Graft-versus-host disease
- Tumor surveillance or destruction
- Intracellular infections
- Viral, fungal, and parasitic infections

## Physiology/Pathophysiology

**FIGURE 50-5** Stages of the immune response. **(I)** In the *recognition stage*, antigens are recognized by circulating lymphocytes and macrophages. **(II)** In the *proliferation stage*, the dormant lymphocytes proliferate and differentiate into cytotoxic (killer) T cells or B cells responsible for formation and release of antibodies. **(III)** In the *response stage*, the cytotoxic T cells and the B cells perform cellular and humoral functions, respectively. **(IV)** In the *effector stage*, antigens are destroyed or neutralized through the action of antibodies, complement, macrophages, and cytotoxic T cells.

### Humoral Immune Response

The humoral response is characterized by production of antibodies by the B lymphocytes in response to a specific antigen. Although the B lymphocyte is ultimately responsible for the production of antibodies, both the macrophages of natural immunity and the special T-cell lymphocytes of cellular immunity are involved in recognizing the foreign substance and in producing antibodies.

### ANTIGEN RECOGNITION

Several theories exist about the mechanisms by which the B lymphocytes recognize the invading antigen and respond by producing antibodies. This is probably because the B lymphocytes recognize invading antigens in more than one way and respond in several ways as well. Additionally, the B lymphocytes appear to respond to some antigens by triggering antibody formation directly. In response to other antigens, however, they need the assistance of T cells to trigger antibody formation.

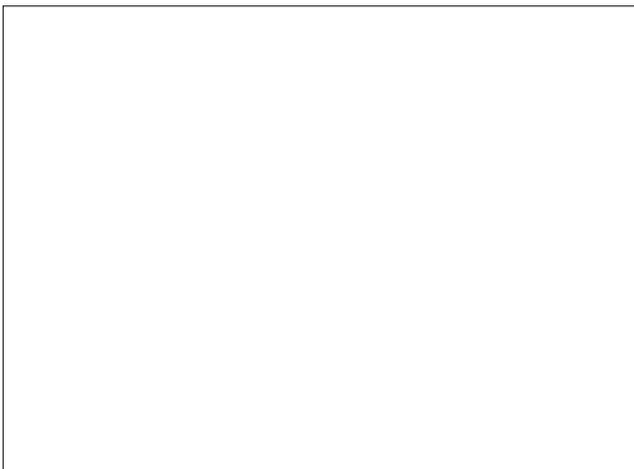

T cells (or T lymphocytes), part of a surveillance system dispersed throughout the body, recycle through the general circulation, tissues, and lymphatic system. With the assistance of macrophages, the T lymphocytes are believed to recognize the antigen of a foreign invader. The T lymphocyte picks up the antigenic message, or “blueprint,” of the antigen and returns to the nearest lymph node with that message.

**Production of B Lymphocytes.** B lymphocytes stored in the lymph nodes are subdivided into thousands of clones, each responsive to a single group of antigens having almost identical characteristics. When the antigenic message is carried back to the lymph node, specific clones of the B lymphocyte are stimulated to enlarge, divide, proliferate, and differentiate into plasma cells capable of producing specific antibodies to the antigen. Other B lymphocytes differentiate into B-lymphocyte clones with a memory for the antigen. These memory cells are responsible for the more exaggerated and rapid immune response in a person who is repeatedly exposed to the same antigen.

### ROLE OF ANTIBODIES

Antibodies are large proteins called immunoglobulins because they are found in the globulin fraction of the plasma proteins. All immunoglobulins are glycoproteins and contain a certain amount of carbohydrate. The carbohydrate concentration, which ranges from approximately 3% to 13%, is dependent upon the class of the antibody. Each antibody molecule consists of two subunits, each of which contains a light and a heavy peptide chain (Fig. 50-6). The subunits are held together by a chemical link composed of disulfide bonds. Each subunit has a portion that serves as a binding site for a specific antigen referred to as the Fab fragment. This site provides the “lock” portion that is highly specific for an antigen. An additional portion, known as the Fc fragment, allows the antibody molecule to take part in the complement system.

Antibodies defend against foreign invaders in several ways, and the type of defense employed depends on the structure and composition of both the antigen and the immunoglobulin. The antibody molecule has at least two combining sites, or Fab fragments. One antibody can act as a cross-link between two antigens, causing them to bind or clump together. This clumping effect, referred to as **agglutination**, helps clear the body of the in-

**FIGURE 50-6** An antibody molecule. The Fab fragment serves as the binding site for a specific antigen. The Fc fragment initiates classic complement activation.

vading organism by facilitating phagocytosis. Some antibodies assist in removing offending organisms through **opsonization**. In this process, the antigen–antibody molecule is coated with a sticky substance that also facilitates phagocytosis.

Antibodies also promote the release of vasoactive substances, such as histamine and slow-reacting substance, two of the chemical mediators of the inflammatory response.

Antibodies do not function in isolation but rather mobilize other components of the immune system to defend against the invader. Their usual role is to focus components of the natural immune system on the invader. This includes activation of the complement system and activation of phagocytosis (Delves & Roitt, 2000a).

**Types of Immunoglobulins.** The body can produce five different types of immunoglobulins. (Immunoglobulins are commonly designated by the abbreviation Ig.) Each of the five types, or classes, is identified by a specific letter of the alphabet (IgA, IgD, IgE, IgG, and IgM). Classification is based on the chemical structure and biologic role of the individual immunoglobulin. The following list summarizes major characteristics of the immunoglobulins:

#### **IgG (75% of Total Immunoglobulin)**

- Appears in serum and tissues (interstitial fluid)
- Assumes a major role in bloodborne and tissue infections
- Activates the complement system
- Enhances phagocytosis
- Crosses the placenta

#### **IgA (15% of Total Immunoglobulin)**

- Appears in body fluids (blood, saliva, tears, breast milk, and pulmonary, gastrointestinal, prostatic, and vaginal secretions)
- Protects against respiratory, gastrointestinal, and genitourinary infections
- Prevents absorption of antigens from food
- Passes to neonate in breast milk for protection

#### **IgM (10% of Total Immunoglobulin)**

- Appears mostly in intravascular serum
- Appears as the first immunoglobulin produced in response to bacterial and viral infections
- Activates the complement system

#### **IgD (0.2% of Total Immunoglobulin)**

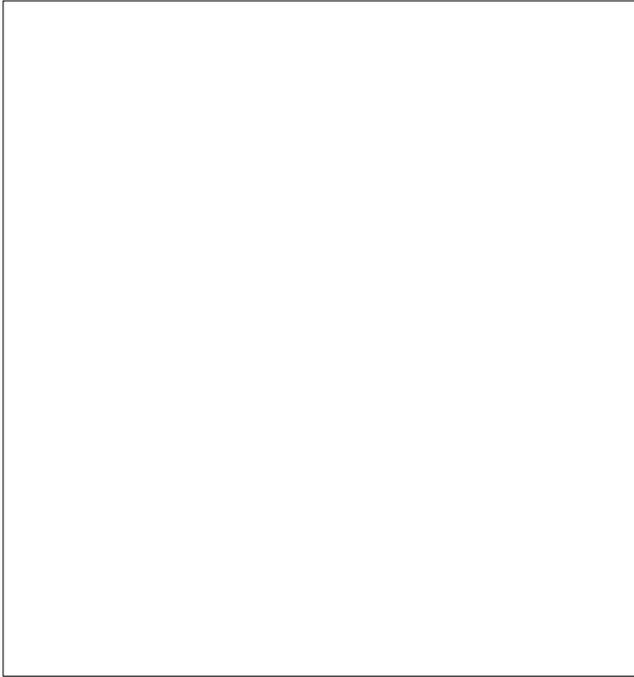

- Appears in small amounts in serum
- Possibly influences B-lymphocyte differentiation, but role is unclear

#### **IgE (0.004% of Total Immunoglobulin)**

- Appears in serum
- Takes part in allergic and some hypersensitivity reactions
- Combats parasitic infections

### ANTIGEN–ANTIBODY BINDING

The portion of the antigen involved in binding with the antibody is referred to as the antigenic determinant. The binding of the Fab fragment (antibody-binding site) to the antigenic determinant can be likened to a lock-and-key situation (Fig. 50-7). The most efficient immunologic responses occur when the antibody and antigen fit exactly. Poor fit can occur with an antibody that was produced in response to a different antigen. This phenomenon is known as cross-reactivity. For example, in acute rheumatic fever, the antibody produced against *Streptococcus pyogenes* in the upper respiratory tract may cross-react with the patient’s heart tissue, leading to heart valve damage.

**FIGURE 50-7** Antigen–antibody binding. (*Top*) A highly specific antigen–antibody complex. (*Middle*) No match and therefore, no immune response. (*Bottom*) Poor fit or match with low specificity; antibody reacts to antigen with similar characteristics, producing cross-reactivity.

## Cellular Immune Response

Whereas the B lymphocytes are responsible for humoral immunity, the T lymphocytes (or T cells) are primarily responsible for cellular immunity. Stem cells continuously migrate from the bone marrow to the thymus gland, where they develop into T cells. T cells continue to develop in the thymus gland, despite partial degeneration of the thymus gland that occurs at puberty (Delves & Roitt, 2000a). By spending time in the thymus, these cells are programmed to become T cells rather than antibody-producing B lymphocytes. Several types of T cells exist, each with designated roles in the defense against bacteria, viruses, fungi, parasites, and malignant cells. T cells attack foreign invaders directly rather than by producing antibodies.

Cellular reactions are initiated by the binding of an antigen with an antigen receptor located on the surface of a T cell. This may occur with or without the assistance of macrophages. The T cells then carry the antigenic message, or blueprint, to the lymph nodes, where the production of other T cells is stimulated. Some T cells remain in the lymph nodes and retain a memory for the antigen. Other T cells migrate from the lymph nodes into the general circulatory system and ultimately to the tissues, where they remain until they either come in contact with their respective antigens or die.

### ROLE OF T LYMPHOCYTES

Two major categories of effector T cells are helper T cells and cytotoxic T cells. These cells participate in destroying foreign organisms. Other T cells include suppressor T cells and memory T cells. T cells interact closely with B cells, indicating that humoral and cellular immune responses are not separate, unrelated processes but rather branches of the immune response that can and do affect each other.

**Helper T cells** are activated upon recognition of antigens and stimulate the rest of the immune system. When activated, helper T cells secrete **cytokines** that attract and activate B cells, cytotoxic T cells, natural killer cells, macrophages, and other cells of the immune system. Separate subpopulations of helper T cells produce different types of cytokines and determine whether the immune response will be the production of antibodies or a cell-mediated immune response. Helper T cells produce **lymphokines**, one category of cytokines. These lymphokines activate other T cells (interleukin-2 [IL-2]), natural and cytotoxic T cells (interferon-gamma), and other inflammatory cells (tumor necrosis factor). Helper T cells produce IL-4 and IL-5, lymphokines that activate B cells to grow and differentiate (Table 50-2).

**Cytotoxic T cells** (killer T cells) attack the antigen directly by altering the cell membrane and causing cell lysis (disintegration) and releasing cytolytic enzymes and cytokines. Lymphokines can recruit, activate, and regulate other lymphocytes and WBCs. These cells then assist in destroying the invading organism. Delayed-type hypersensitivity is an example of an immune reaction that protects the body from antigens through the production and release of lymphokines and is discussed in more detail later.

Another type of cell, the **suppressor T cell**, has the ability to decrease B-cell production, thereby keeping the immune response at a level that is compatible with health (eg, sufficient to fight infection adequately without attacking the body's healthy tissues). **Memory cells** are responsible for recognizing antigens from previous exposure and mounting an immune response (Table 50-3).

### ROLES OF NULL LYMPHOCYTES AND NATURAL KILLER CELLS

Null lymphocytes and natural killer (NK) cells are other lymphocytes that assist in combating organisms. These are distinct from B cells and T cells and lack the usual characteristics of B cells and T cells. **Null lymphocytes**, a subpopulation of lymphocytes, destroy antigens already coated with antibody. These cells have special Fc receptor sites on their surfaces that allow them to couple with the Fc end of antibodies (antibody-dependent, cell-mediated cytotoxicity).

**Natural killer cells**, another subpopulation of lymphocytes, defend against microorganisms and some types of malignant cells. NK cells are capable of directly killing invading organisms and producing cytokines. The helper T cells contribute to the differentiation of null and NK cells.

### Complement System

Circulating plasma proteins, which are made in the liver and activated when an antibody couples with its antigen, are known as **complement**. These proteins interact sequentially with one another in a cascade or “falling domino” effect. This complement cascade alters the cell membranes on which antigen and antibody complex forms, permitting fluid to enter the cell and leading eventually to cell lysis and death. In addition, activated complement molecules attract macrophages and granulocytes to areas of antigen–antibody reactions. These cells continue the body's defense by devouring the antibody-coated microbes and by releasing bacterial agents.

Complement plays an important role in the immune response. Destruction of an invading or attacking organism or toxin is not achieved merely by the binding of the antibody and antigens; it also requires activation of complement, the arrival of killer T cells, or the attraction of macrophages. Complement has three major physiologic functions: defending the body against bacterial infection,

**Table 50-2 • Cytokines and Their Biologic Effects**

CYTOKINE*	ACTION
Interleukin-1	Promotes differentiation of T and B cells, natural killer (NK) cells, and null cells
Interleukin-2	Stimulates growth of T cells and special activated killer lymphocytes (known as lymphocyte-activated killer cells [LAK cells])
Interleukin-3	Stimulates growth of mast cells and other blood cells
Interleukin-4	Stimulates growth of T and B cells, mast cells, and macrophages
Interleukin-5	Stimulates antibody responses
Interleukin-6	Stimulates growth and function of B cells and antibodies
Interleukin-7	Stimulates growth of pre-B, CD4, and CD8, T cells and activates mature T cells
Interleukin-8	Promotes chemotaxis and activation of neutrophils
Interleukin-9	Stimulates growth and proliferation of T cells
Interleukin-10	Inhibits interferon-gamma and mononuclear cell inflammation
Interleukin-11	Promotes induction of acute-phase proteins
Interleukin-12	Introduces helper T cells
Interleukin-13	Inhibits mononuclear phagocyte inflammation and promotes differentiation of B cells
Interleukin-16	Promotes chemotaxis CD4 T cells and eosinophils
Permeability factor	Increases vascular permeability, allowing white cells into area
Interferon	Interferes with viral growth, stopping the spread of viral infection
Migration inhibitory factor	Suppresses movement of macrophages, keeping macrophages in area of foreign cells
Skin reactive factor	Induces inflammatory response
Cytotoxic factor (lymphotoxin)	Kills certain antigenic cells
Macrophage chemotactic factor	Attracts macrophages into the area
Lymphocyte blastogenic factor	Stimulates more lymphocytes, recruiting additional lymphocytes into the area
Macrophage aggregation factor	Causes clumping of macrophages and lymphocytes
Macrophage activation factor	Allows macrophages to adhere to surfaces more readily
Proliferation inhibitor factor	Inhibits growth of certain antigenic cells
Cytophilic antibody	Binds to an Fc receptor on macrophages, thereby permitting macrophages to bind to antigens
Tumor necrosis factor (alpha)	Stimulates inflammation, wound healing, and tissue remodeling
Tumor necrosis factor (beta)	Mediates inflammation and graft rejection

\* Cytokines are biologically active substances released by cells to regulate growth and function of other cells within the immune system. Lymphocytes produce lymphokines, and monocytes and macrophages produce monokines. This table lists some of the cytokines that play a role in immune system functioning.

bridging natural and acquired immunity, and disposing of immune complexes and the byproducts associated with inflammation (Walport, 2001a). Complement-mediated immune responses are summarized in Table 50-4.

There are several ways to activate the complement system: the classic pathway, the alternate pathway, and the lectin pathway (Delves & Roitt, 2000a).

### CLASSIC PATHWAY OF COMPLEMENT ACTIVATION

The classic pathway (the first method discovered) is activated by antigen-antibody complexes; it begins when antibody binds to a cell surface and ends with lysis of the cell. It involves the reaction of the first of the circulating complement proteins ( $C_1$ ) with the receptor site of the Fc portion of an antibody molecule after formation of an antigen-antibody complex. The activation of the first complement component then activates all the other components in the following sequence:  $C_4$ ,  $C_2$ ,  $C_3$ ,  $C_5$ ,  $C_6$ ,  $C_7$ ,  $C_8$ , and  $C_9$ . (The components are named in the sequence in which they were discovered.)

### ALTERNATE AND LECTIN PATHWAYS

The alternate and lectin pathways of complement activation are activated without the formation of antigen-antibody complexes. These pathways can be initiated by the release of bacterial products, such as endotoxins. When complement is activated without the formation of antigen-antibody complexes, the process bypasses the first three components ( $C_1$ ,  $C_4$ , and  $C_2$ ) and begins

with  $C_3$ . Whatever the method of activation, once activated, the complement destroys cells by altering or damaging the cell membrane of the antigen, by chemically attracting phagocytes to the antigen (chemotaxis), and by rendering the antigen more vulnerable to phagocytosis (opsonization). The complement system enhances the inflammatory response by releasing vasoactive substances.

Complement components, prostaglandins, leukotrienes, and other inflammatory mediators all contribute to the recruitment of inflammatory cells, as do chemokines, a group of cytokines. The activated neutrophils pass through the vessel walls to accumulate at the site of infection, where they phagocytose complement-coated microbes (Delves & Roitt, 2000a).

This response is usually therapeutic and can be lifesaving if the cell attacked by the complement system is a true foreign invader, such as a streptococcal or staphylococcal organism. If that cell, however, is in reality part of the person—a cell of the brain or liver, the tissue lining the blood vessels, or the cells of a transplanted organ or skin graft, for example—the result can be devastating disease and even death. The result of the immune response—the vigorous attack on any material identified as foreign, the deadliness of the struggle—is obvious in the purulent material, or pus (the remains of microbes, granulocytes, macrophages, T-cell lymphocytes, plasma proteins, complement, and antibodies), that accumulates in wound infections and abscesses. In addition, many autoimmune diseases (ie, systemic lupus erythematosus) and disorders characterized by chronic infection

**Table 50-3 • Lymphocytes Involved in Immune Responses**

CELL TYPE	FUNCTION	TYPE OF IMMUNE RESPONSE
<b>B cell</b>	Produces antibodies or immunoglobulins (IgA, IgD, IgE, IgG, IgM)	Humoral
<b>T cell</b>		Cellular
Helper T4	Attacks foreign invaders (antigens) directly	
Helper T <sub>1</sub>	Initiates and augments inflammatory response	
Helper T <sub>2</sub>	Increases activated cytotoxic T cells	
Helper T <sub>2</sub>	Increases B-cell antibody production	
Suppressor T	Suppresses the immune response	
Memory T	Remembers contact with an antigen and on subsequent exposures mounts an immune response	
Cytotoxic T (killer T)	Lyses cells infected with virus; plays a role in graft rejection	
<b>Non-T or non-B lymphocytes</b>		Nonspecific
Null cells	Destroys antigens already coated with antibody	
Natural killer (NK) (granular lymphocyte)	Defends against microorganisms and some types of malignant cells; produces cytokines	

(ie, hepatitis C, bacterial endocarditis) and necrosis (myocardial infarction, stroke) are thought to be due in part to continued or chronic activation of complement, which in turn causes chronic inflammation (Walport, 2001b).

The red blood cells (erythrocytes) and platelets (thrombocytes) also have a role in the immune response. Red blood cells

and platelets have complement receptors and as a result play an important role in the clearance of immune complexes that consist of antigen, antibody, and components of the complement system (Delves & Roitt, 2000a).

## Role of Interferons

Biologic response modifiers, such as the interferons, are under investigation to determine their roles in the immune system and their potential therapeutic effects in disorders characterized by disturbed immune responses. Interferons have antiviral and antitumor properties. In addition to responding to viral infection, they are produced by T lymphocytes, B lymphocytes, and macrophages in response to antigens. They are thought to modify the immune response by suppressing antibody production and cellular immunity. They also facilitate the cytolytic role of macrophages and NK cells. Interferons are undergoing extensive testing to evaluate their effectiveness in treating tumors and acquired immunodeficiency syndrome (AIDS). Some interferons are already used to treat immune-related disorders (eg, multiple sclerosis) and chronic inflammatory conditions (eg, chronic hepatitis).

## Advances in Immunology

### GENETIC ENGINEERING

One of the more remarkable technologies that is evolving is **genetic engineering**, which involves the use of recombinant DNA technology. Two facets exist with this technology. The first permits scientists to combine genes from one type of organism with genes of a second organism. This type of technology allows cells and microorganisms to manufacture proteins, monokines and lymphokines, which can alter and enhance immune system function. The second facet of recombinant DNA technology involves gene therapy. For example, if a particular gene is abnormal or missing, a recombinant gene can be inserted onto a virus particle. When the virus splices its genes, it will automatically insert the missing gene, which theoretically will correct the situation and revitalize the immune system in an immune deficiency disorder. These genes can be carried via harmless viruses, inactivated retroviruses, grafted onto a protein carrier, or hidden in fat globules that are known as liposomes (Delves & Roitt, 2000b). Extensive research into recombinant DNA technology and gene therapy is ongoing.

### STEM CELLS

Stem cell research also is underway. The stem cell is known as a precursor cell that continually replenishes the body's entire supply of both red and white cells. Stem cells represent only a small portion of all types of bone marrow cells. Research conducted with mouse models has demonstrated that once the immune system has been destroyed experimentally, it can be completely restored with the implantation of just a few purified stem cells. Stem cell transplantation has been carried out in humans with certain types of immune dysfunction, such as severe combined immunodeficiency (SCID) (Parslow, Stites, Terr & Imboden, 2001). Clinical trials using stem cells are underway in patients with a variety of disorders with an autoimmune component, including systemic lupus erythematosus, rheumatoid arthritis, scleroderma, and multiple sclerosis (Davidson & Diamond, 2001).

**Table 50-4 • Complement-Mediated Immune Responses**

RESPONSE	EFFECTS
Cytolysis	Lysis and destruction of cell membranes of body cells or pathogens
Isonization	Targeting of the antigen so that it can be easily engulfed and digested by the macrophages and other phagocytic cells
Chemotaxis	Chemical attraction of neutrophils and phagocytic cells to the antigen
Anaphylaxis	Activation of mast cells and basophils with release of inflammatory mediators that produce smooth muscle contraction and increased vascular permeability

## IMMUNOREGULATION

A successful immune response eliminates the inciting antigen. Once the antigen that has stimulated the immune response is eliminated, the response returns to a nearly normal level. This process, known as **immunoregulation**, balances and counterbalances the immune response. For example, autoimmune diseases can be better controlled by suppressing areas of the immune system that are overactive and boosting those areas that are underactive. Immunoregulation research holds the promise of preventing graft rejection and aiding the body in dispersing cells that are cancerous or infected (Delves & Roitt, 2000b).

## Assessment

An assessment of immune function begins with a health history and physical examination. The history should note the patient's age along with information about past and present conditions and events that may provide clues to the status of the patient's immune system. Areas to be addressed include nutritional status; infections and immunizations; allergies; disorder and disease states, such as autoimmune disorders, cancer, and chronic illnesses; surgery; medications; and blood transfusions. Physical assessment includes palpation of the lymph nodes and examination of the skin, mucous membranes, and respiratory, gastrointestinal, genitourinary, cardiovascular, and neurosensory systems (Chart 50-2).

## HEALTH HISTORY

### Age

Age is an important factor to elicit from the patient as people at the extremes of the life span are more likely to develop problems related to immune system functioning than are those in their middle years (Table 50-5).

### Gerontological Considerations

The frequency and severity of infections are increased in elderly people, possibly due to a decreased ability to respond adequately to invading organisms. Both the production and the function of T and B lymphocytes may be impaired. Responses to antigen stimulation may be altered, with increasing proportions of lymphocytes becoming unresponsive with age (Porth, 2002). The incidence of autoimmune diseases also increases with aging, possibly from a decreased ability of antibodies to differentiate between self and nonself. Failure of the surveillance system to recognize mutant, or abnormal, cells may be responsible for the high incidence of cancer associated with increasing age.

Declining function of various organ systems associated with increasing age also contributes to impaired immunity. Decreased gastric secretions and motility allow normal intestinal flora to proliferate and produce infection, causing gastroenteritis and diarrhea. Decreased renal circulation, filtration, absorption, and excretion contribute to risk for urinary tract infections. Moreover, prostatic enlargement and neurogenic bladder can impede urine passage and subsequently bacterial clearance through the urinary system. Urinary stasis, common in elderly people, permits the growth of microorganisms. Exposure to tobacco and environmental toxins impairs pulmonary function. Prolonged exposure to these agents decreases the elasticity of lung tissue, the effec-

### Chart 50-2 • ASSESSMENT

#### Indications of Immune Dysfunction

##### Respiratory System

- Changes in respiratory rate
- Cough (dry or productive)
- Abnormal lung sounds (wheezing, crackles, rhonchi)
- Rhinitis
- Hyperventilation
- Bronchospasm

##### Cardiovascular System

- Hypotension
- Tachycardia
- Dysrhythmia
- Vasculitis
- Anemia

##### Gastrointestinal System

- Hepatosplenomegaly
- Colitis
- Vomiting
- Diarrhea

##### Genitourinary System

- Frequency and burning on urination
- Hematuria
- Discharge

##### Skin

- Rashes
- Lesions
- Dermatitis
- Hematomas or purpura
- Edema or urticaria
- Inflammation
- Discharge

##### Neurosensory System

- Cognitive dysfunction
- Hearing loss
- Visual changes
- Headaches and migraines
- Ataxia
- Tetany

tiveness of cilia, and the ability to cough effectively. These impairments hinder the removal of infectious organisms and toxins, increasing the elderly person's susceptibility to pulmonary infections and cancers.

Finally, with aging, the skin becomes thinner and less elastic. Peripheral neuropathy and the accompanying decreased sensation and circulation may lead to stasis ulcers, pressure ulcers, abrasions, and burns. Impaired skin integrity predisposes the aging person to infection from organisms that are part of normal skin flora.

## Nutrition

The nurse assesses the patient's nutritional status, including caloric intake as well as the type of calories that the patient is consuming. Adequate nutrition is essential for optimal functioning of the immune system. Inadequate intake of vitamins that are essential for DNA and protein synthesis may lead to protein-calorie deficiency and subsequently to impaired immune function. Vitamins also

**Table 50-5 • Age-Related Changes in Immunologic Function**

BODY SYSTEM	CHANGES	CONSEQUENCES
Immune system	Impaired function of B and T lymphocytes Failure of lymphocytes to recognize mutant or abnormal cells Decreased antibody production Failure of immune system to differentiate “self” from “non-self” Suppressed phagocytic immune response	Suppressed responses to pathogenic organisms with increased risk for infection Increased incidence of cancers Anergy (lack of response to antigens applied to the skin [PPD, allergens]) Increased incidence of autoimmune diseases Absence of typical signs and symptoms of infection and inflammation Dissemination of organisms usually destroyed or suppressed by phagocytes (reactivation or spread of TB)
Gastrointestinal system	Decreased gastric secretions and motility Decreased phagocytosis by the liver’s Kupffer cells Altered nutritional intake with inadequate protein intake	Proliferation of intestinal organisms resulting in gastroenteritis and diarrhea Increased incidence and severity of hepatitis B; increased incidence of liver abscesses Suppressed immune response
Urinary system	Decreased kidney function and changes in lower urinary tract function (enlargement of prostate gland, neurogenic bladder). Altered genitourinary tract flora.	Urinary stasis and increased incidence of urinary tract infections
Pulmonary system	Impaired ciliary action due to exposure to smoke and environmental toxins	Impaired clearance of pulmonary secretions; increased incidence of respiratory infections
Integumentary system	Thinning of skin with less elasticity; loss of adipose tissue	Increased risk of skin injury, breakdown and infection
Circulatory system	Impaired microcirculation	Stasis and pressure ulcers
Neurologic function	Decreased sensation and slowing of reflexes	Increased risk of injury (ulcers, abrasions, burns)

help in the regulation of cell proliferation and maturation of immune cells. Excess or deficiency of trace elements (ie, copper, iron, manganese, selenium, or zinc) in the diet generally suppresses immune function.

Fatty acids are the building blocks that make up the structural components of cell membranes. Lipids are precursors of vitamins A, D, E, and K as well as cholesterol. Both excess and deficiency of fatty acids have been found to suppress immune function.

Depletion of protein reserves results in atrophy of lymphoid tissues, depression of antibody response, reduction in the number of circulating T cells, and impaired phagocytic function. As a result, susceptibility to infection is greatly increased. During periods of infection and serious illness, nutritional requirements may be exaggerated further, potentially contributing to depletion of protein, fatty acid, vitamin, and trace elements and an even greater risk of impaired immune response and sepsis.

## Infection and Immunization

The patient is asked about immunizations (including those received recently and those received in childhood) and the usual childhood diseases. Known past or present exposure to tuberculosis is assessed, and the dates and results of any tuberculin tests (purified protein derivative [PPD] or tine test) and chest x-rays are obtained. Recent patient exposure to any infections and the exposure dates are elicited. It is important for the nurse to assess whether the patient has been exposed to any sexually transmitted diseases and bloodborne pathogens such as hepatitis A, B, C, D, and E infections, and HIV infection. A history of sexually transmitted diseases, such as gonorrhea, syphilis, HPV infection, and chlamydia, can alert the nurse that the patient may have been exposed to HIV infection or hepatitis. A history of past and present

infections and the dates and types of treatments that were used, along with a history of any multiple persistent infections, fevers of unknown origin, lesions or sores, or any type of drainage, are obtained.

## Allergy

The patient is asked about history of any allergies, including types of allergens (pollens, dust, plants, cosmetics, food, medications, vaccines), the symptoms experienced, and seasonal variations in occurrence or severity in the symptoms. A history of testing and treatments that the patient has received or is currently receiving for these allergies and the effectiveness of the treatments is obtained. All medication and food allergies are listed on an allergy alert sticker and placed on the front of the patient’s health record or chart to alert others to the possibility of these allergies. Continued assessment for potential allergic reactions in this patient is vital.

## Disorders and Diseases

### AUTOIMMUNE DISORDERS

The patient is asked about any autoimmune disorders, such as lupus erythematosus, rheumatoid arthritis, or psoriasis. The onset, severity, remissions and exacerbations, functional limitations, treatments that the patient has received or is currently receiving, and the effectiveness of the treatments are described. Although most autoimmune disorders are individually rare, together they affect approximately 5% of the U.S. population. The occurrence of different autoimmune diseases within a family strongly suggests a genetic predisposition to more than one autoimmune disease (Davidson & Diamond, 2001).

In general, autoimmune disorders are more common in females than in males. This is believed to be the result of the activity of the sex hormones. The ability of sex hormones to modulate immunity has been well established. There is evidence that estrogen modulates the activity of T lymphocytes (especially suppressor cells), whereas androgens act to preserve IL-2 production and suppressor cell activity. The effects of sex hormones on B cells are less pronounced. Estrogen activates the autoimmune-associated B-cell population that expresses the CD5 marker (an antigenic marker on the B cell). Estrogen tends to enhance immunity, whereas androgen tends to be immunosuppressive.

### NEOPLASTIC DISEASE

A history of cancer in the patient is obtained, along with the type of cancer and date of diagnosis. Dates and results of any cancer screening tests are also obtained.

Immunosuppression contributes to the development of cancers; however, cancer itself is immunosuppressive. Large tumors can release antigens into the blood, and these antigens combine

with circulating antibodies and prevent them from attacking the tumor cells. Furthermore, tumor cells may possess special blocking factors that coat tumor cells and prevent destruction by killer T lymphocytes. During the early development of tumors, the body may fail to recognize the tumor antigens as foreign and subsequently fail to initiate destruction of the malignant cells. Hematologic cancers, such as leukemia and lymphoma, are associated with altered production and function of WBCs and lymphocytes.

All treatments that the patient has received or is currently receiving, such as radiation or chemotherapy, are identified and documented in the health history. Radiation destroys lymphocytes and decreases the population of cells required to replace them. The size or extent of the irradiated area determines the extent of immunosuppression. Whole-body irradiation may leave the patient totally immunosuppressed. Chemotherapy also destroys immune cells and causes immunosuppression.

A family history of cancer is obtained. If there is a family history of cancer, the type of cancer, age of onset, and relationship (maternal or paternal) of the patient to the affected family member is noted. (See Genetics in Nursing Practice.)

## GENETICS IN NURSING PRACTICE—Immunologic Disorders

### IMMUNOLOGIC DISORDERS INFLUENCED BY GENETIC FACTORS

- Ankylosing spondylitis
- Ataxia-telangiectasia
- Bloom syndrome
- Common variable immunodeficiency
- Fanconi anemia
- Rheumatoid arthritis
- Systemic lupus erythematosus (SLE)
- Severe combined immune deficiency (SCID)

### NURSING ASSESSMENTS

#### FAMILY HISTORY ASSESSMENT

- Inquire about rheumatic diseases such as rheumatoid arthritis, ankylosing spondylitis, and systemic lupus erythematosus in other family members in several generations.
- Inquire about ethnic background (eg, Bloom syndrome is common among individuals of Ashkenazi heritage).
- Assess family history for closely related members with immune deficiency.
- Determine the age of onset of symptoms in affected family members (eg, for SCID, symptoms of pneumonia and unresponsive candidiasis are evident within the first 3 months of life).

#### PHYSICAL ASSESSMENT

- In children, assess for other clinical signs of immune dysfunction, including failure to thrive, growth retardation, developmental delays, pallor, irritability.
- Assess skin for cutaneous telangiectases (spider-like blood vessels in ataxia telangiectasia, or as in Bloom syndrome in a butterfly pattern on the nose and cheeks).
- Assess for hyperpigmentation, short stature, and other organ involvement seen in Fanconi anemia.

### MANAGEMENT ISSUES SPECIFIC TO GENETICS

- Inquire whether DNA mutation or other genetic testing has been performed on affected family members.
- If indicated, refer for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, availability of genetic testing and gene-based interventions.
- Offer appropriate genetics information and resources.
- Assess patient's understanding of genetics information.
- Provide support to families with newly diagnosed genetic-related immune disorders.
- Participate in management and coordination of care of patients with genetic conditions and individuals predisposed to develop or pass on a genetic condition.

National Organization of Rare Disorders <http://www.rarediseases.org>—a directory of support groups and information for patients and families with rare genetic disorders

OMIM: Online Mendelian Inheritance in Man <http://www.ncbi.nlm.nih.gov/omim/stats/html>—a complete listing of inherited genetic conditions

## CHRONIC ILLNESS AND SURGERY

The health assessment includes a history of chronic illnesses, such as diabetes mellitus, renal disease, or chronic obstructive pulmonary disease. The onset and severity of illnesses, as well as treatment that the patient is receiving for the illness, are obtained. Chronic illness may contribute to immune system impairments in various ways. Renal failure is associated with a deficiency in circulating lymphocytes. In addition, immune defenses may be altered by acidosis and uremic toxins. In diabetes, an increased incidence of infection has been associated with vascular insufficiency, neuropathy, and poor control of serum glucose levels. Recurrent respiratory tract infections are associated with chronic obstructive pulmonary disease as a result of altered inspiratory and expiratory function and ineffective airway clearance. Additionally, a history of surgical removal of the spleen, lymph nodes, or thymus or a history of organ transplantation is noted because these conditions may place the patient at risk for impaired immune function.

## SPECIAL PROBLEMS

Conditions such as burns and other forms of injury and infection may contribute to altered immune system function. Major burns or other factors cause impaired skin integrity and compromise the body's first line of defense. Loss of large amounts of serum with burn injuries depletes the body of essential proteins, including immunoglobulins. The physiologic and psychological stressors associated with surgery or injury stimulate cortisol release from the adrenal cortex; increased serum cortisol also contributes to suppression of normal immune responses.

## Medications and Blood Transfusions

A list of past and present medications is obtained. In large doses, antibiotics, corticosteroids, cytotoxic agents, salicylates, nonsteroidal anti-inflammatory drugs (NSAIDs), and anesthetics can cause immune suppression (Table 50-6).

A history of blood transfusions is obtained because previous exposure to foreign antigens through transfusion may be associated with abnormal immune function. Additionally, although the risk of human immunodeficiency virus (HIV) transmission through blood transfusion is extremely low in patients who received a transfusion after 1985 (the year that testing of blood for HIV was initiated in the United States), a risk still exists.

The patient is also asked about use of herbal agents and over-the-counter medications. Because many of these products have not been subjected to rigorous testing, not all of their effects have been identified. It is important, therefore, to ask patients about their use of these substances and to document their use.

## Lifestyle and Other Factors

Like any other body system, the immune system functions depend on other body systems. A detailed history of smoking, alcohol consumption, dietary intake and nutritional status, amount of perceived stress, injection drug use, sexual practices, sexually transmitted diseases, and occupational or residential exposure to radiation or pollutants is obtained. Poor nutritional status, smoking, excessive consumption of alcohol, injection drug use, sexually transmitted diseases, and exposure to environmental radiation and pollutants have been associated with impaired immune function and are assessed in the patient history.

**Table 50-6 • Selected Medications and Effects on the Immune System**

DRUG CLASSIFICATION (AND EXAMPLES)	EFFECTS ON THE IMMUNE SYSTEM
<b>Antibiotics (in large doses)</b>	<b>Bone Marrow Suppression</b>
ceftriaxone (Rocefin)	Eosinophilia, hemolytic anemia, hypoprothrombinemia, neutropenia, thrombocytopenia
cefuroxime sodium (Ceftin)	Eosinophilia, hemolytic anemia, hypoprothrombinemia, neutropenia, thrombocytopenia
chloramphenicol (Chloromycetin)	Leukopenia, aplastic anemia
dactinomycin (Cosmogen)	Agranulocytosis, neutropenia
fluoroquinolones (Cipro, Levaquin, Tequin)	Hemolytic anemia, methemoglobinemia, eosinophilia, leukopenia, pancytopenia
gentamicin sulfate (Garamycin)	Agranulocytosis, granulocytosis
macrolides (erythromycin, Zithromax, Biaxin)	Neutropenia, leukopenia
penicillins	Agranulocytosis
streptomycin	Leukopenia, neutropenia, pancytopenia
vancomycin (Vancocin, Vancoled)	Transient leukopenia
<b>Antithyroid Drugs</b>	
propylthiouracil (PTU)	Agranulocytosis, leukopenia
<b>Nonsteroidal Anti-inflammatory Drugs (NSAIDs) (in large doses)</b>	<b>Inhibit Prostaglandin Synthesis or Release</b>
aspirin	Agranulocytosis
cox-2 inhibitors (Vioxx, Celebrex, Bextra)	Anemia, allergy, no major other adverse affects to the immune system
ibuprofen (Advil, Motrin)	Leukopenia, neutropenia
indomethacin (Indocid, Indocin)	Agranulocytosis, leukopenia
phenylbutazone	Pancytopenia, agranulocytosis, aplastic anemia
<b>Adrenal Corticosteroids</b>	<b>Immunosuppression</b>
prednisone	
<b>Antineoplastic Agents (Cytotoxic Agents)</b>	<b>Immunosuppression</b>
alkylating agents	Leukopenia
cyclophosphamide (Cytoxan)	Leukopenia, neutropenia
mechlorethamine HCl (Mustargen)	Agranulocytosis, neutropenia
cyclosporine	Leukopenia, inhibits T-cell function
<b>Antimetabolites</b>	<b>Immunosuppression</b>
fluorouracil (pyrimidine antagonist)	Leukopenia, eosinophilia
methotrexate (folic acid antagonist)	Leukopenia, aplastic bone marrow
mercaptopurine (6-MP) (purine antagonist)	Leukopenia, pancytopenia

## PSYCHONEUROIMMUNOLOGIC FACTORS

The assessment also addresses psychoneuroimmunologic factors. It is thought that the immune response is regulated and modulated in part by neuroendocrine influences. Lymphocytes and macrophages have receptors capable of responding to neurotransmitters and endocrine hormones. Lymphocytes can produce and secrete adrenocorticotrophic hormone and endorphin-like

compounds. Neurons in the brain, especially in the hypothalamus, can recognize prostaglandins, interferons, and interleukins as well as histamine and serotonin, which are released during the inflammatory process. Like all other biologic systems functioning in the interest of homeostasis, the immune system is integrated with other psychophysiological processes and is subject to regulation and modulation by the brain.

Conversely, the immune processes can affect neural and endocrine function, including behavior. Thus, the interaction of the nervous system and immune system appears to be bidirectional. Growing evidence indicates that measurable immune system parameters can be influenced by biobehavioral strategies involving self-regulation. Examples of these strategies are relaxation and imagery techniques, biofeedback, humor, hypnosis, and conditioning. The assessment should address the patient's general psychological status and the patient's use of these strategies.

## PHYSICAL EXAMINATION

On physical examination (see Chart 50-2), the skin and mucous membranes are assessed for lesions, dermatitis, purpura (subcutaneous bleeding), urticaria, inflammation, or any discharge. Any signs of infection are noted. The patient's temperature is recorded, and the patient is observed for chills and sweating. The anterior and posterior cervical, axillary, and inguinal lymph nodes are palpated for enlargement; if palpable nodes are detected, the location, size, consistency, and reports of tenderness upon palpation are noted. Joints are assessed for tenderness and swelling and for limited range of motion. The patient's respiratory, cardiovascular, gastrointestinal, genitourinary, and neurosensory status is evalu-

ated for signs and symptoms indicative of immune dysfunction. The patient's nutritional status, level of stress, and coping ability are also assessed, along with his or her age and any functional limitations or disabilities.

## Diagnostic Evaluation

A series of blood tests and skin tests and a bone marrow biopsy may be performed to evaluate the patient's immune competence. Specific laboratory and diagnostic tests are discussed in greater detail along with specific disease processes in subsequent chapters in this unit. Laboratory and diagnostic tests used to evaluate immune competence are summarized in Chart 50-3.

## Nursing Management

The nurse needs to be aware that patients undergoing evaluation for possible immune system disorders experience not only physical pain and discomfort with certain types of diagnostic procedures, but many psychological reactions as well. For example, patients may fear test results that demonstrate decreased immune function that makes them more prone to certain infections, cancers, and other disorders. It is the nurse's role to counsel, educate, and support patients throughout the diagnostic process. Further, many patients may be extremely anxious about the results of diagnostic tests and the possible implications of those results for their employment, insurance, and personal relationships. This is an opportune time for the nurse to provide counseling and education should these interventions be warranted.

### Chart 50-3

#### Selected Tests for Evaluating Immunologic Status

Various laboratory tests may be performed to assess immune system activity or dysfunction. The studies assess leukocytes and lymphocytes, humoral immunity, cellular immunity, phagocytic cell function, complement activity, hypersensitivity reactions, specific antigen-antibodies, or HIV infection.

##### Leukocytes and Lymphocyte Tests

- White blood cell count and differential
- Bone marrow biopsy

##### Humoral (Antibody-Mediated) Immunity Tests

- B-cell quantification with monoclonal antibody
- In vivo immunoglobulin synthesis with T-cell subsets
- Specific antibody response
- Total serum globulins and individual immunoglobulins (by electrophoresis, immunoelectrophoresis, single radial immunodiffusion, nephelometry, isohemagglutinin techniques)

##### Cellular (Cell-Mediated) Immunity Tests

- Total lymphocyte count
- T-cell and T-cell subset quantification with monoclonal antibody
- Delayed hypersensitivity skin test
- Cytokine production
- Lymphocyte response to mitogens, antigens, and allogenic cells
- Helper and suppressor T-cell functions

##### Phagocytic Cell Function Tests

- Nitroblue tetrazolium reductase assay

##### Complement Component Tests

- Total serum hemolytic complement
- Individual complement component titrations
- Radial immunodiffusion
- Electroimmunoassay
- Radioimmunoassay
- Immunonephelometric assay
- Immunoelectrophoresis

##### Hypersensitivity Tests

- Scratch test
- Patch test
- Intradermal test
- Radioallergosorbent test (RAST)

##### Specific Antigen-antibody Tests

- Radioimmunoassay
- Immunofluorescence
- Agglutination
- Complement fixation test

##### HIV Infection Tests

- Enzyme-linked immunosorbent assay (ELISA)
- Western blot
- CD4 and CD8 cell counts
- P24 antigen test
- Polymerase chain reaction (PCR)

## Critical Thinking Exercises

1. An 18-year-old man presents for a physical examination to enter college. His mother asks if her son should receive a vaccination to prevent meningococcal meningitis. How would you respond? What recommendations would you give her, and why?
2. A 68-year-old woman is hospitalized for a heart transplant, and immune suppressant medications are given. Describe the parameters you would use to assess her immune function. How would altered immune function affect the care that you provide?
3. An 84-year-old woman who lives alone and has a long history of use of corticosteroids to treat rheumatoid arthritis is hospitalized with pneumonia. Discuss the changes in her immune status due to aging that need to be considered in her care. Identify the assessment strategies that are indicated.

# ● Management of Patients With Immunodeficiency

## **LEARNING OBJECTIVES**

*On completion of this chapter, the learner will be able to:*

1. Compare the different types of primary immunodeficiency disorders, addressing causes, clinical manifestations, management, possible complications, and available treatments.
2. Discuss the possible management of patients with immunodeficiency disorders.
3. Describe the nursing management of the patient with an immunodeficiency.
4. Identify the teaching points necessary for a patient with an immunodeficiency.

**I**mmunodeficiency disorders may be caused by a defect or deficiency in phagocytic cells, B lymphocytes, T lymphocytes, or the complement system. The specific symptoms and their severity, age of onset, and prognosis depend on the immune system components affected and their degree of functional impairment. Regardless of the underlying cause, the cardinal symptoms of immunodeficiency include chronic or recurrent severe infections, infections caused by unusual organisms or organisms that are normal body flora, poor response to treatment of infections, and chronic diarrhea. In addition, the patient is susceptible to a variety of secondary disorders, including cancer (Buckley, 2000).

Immunodeficiencies may be classified as either primary or secondary and by the components of the immune system that are affected. Primary immunodeficiency diseases are genetic in origin and are caused by intrinsic defects in the cells of the immune system. This is in contrast to secondary immunodeficiencies such as AIDS, caused by infection with human immunodeficiency virus (HIV). Knowledge of the immune system and of the possibility of secondary disorders, skillful assessment and management, and sensitivity and responsiveness to the learning needs of the patient and caregiver are the essential elements for effective nursing care.

## Primary Immunodeficiencies

Primary immunodeficiencies, rare disorders with genetic origins, are seen primarily in infants and young children. To date, more than 95 immunodeficiencies of genetic origin have been identified (Buckley, 2000). Symptoms usually develop early in life after protection from maternal antibodies decreases. Without treatment, infants and children with these disorders seldom survive to adulthood. These disorders may involve one or more components of the immune system. Symptoms of immune deficiency diseases are related to the role that the deficient component normally plays (Table 51-1).

## PHAGOCYtic DYSFUNCTION

### Pathophysiology

A variety of primary defects of phagocytes may occur; nearly all of them are genetic in origin and affect the innate immune system. In some types of phagocytic disorders, the neutrophils are impaired so that they cannot exit the circulation and travel to sites of infection. As a result the patient cannot mount a normal inflammatory response against pathogenic organisms (Lekstrom-Himes & Gallin, 2002). In some disorders, the neutrophil count may be very low; in others, it may be very high because the neutrophils remain in the vascular system.

## Clinical Manifestations

Phagocytic cell disorders are manifested by an increased incidence of bacterial and fungal infections due to normally nonpathogenic organisms (Lekstrom-Himes & Gallin, 2002). People with these disorders may also develop fungal infections from *Candida* organisms and viral infections from herpes simplex or herpes zoster virus. These patients experience recurrent furunculosis, cutaneous abscesses, chronic eczema, bronchitis, pneumonia, chronic otitis media, and sinusitis. In one type of phagocytic disorder, hyperimmunoglobulinemia E (HIE) syndrome, formerly known as Job syndrome, white blood cells cannot produce an inflammatory response to the skin infections; this results in deep-seated cold abscesses that lack the classic signs and symptoms of inflammation (redness, heat, and pain).

While patients with phagocytic cell disorders may be asymptomatic, severe neutropenia may be accompanied by deep and painful mouth ulcers, gingivitis, stomatitis, and cellulitis. Death from overwhelming infection occurs in about 10% of patients with severe neutropenia. Chronic granulomatous disease, another type of primary phagocytic disorder, produces recurrent or persistent infections of the soft tissues, lungs, and other organs; these are resistant to aggressive treatment with antibiotics (Lekstrom-Himes & Gallin, 2002).

## Assessment and Diagnostic Findings

Diagnosis is based on the history, signs and symptoms, and laboratory analysis of the cytotoxic (causing the death of cells) activity of the phagocytic cells by the nitroblue tetrazolium reductase test (see Chart 50-3 in Chap. 50). A history of recurrent infection and fever in a child and occasionally in an adult is an important key to the diagnosis. Failure of an infection to resolve with usual treatment is also an important indicator (Lekstrom-Himes & Gallin, 2002). See Chart 51-1 for a summary of warning signs of primary immunodeficiency disorders.

## Medical Management

Because the signs and symptoms of infection are often blunted because of an impaired inflammatory response, early diagnosis and treatment of infectious complications can be lifesaving (Lekstrom-Himes & Gallin, 2002). Management of phagocytic cell disorders includes treating bacterial infections with prophylactic antibiotic therapy. Additional treatment for fungal and viral infections is often needed. Granulocyte transfusions, although used, are seldom successful because of the short half-life of the cells. Treatment with granulocyte-macrophage colony-stimulating factor (GM-CSF) or granulocyte colony-stimulating factor (G-CSF) may

## Glossary

**agammaglobulinemia:** disorder marked by an almost complete lack of immunoglobulins or antibodies

**angioneurotic edema:** condition marked by development of urticaria and an edematous area of skin, mucous membranes, or viscera

**ataxia:** uncoordinated muscle movement

**ataxia-telangiectasia:** autosomal recessive disorder affecting T- and B-cell immunity primarily seen in children and resulting in a degenerative brain disease

**hypogammaglobulinemia:** lack of one or more of the five immunoglobulins; caused by B-cell deficiency

**immunocompromised host:** person with a secondary immunodeficiency and associated immunosuppression

**panhypoglobulinemia:** general lack of immunoglobulins in the blood

**severe combined immunodeficiency disease (SCID):** disorder involving a complete absence of humoral and cellular

immunity resulting from an X-linked or autosomal genetic abnormality

**telangiectasia:** vascular lesions caused by dilated blood vessels

**thymic hypoplasia:** T-cell deficiency that occurs when the thymus gland fails to develop normally during embryogenesis; also known as DiGeorge syndrome

**Wiskott-Aldrich syndrome:** immunodeficiency characterized by thrombocytopenia and the absence of T and B cells

Table 51-1 • Selected Primary Immunodeficiency Disorders

IMMUNE COMPONENT	DISORDER	MAJOR SYMPTOMS	TREATMENT
Phagocytic cells	Hyperimmunoglobulinemia E (HIE) syndrome	Bacterial, fungal, and viral infections; deep-seated cold abscesses	Antibiotic therapy and treatment for viral and fungal infections Granulocyte-macrophage colony-stimulating factor (GM-CSF); granulocyte colony-stimulating factor (G-CSF)
B lymphocytes	Sex-linked agammaglobulinemia (Bruton's disease)	Severe infections soon after birth	Passive pooled plasma or gamma-globulin
	Common variable immunodeficiency (CVID)	Bacterial infections, infection with <i>Giardia lamblia</i>  Pernicious anemia Chronic respiratory infections	IV immunoglobulin Metronidazole (Flagyl) Quinacrine HCl (Atabrine) Vitamin B <sub>12</sub> Antimicrobial therapy
	Immunoglobulin A (IgA) deficiency	Predisposition to recurrent infections, adverse reactions to blood transfusions or immunoglobulin, autoimmune diseases, hypothyroidism	None
	IgC <sub>2</sub> deficiency	Heightened incidence of infectious diseases	Pooled immunoglobulin
T lymphocytes	Thymic hypoplasia (DiGeorge syndrome)	Recurrent infections; hypoparathyroidism; hypocalcemia, tetany, convulsions; congenital heart disease; possible renal abnormalities; abnormal facies	Thymus graft
	Chronic mucocutaneous candidiasis	<i>Candida albicans</i> infections of mucous membrane, skin, and nails; endocrine abnormalities (hypoparathyroidism, Addison's disease)	Antifungal agents: Topical: miconazole Oral: clotrimazole, ketoconazole IV: amphotericin B
B and T lymphocytes	Ataxia-telangiectasia	Ataxia with progressive neurologic deterioration; telangiectasia (vascular lesions); recurrent infections; malignancies	Antimicrobial therapy; management of presenting symptoms; fetal thymus transplant, IV immunoglobulin
	Nezelof's syndrome	Severe infections; malignancies	Antimicrobial therapy; IV immunoglobulin, bone marrow transplantation; thymus transplantation; thymus factors
	Wiskott-Aldrich syndrome	Thrombocytopenia, resulting in bleeding; infections; malignancies	Antimicrobial therapy; splenectomy with continuous antibiotic prophylaxis; IV immunoglobulin and bone marrow transplantation
	Severe combined immunodeficiency disease (SCID)	Overwhelming severe fatal infections soon after birth (also includes opportunistic infections)	Antimicrobial therapy; IV immunoglobulin and bone marrow transplantation
Complement system	Angioneurotic edema	Episodes of edema in various parts of the body, including respiratory tract and bowels	Pooled plasma, androgen therapy
	Paroxysmal nocturnal hemoglobinuria (PNH)	Lysis of erythrocytes due to lack of decay-accelerating factor (DAF) on erythrocytes	None

Chart  
51-1

## The 10 Warning Signs of Primary Immune Deficiency

Primary immune deficiency causes children and adults to have infections that come back frequently or are unusually hard to cure. In America alone, up to 1/2 million people suffer from one or more of the 70 known primary immune deficiency diseases.

If you or your child is affected by more than one of the following conditions, speak to your doctor about the possible presence of primary immune deficiency.

- |  |   |
|--|---|
| <p>1 Eight or more new ear infections within 1 year.</p>       | <p>6 Recurrent, deep skin or organ abscesses.</p>   |
| <p>2 Two or more serious sinus infections within 1 year.</p>   | <p>7 Persistent thrush in mouth or elsewhere on skin, after age 1.</p>                                |
| <p>3 Two or more months on antibiotics with little effect.</p> | <p>8 Need for intravenous antibiotics to clear infections.</p>  |
| <p>4 Two or more pneumonias within 1 year.</p>                 | <p>9 Two or more deep-seated infections such as meningitis, osteomyelitis, cellulitis, or sepsis.</p> |
| <p>5 Failure of an infant to gain weight or grow normally.</p> | <p>10 A family history of primary immune deficiency.</p>  |

Though the primary immune deficiency diseases can be serious, they are rarely fatal and can generally be controlled. Primary immune deficiency should not be confused with AIDS. Primary immune deficiency can be diagnosed through blood tests and should be detected as soon as possible to prevent avoidable permanent damage. As with all disease, only direct examination by a physician should be used to determine the presence of primary immune deficiency.

Educational materials developed by the Jeffrey Modell Foundation Medical Advisory Board, New York, NY. Used with permission.

prove successful because these proteins draw nonlymphoid stem cells from the bone marrow and hasten their maturation.

## B-CELL DEFICIENCIES

### Pathophysiology

Two types of inherited B-cell deficiencies exist. The first type results from lack of differentiation of B-cell precursors into mature B cells. As a result, plasma cells are lacking, and the germinal centers from all lymphatic tissues disappear, leading to a complete lack of antibody production against invading bacteria, viruses, and other pathogens. Infants born with this disorder suffer from severe infections starting soon after birth. This syndrome is called sex-linked **agammaglobulinemia** (Bruton's disease) because all antibodies disappear from the patient's plasma. B cells in the peripheral blood and the immunoglobulins IgG, IgM, IgA, IgD, and IgE are low or absent. The prevalence of this disorder is approximately 1 case per 100,000 population (Parslow, Stites, Terr & Imboden, 2001).

The second type of B-cell deficiency results from a lack of differentiation of B cells into plasma cells. Only diminished an-

tibody production occurs with this disorder. Although plasma cells are the most vigorous producers of antibodies, affected patients have normal lymph follicles and many B lymphocytes that produce some antibodies. This syndrome, called **hypogammaglobulinemia**, is a frequently occurring immunodeficiency (CVID), a term that encompasses a variety of defects ranging from immunoglobulin A (IgA) deficiency, in which only the plasma cells that produce IgA are lacking, to the other extreme, in which there is severe **panhypoglobulinemia** (general lack of immunoglobulins in the blood).

CVID is the most common primary immunodeficiency seen in adults; it can occur in either gender. Although it can occur at any age, its onset is most often in the second decade of life. The vast majority of patients do not become symptomatic until 15 to 35 years of age. The major immunologic features of CVID include recurrent pyogenic infections, an increased incidence of autoimmune diseases, and a decreased level of total immunoglobulins, with IgG below 250 mg/dL. The B-cell numbers usually remain normal. The etiology of this disorder is unknown and believed to be multifactorial. The prevalence of CVID is about

1 case per 80,000 population in the United States (Tierney, McPhee & Papdakis, 2001).

## Clinical Manifestations

Infants with sex-linked agammaglobulinemia usually become symptomatic after the natural loss of maternally transmitted immunoglobulins, which occurs at about 5 to 6 months of age. Symptoms of recurrent pyogenic infections usually occur by 5 to 6 months of age.

More than half of patients with CVID develop pernicious anemia. Lymphoid hyperplasia of the small intestine and spleen and gastric atrophy detected by biopsy of the stomach are common findings. Other autoimmune diseases, such as arthritis and hypothyroidism, frequently develop in patients with CVID. Those who develop late-onset disease also have an increased incidence of chronic lung disease, hepatitis, gastric cancer, and malabsorption that results in chronic diarrhea (Porth, 2002). CVID must be distinguished from secondary immunodeficiency diseases caused by protein-losing enteropathy, nephrotic syndrome, or burns.

Patients with CVID are susceptible to infections with encapsulated bacteria, such as *Haemophilus influenzae*, *Streptococcus pneumoniae*, and *Staphylococcus aureus*. Frequent respiratory tract infections typically lead to chronic progressive bronchiectasis and pulmonary failure. Commonly, infection with *Giardia lamblia* occurs. Opportunistic infections with *Pneumocystis carinii*, however, are seen only in patients who have a concomitant deficiency in T-cell immunity.

## Assessment and Diagnostic Findings

Sex-linked agammaglobulinemia may be diagnosed by the marked deficiency or complete absence of all serum immunoglobulins. The diagnosis of CVID is based on the history of bacterial infections, quantification of B-cell activity, and reported signs and symptoms. The number of B lymphocytes and the total and specific immunoglobulin levels are measured. Total serum globulin level alone is an inadequate measure because a compensatory overproduction of one globulin may mask the loss of a missing globulin or one present in very low amounts. Antibody titers to confirm successful childhood vaccination are determined by specific serologic tests. Previous successful childhood immunization indicates that B cells were functioning adequately earlier in life. If the patient exhibits signs and symptoms suggestive of pernicious anemia, hemoglobin and hematocrit levels are also obtained.

## Medical Management

Patients with primary phagocytic disorders may be treated with intravenous immunoglobulin (IVIG). Those who are receiving adequate treatment with IVIG usually do not require prophylactic antibiotics unless they also have chronic respiratory disease. Antimicrobial therapy is prescribed for respiratory infections to prevent complications such as pneumonia, sinusitis, and otitis media. Intestinal infestation with *G. lamblia* is treated with a 10-day course of metronidazole (Flagyl) or a 7-day course of quinacrine hydrochloride (Atabrine) (Parslow et al., 2001). Patients with pernicious anemia receive parenteral

injections of vitamin B<sub>12</sub> at monthly intervals. Management may also include physical therapy with postural drainage for patients with chronic lung disease or bronchiectasis (Parslow et al., 2001).

## T-CELL DEFICIENCIES

### Pathophysiology

Defects in T cells lead to opportunistic infections. Most primary T-cell immunodeficiencies are genetic in origin. An increased susceptibility to infection is common. Symptoms can vary considerably depending on the type of T-cell defect. Because the T cells play a regulatory role in immune system function, the loss of T-cell function is usually accompanied by some loss of B-cell activity.

DiGeorge syndrome, or **thymic hypoplasia**, is one example of a primary T-cell immunodeficiency. This rare congenital disease results from the absence of several genes on chromosome 22 (Porth, 2002). The variation in symptoms is a result of differences in the amount of genetic material affected. T-cell deficiency occurs when the thymus gland fails to develop normally during embryogenesis. DiGeorge syndrome is one of the few immunodeficiency disorders with symptoms that present almost immediately following birth (Parslow et al., 2001).

Chronic mucocutaneous candidiasis with or without endocrinopathy is another T-cell disorder associated with a selective defect in T-cell immunity; it is thought to be caused by an autosomal recessive inheritance, affecting both males and females. It is considered an autoimmune disorder in which the thymus and other endocrine glands are involved in the autoimmune process. The disease causes extensive morbidity resulting from endocrine dysfunction.

### Clinical Manifestations

Infants born with DiGeorge syndrome have hypoparathyroidism with resultant hypocalcemia resistant to standard therapy, congenital heart disease, characteristic facial features, and possibly renal abnormalities. These infants, susceptible to yeast, fungal, protozoan, and viral infections, are particularly susceptible to childhood diseases (chickenpox, measles, and rubella), which are usually severe and may be fatal. Many of these infants are also born with congenital heart defects, which can result in congestive heart failure. The most frequent presenting sign in patients with DiGeorge syndrome is hypocalcemia that is resistant to standard therapy. It usually occurs within the first 24 hours of life (Parslow et al., 2001).

The initial presentation of chronic mucocutaneous candidiasis may be either chronic candidal infection or idiopathic endocrinopathy. Patients may survive to the second or third decade of life. Problems may include hypocalcemia and tetany secondary to hypofunction of the parathyroid glands. Hypofunction of the adrenal cortex (Addison's disease) is the major cause of death in these patients; it may develop suddenly and without any history of previous symptoms.

### Assessment and Diagnostic Findings

The status of T cells can be evaluated by peripheral blood lymphocyte counts. Because T cells constitute 65% to 85% of peripheral blood lymphocytes, lymphopenia may signify a T-cell

deficit. Dermal sensitization of the patient or stimulation of the patient's T cells in vitro may be conducted to determine if the T cells are capable of producing the expected responses. Immunoglobulin evaluation is not useful in infants because of the presence of maternally transmitted immunoglobulin (Parslow et al., 2001).

### Medical Management

Patients with T-cell deficiency should receive *P. carinii* prophylaxis. General care includes management of hypocalcemia and correction of cardiac abnormalities. Hypocalcemia is controlled by oral calcium supplementation in conjunction with vitamin D or parathyroid hormone administration. Congenital heart disease frequently results in heart failure, and these patients may require immediate surgical intervention in a tertiary pediatric center. Transplantation of the fetal thymus, postnatal thymus, and human leukocyte antigen (HLA)-matched bone marrow has been used for permanent reconstitution of T-cell immunity. IVIG therapy may be used if an antibody deficiency exists. This therapy may also be used to control recurrent infections. Prolonged survival has been reported following the successful transplantation of the thymus gland or spontaneous remission of immunodeficiency, which occurs in some patients (Parslow et al., 2001).

## COMBINED B-CELL AND T-CELL DEFICIENCIES

### Pathophysiology

Combined B-cell and T-cell deficiencies are those disorders of the immune system that have elements of dysfunction of both the B cells and T cells. A variety of inherited (autosomal recessive and X-linked) conditions fit this description. These conditions have in common disruption of the normal communication system of B cells and T cells and impairment of the immune response (Porth, 2002). These conditions generally appear early in life. Examples of these deficiencies are discussed below.

**Ataxia-telangiectasia** is an autosomal recessive disorder affecting both T- and B-cell immunity. In 40% of patients with this disease, a selective IgA deficiency exists. IgA and IgG subclass deficiencies, along with IgE deficiencies, have been identified. Variable degrees of T-cell deficiencies are observed and become more severe with advancing age. The disease is associated with neurologic, vascular, endocrine, hepatic, and cutaneous abnormalities. It is accompanied by progressive cerebellar ataxia, telangiectasias, recurrent bacterial infection of the sinuses and lungs, and an increased incidence of cancer (Buckley, 2000).

Both B and T cells are missing in **severe combined immunodeficiency disease (SCID)**. SCID is a phenotypic term that is used for a wide variety of congenital and hereditary immunologic defects that are characterized by early onset of infections, defects in both B- and T-cell systems, lymphoid aplasia, and thymic dysplasia. Inheritance of this disorder can be X-linked, autosomal-recessive, or sporadic. The exact incidence of SCID is unknown; it is recognized as a rare disease in most population groups, with an incidence of about 1 case in 1,000,000. This illness occurs in all racial groups and both genders (Parslow et al., 2001).

**Wiskott-Aldrich syndrome** is a variation of SCID compounded by thrombocytopenia (loss of platelets). The prognosis is generally poor because most affected infants develop overwhelming fatal infections.

### Clinical Manifestations

The onset of **ataxia** (uncoordinated muscle movement) **telangiectasia** (vascular lesions caused by dilated blood vessels) usually occurs in the first 4 years of life of those with ataxia-telangiectasia. Many patients, however, remain symptom-free for 10 years or longer. As patients approach the second decade of life, chronic lung disease, mental retardation, neurologic symptoms, and physical disability become severe. Long-term survivors develop progressive deterioration of immunologic and neurologic functions. Some affected patients have reached the fifth decade of life. The primary causes of death in these patients are overwhelming infection and lymphoreticular or epithelial cancer.

The onset of symptoms occurs within the first 3 months of life in the majority of patients with SCID with respiratory infections, pneumonia (often secondary to *P. carinii*), thrush, diarrhea, and failure to thrive. Many of these infections are resistant to treatment. Shedding of viruses such as respiratory syncytial virus or cytomegalovirus from the respiratory and gastrointestinal tracts is persistent. Maculopapular and erythematous skin rashes may occur. Vomiting, fever, and a persistent diaper rash are also common manifestations (Parslow et al., 2001).

### Medical Management

Treatment of ataxia-telangiectasia includes early management of infections with antimicrobial therapy, management of chronic lung disease with postural drainage and physical therapy, and management of other presenting symptoms. Other treatments include transplantation of fetal thymus tissue and IVIG administration (Chart 51-2).

Treatment options for SCID include stem cell and bone marrow transplantation. The ideal donor is an HLA-identical sibling (Parslow et al., 2001). Other treatment regimens include IVIG replacement, administration of thymus-derived factors, and thymus gland transplantation. Gene therapy has been used, but the results have thus far been disappointing. As treatment improves, an increased number of those who previously would have died in infancy may live to adulthood.

### Nursing Management

As many patients require immunosuppression to ensure engraftment of depleted bone marrow during certain transplantation procedures, nursing care must be exquisite, with attention to preventing the transmission of infection to patients. Use of standard precautions and meticulous hand hygiene is essential in caring for these patients. Reverse isolation procedures, where nurses protect the patient by donning gowns, gloves, caps, and so on, is essential. The patient's condition must be monitored at all times as a certain number of patients experience reactions to transplantation that can be fatal.

## DEFICIENCIES OF THE COMPLEMENT SYSTEM

The complement system is an integral part of the immune system, and alterations in normal components of complement can result in increased susceptibility to infectious diseases and to immune-mediated disorders (Porth, 2002). Improved techniques to identify the individual components of the complement system have led to a steady increase in the number of deficiencies identified. Disorders of the complement system can be primary or secondary.

### Chart 51-2 • PHARMACOLOGY Managing an IV Immunoglobulin Infusion

Previously available only for intramuscular injection, immunoglobulin can now be administered for replacement therapy as an IV infusion in greater, more effective doses without painful side effects.

#### How Supplied

Immunoglobulin is supplied in a 5% solution or a lyophilized powder with a reconstituting diluent prepared from Cohn fraction II obtained from pools of 1,000 to 10,000 donors. Currently, a number of different IV preparations are approved for use and have been shown to be effective and safe by the Food and Drug Administration.

#### Dosage

The optimal dose is that determined by the patient's response. In most instances, an IV dose of 100 to 400 mg/kg of body weight is administered monthly or more frequently to ensure adequate serum IgG levels.

#### Adverse Effects

- Complaints of flank pain, shaking chills, and tightness in the chest, terminating with a slight rise in body temperature
- Hypotension (possible with severe reactions)
- Anaphylactic reactions

#### Guidelines for Nursing Management

- Weigh the patient before treatment.
- Obtain vital signs before, during, and after treatment.

- Administer the prescribed pretreatment prophylactic aspirin or IV antihistamine, such as diphenhydramine (Benadryl).
- Be aware that corticosteroids may be used to prevent possible severe reactions.
- Administer the IV infusion at a slow rate, not to exceed 3 mL/minute.
- Assess the patient for adverse reactions, including the early signs of anaphylactic shock; prepare to slow the infusion rate if necessary.
- Be aware that patients with low gammaglobulin levels have more severe reactions than those with normal levels (eg, patients who receive gammaglobulin for thrombocytopenia or Kawasaki disease).
- Keep in mind that patients who have an immunoglobulin A (IgA) deficiency have IgE antibodies to IgA, which requires administration of plasma or immunoglobulin replacement from IgA-deficient patients. Because all IV immunoglobulin preparations contain some IgA, they may cause an anaphylactic reaction in patients with IgE anti-IgA antibodies.
- Remember that the risk for transmission of hepatitis, HIV, or other known viruses is extremely low.

C2 and C3 component deficiencies result in diminished resistance to bacterial infections. **Angioneurotic edema** is caused by an inherited deficiency of the inhibitor of C1 esterase, which opposes the release of inflammatory mediators. A deficiency of this inhibitor results in frequent episodes of urticaria and edema in various parts of the body.

Patients with paroxysmal nocturnal hemoglobinuria (PNH) lack decay-accelerating factor (DAF), which is found on erythrocytes (red blood cells). DAF normally protects the erythrocytes from lysis (disintegration). In PNH, the complement component C3b accumulates on the CR1 molecule on the erythrocyte, acts as a binding site for the late-acting component, and allows lysis to occur.

## Secondary Immunodeficiencies

Secondary immunodeficiencies are more common than primary immunodeficiencies and frequently occur as a result of underlying disease processes or from the treatment of these diseases. Common causes of secondary immunodeficiencies include malnutrition, chronic stress, burns, uremia, diabetes mellitus, certain autoimmune disorders, certain viruses, exposure to immunotoxic medications and chemicals, and self-administration of recreational drugs and alcohol. AIDS, the most common secondary immunodeficiency disorder, is discussed in detail in Chapter 52. Patients with secondary immunodeficiencies have immunosuppression and are often referred to as **immunocompromised hosts**.

### Medical Management

Management of secondary immunodeficiencies includes diagnosis and treatment of the underlying disease process. Interventions include eliminating the contributing factors, treating the underlying condition, and using sound principles of infection control.

## Nursing Management for Patients With Immunodeficiencies

Nursing management includes assessment, patient teaching, and supportive care. Assessment of the patient for infection and for response to treatment is important if it is to be effective. Nursing care of patients with primary and secondary immunodeficiencies depends on the underlying cause of the immunodeficiency, the type of immunodeficiency, and its severity. Because immunodeficiencies result in a compromised immune system and high risk for infection, careful assessment of the patient's immune status is essential. The assessment focuses on history of past infections, particularly the type and frequency of infection; signs and symptoms of any current skin, respiratory, gastrointestinal, or genitourinary infection; and measures that prevent infection. The nurse monitors the patient for signs and symptoms of infection: fever; chills; cough with or without sputum; shortness of breath; difficulty breathing; difficulty swallowing; white patches in the oral cavity; swollen lymph nodes; nausea; vomiting; persistent diarrhea; frequency, urgency, or pain on urination; redness, swelling, or drainage from skin wounds; lesions on the face, lips, or perianal area; persistent vaginal discharge with or without perianal itching; and persistent abdominal pain.

Because the inflammatory response may be blunted, the patient is monitored for subtle and unusual signs and changes in physical status. Vital signs and the development of pain, neurologic signs, cough, and skin lesions are monitored and reported. Pulse rate and respiratory rate should be counted for a full minute, as even subtle changes can signal deterioration in the patient's clinical status. Thorough auscultation and assessment of the breath sounds are also key in detecting changes in respiratory status. Any unusual response to treatment and any significant change in the patient's clinical condition are promptly reported to the physician.

## NURSING RESEARCH PROFILE 51-1

### Substance P and Anxiety Levels

Fehder, W. P., Sachs, J., Uvaydova, M., & Douglas, S. D. (1997). Substance P as an immune modulator of anxiety. *Neuroimmunomodulation*, 4(1), 42–48.

#### Purpose

Proinflammatory peptide substance P (SP), a protein that is widely distributed in the central and peripheral nervous systems, has been implicated in modulation of the immune and hematopoietic systems. Studies have demonstrated that peripheral blood concentrations of SP have increased in response to psychological anxiety in humans. The purposes of this study were to 1) examine changes in SP levels in peripheral blood in response to anxiety over time, and 2) correlate changes in percentages of CD8-expressing T lymphocytes with alterations in measures of anxiety and SP.

#### Study Sample and Design

Two groups of patients were included in the sample in an effort to have two groups of patients receiving similar diagnostic procedures but with different levels of anxiety. Subjects ( $n = 11$ ) in one group underwent colonoscopy with sedation and subjects ( $n = 12$ ) in the second group underwent sigmoidoscopy without sedation. It was expected that the patients who received sedation would have lower levels of anxiety than the nonsedated group. Anxiety was assessed by the Multiple Affect Adjective Checklist-Revised state forms (MAACL-R), which were administered to patients prior to the diagnostic procedure, after the diagnostic procedure, and at a home visit 3 days after the procedure. At the same times that the MAACL-R was administered, blood samples were collected. A competitive solid-phase, enzyme-linked immunosorbent assay was used to measure blood levels of SP. Flow cytometry was used to express the percentage of mononuclear cells bearing the specific marker.

Data from the two groups were compared using repeated-measure analysis of variance (ANOVA) with post-hoc  $t$  test and Pearson's cor-

relation coefficients. A  $p$  value of  $< 0.05$  was used to determine statistical significance.

#### Findings

Data analysis revealed no significant differences between the anxiety levels of the two groups of patients before, immediately after, and 3 days after the procedures. As patients in both groups experienced high levels of preprocedure anxiety, the researchers divided the subjects into anxiety groups on the basis of the initial anxiety scores using a median split technique. SP levels were then examined by high and low levels of anxiety by repeated-measures ANOVA. The high-anxiety group had significantly higher SP levels than the low-anxiety group. Post-hoc  $t$  tests revealed SP levels were significantly elevated in the high-anxiety group compared with the low-anxiety group both before and after the procedures. Blood levels of SP, once elevated, remained elevated after the cause of the initial anxiety was removed. Levels of SP in the peripheral blood were found to be significantly correlated with the percent and absolute numbers of CD8 and T lymphocytes.

#### Nursing Implications

This study demonstrated that peripheral blood levels of SP may be influenced by levels of anxiety. These findings suggest that patients' anxiety level may have an effect on their immune system; therefore, nurses need to monitor anxiety levels in patients preparing for diagnostic and other procedures and design and implement measures to alleviate such anxiety-provoking situations. Such interventions may prevent changes in the immune system secondary to anxiety.

The nurse also monitors laboratory values (ie, white blood cell count and differential cell count) for changes indicating infection. Culture and sensitivity reports from wound drainage, lesions, sputum, stool, urine, and blood are monitored to identify pathogenic organisms and appropriate antimicrobial therapy. Changes in laboratory results and subtle changes in clinical status must be reported to the physician because the immunocompromised patient may not develop typical signs and symptoms of infection.

Assessment also focuses on nutritional status; stress level and coping skills; use of alcohol, drugs, or tobacco; and general hygiene, all of which may affect immune function. Strategies the patient has used to reduce risk for infection are identified.

Other aspects of nursing care are directed toward reducing the patient's risk for infection, assisting with medical measures aimed at improving immune status and treating infection, improving the nutritional status, and maintaining bowel and bladder function. These include careful hand hygiene, encouraging the patient to cough and perform deep-breathing exercises at regular intervals, and protecting the integrity of the skin and mucous membranes. All health care personnel must use strict aseptic technique when performing invasive procedures, such as dressing changes, venipunctures, and bladder catheterizations.

Other aspects of nursing care include assisting the patient in managing stress and in adopting a lifestyle that enhances immune system function.

If the patient is a candidate for any of the newer or experimental therapies (gene therapy, bone marrow transplantation, immunomodulators such as interferon gamma), the patient or

parents (if the patient is a child) must be informed about the potential risks and benefits of the treatment regimen. A major role of the nurse is to assist the patient and family to understand the treatment options and to cope with the uncertainties of treatment outcomes.

## PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** The patient and the caregivers are instructed about the signs and symptoms that indicate infection. The nurse explains that the immunosuppressed patient may also have atypical symptoms secondary to underlying immunosuppression. Patients should be advised that they know themselves best; therefore, whenever they experience a symptom that is not typical for them, they should contact their health care provider. The health care provider will then determine and initiate indicated therapy. The patient and caregiver need instruction about any prophylactic medication regimen, including dosage, indications, times, actions, and side effects. The patient is instructed about the importance of avoiding others with infections and avoiding crowds. The patient and family also need to learn about other ways to prevent infection (Chart 51-3).

The patient who is to receive IVIG at home will need information about the expected benefits and outcomes of the treatment as well as expected adverse reactions and their management (Chart 51-4). Patients who can perform self-infusion at home are instructed in sterile technique, medication dosages, administration rate, and detection and management of adverse reactions.

Chart 51-3

## Home Care Checklist • Infection Prevention for the Patient With Immunodeficiency

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Identify signs and symptoms of infection to report to the health care provider, such as fever, chills; wet or dry cough; breathing problems; white patches in the mouth; swollen glands; nausea; vomiting; persistent abdominal pain; persistent diarrhea; problems with urination; red, swollen, or draining wounds; sores or lesions on the body; and persistent vaginal discharge with or without itching.	✓	✓
• Demonstrate correct handwashing procedure.	✓	✓
• State rationale for thorough handwashing before eating, after using the bathroom, and before and after performing health care procedures.	✓	✓
• State rationale for use of cream and emollients to prevent or manage dry, chaffed, or cracked skin.	✓	✓
• Demonstrate recommended personal hygiene in bathing and foot care to prevent bacterial and fungal diseases.	✓	✓
• State rationale for avoiding contact with people who have known illness or who have recently been vaccinated.	✓	✓
• Verbalize understanding of ways to maintain a well-balanced diet and adequate calories.	✓	✓
• State the reason for avoiding the eating of raw fruits and vegetables, cooking all foods thoroughly, and immediately refrigerating all leftover food.	✓	✓
• Identify the rationale for frequent cleaning of kitchen and bathroom surfaces with disinfectant.	✓	✓
• Identify rationale and benefits of avoiding alcohol, tobacco, and unprescribed medications.	✓	✓
• State rationale for taking prescribed medications as directed.	✓	✓
• Verbalize ways to cope with stress successfully, plans for regular exercise, and rationale for obtaining adequate rest.	✓	✓

The patient and family must be instructed to monitor for subtle changes in physical status and must be informed of the importance of seeking immediate health care if changes occur. Patients and their families are also instructed about the importance of continuing the treatment regimen and assisted in incorporating it into their lives.

**Continuing Care.** The importance of follow-up appointments is emphasized to the patient and family. They are urged to notify the primary health care provider about early signs and symptoms of infection, including any subtle changes. The importance of continuing disease-prevention strategies is stressed because these strategies need to be followed lifelong. The patient should be encouraged to have recommended health screening because of the increased susceptibility for cancer secondary to the immune suppression.

If the patient's treatment includes IVIG and the patient or family cannot administer it, a referral for home care or an infusion service may be warranted.

## Critical Thinking Exercises

1. Intravenous immunoglobulin (IVIG) infusions have been prescribed for your patient, who has an immunodeficiency. He tells you that he is very fearful that he may contract hepatitis, HIV infection, AIDS, and other blood-borne diseases from the infusion. How would you respond to these fears and concerns?
2. You are scheduled to make a home care visit to a patient who was recently discharged from the hospital for an opportunistic infection secondary to AIDS. Upon arrival at the patient's home, you note a very unkempt environment, with many cats roaming around and several other unsanitary conditions. Explain the course of action that you would take to address these issues, given the patient's diagnosis and condition.

Chart 51-4

## Home Care Checklist • Home Infusion of Intravenous Immunoglobulin (IVIG)

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Identify the benefits and expected outcome of IVIG.	✓	✓
• Demonstrate how to check for patency of IV access device.	✓	✓
• Demonstrate how to prepare IVIG.	✓	✓
• Demonstrate how to infuse IVIG.	✓	✓
• Demonstrate how to clean and maintain IV equipment.	✓	✓
• Identify side effects and adverse effects of IVIG.	✓	✓
• State rationale for prophylactic use of aspirin and an antihistamine before treatment begins.	✓	✓
• Verbalize understanding of emergency measures for anaphylactic shock.	✓	✓

**3.** Describe the teaching plan you would use to instruct a patient with an immunodeficiency disorder about prevention and management of infection. How would you modify your approach if the patient did not believe in medications or vaccinations? Are vaccinations recommended in a patient with an underlying immunodeficiency disease? If not, why not?

# ● Management of Patients With HIV Infection and AIDS

## **LEARNING OBJECTIVES** ●

*On completion of this chapter, the learner will be able to:*

1. Describe the modes of transmission of HIV infection.
2. Describe the pathophysiology of HIV infection.
3. Explain the physiology underlying the clinical manifestations of HIV infection.
4. Describe the management of patients with HIV infection.
5. Discuss the nursing interventions appropriate for patients with HIV infection and AIDS.
6. Use the nursing process as a framework for care of the patient with AIDS.

Although progress has been made in treating HIV infection and AIDS, the epidemic remains a critical public health issue in all communities across the country and around the world. Prevention, early detection, and ongoing treatment remain important aspects of care for people with HIV infection and AIDS. Nurses in all settings encounter people with this disease; thus, nurses need an understanding of the disorder, knowledge of the physical and psychological consequences associated with the diagnosis, and expert assessment and clinical management skills to provide optimal care for people with HIV infection and AIDS.

In 1987, just 6 years after the first cases of AIDS were reported, the U.S. Food and Drug Administration (FDA) approved the first antiretroviral agent; in 1988 the first randomized controlled trial of primary prophylaxis of *Pneumocystis carinii* pneumonia appeared in the literature; and in 1995 protease inhibitors joined the growing number of antiretroviral agents. Improved treatment of HIV and AIDS has resulted in increased survival times; in 1996, 1997, and 1998, age-adjusted death rates fell 29%, 48%, and 21%, respectively (Lee et al., 2001).

## HIV Infection and AIDS

Since acquired immunodeficiency syndrome (AIDS) was first recognized more than 20 years ago, remarkable progress has been made in improving the quality and duration of life of persons

with HIV infection. During the first decade, this progress was associated with recognition of opportunistic disease processes, more effective therapy for complications, and introduction of prophylaxis against common **opportunistic infections** (OIs). The second decade has witnessed progress in developing highly active anti-retroviral therapies (HAART) as well as continuing progress in treating OIs (Masur, Kaplan & Holmes, 1999). Since the HIV serologic test (enzyme immunoassay [EIA], formerly enzyme-linked immunosorbent assay [ELISHA]), became available in 1984, allowing early diagnosis of the infection before onset of symptoms, HIV infection has been best managed as a chronic disease and most appropriately managed in an outpatient care setting (Gallant, 2001).

## Epidemiology

In fall 1982, the Centers for Disease Control and Prevention (CDC) issued a case definition of AIDS after the first 100 cases were reported. Since then, the CDC has revised the case definition a number of times (1985, 1987, and 1993). All 50 states, the District of Columbia, U.S. dependencies and possessions, and independent nations in free association with the United States report AIDS cases to the CDC using a uniform surveillance case definition and case report form (CDC, 2000). Starting in the late 1990s, more states started to implement HIV case reporting in response to the changing epidemic and the need for information on persons with HIV infection who have not developed AIDS.

## Glossary

**alpha-interferon:** protein substance that the body produces in response to infection

**anergy:** loss or weakening of the body's immunity to an irritating agent or antigen

**B-cell lymphoma:** common malignancy in patients with HIV/AIDS

**candidiasis:** yeast infection of skin or mucous membrane

**CCR5:** cell surface molecule that is needed along with the CD4 molecule to fuse with the membranes of the host's immune system cells

**cytomegalovirus:** a species-specific herpes virus that may cause retinitis in people with AIDS

**EIA (enzyme immunoassay):** a blood test that determines the presence of antibodies to HIV in the blood or saliva; also referred to as **enzyme-linked immunosorbent assay (ELISA)**. Positive results must be validated, usually with Western blot test.

**HIV-1:** retrovirus isolated and recognized as the etiologic agent of AIDS

**HIV-2:** virus closely related to HIV-1 that has also been found to cause AIDS

**HIV encephalopathy:** degenerative neurologic condition characterized by a group of clinical presentations including loss of coordination, mood swings, loss of inhibitions, and widespread cognitive dysfunctions; formerly referred to as AIDS dementia complex (ADC)

**human papillomavirus (HPV):** virus that causes venereal warts

**Kaposi's sarcoma:** malignancy that involves the epithelial layer of blood and lymphatic vessels

**macrophage:** large immune cell that devours invading pathogens and other intruders.

Can harbor large quantities of HIV without being killed, acting as a reservoir of the virus.

**monocyte:** large white blood cell that ingests microbes or other cells and foreign particles. When a monocyte enters tissues, it develops into a macrophage.

**Mycobacterium avium complex (MAC):** opportunistic infection caused by mycobacterial organisms that commonly causes a respiratory illness but can also infect other body systems

**opportunistic infection (OI):** illness caused by various organisms, some of which usually do not cause disease in persons with normal immune systems

**p24 antigen:** blood test that measures viral core protein; accuracy of test is limited because the p24 antibody binds with the antigen and makes it undetectable

**peripheral neuropathy:** disorder characterized by sensory loss, pain, muscle weakness, and wasting of muscles in the hands or legs and feet

**Pneumocystis carinii pneumonia (PCP):** common opportunistic lung infection caused by an organism, initially thought to be a protozoan but now believed to be a fungus based on its structure

**polymerase chain reaction (PCR):** a sensitive laboratory technique that can detect and quantify HIV in a person's blood or lymph nodes

**primary infection:** 4- to 7-week period of rapid viral replication immediately follow-

ing infection; also known as acute HIV infection

**progressive multifocal leukoencephalopathy (PML):** opportunistic infection that infects brain tissue and causes damage to the brain and spinal cord

**protease inhibitor:** medication that inhibits the function of protease, an enzyme needed for HIV replication

**provirus:** viral genetic material in the form of DNA that has been integrated into the host genome. When it is dormant in human cells, HIV is in a proviral form.

**retrovirus:** a virus that carries genetic material in RNA instead of DNA and contains reverse transcriptase

**reverse transcriptase:** enzyme that transforms single-stranded RNA into a double-stranded DNA

**viral load test:** measures the quantity of HIV RNA in the blood

**viral set point:** amount of virus present in the blood after the initial burst of viremia and the immune response that follows

**wasting syndrome:** involuntary weight loss of 10% of baseline body weight with chronic diarrhea or chronic weakness and documented fever.

**Western blot assay:** a blood test that identifies antibodies to HIV and is used to confirm the results of an EIA (ELISA) test

**window period:** time from infection with HIV until seroconversion detected on HIV antibody test

As of December 2001, there were 816,149 reported cases of HIV/AIDS and 506,154 adults, adolescents, and children in the United States (including U. S. dependencies, possessions, and associated nations) living with AIDS. Unprotected sex and sharing of injection drug use equipment are the major means of transmission of HIV. A total of 43,158 AIDS cases were diagnosed in 2001. For men diagnosed with AIDS during 2001, 59% were in the exposure category of men who have sex with men; 24% in injection drug use; and 7% in heterosexual contact. In women diagnosed with AIDS during that same period, 44% reported injection drug use and 52% reported heterosexual contact. Comparing race/ethnicity among the three largest groups diagnosed in 2001, 20,752 were black, not Hispanic; 11,675 were Caucasian; and 8,221 were Hispanic (CDC, 2002).

The number of people living with AIDS is not evenly distributed throughout the United States. States with the largest number of reported AIDS cases during 2001 were New York (7,476), Florida (5,138), California (4,315), Texas (2,892), and Maryland (1,860) (CDC, 2002).

AIDS has reached epidemic proportions in some other parts of the world. According to the Joint United Nations Programme on HIV/AIDS, more than 18.8 million people worldwide have died of AIDS and 34.3 million people are infected with HIV, with 5.4 million people newly infected with HIV in 1999 alone (Letvin, Bloom & Hoffman, 2001). UNAIDS (2001) reports that since the epidemic began, more than 60 million people have been infected with the virus, making it the most devastating disease ever.

The earliest confirmed case of HIV infection was found in blood drawn from an African man in 1959 (Stephenson, 1998). Although factors associated with the spread of HIV in Africa remain unknown, possibilities include the reuse of unsterilized needles in large-scale vaccination campaigns that began in Africa in the 1960s; however, social changes such as easier access to transportation, increasing population density, and more frequent sexual contacts may have been more important (Stephenson, 1998).

## HIV Transmission

**HIV-1** is transmitted in body fluids containing HIV and/or infected CD4+ (or CD4) T lymphocytes. These fluids include blood, seminal fluid, vaginal secretions, amniotic fluid, and breast milk. Mother-to-child transmission of HIV-1 may occur in utero, at the time of delivery, or through breastfeeding, but transmission frequency during each period has been difficult to determine (Nduati et al., 2000). Any behavior that results in breaks in the skin or mucosa results in the increased probability of exposure to HIV (Chart 52-1). Since HIV is harbored within lymphocytes, a type of white blood cell, any exposure to infected blood results in a significant risk of infection. The amount of virus and infected cells in the body fluid is associated with the risk of new infections.

Blood and blood products can transmit HIV to recipients. However, the risk associated with transfusions has been virtually eliminated as a result of voluntary self-deferral, serologic testing, heat treatment of clotting factor concentrates, and more effective virus inactivation methods. Blood donor screening tests detect antibodies to HIV-1 and **HIV-2**, and **p24 antigen** testing has been added as an interim measure (American Red Cross, 2001). However, blood donated during the **window period** will be infectious but will test negative for HIV antibodies. The window period is the period of time between initial infection of HIV and development of a positive antibody test for HIV. Although antibodies will usually be detected within 3 to 6 months, the window period can last up to a year (<http://www.cdc.gov/hiv/pubs/pcrs/pcrs-app.htm>).

Chart 52-1

### Risk Factors for HIV Infection and AIDS

In the United States, most people with HIV/AIDS have engaged in high-risk behaviors, such as the following:

- Intravenous or injection drug use (the term “*intravenous drug user*” has been replaced by the term “*injecting (or injection) drug user*.” This term includes people who inject drugs intravenously as well as those who inject drugs intradermally. This method is sometimes referred to as “skin popping.”)
- Sexual relations with infected individuals (both male and female)

Also at risk are people who received blood or blood products contaminated with HIV (especially before blood screening was instituted in 1985) and children born to mothers with HIV infection.

## Prevention of HIV Infection

Until an effective vaccine is developed, preventing HIV by eliminating or reducing risk behaviors is essential. Primary prevention efforts through effective educational programs are vital for control and prevention. HIV is not transmitted by casual contact.

### PREVENTIVE EDUCATION

Effective educational programs have been initiated to educate the public regarding safer sexual practices to decrease the risk of transmitting HIV-1 infection to sexual partners (Chart 52-2). Latex condoms should be used during vaginal or anal intercourse. Non-latex condoms are available for people with latex allergy. A condom should be used for oral contact with the penis, and dental dams (a piece of latex used by dentists to isolate a tooth for treatment) should be used for oral contact with the vagina or rectum. As a result of a clinical trial that found that female sex workers who used a nonoxynol-9 (N-9) gel intravaginally in addition to condoms were 50% more likely to be infected with HIV than those who did not use N-9 gel, the CDC issued the recommendation that intravaginal application of N-9 should no longer be recommended as an effective means of HIV prevention (AIDS Institute, 9/21/00).

Other topics important in preventive education include the importance of avoiding sexual practices that might cut or tear the lining of the rectum, penis, or vagina and avoiding sexual contact with multiple partners or people who are known to be HIV positive or injection drug users. In addition, people who are HIV positive or use injection drugs should be instructed not to donate blood or share drug equipment with others. Increasingly, needle exchange programs are available to enable injection drug users to obtain sterile drug equipment at no cost. Extensive research has demonstrated that needle exchange programs do not promote increased drug use; on the contrary, they have been found to decrease the incidence of blood-borne infections in persons who use injection drugs (Trzcianowska & Mortensen, 2001). In the absence of needle exchange programs, injection drug users should be instructed on methods to clean their syringes and to avoid sharing cotton and other drug use equipment.

### RELATED REPRODUCTIVE EDUCATION

Because HIV infection in women usually occurs during the child-bearing years, family planning issues need to be addressed. Attempts to achieve pregnancy by couples in which one partner has HIV and the other does not expose the unaffected partner to the

### Chart 52-2

#### Health Promotion and Illness Prevention Safer Sex and Safer Behaviors

- Practice abstinence.
- Reduce the number of sexual partners to one.
- Always use latex condoms; if allergic to latex, use female condoms (nonlatex).
- Do not reuse condoms.
- Do not use cervical caps or diaphragms without using a condom as well.
- Always use dental dams for oral female genital or anal stimulation.
- Avoid anal intercourse because this practice may injure tissues.
- Avoid manual–anal intercourse (“fisting”).
- Do not ingest urine or semen.
- Engage in nonpenetrative sex such as body massage, social kissing (dry), mutual masturbation, fantasy, and sex films.
- Inform prospective sexual and drug-using partners of your HIV-positive status.
- Notify previous and present sexual partners if you learn that you are HIV seropositive. If you are afraid for your safety, many states have established mechanisms through the public health department in which professionals are available to notify exposed people.
- If you are HIV seropositive, do not have unprotected sex with another HIV-seropositive person, because cross-infection with another HIV strain can increase the severity of the disease.
- Do not share needles, razors, toothbrushes, sex toys, or other blood-contaminated articles.
- If you are HIV seropositive, do not donate blood, plasma, body organs, or sperm.

virus. Efforts at artificial insemination using processed semen from an HIV-infected partner are underway. Studies are needed because HIV has been found in the spermatozoa of patients with AIDS, with possible HIV replication in the male germ cell. Women considering pregnancy need to have adequate information about the risks of transmitting HIV infection to themselves, their partner, and their future children and about the benefits of antiretroviral agents in reducing perinatal HIV transmission. Other than abstinence, the condom has been the only method that has proved to decrease the risk of sexual transmission of HIV infection.

Certain contraceptive methods may pose additional health risks for women. Estrogen in oral contraceptives may increase a woman's risk for HIV infection. In addition, women infected with HIV who use estrogen oral contraceptives have shown increased shedding of HIV in vaginal and cervical secretions. The intrauterine contraceptive device (IUD) may also increase the risk for HIV transmission because the device's string may serve as a means to transmit HIV infection. It also can cause penile abrasions. The female condom is as effective in preventing pregnancy as other barrier methods, such as the diaphragm and the male condom. Unlike the diaphragm, the female condom is also effective in preventing the transmission of HIV infection and sexually transmitted diseases (STDs). The female condom has the distinction of being the first barrier method that can be controlled by women (see Chap. 46).

## Transmission to Health Care Providers

### STANDARD PRECAUTIONS

In 1996, efforts were made by the CDC and its Hospital Infection Control Practices Advisory Committee (HICPAC) to stan-

dardize procedures and reduce the risk for exposure through development of Standard Precautions. Standard Precautions incorporate the major features of Universal Precautions (designed to reduce the risk of transmission of blood-borne pathogens) and Body Substance Isolation (designed to reduce the risk of transmission of pathogens from moist body substances); they are applied to all patients receiving care in hospitals regardless of their diagnosis or presumed infectious status (Chart 52-3). Standard Precautions apply to blood; all body fluids, secretions, and excretions, except sweat, regardless of whether they contain visible blood; nonintact skin; and mucous membranes (Hospital Infection Control Practices Advisory Committee [HICPAC], 1996).

The primary goal of Standard Precautions is to prevent the transmission of nosocomial infection. The first tier, referred to as Standard Precautions, was developed to reduce the risk for all recognized or unrecognized sources of infections in hospitals. A second tier for infection control precautions for specified conditions, called Transmission-Based Precautions, was designed for use in addition to Standard Precautions for patients with documented or suspected infections involving highly transmissible pathogens. The three types of Transmission-Based Precautions are referred to as Airborne Precautions, Droplet Precautions, and Contact Precautions. They can be used singularly or in combination, but they are always to be used in addition to Standard Precautions (HICPAC, 1997).

Large-scale studies of exposed health care workers continue to be conducted by the CDC and other groups. In November 2000, the Needlestick Safety and Prevention Act became law, mandating health care facilities to use devices to protect against sharps injuries (Worthington, 2001).

### POSTEXPOSURE PROPHYLAXIS FOR HEALTH CARE PROVIDERS

Postexposure prophylaxis in response to exposure of health care personnel to blood or other body fluids has been proven to reduce the risk for HIV infection (Worthington, 2001). The CDC (1998) recommends that all health care providers who have sustained a significant exposure to HIV be counseled and offered anti-HIV postexposure prophylaxis, if appropriate. Some clinicians are considering using postexposure prophylaxis for patients exposed to HIV from high-risk sexual behavior or possible contact through injection drug use. This use of postexposure prophylaxis is controversial because of concern that it may be substituted for safer sex practices and safer injection drug use. Postexposure prophylaxis should not be considered an acceptable method of preventing HIV infection.

The medications recommended for postexposure prophylaxis are those used to treat established HIV infection. Ideally, prophylaxis needs to start immediately after exposure; therapy started more than 72 hours after exposure is thought to offer no benefit.

The recommended course of therapy involves taking the prescribed medications for 4 weeks. Those who choose postexposure prophylaxis must be prepared for the side effects of the medications and must be willing to face the unknown long-term risks, because HIV often becomes resistant to the medications used to treat it. If the person becomes infected despite prophylaxis, viral drug resistance may reduce future treatment options. The cost is also of concern; the cost of a drug regimen ranges from \$500 to more than \$1,000, plus the costs of testing and counseling. Health insurance generally does not cover the costs of medications, laboratory tests, and counseling (Chart 52-4).

Chart  
52-3

## Standard Precautions

The following guidelines were developed to prevent the transmission of infection during patient care for all patients, regardless of known or unknown infectious status.

**Hand Washing/Hand Hygiene**

- Wash hands/perform hand hygiene after touching blood, body fluids, secretions, excretions, and contaminated items, whether or not gloves are worn.
- Wash hands/perform hand hygiene immediately after gloves are removed, between patient contacts, and when otherwise indicated to avoid transfer of microorganisms to other patients or environments.
- Wash hands/perform hand hygiene between tasks and procedures on the same patient to prevent cross-contamination of different body sites.
- Use a plain (nonantimicrobial) soap or alcohol-based hand rub for routine hand washing.
- Use an antimicrobial agent or waterless antiseptic agent for specific circumstances (control of outbreaks or hyperendemic infections). (See Contact Precautions.)

**Gloves**

- Wear clean, nonsterile gloves when touching blood, body fluids, secretions, excretions, and contaminated items.
- Put on clean gloves just before touching mucous membranes and nonintact skin.
- Change gloves between tasks and procedures on the same patient after contact with materials that may contain a high concentration of microorganisms.
- Remove gloves promptly after use, before touching noncontaminated items and environmental surfaces, and before going to another patient.
- Wash hands/perform hand hygiene immediately after removing gloves.

**Mask, Eye Protection, Face Shield**

- Wear a mask and eye protection or a face shield to protect mucous membranes of the eyes, nose, and mouth during procedures and patient care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, or excretions.

**Gown**

- Wear a clean, nonsterile gown to protect skin and prevent soiling of clothing during procedures and patient care activities that are likely to generate splashes or sprays of blood, body fluids, secretions, or excretions.
- Select a gown that is appropriate for the activity and amount of fluid likely to be encountered.
- Remove a soiled gown as promptly as possible and wash hands/perform hand hygiene to prevent the transfer of microorganisms to other patients or environments.

**Patient Care Equipment**

- Handle used patient care equipment soiled with blood, body fluids, secretions, and excretions in a manner that prevents skin

and mucous membrane exposures, contamination of clothing, and transfer of microorganisms to other patients and environments.

- Ensure that reusable equipment is not used for the care of another patient until it has been cleaned and reprocessed appropriately.
- Ensure that single-use items are discarded properly.

**Environmental Control**

- Ensure that the hospital has adequate procedures for the routine care, cleaning, and disinfection of environmental surfaces, beds, bed rails, bedside equipment, and other frequently touched surfaces.
- Ensure that procedures are being followed.

**Linen**

- Handle, transport, and process used linen soiled with blood, body fluids, secretions, and excretions in a manner that prevents skin and mucous membrane exposures and contamination of clothing and that avoids transfer of microorganisms to other patients and environments.

**Occupational Health and Bloodborne Pathogens**

- Take care to prevent injuries when using needles, scalpels, and other sharp instruments or devices:
  - When handling sharp instruments after procedures
  - When cleaning used instruments
  - When disposing of used needles
- Never recap used needles or otherwise manipulate them by using both hands or use any technique that involves directing the point of the needle toward any part of the body.
- Use either a one-handed scoop technique or a mechanical device designed for holding the needle sheath.
- Do not remove used needles from disposable syringes by hand and do not bend, break, otherwise manipulate used needles by hand.
- Place used disposable syringes and needles, scalpel blades, and other sharp items in appropriate puncture-resistant containers as close as practical to the area in which the items were used.
- Place reusable syringes and needles in a puncture-resistant container for transport to the reprocessing area.
- Use mouthpieces, resuscitation bags, or other ventilation devices as an alternative to mouth-to-mouth resuscitation methods in areas where the need for resuscitation is predictable.

**Patient Placement**

- Place a patient who contaminates the environment or who does not or cannot be expected to assist in maintaining appropriate hygiene or environmental control in a private room.
- If a private room is not available, consult with infection control professionals regarding patient placement or other alternatives.

Adapted from (1996) Guideline for isolation precautions in hospitals. *Infection Control and Hospital Epidemiology*, 17, 53–80 and (2002). Guideline for hand hygiene in health-care settings. *Morbidity and Mortality Weekly Report*, 51(RR-16), 1–45.

**Pathophysiology**

Since HIV infection is an infectious disease, it is important to understand how HIV integrates itself into a person's immune system and how immunity plays a role in the course of infection. This knowledge is also essential for understanding drug therapy and vaccine development.

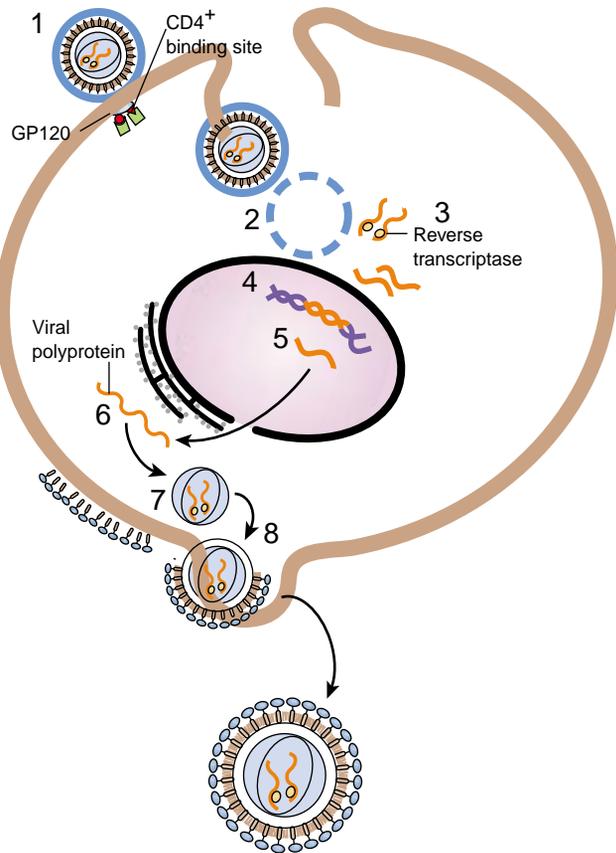

Viruses are intracellular parasites. HIV belongs to a group of viruses known as **retroviruses**. These viruses carry their genetic material in the form of ribonucleic acid (RNA) rather than deoxyribonucleic acid (DNA). As can be seen in Figure 52-1, HIV consists of a viral core containing the viral RNA that is surrounded by an envelope consisting of glycoproteins (gp) that protrude. For HIV to enter the targeted cell, the membrane of the

Chart  
52-4Postexposure Prophylaxis  
for Health Care Providers

If you sustain a needlestick injury, take the following actions immediately:

- Wash the area with soap and water.
- Alert your supervisor and initiate the injury-reporting system used in the setting.
- Identify the source patient, who may need to be tested for HIV, hepatitis B, and hepatitis C. (State laws will determine if written informed consent must be obtained from the source patient prior to his or her testing.)
- Report to the employee health services, the emergency department, or other designated treatment facility.
- Give consent for baseline testing for HIV, hepatitis B, and hepatitis C.
- Get postexposure prophylaxis for HIV in accordance with CDC guidelines. Start the prophylaxis medications within 2 hours after exposure. Make sure that you are being monitored for symptoms of toxicity. Practice safer sex until follow-up testing is complete.
- Follow up with postexposure testing at 6 weeks, 3 months, and 6 months and perhaps 1 year.
- Document the exposure in detail for your own records as well as for the employer.

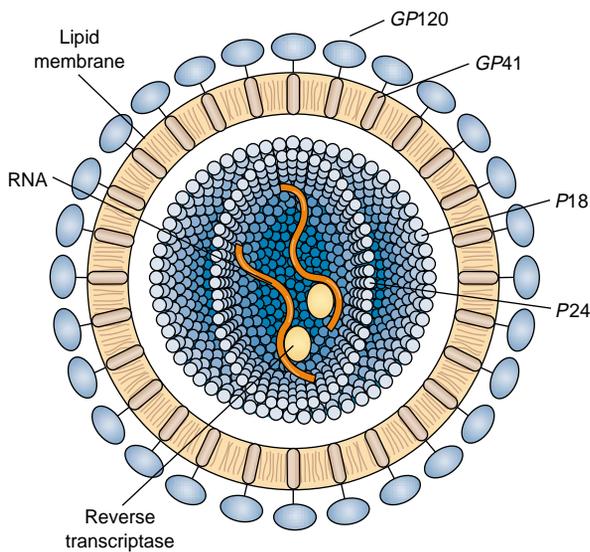

Worthington, K. (2001). You've been stuck: What do you do? *American Journal of Nursing*, 101(3); 104.

**FIGURE 52-2** Life cycle of the HIV-1: (1) Attachment of the HIV virus to CD4+ receptor; (2) internalization and uncoating of the virus with viral RNA and reverse transcriptase; (3) reverse transcription, which produces a mirror image of the viral RNA and double-stranded DNA molecule; (4) integration of viral DNA into host DNA using the integrase enzyme; (5) transcription of the inserted viral DNA to produce viral messenger RNA; (6) translation of viral messenger RNA to create viral polyprotein; (7) cleavage of viral polyprotein into individual viral proteins that make up the new virus; and (8) assembly and release of the new virus from the host cell. From Porth, C. (2002). *Pathophysiology: Concepts of altered health states* (6th ed.). Philadelphia: Lippincott Williams & Wilkins.

viral envelope must be fused with the plasma membrane of the cell, a process mediated by the envelope glycoproteins of HIV (Wyatt & Sodroski, 1998).

The HIV life cycle is complex and consists of a number of steps (Fig. 52-2). First, the HIV GP120 and GP41 attach to the uninfected CD4 cell surface (receptor) and fuse with the cell

**FIGURE 52-1** Structure of the HIV-1 virus. A glycoprotein envelope surrounds the virus, which carries its genetic material in RNA. Knobs, consisting of protein GP120 and GP41, protrude from the envelope. These proteins are essential for binding the virus to the CD4+ T lymphocyte. From Porth, C. (2002). *Pathophysiology: Concepts of altered health states* (6th ed.). Philadelphia: Lippincott Williams & Wilkins.

membrane. Second, the viral core contents are emptied into the host cell, a process known as uncoating. Third, HIV enzyme **reverse transcriptase** copies the viral genetic material from RNA into double-stranded DNA. Fourth, double-stranded DNA is spliced into the cellular DNA by the action of another HIV enzyme integrase. Fifth, using the integrated DNA or **provirus** as a blueprint, the cell makes new viral proteins and viral RNA. Sixth, HIV protease cleaves the new proteins (polyproteins). Seventh, the new proteins join the viral RNA into new viral particles. Finally, new viral particles bud from the cell and start the process all over (Porth, 2002).

Perhaps the least understood aspects of the HIV life cycle are the events that occur immediately after entry of the viral core into the host CD4 cell. The process of viral assembly is intimately linked to its subsequent reversal (disassembly). Interactions occur between viral proteins and cellular factors in the cells that produce virus and frequently influence events at the next round of infection (Emerman & Malim, 1998). In resting (nondividing) cells, HIV can apparently survive in a latent state as an integrated provirus that produces few or no viral particles. These resting CD4 T cells can be prodded to churn out new particles if something reactivates

them (Mellors, 1998). When a T cell that harbors this integrated DNA (also known as provirus) becomes activated against HIV or other microbes, the cell replicates and also unwittingly begins to produce new copies of both RNA and viral proteins (Bartlett & Moore, 1998). Activation of the infected cell may be achieved by antigens, mitogens, select cytokines (tumor necrosis factor- $\alpha$  or interleukin-1), or virus gene products of such viruses as **cytomegalovirus** (CMV), Epstein-Barr virus, herpes simplex virus, and hepatitis. Consequently, whenever the infected T4 cell is activated, HIV replication and budding occur, which often destroys the host cell. Newly formed HIV is then released into the blood plasma and infects other CD4+ cells (see Fig. 52-1).

HIV-1 mutates quickly, at a relatively constant rate, with about 1% of the virus's genetic material changing annually. Over the years, 10 distinct subtypes of HIV-1 have emerged, designated A through J. Subtype B is the dominant subtype in North America and Europe, while subtype D predominates in Africa (Stephenson, 1998).

All viruses target specific cells. Lymphocytes consist of three major populations: T cells, B cells, and natural killer cells (Huston, 1997). Mature T cells are phenotypically composed of two major subpopulations defined by cell surface reciprocal expression of CD4 or CD8 (Huston, 1997). Approximately two thirds of peripheral blood T cells are CD4 and approximately one third are CD8. Most people have about 700 to 1,000 CD4 cells/mm<sup>3</sup>, but as low as 500/mm<sup>3</sup> can be considered "normal." HIV targets cells with the CD4 glycoprotein, which is expressed on the surface of T lymphocytes, **monocytes**, dendritic cells, and brain microglia (Wyatt & Sodroski, 1998). A major function of CD4 binding is to induce conformational changes in the GP120 glycoprotein of the HIV envelope that contribute to the formation or exposure of the binding site for the chemokine receptors (Wyatt & Sodroski, 1998). Most primary clinical isolates of HIV use the chemokine receptor **CCR5** for entry. HIV-1 isolates arising later in the course of infection often use other chemokine receptors such as CXCR4 in addition to CCR5 (Wyatt & Sodroski, 1998). HIV must attach to both the CD4 and CCR5 binding sites in order to infect CD4+ cells. CD4 fits into a recessed pocket in the viral envelope GP120 that may simply be too deep to be easily accessed by antibodies (Balter, 1998). A mutation of CCR5 was identified that is common among Caucasians but not other ethnic groups. About 1% of Caucasians lack functional CCR5 and are highly protected against HIV infection even if exposed (although protection is not absolute); about 18% are not markedly protected against infection but if infected demonstrate significantly slower rates of disease progression (Collman, 1997).

## Stages of HIV Disease

The stage of HIV disease is based on clinical history, physical examination, laboratory evidence of immune dysfunction, signs and symptoms, and infections and malignancies. The CDC standard case definition of AIDS categorizes HIV infection and AIDS in adults and adolescents on the basis of clinical conditions associated with HIV infection and CD4+ T-cell counts. The classification system (Table 52-1) groups clinical conditions into one of three categories denoted as A, B, or C.

### PRIMARY INFECTION (ALSO KNOWN AS ACUTE HIV INFECTION OR ACUTE HIV SYNDROME)

The period from infection with HIV to the development of antibodies to HIV is known as **primary infection**. During this period, there is intense viral replication and widespread dissemination of HIV throughout the body. Symptoms associated with the

viremia range from none to severe flu-like symptoms. During the primary infection period, the window period occurs because a person is infected with HIV but tests negative on the HIV antibody blood test. Although antibodies to the HIV envelope glycoproteins typically can be detected in the sera of HIV-infected individuals by 2 to 3 weeks after infection, most of these antibodies lack the ability to inhibit virus infection. By the time neutralizing antibodies are detected, HIV-1 is firmly established in the host (Wyatt & Sodroski, 1998). During this period, there are high levels of viral replication and the killing of CD4 T cells, resulting in high levels of HIV in the blood and a dramatic drop in CD4 T cell counts from the normal level of at least 800 cells/mm<sup>3</sup> of blood. About 3 weeks into this acute phase, individuals may display symptoms reminiscent of mononucleosis, such as fever, enlarged lymph nodes, rash, muscle aches, and headaches. These symptoms resolve within another 1 to 3 weeks as the immune system begins to gain some control over the virus. That is, the CD4 T-cell population responds in ways that spur other immune cells, such as CD8 lymphocytes, to increase their killing of infected, virus-producing cells. The body produces antibody molecules in an effort to contain the virus; they bind to free HIV particles (outside cells) and assist in their removal (Bartlett & Moore, 1998). This balance between the amount of HIV in the body and the immune response is referred to as the **viral set point** and results in a steady state of infection. During this steady state, which can last for years, the amount of virus in circulation and the number of infected cells equal the rate of viral clearance (Ropka & Williams, 1998).

Primary HIV infection, the time during which the viral burden set point is achieved, includes the acute symptomatic and early infection phases. During this initial stage, viral replication is associated with dissemination in lymphoid tissue and a distinct immunologic response. The final level of the viral set point is inversely correlated with disease prognosis; that is, the higher the viral set point, the poorer the prognosis (Cates, Chesney & Cohen, 1997). The primary infection stage is part of CDC category A.

### HIV ASYMPTOMATIC (CDC CATEGORY A: MORE THAN 500 CD4+ T LYMPHOCYTES/MM<sup>3</sup>)

On reaching a viral set point, a chronic, clinically asymptomatic state begins. Despite its best efforts, the immune system rarely if ever fully eliminates the virus. By about 6 months, the rate of viral replication reaches a lower but relatively steady state that is reflected in the maintenance of viral levels at a kind of "set point." This set point varies greatly from patient to patient and dictates the subsequent rate of disease progression; on average, 8 to 10 years pass before a major HIV-related complication develops. In this prolonged, chronic stage, patients feel well and show few if any symptoms (Bartlett & Moore, 1998). Apparent good health continues because CD4 T-cell levels remain high enough to preserve defensive responses to other pathogens.

### HIV SYMPTOMATIC (CDC CATEGORY B: 200 TO 499 CD4+ T LYMPHOCYTES/MM<sup>3</sup>)

Over time, the number of CD4 T cells gradually falls. Category B consists of symptomatic conditions in HIV-infected patients that are not included in the conditions listed in category C. These conditions must also meet one of the following criteria: (1) the condition is due to HIV infection or a defect in cellular immunity, or (2) the condition must be considered to have a clinical course or require management that is complicated by HIV infection. If an individual was once treated for a category B condition and has not developed a category C disease but is now symptom-free, that person's illness would be considered category B.

**Table 52-1 • Classification System for HIV Infection and Expanded AIDS Surveillance Case Definition for Adolescents and Adults**

DIAGNOSTIC CATEGORIES	CLINICAL CATEGORIES		
	A Asymptomatic, Acute (Primary) HIV or PGL	B Symptomatic, Not (A) or (C) Conditions	C AIDS-Indicator Conditions
CD4+ T-Cell Categories			
(1) $\geq 500/\mu\text{L}$	A1	B1	C1
(2) 200–499/ $\mu\text{L}$	A2	B2	C2
(3) $< 200/\mu\text{L}$	A3	B3	C3
AIDS-indicator T-cell count			
<p><i>People with AIDS-indicator conditions (clinical category C) and those in categories A3 or B3 are considered to have AIDS.</i></p>			
<p><b>Clinical Category A</b> Includes one or more of the following in an adult or adolescent with confirmed HIV infection and without conditions in clinical categories B and C:</p> <ul style="list-style-type: none"> <li>• Asymptomatic HIV infection</li> <li>• Persistent generalized lymphadenopathy (PGL)</li> <li>• Acute (primary) HIV infection with accompanying illness or history of acute HIV infection</li> </ul>		<p><b>Clinical Category C</b> Examples of conditions in adults and adolescents include the following:</p> <ul style="list-style-type: none"> <li>• Candidiasis of bronchi, trachea, or lungs; esophagus</li> <li>• Cervical cancer, invasive</li> <li>• Coccidioidomycosis, disseminated or extrapulmonary</li> <li>• Cryptococcosis, extrapulmonary</li> <li>• Cryptosporidiosis, chronic intestinal (exceeding 1 month's duration)</li> <li>• Cytomegalovirus disease (other than liver, spleen, or lymph nodes)</li> <li>• Cytomegalovirus retinitis (with loss of vision)</li> <li>• Encephalopathy, HIV-related</li> <li>• Herpes simplex: chronic ulcer(s) (exceeding 1 month's duration); or bronchitis, pneumonitis, or esophagitis</li> <li>• Histoplasmosis, disseminated or extrapulmonary</li> <li>• Isosporiasis, chronic intestinal (exceeding 1 month's duration)</li> <li>• Kaposi's sarcoma</li> <li>• Lymphoma, Burkitt's (or equivalent term); immunoblastic (or equivalent term); primary, of brain</li> <li>• <i>Mycobacterium avium</i> complex or <i>M. kansasii</i>, disseminated or extrapulmonary</li> <li>• <i>Mycobacterium tuberculosis</i>, any site (pulmonary or extrapulmonary)</li> <li>• <i>Mycobacterium</i>, other species or unidentified species, disseminated or extrapulmonary</li> <li>• <i>Pneumocystis carinii</i> pneumonia</li> <li>• Pneumonia, recurrent</li> <li>• Progressive multifocal leukoencephalopathy</li> <li>• <i>Salmonella</i> septicemia, recurrent</li> <li>• Toxoplasmosis of brain</li> <li>• Wasting syndrome due to HIV</li> </ul>	
<p><b>Clinical Category B</b> Examples of conditions in clinical category B include, but are not limited to, the following:</p> <ul style="list-style-type: none"> <li>• Bacillary angiomatosis</li> <li>• Candidiasis, oropharyngeal (thrush) or vulvovaginal (persistent, frequent, or poorly responsive to therapy)</li> <li>• Cervical dysplasia (moderate or severe)/cervical carcinoma in situ</li> <li>• Constitutional symptoms, such as fever (<math>38.5^\circ\text{C}</math>) or diarrhea exceeding 1 month in duration</li> <li>• Hairy leukoplakia, oral</li> <li>• Herpes zoster (shingles), involving at least two distinct episodes or more than one dermatome</li> <li>• Idiopathic thrombocytopenic purpura</li> <li>• Listeriosis</li> <li>• Pelvic inflammatory disease, particularly if complicated by tuboovarian abscess</li> <li>• Peripheral neuropathy</li> </ul>			

Adapted from Centers for Disease Control, U.S. Department of Health and Human Services. (1992). 1993 revised classification system for HIV infection and expanded surveillance case definition for AIDS among adolescents and adults. *MMWR CDC Recommendations and Reports*, 41 (RR 17), 1–19.

### AIDS (CDC CATEGORY C): LESS THAN 200 CD4+ T LYMPHOCYTES/MM<sup>3</sup>

When CD4 T-cell levels drop below 200 cells/mm<sup>3</sup> of blood, patients are said to have AIDS. As levels fall below 100, the immune system is significantly impaired (Bartlett & Moore, 1998). Once a patient has had a category C condition, he or she remains in category C. This classification has implications for entitlements (ie, disability benefits, housing, and food stamps) since these programs are often linked to an AIDS diagnosis. Although the revised classification emphasizes CD4+ T-cell counts, it allows for CD4+ percentages (percentage of CD4+ T cells of total lymphocytes). The CD4+ percentage is less subject to variation on repeated measurements than is the absolute CD4+ T-cell count. Less than 14% of the CD4+ T cells of the total lymphocytes is consistent with an AIDS diagnosis. The percentage, as compared to the absolute number of CD4+ T cells, becomes particularly important when the patient has a heightened immune response to infections in addition to HIV. One complication of advanced

HIV infection is anemia, which may be caused by HIV, opportunistic diseases, and medications (Collier et al., 2001).

### Assessment and Diagnostic Findings

During the first stage of HIV infection, the patient may be asymptomatic or may exhibit various signs and symptoms. The patient history should alert the health care provider about the need for HIV screening based on the patient's sexual practices, injection drug use, and receipt of blood transfusions. Additionally, exposure to body fluids containing infected blood while providing care to others with HIV infection, such as through needlesticks, should alert health care providers to possible HIV infection. Patients who are in later stages of HIV infection may have a variety of symptoms related to their immunosuppressed state.

Several screening tests are used to diagnose HIV infection. Others are used to assess the stage and severity of the infection. Table 52-2 identifies common blood tests.

**Table 52-2 • Selected Laboratory Tests for Diagnosing and Tracking HIV and Assessing Immune Status**

TEST	FINDINGS IN HIV INFECTION
EIA (enzyme immunoassay), formerly referred to as ELISA (enzyme-linked immunosorbent assay)	Antibodies are detected, resulting in positive results and marking the end of the window period.
Western blot	Also detects antibodies to HIV; used to confirm EIA
Viral load	Measures HIV RNA in the plasma
CD4/CD8 ratio	These are lymphocytes. HIV kills CD4 cells, which results in a significantly impaired immune system.

### HIV ANTIBODY TESTS

In 1985, the FDA licensed an HIV-1 antibody assay, which is used to screen all blood and plasma donations. When an individual is infected with HIV, the immune system responds by producing antibodies against the virus, usually within 3 to 12 weeks after infection. This delay in the production of antibody helps to explain why a person may be infected but not test antibody-positive during primary infection. The ability to document HIV antibodies in the blood has permitted screening of blood products and facilitated identification of individuals with HIV infection. Before an HIV antibody test is performed, the meaning of the test and possible test results are explained, and informed consent for the test is obtained from the patient. When results of the HIV antibody testing are received, they are carefully explained to the patient in private (Chart 52-5). All test results are kept confidential. Education and counseling about the test results and disease transmission are essential.

Blood samples are tested with two different blood tests to determine the presence of antibodies to HIV. The **EIA (enzyme immunoassay)**, formerly referred to as the **ELISA (enzyme-linked immunosorbent assay)** test, identifies antibodies directed specifically against HIV. The **Western blot assay** is used to con-

firm seropositivity when the EIA is positive. People whose blood contains antibodies for HIV are seropositive. Saliva can also be tested using the EIA antibody test.

The FDA approved a rapid HIV antibody screening test in November 2002. Using less than a drop of blood, this new test can quickly (approximately 20 minutes) and reliably (99.6% accuracy) detect antibodies to HIV-1. It is anticipated that the newly approved HIV test, the OraQuick Rapid HIV-1 Antibody Test, will allow more rapid notification of individuals about their HIV status so that they can obtain care early in the course of HIV infection and take measures to help prevent the spread.

Patients' psychological responses to seropositive test results may include feelings of panic, depression, and hopelessness. The social and interpersonal consequences of a positive test result can be devastating. Patients may lose their sexual partners and their health insurance because of disclosure; they may experience discrimination in employment and housing as well as social ostracism. For these reasons and others, patients who test positive may need ongoing counseling as well as referrals for social, financial, medical, and psychological support services. Patients whose test results are seronegative may develop a false sense of security, possibly resulting in continued high-risk behaviors or feelings that they are immune to the virus. They may need ongoing counseling to help them modify high-risk behaviors and to return for repeated testing. Other patients may experience anxiety regarding the uncertainty of their status.

Home-based testing for HIV antibodies using a small amount of blood was first proposed in 1985 but not approved by the FDA until 1995. Although home testing kits are commercially available, they do raise concerns because of the lack of counseling and the possibility of inaccurate results, including both false-positive and false-negative results (Lewis, 2001).

**Chart 52-5 • PATIENT EDUCATION**  
**HIV Test Results: Implications for Patients**

#### Interpretation of Positive Test Results

- Antibodies to HIV are present in the blood (the patient has been infected with the virus, and the body has produced antibodies).
- HIV is active in the body, and the patient can transmit the virus to others.
- Despite HIV infection, the patient does not necessarily have AIDS.
- The patient is not immune to AIDS (the antibodies do not indicate immunity).

#### Interpretation of Negative Test Results

- Antibodies to HIV are not present in the blood at this time, which can mean that the patient has not been infected with HIV or, if infected, the body has not yet produced antibodies (which takes from 3 weeks to 6 months or longer).
- The patient should continue taking precautions. The test result does not mean that the patient is immune to the virus, nor does it mean the patient is not infected; it just means that the body may not have produced antibodies yet.

### VIRAL LOAD TESTS

Target amplification methods quantify HIV RNA or DNA levels in the plasma and have replaced p24 antigen capture assays. Target amplification methods include reverse transcriptase **polymerase chain reaction** (RT-PCR) or nucleic acid sequence-based amplification (NASBA). A widely used **viral load test** measures plasma HIV RNA levels. Currently, these tests are used to track viral load and response to treatment for HIV infection. RT-PCR is also used to detect HIV in high-risk seronegative people before the development of antibodies, to confirm a positive EIA, and to screen neonates. HIV culture or quantitative plasma culture and plasma viremia are additional tests that measure viral burden, but they are used infrequently. Viral load is a better predictor of the risk of HIV disease progression than the CD4

count. The lower the viral load, the longer the time to AIDS diagnosis and the longer the survival time.

## Treatment of HIV Infection

Protocols of how to treat HIV disease change relatively often. Yearly a team of physicians from throughout the United States evaluates the latest evidence and makes recommendations that are widely disseminated, and monthly a subgroup evaluates available evidence (Panel on Clinical Practices for Treatment of HIV Infection [Panel], 2002). Treatment decisions for an individual patient are based on three factors: HIV RNA (viral load); CD4 T-cell count; and the clinical condition of the patient (Panel, 2000). Treatment should be offered to all patients with the primary infection (acute HIV syndrome, as previously described). In general, treatment should be offered to individuals with a T-cell count of less than 350 or plasma HIV RNA levels exceeding 55,000 copies/mL (RT-PCR assay) (Panel, 2002).

The increasing number of antiretroviral agents (Table 52-3) and the rapid evolution of new information have introduced extraordinary complexity into the treatment of HIV-infected persons (Panel, 2000). Adherence rates among persons living with HIV and AIDS are no different from those of patients with other chronic diseases (Williams, 2001). Antiretroviral regimens are complex, have major side effects, pose difficulties with regard to adherence, and carry serious potential consequences from the development of viral resistance due to lack of adherence to the drug regimen or suboptimal levels of antiretroviral agents (Panel, 2000). The goals of treatment are maximal and durable suppression of viral load, restoration and/or preservation of immunologic function, improved quality of life, and reduction of HIV-related morbidity and mortality. The Panel's guidelines recommend viral load testing at diagnosis and every 3 to 4 months thereafter in the untreated person; T-cell counts should be measured at diagnosis and generally every 3 to 6 months thereafter.

It is difficult to predict which patients will adhere to medication regimens (Holzemer, Corless, Nokes, et al., 1999). Perceived engagement with the health care provider has been associated with greater adherence to HIV medication regimens (Bakken et al., 2000). Individualized plans of care that take into consideration housing and social support issues in addition to health indicators are essential.

Results of therapy are evaluated with viral load tests (Panel, 2000). Viral load levels should be measured immediately prior to and again at 2 to 8 weeks after initiation of antiretroviral therapy, since in most patients adherence to a regimen of potent antiretroviral agents should result in a large decrease in the viral load by 2 to 8 weeks. The viral load should continue to decline over the following weeks and in most individuals will drop below detectable levels (currently defined as less than 50 RNA copies/mL) by 16 to 20 weeks. The rate of viral load decline toward undetectable levels is affected by the baseline T-cell count, the initial viral load, the potency of the medication, adherence of the patient to the medication regimen, prior exposure to antiretroviral agents, and the presence of any OIs (Panel, 2000). The confirmed absence of a viral load response should prompt the health care team to re-evaluate the regimen.

All approved anti-HIV drugs attempt to block viral replication within cells by inhibiting either reverse transcriptase or the HIV protease (Bartlett & Moore, 1998). A treatment duration of 5 to 7 years of continuous therapy is difficult because of the complexity, toxicity, and cost of the current drug regimens, especially when the concept of maintenance therapy with a simplified reg-

imen does not seem viable (Ho, 1998). Medication side effects can make life difficult and are one of the main reasons people miss doses of the medications or stop taking them completely (Horn & Pieribone, 1999).

All medications have toxic side effects. The nurse can obtain Web-based information to remain current about medications used to treat HIV/AIDS. The NIH (National Institutes of Health) maintains an AIDS drug line Website (see resources at the end of this chapter). Increasing numbers of patients with HIV infection receiving medications are presenting with metabolic complications such as increases in cholesterol and triglyceride levels, hyperglycemia, and altered body habitus (NIAID, 2001). Toxicity to cell mitochondria may be involved in many of the side effects of HIV medications, including peripheral neuropathy, myopathy and cardiomyopathy, lactic acidosis and hepatic steatosis (fatty degeneration of liver), pancreatitis, osteopenia and osteoporosis, and bone marrow suppression. Fat redistribution (lipodystrophy syndrome, also known as pseudo-Cushing's syndrome [Panel, 2001]) is one of the most frequent systemic side effects. Many people who have lipodystrophy experience an increase in fat loss in the legs, arms, and face and/or a buildup of fat around the abdomen and at the base of the neck. Patients may also experience an increase in breast size. These changes in body image can be very disturbing to persons living with HIV/AIDS and have been reported to occur in 6% to 80% of patients receiving HAART (see following discussion). Hepatotoxicity associated with certain protease inhibitors may limit the use of these agents, especially in patients with underlying liver dysfunction (Panel, 2000).

Combination therapy is defined as a regimen containing any combination of two antiretroviral agents; HAART is defined as a regimen consisting of two nucleoside reverse transcriptase inhibitors plus a **protease inhibitor** or a non-nucleoside reverse transcriptase inhibitor, or two protease inhibitors and one other antiretroviral agent (Akins, 2000). As new medications are developed, the number of combinations continues to increase. Safety and efficacy data on many of the combination therapies are limited. Use of three- and four-drug combination regimens has become more widespread, starting earlier in the course of infection, with careful monitoring by viral load measures. In some patients receiving three-drug regimens, viral levels are so low that they are no longer detectable. Future therapy may be individualized based on the viral strain and resistance to antiretroviral drugs. Initially, HAART consisting of a triple-drug regimen (a protease inhibitor and two non-nucleoside reverse transcriptase inhibitors) is recommended. Drawbacks of HAART are the inability of some patients to adhere to the regimen, the need to take multiple medications on different dosing schedules, and the risk for drug interactions. The duration of therapy needed to control acute HIV infection is unknown, but therapy may continue for several years or for life. Combination therapy with different types of fusion and entry inhibitors (such as T-20) may be synergistic against HIV. These agents fall into a new category of HIV medications called fusion inhibitors and target the GP120 during the initial stage of the HIV life cycle, which is cell fusion (Saag, 2001).

## Drug Resistance

Drug resistance can be broadly defined as the ability of pathogens to withstand the effects of medications intended to be toxic to them. Resistance develops as a result of spontaneous genetic mutation of the pathogens or in response to exposure to the

**Table 52-3 • Antiretroviral Agents**

MEDICATION	SIDE/ADVERSE EFFECTS	COMMENTS	COMBINATION PREPARATIONS
<b><i>Nucleoside analog reverse transcriptase inhibitors (NRTIs)</i></b>			
Act by becoming part of HIV's DNA and derail its building process. As a result, the damaged viral DNA cannot take control of the host cell's DNA (Gracia Jones, 2001). Possible adverse reactions associated with medications that act through this mechanism include peripheral neuropathy, pancreatitis, lactic acidosis, bone marrow suppression, neutropenia, anemia, arthralgia, myopathy, kidney dysfunction, hepatomegaly, liver failure, vision changes, neuropathy, hypersensitivity reaction, abdominal pain, fever, chills, sore throat, oral ulcers, dry mouth, muscle and joint pain, irritability, anxiety, nervousness (Gracia Jones, 2001). Lactic acidosis with hepatic steatosis (fatty degeneration of the liver) is a rare but potentially life-threatening toxicity with this classification of medications (Panel on Clinical Practices, 2000, 2001).			
zidovudine (AZT, Retrovir)	Bone marrow suppression: anemia, neutropenia Subjective complaints: GI intolerance, appetite loss, fatigue, headaches, insomnia, asthenia, pain	Take without regard to meals.	Combination agents containing AZT: zidovudine/lamivudine (Combivir); Retrovir, Epivir, and Ziagen (Trizivir)
lamivudine (3TC, Epivir)	Minimal toxicity; anemia, fatigue, hair loss, headache, nausea, peripheral neuropathy.	Take without regard to meals.	Combination agents containing lamivudine: zidovudine/lamivudine (Combivir); Retrovir, Epivir, and Ziagen (Trizivir)
d4t (Zerit, stavudine)	Peripheral neuropathy, pancreatitis, facial wasting, fungal infections, nausea	Take without regard to meals.	
ddi (Videx, didanosine, Videx EC (enteric-coated/delayed-release)	Diarrhea, nausea, oral ulcers, pancreatitis (fatal and non-fatal); peripheral neuropathy	Take ½ hour before or 1 hour after meals; avoid alcohol.	
ddc (Hivid, zalcitabine)	Peripheral neuropathy; stomatitis (mouth ulcers), nausea, more rarely pancreatitis	Take without regard to meals.	
abacavir (Ziagen)	Hypersensitivity reaction (can be fatal); fever, rash, nausea, vomiting, malaise or fatigue, insomnia, loss of appetite	Discontinue drug as soon as hypersensitivity reaction is suspected, and do not restart.	Combination agent containing abacavir: Retrovir, Epivir, and Ziagen (Trizivir)
<b><i>Non-nucleoside reverse transcriptase inhibitors (NNRTIs)</i></b>			
Act by attaching to the reverse transcriptase enzyme, which prevents it from converting HIV RNA into HIV DNA (Gracia Jones, 2001). Possible adverse reactions for this group of agents include abnormal liver function test results, hepatitis, stomatitis, numbness, muscle pain, drowsiness, changes in dreams, trouble concentrating, severe psychiatric symptoms in rare cases (severe depression, suicidal thoughts, angry behavior) (Gracia Jones, 2001). Rare cases of Stevens-Johnson syndrome have been reported with the use of this class of medications (Panel on Clinical Practices, 2000, 2001). Drug resistance develops very easily, which makes adherence essential.			
nevirapine (Viramune)	Skin rash, increased transaminase levels, hepatitis, fever, headache, nausea, stomach upset	Take without regard to meals.	
delavirdine (Rescriptor)	Skin rash, increased transaminase levels, headache, diarrhea, fatigue, stomach upset	Take without regard to meals.	
efavirenz (Sustiva)	Unusual dreams, poor concentration, anxiety, CNS symptoms including dizziness, drowsiness, increased transaminase levels, nausea, false-positive cannabinoid test	Avoid taking after high-fat meals.	
tenofovir (Viread)	Generally well tolerated. Adverse effect data not available at this point. Mild to moderate GI side effects (nausea, diarrhea, vomiting, flatulence)	Take with food. Monitor for lactic acidosis and hepatomegaly.	

***Protease inhibitors***

Work at a later stage in the HIV replication process by preventing the protease enzyme from cutting HIV viral proteins into the viral particles that infect new CD4 T4 cells. As a result, new copies of HIV are defective and unable to infect new host cells (Gracia Jones, 2001). Possible adverse reactions include hemolytic anemia, paresthesia, kidney stones, asymptomatic hyperbilirubinemia, dyspepsia, numbness (of lips, hands, or feet), altered taste, drowsiness, mood alterations (Gracia Jones, 2001); in patients with hemophilia, there are possible increased bleeding episodes (Panel on Clinical Practices, 2000, 2001).

(continued)

Table 52-3 • Antiretroviral Agents (Continued)

DRUG	SIDE/ADVERSE EFFECTS	COMMENTS	COMBINATION PREPARATIONS
nelfinavir (Viracept)	Diarrhea, hyperglycemia, fat redistribution and lipid abnormalities	Take with meal or snack.	
ritonavir (Norvir)	Peripheral neuropathy, liver toxicity (hepatitis), GI intolerance, nausea, vomiting, diarrhea, paraesthesias (circumoral and extremities), asthenia, taste perversion. Triglycerides can increase more than 200%, transaminase elevation, elevated CPK and uric acid, hyperglycemia. Fat redistribution and lipid abnormalities.	Take with food if possible to increase tolerability. Refrigerate capsules; do not refrigerate oral solution.	
saquinavir (Invirase, Fortovase)	Fatigue, GI intolerance, nausea, diarrhea, headache, elevated transaminase enzymes, hyperglycemia, fat redistribution and lipid abnormalities	No food effect for Invirase when taken with ritonavir; take Fortovase with a large meal. Refrigerate Fortovase or store at room temperature up to 3 months.	Combination agent containing ritonavir, lopinavir and ritonavir (Kaletra). Additional side effects: insomnia, abdominal pain, rash. Take with food.
indinavir (Crixivan)	Kidney stones (nephrolithiasis), GI intolerance, nausea, increased indirect bilirubinemia, headache, asthenia, blurred vision, dizziness, rash, metallic taste, thrombocytopenia, hyperglycemia, fat redistribution and lipid abnormalities	Take 1 hour before or 2 hours after meals; may take with skim milk or low-fat meal. Store in original container, which contains desiccant—without this, it is stable for only 3 days. Drink a large volume of water.	
amprenavir (Agenerase)	Diarrhea, nausea, oral tingling and numbness, rash, vomiting	Avoid taking with high-fat meal.	

medication (Esch & Frank, 2001). Factors associated with the development of drug resistance include serial monotherapy (taking one medication at a time), inadequate suppression of virus replication with suboptimal treatment regimens, difficulty with adherence to complex and toxic regimens, and initiation of therapy late in the course of HIV infection (Boden et al., 1999). HIV-1 may find refuge in organ sanctuaries such as behind the blood–brain barrier, where diminished drug concentrations in the central nervous system (CNS) might induce the development of drug-resistant mutants (Cavert & Haase, 1998). HIV-1 persists in lymphoid tissue even in individuals who appear to have responded well to antiviral therapy (Letvin, 1998). Deciding whether the medication regimen is effective or ineffective is a complex phenomenon. Some individuals experience an optimal response to treatment, as shown by effective viral suppression and ensuing immune recovery; others experience increasing CD4+ cell counts in the presence of ongoing viral replication or blunted immune recovery despite viral control, and finally complete treatment failure (Perrin & Telenti, 1998).

Central to the complexity of HIV drug resistance are the phenomenon of HIV quasi-species (the simultaneous presence in a patient of multiple viral variants), the extent of cross-resistance among antiviral agents, the existence in each individual of archival HIV DNA copies representing all viruses that emerged under the

patient's previous treatment, and the preexistence of resistant variants even without prior exposure to the medication (Perrin & Telenti, 1998). Measurement of HIV drug susceptibility for management of HIV infection is now practical using recombinant DNA technology (Hirsch et al., 2000). Although available data support a role for HIV drug resistance testing in selecting medications in many clinical situations, these test results should not be used as the principal criterion for decisions on initiating or changing antiretroviral therapy. Such decisions should be based primarily on the patient's plasma HIV viral load. Several factors in addition to resistance testing must be considered in choosing medications for a new regimen once the prior regimen has failed. These factors include the patient's past treatment history, viral load, medication tolerance, the likelihood of the patient adhering to the medication regimen, and concomitant medical conditions or medications (Hirsch et al., 2000). Blood specimens should be obtained for resistance testing before the failing drug regimen is stopped (Hirsch et al., 2000).

### Structured Intermittent Therapy

Because of drug toxicities, drug resistance, difficulties with adherence, and the high cost of medications, the complex medication regimen is often difficult for patients to follow. In an effort

to determine if alternative treatment approaches are possible, a study is underway to examine patients' responses to stopping HAART therapy by monitoring their immune status and viral load (Dybul et al., 2001). This would allow patients to move from a continuous regimen of anti-HIV therapy to a strategy in which they discontinue therapy for a specific period of time (ie, 7 days) and then resume therapy for 7 days. This approach is known as structured intermittent therapy. While preliminary results of the study are promising, larger studies are needed to determine the effectiveness of these alternative medication regimens.

### IMMUNOMODULATOR THERAPY

Combating HIV infection requires not only agents that will inhibit viral growth but also those that will restore or augment the damaged immune system. New therapies are needed to restore immune function, and immunologic markers need to be identified to predict the success of therapy (NIAID, 2001). Current research is testing the effectiveness of interleukin-2, interleukin-12, and other cytokines and lymphokines (NIAID, 2001).

### VACCINES

HIV-1 is a uniquely difficult target for the development of vaccines (Letvin, 1998). Since HIV-1 was discovered, researchers have been working to develop a vaccine. A vaccine is a substance that triggers the production of antibodies to destroy the offending organism. Most vaccines activate the humoral arm of the immune system, which stimulates the production of protective antibodies. In addition to antibodies, B lymphocytes take the form of memory B cells. These cells do not produce antibodies immediately but respond vigorously to subsequent exposure. Vaccines that stimulate the cellular arm of the immune system are being developed. Since 1995, there have been a variety of vaccines under study using different strategies to prevent HIV infection in animals and humans. Some researchers are exploring whether different immunization schedules, different schedules of boosters, or a combination of several vaccines will result in stronger or more durable responses. Creation of an HIV vaccine is feasible, but a worldwide commitment is needed. Cooperation between all nations is necessary to develop and commit the resources to develop the vaccine and to create and support the infrastructure needed to facilitate testing of vaccine immunogens (Letvin, Bloom & Hoffman, 2001).

Clinical trials began in November 2002 to test an HIV vaccine that incorporates three HIV subtypes that cause about 90% of all HIV-1 infections around the world. The first phase of this yearlong trial, which is being conducted at NIH, is examining the vaccine's safety. Subsequent trials will be conducted to determine the immune response to the vaccines (NIH News Release, 11/13/2002).

### Clinical Manifestations

Treatment of specific manifestations of HIV infection and AIDS in the person with advanced disease targets specific symptoms. These are discussed later in this chapter.

Patients with HIV/AIDS experience a number of symptoms related to the disease as well as the effects of treatment. Nurses need to understand the causes, signs and symptoms, and interventions to enhance the quality of life of patients with HIV across the illness trajectory (Ropka & Williams, 1998; Sherman, 1999). The clinical manifestations of HIV/AIDS are widespread and may affect virtually any organ system. Diseases associated with HIV infection and AIDS result from infections, malignancies, or

the direct effect of HIV on body tissues. Symptom assessment tools developed for research purposes could be useful in clinical practice to assess symptom intensity and severity (Holzemer, Henry, Nokes, et al., 1999; Nokes, Wheeler & Kendrew, 1994; Nokes & Bakken, 2002).

### RESPIRATORY MANIFESTATIONS

Shortness of breath, dyspnea (labored breathing), cough, chest pain, and fever are associated with various OIs, such as those caused by *Pneumocystis carinii*, *Mycobacterium avium-intracellulare*, CMV, and *Legionella* species. The most common infection in people with AIDS is **Pneumocystis carinii pneumonia (PCP)**, one of the first OIs described in association with AIDS.

**PCP.** PCP is the most common OI resulting in an AIDS diagnosis. Without prophylactic therapy (discussed below), PCP will develop in 80% of all HIV-infected individuals. *P. carinii* was originally classified as a protozoan; however, studies and analysis of its ribosomal RNA structure suggest that it is a fungus. Its structure and antimicrobial sensitivity are very different from other disease-causing fungi. *P. carinii* causes disease only in immunocompromised hosts, invading and proliferating within the pulmonary alveoli with resultant consolidation of the pulmonary parenchyma.

The clinical presentation of PCP in HIV infection is generally less acute than in people who are immunosuppressed as a result of other conditions. The time between the onset of symptoms and the actual documentation of disease may be weeks to months. Patients with AIDS initially develop nonspecific signs and symptoms, such as nonproductive cough, fever, chills, shortness of breath, dyspnea, and occasionally chest pain. PCP may be present despite the absence of crackles. Arterial oxygen concentrations in patients breathing room air may be mildly decreased, indicating minimal hypoxemia.

Untreated, PCP eventually progresses and causes significant pulmonary impairment and, ultimately, respiratory failure. A few patients have a dramatic onset and fulminant course involving severe hypoxemia, cyanosis, tachypnea, and altered mental status. Respiratory failure can develop within 2 to 3 days of initial symptoms.

PCP can be diagnosed definitively by identifying the organism in lung tissue or bronchial secretions. This is accomplished by such procedures as sputum induction, bronchial-alveolar lavage, and transbronchial biopsy (by fiberoptic bronchoscopy).

**Mycobacterium avium Complex.** *Mycobacterium avium complex* (MAC) disease is a leading OI in people with AIDS. Organisms belonging to MAC include *M. avium*, *M. intracellulare*, and *M. scrofulaceum*. MAC, comprising a group of acid-fast bacilli, usually causes respiratory infection but is also commonly found in the GI tract, lymph nodes, and bone marrow. Most patients with AIDS who have T-cell counts less than 100 have widespread disease at diagnosis and are usually debilitated. MAC infections are associated with rising mortality rates.

**Tuberculosis.** *Mycobacterium tuberculosis* tends to occur in injection drug users and other groups with a preexisting high prevalence of tuberculosis (TB) infection. Unlike other OIs, TB tends to occur early in the course of HIV infection, usually preceding the diagnosis of AIDS. This early occurrence is associated with the development of caseating granulomas (dry, cheeselike masses of granulation tissue), which should raise the suspicion of TB. At this stage, TB responds well to antituberculosis therapy.

TB that occurs late in HIV infection is characterized by absence of an immune response to a tuberculin skin test response.

This is known as **anergy** and results because the compromised immune system can no longer respond to the TB antigen. In the later stages of HIV infection, TB is associated with dissemination to extrapulmonary sites such as the CNS, bone, pericardium, stomach, peritoneum, and scrotum. Multiple drug-resistant strains of the bacillus have emerged and are often associated with non-compliance with antituberculosis therapy.

### GI MANIFESTATIONS

The GI manifestations of AIDS include loss of appetite, nausea, vomiting, oral and esophageal candidiasis, and chronic diarrhea. Diarrhea is a problem in 50% to 90% of all AIDS patients. GI symptoms may be related to the direct effect of HIV on the cells lining the intestines. Some of the enteric pathogens that occur most frequently, identified by stool cultures or intestinal biopsy, include *Cryptosporidium muris*, *Salmonella* species, *Isospora belli*, *Giardia lamblia*, CMV, *Clostridium difficile*, and *M. avium-intracellulare*. In patients with AIDS, the effects of diarrhea can be devastating in terms of profound weight loss (more than 10% of body weight), fluid and electrolyte imbalances, perianal skin excoriation, weakness, and inability to perform the usual activities of daily living.

**Oral Candidiasis.** **Candidiasis**, a fungal infection, occurs in nearly all patients with AIDS and AIDS-related conditions. Commonly preceding other life-threatening infections, it is characterized by creamy-white patches in the oral cavity. Untreated, oral candidiasis progresses to involve the esophagus and stomach. Associated signs and symptoms include difficult and painful swallowing and retrosternal pain. Some patients also develop ulcerating oral lesions and are particularly susceptible to dissemination of candidiasis to other body systems.

**Wasting Syndrome.** **Wasting syndrome** is part of the category C case definition for AIDS. Diagnostic criteria include profound involuntary weight loss exceeding 10% of baseline body weight and either chronic diarrhea for more than 30 days or chronic weakness and documented intermittent or constant fever in the absence of any concurrent illness that could explain these findings. This protein-energy malnutrition is multifactorial. In some AIDS-associated illnesses, patients experience a hypermetabolic state in which excessive calories are burned and lean body mass is lost. This state is similar to that seen in sepsis and trauma and can lead to organ failure. A distinction between cachexia (wasting) and malnutrition or between cachexia and simple weight loss is important because the metabolic derangement seen in wasting syndrome may not be modified by nutritional support alone.

Anorexia, diarrhea, GI malabsorption, and lack of nutrition in chronic disease all contribute to wasting syndrome. Progressive tissue wasting, however, may occur with only modest GI involvement and without diarrhea. Tumor necrosis factor (TNF) and interleukin-1 (IL-1) are cytokines that play important roles in AIDS-related wasting syndrome. Both act directly on the hypothalamus to cause anorexia. Cytokine-induced fever accelerates the body's metabolism by 14% for every 1°F increase in temperature. TNF causes inefficient use of lipids by reducing enzymes that are needed for fat metabolism, whereas IL-1 triggers the release of amino acids from muscle tissue. People with AIDS generally experience increased protein metabolism in relation to fat metabolism, which results in significant decreases in lean body mass due to muscle and protein breakdown.

Hypertriglyceridemia, seen in people with AIDS and attributed to chronically elevated cytokine levels, can persist in people

with AIDS for months without tissue wasting and loss of lean body mass. It is believed that infections and sepsis lead to transient rises in TNF, IL-1, and other cell mediators above the chronically elevated levels generally seen. These transient rises in TNF and IL-1 trigger muscle wasting.

### ONCOLOGIC MANIFESTATIONS

Patients with AIDS have a higher than usual incidence of cancer, possibly related to HIV stimulation of developing cancer cells or to the immune deficiency allowing cancer-causing substances, such as viruses, to transform susceptible cells into malignant cells. Kaposi's sarcoma, certain types of B-cell lymphomas, and invasive cervical carcinoma are included in the CDC classification of AIDS-related malignancies. Carcinomas of the skin, stomach, pancreas, rectum, and bladder also occur more frequently than expected in people with AIDS.

**Kaposi's Sarcoma.** **Kaposi's sarcoma (KS)**, the most common HIV-related malignancy, is a disease involving the endothelial layer of blood and lymphatic vessels. It is associated with human herpes virus 8 (HHV-8) transmission (USPHS/IDSA, 2002). When first noted in 1872 by Dr. Moritz Kaposi, KS characteristically presented as lower-extremity skin lesions in elderly men of Eastern European ancestry. This form, referred to as classic Kaposi's sarcoma, was slow to progress and easily treated. An endemic form of KS, found in children and young men in equatorial Africa, is more virulent than the classic form. Acquired KS occurs in patients who are treated with immunosuppressive agents and commonly occurs in patients who have undergone organ transplantation. In such patients, acquired KS usually resolves once the dose of the immunosuppressive medication is decreased or discontinued. In people with AIDS, epidemic KS is most often seen in male homosexuals and bisexuals.

Although the histopathology of all forms of KS is virtually identical, the clinical manifestations differ: AIDS-related KS exhibits a more variable and aggressive course, ranging from localized cutaneous lesions to disseminated disease involving multiple organ systems. Cutaneous signs may be the first manifestations of HIV, appearing in more than 90% of HIV-infected patients as immune function deteriorates. These skin signs correlate to low CD4 counts. Some disorders, such as Kaposi's sarcoma, oral hairy leukoplakia, facial molluscum contagiosum, dry skin, and oral candidiasis, indicate CD4 counts at or below 200 to 300.

Cutaneous lesions appearing anywhere on the body are usually brownish pink to deep purple. They may be flat or raised and surrounded by ecchymoses (hemorrhagic patches) and edema (Fig. 52-3). Rapid development of lesions involving large areas of skin is associated with extensive disfigurement. The location and size of some lesions can lead to venous stasis, lymphedema, and pain. Ulcerative lesions disrupt skin integrity and increase discomfort and susceptibility to infection. The most common sites of visceral involvement include the lymph nodes, GI tract, and lungs. Involvement of internal organs may eventually lead to organ failure, hemorrhage, infection, and death.

Diagnosis of KS is confirmed by biopsy of suspected lesions. Prognosis depends on the extent of the tumor, presence of constitutional symptoms, and CD4 count. Death may result from tumor progression. More often, however, it results from other complications of HIV infection.

**B-Cell Lymphomas.** **B-cell lymphomas** are the second most common malignancy occurring in people with AIDS. Lymphomas associated with AIDS usually differ from those occurring

**FIGURE 52-3** Lesions of the AIDS-related Kaposi's sarcoma. Whereas some patients may have lesions that remain flat, others experience extensively disseminated, raised lesions with edema. From DeVita, V. T. Jr., Hellman, S., & Rosenberg, S. (Eds.). *AIDS: Etiology, diagnosis, treatment, and prevention* (4th ed.). Philadelphia: Lippincott Williams & Wilkins.

in the general population. Patients with AIDS are generally much younger than the usual population affected by non-Hodgkin's lymphoma. In addition, AIDS-related lymphomas tend to develop outside the lymph nodes, most commonly in the brain, bone marrow, and GI tract. These types of lymphomas are characteristically of a higher grade, indicating aggressive growth and resistance to treatment. The course of AIDS-related lymphomas includes multiple sites of organ involvement and complications related to OIs. Although aggressive combination chemotherapy is frequently successful in non-Hodgkin's lymphoma not associated with HIV infection, it is less successful in people with AIDS because of the severe hematologic toxicity and complications of OIs that occur from treatment.

### NEUROLOGIC MANIFESTATIONS

An estimated 80% of all patients with AIDS experience some form of neurologic involvement during the course of HIV infection. Many neuropathologic disorders are underreported because patients may have neurologic involvement without overt signs or symptoms. Neurologic complications involve central, peripheral, and autonomic functions.

Neurologic dysfunction results from the direct effects of HIV on nervous system tissue, OIs, primary or metastatic neoplasms, cerebrovascular changes, metabolic encephalopathies, or complications secondary to therapy. Immune system response to HIV infection in the CNS includes inflammation, atrophy, demyelination, degeneration, and necrosis.

**HIV Encephalopathy.** HIV encephalopathy was formerly referred to as AIDS dementia complex. It is a clinical syndrome characterized by a progressive decline in cognitive, behavioral, and motor functions. Substantial evidence exists that HIV encephalopathy is a direct result of HIV infection. HIV has been found in the brain and cerebrospinal fluid (CSF) of patients with HIV encephalopathy. The brain cells infected by HIV are predominantly the CD4 cells of monocyte-macrophage lineage. HIV infection is thought to trigger the release of toxins or lymphokines that result in cellular dysfunction or interference with neurotransmitter function rather than cellular damage.

Signs and symptoms may be subtle and difficult to distinguish from fatigue, depression, or the adverse effects of treatment for

infections and malignancies. Early manifestations include memory deficits, headache, difficulty concentrating, progressive confusion, psychomotor slowing, apathy, and ataxia. Later stages include global cognitive impairments, delay in verbal responses, a vacant stare, spastic paraparesis, hyperreflexia, psychosis, hallucinations, tremor, incontinence, seizures, mutism, and death.

Confirming the diagnosis of HIV encephalopathy may be difficult. Extensive neurologic evaluation includes a computed tomography (CT) scan, which may indicate diffuse cerebral atrophy and ventricular enlargement. Other tests that may detect abnormalities include magnetic resonance imaging (MRI), analysis of CSF through lumbar puncture, and brain biopsy.

**Cryptococcus neoformans.** A fungal infection, *Cryptococcus neoformans*, is another common OI among patients with AIDS and causes neurologic disease. Cryptococcal meningitis is characterized by symptoms such as fever, headache, malaise, stiff neck, nausea, vomiting, mental status changes, and seizures. Diagnosis is confirmed by CSF analysis.

**Progressive Multifocal Leukoencephalopathy.** Progressive multifocal leukoencephalopathy is a demyelinating CNS disorder that affects the oligodendroglia. It occurs in about 3% of AIDS patients. Clinical manifestations often begin with mental confusion and rapidly progress to include blindness, aphasia, paresis (slight paralysis), and death. Treatments have greatly reduced the threat of mortality associated with this disorder.

**Other Neurologic Disorders.** Other common infections involving the nervous system include *Toxoplasma gondii*, CMV, and *M. tuberculosis*. Additional neurologic manifestations include both central and peripheral neuropathies. Vascular myelopathy is a degenerative disorder affecting the lateral and posterior columns of the spinal cord, resulting in progressive spastic paraparesis, ataxia, and incontinence. HIV-related **peripheral neuropathy** is thought to be a demyelinating disorder; it is associated with pain and numbness in the extremities, weakness, diminished deep tendon reflexes, orthostatic hypotension, and impotence.

### DEPRESSIVE MANIFESTATIONS

The prevalence of depression among people with HIV infection is unknown. The causes of depression are multifactorial and may include a history of preexisting mental illness, neuropsychiatric disturbances, and psychosocial factors. Depression also occurs in people with HIV infection in response to the physical symptoms, including pain and weight loss, and the lack of someone to talk with about their concerns. People with HIV/AIDS who are depressed may experience irrational guilt and shame, loss of self-esteem, feelings of helplessness and worthlessness, and suicidal ideation.

### INTEGUMENTARY MANIFESTATIONS

Cutaneous manifestations are associated with HIV infection and the accompanying OIs and malignancies. KS (described above) and OIs such as herpes zoster and herpes simplex are associated with painful vesicles that disrupt skin integrity. *Molluscum contagiosum* is a viral infection characterized by deforming plaque formation. Seborrheic dermatitis is associated with an indurated, diffuse, scaly rash involving the scalp and face. Patients with AIDS may also exhibit a generalized folliculitis associated with dry, flaking skin or atopic dermatitis, such as eczema or psoriasis. Up to 60% of patients treated with trimethoprim-sulfamethoxazole (TMP-SMZ) develop a drug-related rash that is pruritic with

pinkish-red macules and papules. Regardless of the origin of these rashes, patients experience discomfort and are at increased risk for additional infection from disrupted skin integrity.

### ENDOCRINE MANIFESTATIONS

The endocrine manifestations of HIV infection are not completely understood. At autopsy, endocrine glands show infiltration and destruction from OIs or neoplasms. Endocrine function may also be affected by therapeutic agents.

### GYNECOLOGIC MANIFESTATIONS

Persistent, recurrent vaginal candidiasis may be the first sign of HIV infection in women. Past or present genital ulcer disease is a risk factor for the transmission of HIV infection. Women with HIV infection are more susceptible to and have increased rates and recurrence of genital ulcer disease and venereal warts. Ulcerative STDs such as chancroid, syphilis, and herpes are more severe in women with HIV infection. **Human papillomavirus** causes venereal warts and is a risk factor for cervical intraepithelial neoplasia, a cellular change that is frequently a precursor to cervical cancer. Women with HIV are 10 times more likely to develop cervical intraepithelial neoplasia than are those not infected with HIV. There is a strong association between abnormal Pap smears and HIV seropositivity. HIV-seropositive women with cervical carcinoma present with a more advanced stage of disease and have more persistent and recurrent disease and a shorter interval to recurrence and death than women who do not have HIV infection.

A significant percentage of women who require hospitalization for pelvic inflammatory disease (PID) have HIV infection. Women with HIV are at increased risk for PID, and the inflammation associated with PID may potentiate the transmission of HIV infection. Moreover, women with HIV appear to have a higher incidence of menstrual abnormalities, including amenorrhea or bleeding between periods, than women without HIV infection. The failure of health care providers to consider HIV infection in women may lead to a later diagnosis, thereby denying women appropriate treatment.

### Gerontologic Considerations

More than 10% of all AIDS cases in the United States have occurred in people aged 50 years or older. HIV infection in middle-aged and older populations may be underreported and underdiagnosed because health care professionals erroneously believe they are not at risk for HIV infection. Many older adults are sexually active but do not use condoms, viewing them only as a means of unneeded birth control and not considering themselves at risk for HIV infection. Many older gay men who grew up and lived in an era when disclosure of their sexual orientation was not acceptable have lost long-time partners and may turn to younger males for sexual gratification. Older adults may also be injection drug users or may have received HIV-infected blood through transfusions before 1985. As a result, they may be at risk for HIV infection.

Normal age-related changes include a reduction in immune system function similar to that of HIV infection. Older adults are normally at greater risk for infections, cancer, and autoimmune disorders. Many older adults also experience the loss of loved ones, resulting in depression and bereavement, factors that are also associated with depressed immune function. HIV-related dementia in the older adult may mimic Alzheimer's disease and may be misdiagnosed. There are at least three major differences be-

### NURSING RESEARCH PROFILE 52-1

#### Quality of Life in Persons Living With HIV/AIDS by Age Group

Nokes, K., Holzemer, W., Corless, I., et al. (2000). Health-related quality of life in persons younger and older than 50 who are living with HIV/AIDS. *Research on Aging*, 22(3), 290–310.

#### Purpose

Although HIV/AIDS affects individuals across the age spectrum, it is often perceived as a disease that affects younger persons. As a result, there is little information about people living with HIV/AIDS who are older than 50 years of age. The purpose of this study was to explore health-related quality of life (QOL) for people with HIV and to explore differences in QOL in those 50 or older and in those younger than 50.

#### Study Sample and Design

A descriptive survey design was used to identify differences in variables predicting health-related QOL. The conceptual model of QOL of Wilson and Cleary was used as the framework for the study. This model describes measures of health on a continuum of increasing biologic, social, and psychological complexity. The convenience sample consisted of 640 people with HIV disease younger than 50 years of age and 73 who were 50 or older. Data analyzed in this study were collected in a national study of persons living with HIV/AIDS who were recruited from a variety of clinical and community-based sites throughout the United States. Various instruments were used to assess HIV disease severity and comorbidities, symptom status, general health perceptions, and overall QOL. In addition, data on individual and environmental characteristics were collected. Individual characteristics included personality/motivation and values/preferences; environmental characteristics examined included psychological support, social and economic support, professional support, and nonmedical factors.

#### Findings

Older subjects reported significantly more medical conditions and more physical limitations than the younger subjects. They disclosed their HIV status to fewer people than subjects in the younger age group. No significant differences were found between the two groups on any other variables.

#### Nursing Implications

Although few differences were found in the two groups, the ones that were detected may be clinically relevant. Nurses need to be aware of and address the effect of other medical conditions and physical limitations on self-care in older patients with HIV/AIDS. The fact that older persons had disclosed their HIV status to fewer people than the younger age group may affect the availability of others to assist in their care. Nursing assessment of self-care and the availability of support from others is an important aspect of care of the older person with HIV/AIDS.

tween older (age 50 and up) and younger persons with HIV/AIDS: presence of comorbidities such as diabetes or high blood pressure; number of persons to whom HIV status was disclosed; and physical functioning ability (Nokes et al., 2000).

## Medical Management

### TREATMENT OF INFECTIONS

**General Infections.** Trimethoprim-sulfamethoxazole (TMP-SMZ; Bactrim, Septra) is an antibacterial agent for treating various organisms causing infection. Persons with HIV infection who have

a T-cell count of less than 200 should receive chemoprophylaxis against PCP with TMP-SMZ. PCP prophylaxis can be safely discontinued in patients responding to HAART with a sustained increase in T lymphocytes. Its use also confers cross-protection against toxoplasmosis and some common respiratory bacterial infections (USPHS/IDSA, 2002). Patients with AIDS who are treated with TMP-SMZ experience a high incidence of adverse effects, such as fever, rashes, leukopenia, thrombocytopenia, and renal dysfunction. Reintroduction of TMP-SMZ using a gradual increase in dose (desensitization) may be successful in up to 70% of patients.

**PCP.** In the past several years, there have been many advances in the treatment of PCP. TMP-SMZ, the drug of choice for PCP in patients with AIDS and in immunocompromised patients without HIV infection, is available in both intravenous (IV) and oral preparations. Pentamidine (Pentacarinat, Pentam 300, Nebu-Pent), an antiprotozoal medication, is used as an alternative agent for combating PCP. If adverse effects develop or if patients do not improve clinically when treated with TMP-SMZ, the health care provider may recommend pentamidine. Intramuscular administration is avoided because of the potential for painful sterile abscess formation. Also, IV pentamidine may cause severe hypotension if administered too rapidly. Other adverse effects include impaired glucose metabolism (with diabetes mellitus), renal damage, hepatic dysfunction, and neutropenia. Initially, the success of aerosolized pentamidine led to its use as a treatment for mild to moderate PCP. However, it has proved to be less effective and more costly than TMP-SMZ, and early relapses are common. Because of these limitations, the inhalant form of pentamidine is usually reserved for patients with mild to moderate PCP who are intolerant of other treatments. The combination of TMP-SMZ and pentamidine has shown no additional benefit and is avoided because of the cumulative toxic effects that may result.

**MAC.** Chemoprophylaxis against disseminated MAC disease is indicated for HIV-infected persons with T-cell counts less than 50 (USOHS/IDSA, 2002). Treatment for MAC infections involves use of either clarithromycin (Biaxin) or azithromycin (Zithromax). The combination of azithromycin with rifabutin (Mycobutin) is more effective but the additional cost, increased occurrence of adverse effects, potential for drug interactions, and absence of differences in survival do not warrant the recommendation of both medications (USPHS/IDSA, 2002). Secondary prophylaxis for disseminated MAC may be discontinued in patients with sustained increases (eg, longer than 6 months) in CD4 counts greater than 100 in response to HAART, if they have completed 12 months of MAC therapy and have no signs or symptoms attributable to MAC. Primary prophylaxis for disseminated MAC may be discontinued in patients who have responded to HAART with CD4 counts of 100 or more for at least 3 months and reintroduced if counts decrease to 50 to 100 (USPHS/IDSA, 2002).

**Meningitis.** Current primary therapy for cryptococcal meningitis is IV amphotericin B with or without oral flucytosine (5-FC, Ancobon) or fluconazole (Diflucan). Serious potential adverse effects of amphotericin B include anaphylaxis, renal and hepatic impairment, electrolyte imbalances, anemia, fever, and severe chills. Intrathecal administration of amphotericin B has been used in place of or in combination with IV administration in patients who have failed to respond to the latter. Until fluconazole,

an antifungal agent, was approved and used for lifelong suppressive therapy, frequent relapses and high mortality rates often necessitated prolonged therapy with amphotericin B. In some instances, the patient continues to receive IV amphotericin in the home setting. Oral fluconazole is used as suppressive therapy when the CSF tests negative for the organism. This medication is less toxic and better tolerated than amphotericin B.

**Cytomegalovirus Retinitis.** Retinitis caused by CMV is a leading cause of blindness in patients with AIDS. Prophylaxis with oral ganciclovir may be considered for HIV-infected persons with T-cell counts of less than 50. Two antiviral agents, ganciclovir (DHPG, Cytovene, Vitrasert) and foscarnet (Foscavir), offer effective treatment but not a cure for CMV retinitis. Because ganciclovir and foscarnet do not kill the virus but rather control its growth, they must be taken lifelong. Relapse rates of the two agents are similar. Discontinuation of the medication is associated with the relapse of retinitis within 1 month.

A common adverse reaction to ganciclovir is severe neutropenia, which limits the concomitant use of zidovudine (AZT, Compound S, Retrovir). For patients who cannot tolerate systemic ganciclovir because of severe neutropenia, infection at the venous access site, or the need to take zidovudine, intravitreal injections of ganciclovir have been effective. Zidovudine can be given with foscarnet (Foscavir). Common adverse reactions to foscarnet are nephrotoxicity, including acute renal failure, and electrolyte imbalances, including hypocalcemia, hyperphosphatemia, and hypomagnesemia, which can be life-threatening. Other common adverse effects include seizures, GI disturbances, anemia, phlebitis at the infusion site, and low back pain. Possible bone marrow suppression (producing a decrease in white blood cell and platelet counts), oral candidiasis, and liver and renal impairments require close patient monitoring.

**Other Infections.** Oral acyclovir, famciclovir, or valacyclovir can be used to treat infections caused by herpes simplex or herpes zoster. Esophageal or oral candidiasis is treated topically with clotrimazole (Mycelex) oral troches or nystatin suspension. Chronic refractory infection with candidiasis (thrush) or esophageal involvement is treated with ketoconazole (Nizoral) or fluconazole (Diflucan).

### ANTIDIARRHEAL THERAPY

Although many forms of diarrhea respond to treatment, it is not unusual for this condition to recur and become a chronic problem for the patient. Therapy with octreotide acetate (Sandostatin), a synthetic analog of somatostatin, has been shown to be effective in managing chronic severe diarrhea. High concentrations of somatostatin receptors have been found in the GI tract and other tissues. Somatostatin inhibits many physiologic functions, including GI motility and intestinal secretion of water and electrolytes.

### CHEMOTHERAPY

**Kaposi's Sarcoma.** Management of KS is usually difficult because of the variability of symptoms and the organ systems involved. KS is rarely life-threatening except when there is pulmonary or GI involvement. The treatment goal is reduction of symptoms by decreasing the size of the skin lesions, reducing discomfort associated with edema and ulcerations, and controlling symptoms associated with mucosal or visceral involvement. No one treatment has been shown to increase survival. Localized treatment

includes surgical excision of the lesions or application of liquid nitrogen to local skin lesions and injections of intraoral lesions with dilute vinblastine. Injection of intraoral lesions has been associated with local pain and skin irritation. Radiation therapy is effective as a palliative measure to relieve localized pain due to tumor mass (especially in the legs) or for KS lesions that are in sites such as the oral mucosa, conjunctiva, face, and soles of the feet.

Interferon is known for its antiviral and antitumor effects. Patients with cutaneous KS treated with **alpha-interferon** have experienced tumor regression and improved immune system function. Positive responses have been observed in 30% to 50% of patients, with the best responses seen in those with limited disease and no OIs. Alpha-interferon is administered by the IV, intramuscular, or subcutaneous route. Patients may self-administer interferon at home or receive it in an outpatient setting.

**Lymphoma.** Successful treatment of AIDS-related lymphomas has been limited because of the rapid progression of these malignancies. Combination chemotherapy and radiation therapy regimens may produce an initial response, but it is usually short-lived. Because standard regimens for non-AIDS lymphomas have been ineffective, many clinicians suggest that AIDS-related lymphomas be studied as a separate group in clinical trials.

#### ANTIDEPRESSANT THERAPY

Treatment for depression in people with HIV infection involves psychotherapy integrated with pharmacology. If depressive symptoms are severe and of sufficient duration, treatment with antidepressants may be initiated. Antidepressants such as imipramine (Tofranil), desipramine (Norpramin), and fluoxetine (Prozac) may be used because these medications also alleviate the fatigue and lethargy that are associated with depression. A psychostimulant such as methylphenidate (Ritalin) may be used in low doses in patients with neuropsychiatric impairment. Electroconvulsive therapy may be an option for patients with severe depression that has not responded to pharmacologic interventions.

#### NUTRITION THERAPY

Malnutrition increases the risk for infection and may also increase the incidence of OIs. Nutrition therapy should be integrated into the overall management plan and should be tailored to meet the nutritional needs of the patient, from oral diet to enteral tube feedings through parenteral nutritional support if needed. As with all patients, a healthy diet is essential for the patient with HIV infection. Calorie counts should be obtained for all patients with AIDS with unexplained weight loss to evaluate nutritional status and to initiate appropriate therapy. The goal is to maintain the ideal weight and, when necessary, to increase weight.

Appetite stimulants have been successfully used in patients with AIDS-related anorexia. Megestrol acetate (Megace), a synthetic oral progesterone preparation used to treat breast cancer, promotes significant weight gain and inhibits cytokine IL-1 synthesis. In patients with HIV infection, it increases body weight primarily by increasing body fat stores. Dronabinol (Marinol), synthetic tetrahydrocannabinol (THC), the active ingredient in marijuana, has been used to relieve nausea and vomiting associated with cancer chemotherapy. Preliminary results show that after beginning Marinol therapy, almost all patients with HIV infection experience a modest weight gain. The effects on body composition are unknown.

Oral supplements may be used to supplement diets deficient in calories and protein. Ideally, oral supplements should be lactose-

free (many people with HIV infection are intolerant to lactose), high in calories and easily digestible protein, low in fat with the fat easily digestible, palatable, inexpensive, and tolerated without causing diarrhea. Advera is a nutritional supplement that has been developed specifically for people with HIV infection and AIDS. Parenteral nutrition is the final option because of the costs and associated risks, including infections.

### Complementary and Alternative Modalities

Traditional Western medicine focuses on the treatment of disease. These treatments or interventions are taught in medical schools and are used by physicians in the care of patients. Complementary and alternative therapies are often viewed as unconventional and unorthodox treatments or interventions not traditionally taught in medical schools. Alternative therapy stresses the need to treat the whole person, recognizing the interaction of the body, mind, and spirit. What is considered to be an alternative therapy in one culture may actually be a traditional therapy in another. Persons with HIV infection report substantial use of complementary and alternative medical therapies for symptom management (Swanson et al., 2000). The use of alternative therapy in HIV infection and AIDS has resulted from disillusionment with standard medical treatment, which to date has provided no cure. Used with traditional therapies, alternative therapies may improve the patient's overall well-being.

Alternative therapies can be divided into four categories:

- Spiritual or psychological therapies may include humor, hypnosis, faith healing, guided imagery, and positive affirmations.
- Nutritional therapies may include vegetarian or macrobiotic diets, vitamin C or beta-carotene supplements, and turmeric, which contains curcumin, a food spice supplement. Chinese herbs, such as traditional herbal mixtures, as well as compound Q (a Chinese cucumber extract) and *Monmordica charantia* (bitter melon), which is given as an enema, are also used.
- Drug and biologic therapies include medicines not approved by the FDA. Examples of these include N-acetylcysteine, pentoxifylline (Trental), and 1-chloro-2, 4-dinitrobenzene. Also included in this category are oxygen therapy, ozone therapy, and urine therapy.
- Treatment with physical forces and devices may include acupuncture, acupressure, massage therapy, reflexology, therapeutic touch, yoga, and crystals.

Although there is insufficient research on the effects of alternate therapies, there is a growing body of literature reporting benefits in the areas of nutrition, exercise, psychosocial treatment, and Chinese medicine. Clinical trials are in progress to examine the effect of Chinese herbal treatments of HIV-associated symptoms related to inadequate nutrition, such as fatigue, nausea, vomiting, painful or difficult swallowing, altered taste sensation, and diarrhea. At present there are no definitive study results that indicate that these treatments are effective, but some appear promising.

Many patients who use these alternative therapies do not report their use to their health care providers. To obtain a complete health history, the nurse should ask about the patient's use of alternative therapies. Patients may need to be encouraged to report their use to their primary health care provider. Problems may arise when patients are using alternative therapies while they are participating in clinical drug trials. They may have significant ad-

verse side effects, making it difficult to assess the effects of the medications in the clinical trial. The nurse needs to become familiar with the potential adverse side effects of alternative therapies. The nurse who suspects that the alternative therapy is causing a side effect needs to discuss this with the patient, the alternative therapy provider, and the primary health care provider. It is important for the nurse to view alternative therapies with an open mind and to try to understand the importance of this treatment to the patient. Doing so will improve communication with the patient and reduce conflict, so that all involved in care can meet the patient's needs.

## Supportive Care

Patients who are weak and debilitated as a result of chronic illness associated with HIV infection typically require many kinds of supportive care. Nutritional support may be as simple as providing assistance in obtaining or preparing meals. For patients with more advanced nutritional impairment that results from decreased intake, wasting syndrome, or GI malabsorption associated with diarrhea, parenteral feedings may be required. Imbalances that result from nausea, vomiting, and profuse diarrhea often necessitate IV fluid and electrolyte replacement.

Skin breakdown associated with KS, perianal skin excoriation, and immobility is managed with thorough and meticulous skin care involving regular turning, cleansing, and applying medicated ointments and dressings.

Pain associated with skin breakdown, abdominal cramping, peripheral neuropathy, or KS is managed by analgesics given at regular intervals around the clock. Relaxation and guided imagery may be helpful in reducing pain and anxiety.

Pulmonary symptoms, such as dyspnea and shortness of breath, may be related to infection, KS, or fatigue. For these patients, oxygen therapy, relaxation training, and energy conservation techniques may be helpful. Patients with severe respiratory dysfunction may require mechanical ventilation. Before placing a patient on mechanical ventilation, the procedure is explained to the patient and the caregiver. The patient may elect not to be placed on mechanical ventilation, and the patient's wishes should be followed. Ideally, the patient has prepared an advanced directive identifying preferences for treatments and end-of-life care, including hospice care. If the patient has not identified preferences in advance, treatment options are described so that the patient can make informed decisions and have those wishes respected.

## NURSING PROCESS: THE PATIENT WITH AIDS

The nursing care of patients with AIDS is challenging because of the potential for any organ system to be the target of infections or cancer. In addition, this disease is complicated by many emotional, social, and ethical issues. The plan of care for the patient with AIDS is individualized to meet the needs of the patient (see Plan of Nursing Care). Care includes many of the interventions and concerns cited in the supportive care section.

### Assessment

Nursing assessment includes identification of potential risk factors, including a history of risky sexual practices and injection drug use. The patient's physical status and psychological status

are assessed. All factors affecting immune system functioning are thoroughly explored.

### NUTRITIONAL STATUS

Nutritional status is assessed by obtaining a dietary history and identifying factors that may interfere with oral intake, such as anorexia, nausea, vomiting, oral pain, or difficulty swallowing. In addition, the patient's ability to purchase and prepare food is assessed. Weight, anthropometric measurements, and blood urea nitrogen (BUN), serum protein, albumin, and transferrin levels provide objective measurements of nutritional status.

### SKIN INTEGRITY

The skin and mucous membranes are inspected daily for evidence of breakdown, ulceration, or infection. The oral cavity is monitored for redness, ulcerations, and the presence of creamy-white patches indicative of candidiasis. Assessment of the perianal area for excoriation and infection in patients with profuse diarrhea is important. Wounds are cultured to identify infectious organisms.

### RESPIRATORY STATUS

Respiratory status is assessed by monitoring the patient for cough, sputum production, shortness of breath, orthopnea, tachypnea, and chest pain. The presence and quality of breath sounds are investigated. Other measures of pulmonary function include chest x-ray results, arterial blood gas values, pulse oximetry, and pulmonary function test results.

### NEUROLOGIC STATUS

Neurologic status is determined by assessing level of consciousness; orientation to person, place, and time; and memory lapses. Mental status is assessed as early as possible to provide a baseline (Chart 52-6). The patient is also assessed for sensory deficits (visual changes, headache, or numbness and tingling in the extremities) and motor involvement (altered gait, paresis, or paralysis) and seizure activity.

### FLUID AND ELECTROLYTE BALANCE

Fluid and electrolyte status is assessed by examining the skin and mucous membranes for turgor and dryness. Increased thirst, decreased urine output, low blood pressure or a decrease in systolic blood pressure between 10 and 15 mm Hg with a concurrent rise in pulse rate when the patient sits up or stands, weak and rapid pulse, and urine specific gravity of 1.025 or more may indicate dehydration. Electrolyte imbalances, such as decreased serum sodium, potassium, calcium, magnesium, and chloride, typically result from profuse diarrhea. The patient is assessed for signs and symptoms of electrolyte deficits, including decreased mental status (see Chart 52-6), muscle twitching, muscle cramps, irregular pulse, nausea and vomiting, and shallow respirations.

### KNOWLEDGE LEVEL

The patient's level of knowledge about the disease and the modes of disease transmission is evaluated. In addition, the level of knowledge of family and friends is assessed. The patient's psychological reaction to the diagnosis of HIV infection or AIDS is important to explore. Reactions vary among patients and may include denial, anger, fear, shame, withdrawal from social interactions, and depression. It is often helpful to gain an understanding of how the patient has dealt with illness and major life stress in the past. The patient's resources for support are also identified.

*(text continues on page 1571)*

## Plan of Nursing Care

### Care of the Patient With AIDS

#### Nursing Interventions

#### Rationale

#### Expected Patient Outcomes

**Nursing Diagnosis:** Diarrhea related to enteric pathogens or HIV infection

**Goal:** Resumption of usual bowel habits

<ol style="list-style-type: none"> <li>1. Assess patient's normal bowel habits.</li> <li>2. Assess for diarrhea: frequent, loose stools; abdominal pain or cramping, volume of liquid stools, and exacerbating and alleviating factors.</li> <li>3. Obtain stool cultures and administer antimicrobial therapy as prescribed.</li> <li>4. Initiate measures to reduce hyperactivity of bowel:               <ol style="list-style-type: none"> <li>a. Maintain food and fluid restrictions as prescribed. Suggest BRAT diet (<i>bananas, rice, applesauce, tea and toast</i>).</li> <li>b. Discourage smoking.</li> <li>c. Avoid bowel irritants such as fatty or fried foods, raw vegetables, and nuts. Offer small, frequent meals.</li> </ol> </li> <li>5. Administer anticholinergic antispasmodics and opioids or other medications as prescribed.</li> <li>6. Maintain fluid intake of at least 3 L unless contraindicated.</li> </ol>	<ol style="list-style-type: none"> <li>1. Provides baseline for evaluation</li> <li>2. Detects changes in status, quantifies loss of fluid, and provides basis for nursing measures</li> <li>3. Identifies pathogenic organism; therapy targets specific organism</li> <li>4. Promotes bowel rest, which may decrease acute episodes               <ol style="list-style-type: none"> <li>a. Reduces stimulation of bowel</li> <li>b. Eliminates nicotine, which acts as bowel stimulant</li> <li>c. Prevents stimulation of bowel and abdominal distention and promotes adequate nutrition</li> </ol> </li> <li>5. Decreases intestinal spasms and motility</li> <li>6. Prevents hypovolemia</li> </ol>	<ul style="list-style-type: none"> <li>• Exhibits return to normal bowel patterns</li> <li>• Reports decreasing episodes of diarrhea and abdominal cramping</li> <li>• Identifies and avoids foods that irritate the gastrointestinal tract</li> <li>• Appropriate therapy is initiated as prescribed.</li> <li>• Exhibits normal stool cultures</li> <li>• Maintains adequate fluid intake</li> <li>• Maintains body weight and reports no additional weight loss</li> <li>• States rationale for avoiding smoking</li> <li>• Enrolls in program to stop smoking</li> <li>• Uses medication as prescribed</li> <li>• Maintains adequate fluid status</li> <li>• Exhibits normal skin turgor, moist mucous membranes, adequate urine output, and absence of excessive thirst</li> </ul>
--	--	---

**Nursing Diagnosis:** Risk for infection related to immunodeficiency

**Goal:** Absence of infection

<ol style="list-style-type: none"> <li>1. Monitor for infection: fever, chills, and diaphoresis; cough; shortness of breath; oral pain or painful swallowing; creamy-white patches in oral cavity; urinary frequency, urgency, or dysuria; redness, swelling, or drainage from wounds; vesicular lesions on face, lips, or perianal area.</li> <li>2. Teach patient or caregiver about need to report possible infection.</li> <li>3. Monitor white blood cell count and differential.</li> <li>4. Obtain cultures of wound drainage, skin lesions, urine, stool, sputum, mouth, and blood as prescribed. Administer antimicrobial therapy as prescribed.</li> <li>5. Instruct patient in ways to prevent infection:               <ol style="list-style-type: none"> <li>a. Clean kitchen and bathroom surfaces with disinfectants.</li> <li>b. Clean hands thoroughly after exposure to body fluids.</li> <li>c. Avoid exposure to others' body fluids or sharing eating utensils.</li> <li>d. Turn, cough, and deep breathe, especially when activity is decreased.</li> <li>e. Maintain cleanliness of perianal area.</li> <li>f. Avoid handling pet excreta or cleaning litter boxes, bird cages, or aquariums.</li> <li>g. Cook meat and eggs thoroughly.</li> </ol> </li> </ol>	<ol style="list-style-type: none"> <li>1. Allows for early detection of infection, essential for prompt initiation of treatment. Repeated and prolonged infections contribute to patient's debilitation.</li> <li>2. Allows early detection of infection</li> <li>3. Identifies elevated WBC possibly associated with infection</li> <li>4. Assists in determining offending organism to initiate appropriate treatment</li> <li>5. Minimizes exposure to infection and transmission of HIV infection to others</li> </ol>	<ul style="list-style-type: none"> <li>• Identifies reportable signs and symptoms of infection</li> <li>• Reports signs and symptoms of infection if present</li> <li>• Exhibits and reports absence of fever, chills, and diaphoresis</li> <li>• Exhibits normal (clear) breath sounds without adventitious breath sounds</li> <li>• Maintains weight</li> <li>• Reports adequate energy level without excessive fatigue</li> <li>• Reports absence of shortness of breath and cough</li> <li>• Exhibits pink, moist oral mucous membranes without fissures or lesions</li> <li>• Takes appropriate therapy as prescribed</li> <li>• Experiences no infection</li> <li>• States rationale for strategies to avoid infection</li> <li>• Modifies activities to reduce exposure to infection or infectious persons</li> <li>• Practices "safer sex"</li> <li>• Avoids sharing eating utensils and toothbrush</li> <li>• Exhibits normal body temperature</li> <li>• Uses recommended techniques to maintain cleanliness of skin, skin lesions, and perianal area</li> </ul>
--	--	--

(continued)

## Plan of Nursing Care

### Care of the Patient With AIDS (Continued)

Nursing Interventions	Rationale	Expected Patient Outcomes
6. Maintain aseptic technique when performing invasive procedures such as venipunctures, bladder catheterizations, and injections.	6. Prevents hospital-acquired infections	<ul style="list-style-type: none"> <li>• Has others handle pet excreta and cleanup</li> <li>• Uses recommended cooking techniques</li> </ul>

**Nursing Diagnosis:** Ineffective airway clearance related to *Pneumocystis carinii* pneumonia, increased bronchial secretions, and decreased ability to cough related to weakness and fatigue

**Goal:** Improved airway clearance

1. Assess and report signs and symptoms of altered respiratory status, tachypnea, use of accessory muscles, cough, color and amount of sputum, abnormal breath sounds, dusky or cyanotic skin color, restlessness, confusion, or somnolence.	1. Indicates abnormal respiratory function	<ul style="list-style-type: none"> <li>• Maintains normal airway clearance: Respiratory rate &lt;20 breaths/min</li> <li>• Unlabored breathing without use of accessory muscles and flaring nares (nostrils)</li> <li>• Skin color pink (without cyanosis)</li> <li>• Alert and aware of surroundings</li> <li>• Arterial blood gas values normal</li> <li>• Normal breath sounds without adventitious breath sounds</li> <li>• Begins appropriate therapy</li> <li>• Takes medication as prescribed</li> <li>• Reports improved breathing</li> <li>• Maintains clear airway</li> <li>• Coughs and takes deep breaths every 2–4 hours as recommended</li> <li>• Demonstrates appropriate positions and practices postural drainage every 2–4 hours</li> <li>• Reports reduced breathing difficulty when in semi- or high Fowler's position</li> <li>• Practices energy-conserving strategies and alternates rest with activity</li> <li>• Demonstrates reduction in thickness (viscosity) of pulmonary secretions</li> <li>• Reports increased ease in coughing up sputum</li> <li>• Uses humidified air or oxygen as prescribed and indicated</li> <li>• Indicates need for assistance with removal of pulmonary secretions</li> <li>• Understands need for and cooperates with endotracheal intubation and use of a mechanical ventilator</li> <li>• Verbalizes concerns about respiratory difficulty, intubation, and mechanical ventilation</li> </ul>
2. Obtain sputum sample for culture prescribed. Administer antimicrobial therapy as prescribed.	2. Aids in identification of pathogenic organisms	
3. Provide pulmonary care (cough, deep breathing, postural drainage, and vibration) every 2 to 4 hours.	3. Prevents stasis of secretions and promotes airway clearance	
4. Assist patient in attaining semi- or high Fowler's position.	4. Facilitates breathing and airway clearance	
5. Encourage adequate rest periods.	5. Maximizes energy expenditure and prevents excessive fatigue	
6. Initiate measures to decrease viscosity of secretions: <ol style="list-style-type: none"> <li>Maintain fluid intake of at least 3 L per day unless contraindicated.</li> <li>Humidify inspired air as prescribed.</li> <li>Consult with physician concerning use of mucolytic agents delivered through nebulizer or IPPB treatment.</li> </ol>	6. Facilitates expectoration of secretions; prevents stasis of secretions	
7. Perform tracheal suctioning as needed.	7. Removes secretions if patient is unable to do so	
8. Administer oxygen therapy as prescribed.	8. Increases availability of oxygen	
9. Assist with endotracheal intubation; maintain ventilator settings as prescribed.	9. Maintains ventilation	

**Nursing Diagnosis:** Imbalanced nutrition, less than body requirements, related to decreased oral intake

**Goal:** Improvement of nutritional status

1. Assess for malnutrition with height, weight, age, BUN, serum protein, and albumin, transferrin levels, hemoglobin, hematocrit, and cutaneous anergy.	1. Provides objective measurement of nutritional status	<ul style="list-style-type: none"> <li>• Identifies factors limiting oral intake and uses resources to promote adequate dietary intake</li> <li>• Reports increased appetite</li> <li>• States understanding of nutritional needs</li> <li>• Identifies ways to reduce factors that limit oral intake</li> <li>• Rests before meals</li> <li>• Eats in pleasant, odor-free environment</li> </ul>
2. Obtain dietary history, including likes and dislikes and food intolerances.	2. Defines need for nutritional education; helps individualize interventions	
3. Assess factors that interfere with oral intake.	3. Provides basis and directions for interventions	

(continued)

## Plan of Nursing Care

### Care of the Patient With AIDS (Continued)

Nursing Interventions	Rationale	Expected Patient Outcomes
<ol style="list-style-type: none"> <li>4. Consult with dietitian to determine patient's nutritional needs.</li> <li>5. Reduce factors limiting oral intake:               <ol style="list-style-type: none"> <li>a. Encourage patient to rest before meals.</li> <li>b. Plan meals so that they do not occur immediately after painful or unpleasant procedures.</li> <li>c. Encourage patient to eat meals with visitors or others when possible.</li> <li>d. Encourage patient to prepare simple meals or to obtain assistance with meal preparation if possible.</li> <li>e. Serve small, frequent meals: 6 per day.</li> <li>f. Limit fluids 1 hour before meals and with meals.</li> </ol> </li> <li>6. Instruct patient in ways to supplement nutrition: consume protein-rich foods (meat, poultry, fish) and carbohydrates (pasta, fruit, breads).</li> <li>7. Consult with physician and dietitian about alternative feeding (enteral or parenteral nutrition).</li> <li>8. Consult with social worker or community liaison about financial assistance if patient cannot afford food.</li> </ol>	<ol style="list-style-type: none"> <li>4. Facilitates meal planning</li> <li>5. Addresses factors limiting intake:               <ol style="list-style-type: none"> <li>a. Minimizes fatigue, which can decrease appetite</li> <li>b. Decreases noxious stimuli</li> </ol> </li> <li>c. Limits social isolation</li> <li>d. Limits energy expenditure</li> <li>e. Prevents overwhelming patient</li> <li>f. Reduces satiety</li> <li>6. Provides additional proteins and calories</li> <li>7. Provides nutritional support if patient is unable to take sufficient amounts by mouth</li> <li>8. Increases availability of resources and nutrition</li> </ol>	<ul style="list-style-type: none"> <li>• Arranges meals to coincide with visitors' visits</li> <li>• Reports increased dietary intake</li> <li>• Uses oral hygiene before meals</li> <li>• Takes analgesics before meals as prescribed</li> <li>• Identifies ways to increase protein and caloric intake</li> <li>• Identifies foods high in protein and calories</li> <li>• Consumes foods high in protein and calories</li> <li>• Reports decreased rate of weight loss.</li> <li>• Maintains adequate intake</li> <li>• States rationale for enteral or parenteral nutrition if needed</li> <li>• Demonstrates skill in preparing alternate sources of nutrition</li> </ul>

**Nursing Diagnosis:** Deficient knowledge related to means of preventing HIV transmission

**Goal:** Increased knowledge concerning means of preventing disease transmission

<ol style="list-style-type: none"> <li>1. Instruct patient, family, and friends about routes of transmission of HIV.</li> <li>2. Instruct patient, family, and friends about means of preventing transmission of HIV:               <ol style="list-style-type: none"> <li>a. Avoid sexual contact with multiple partners, and use precautions if sexual partner's HIV status is not certain.</li> <li>b. Use condoms during sexual intercourse (vaginal, anal, oral-genital); avoid mouth contact with the penis, vagina, or rectum; avoid sexual practices that can cause cuts or tears in the lining of the rectum, vagina, or penis.</li> <li>c. Avoid sex with prostitutes and others at high risk.</li> <li>d. Do not use injection drugs; if addicted and unable or unwilling to change behavior, use clean needles and syringes.</li> <li>e. Women who may have been exposed to AIDS through sexual or drug practices should consult with a physician before becoming pregnant; consider use of antiretroviral agents if pregnant.</li> </ol> </li> </ol>	<ol style="list-style-type: none"> <li>1. Knowledge about disease transmission can help prevent spread of disease; may also alleviate fears.</li> <li>2. Reduces transmission risk               <ol style="list-style-type: none"> <li>a. The risk of infection increases with the number of sexual partners, male or female, and sexual contact with those who engage in high-risk behaviors.</li> <li>b. Risk of HIV transmission is reduced.</li> <li>c. Many prostitutes are infected with HIV through sexual contact with multiple partners or IV/injection drug use.</li> <li>d. Clean needles and syringes are the only way to prevent HIV transmission for those who continue to use drugs. Taking precautions is important for those who are antibody positive to prevent transmitting HIV.</li> <li>e. AIDS can be transmitted from mother to child in utero; use of antiretroviral agents during pregnancy significantly reduces perinatal transmission of HIV.</li> </ol> </li> </ol>	<ul style="list-style-type: none"> <li>• Patient, family, and friends state means of transmission.</li> <li>• Reports and demonstrates practices to reduce exposure of others to HIV</li> <li>• Avoids intravenous drug use</li> <li>• Demonstrates knowledge of safer sexual practices</li> <li>• Identifies means of preventing disease transmission</li> <li>• States that sexual partners are informed about positive HIV antibodies in blood</li> <li>• Avoids IV/injection drug use and sharing of drug equipment with others</li> </ul>
---	--	--

(continued)

## Plan of Nursing Care

### Care of the Patient With AIDS (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Patient Outcomes

**Nursing Diagnosis:** Social isolation related to stigma of the disease, withdrawal of support systems, isolation procedures, and fear of infecting others

**Goal:** Decreased sense of social isolation

1. Assess patient's usual patterns of social interaction.	1. Establishes basis for individualized interventions	• Shares with others the need for valued social interaction
2. Observe for behaviors indicative of social isolation, such as decreased interaction with others, hostility, noncompliance, sad affect, and stated feelings of rejection or loneliness.	2. Promotes early detection of social isolation, which may be manifested in several ways	• Demonstrates interest in events, activities, and communication
3. Provide instruction concerning modes of transmission of HIV.	3. Provides accurate information, corrects misconceptions, and alleviates anxiety	• Verbalizes feelings and reactions to diagnosis, prognosis, and life changes
4. Assist patient to identify and explore resources for support and positive mechanisms for coping (eg, contact with family, friends, AIDS task force).	4. Enables mobilization of resources and supports	• Identifies modes of transmission of AIDS
5. Allow time to be with patient other than for medications and procedures.	5. Promotes feelings of self-worth and provides social interaction	• States ways of preventing transmission of AIDS virus to others while maintaining contact with valued friends and relatives
6. Encourage participation in diversional activities such as reading, television, or hand crafts.	6. Provides distraction	• Reveals AIDS diagnosis to others when appropriate
		• Identifies resources (ie, family, friends, and support groups)
		• Uses resources when appropriate
		• Accepts offers of assistance and support
		• Reports decreased sense of isolation
		• Maintains contacts with those of importance to him or her
		• Develops or continues hobbies that effectively serve as diversion or distraction

**Collaborative Problems:** Opportunistic infections; impaired breathing; wasting syndrome and fluid and electrolyte imbalances; adverse reaction to medications

**Goal:** Absence of complications

#### Opportunistic Infections

1. Monitor vital signs.	1. Changes in vital signs such as increases in pulse rate, respirations, blood pressure, and temperature may indicate infection.	• Exhibits stable vital signs
2. Obtain laboratory specimens and monitor test results.	2. Smears and cultures can identify causative agents such as bacteria, fungi, and protozoa, and sensitivity studies can identify antibiotics or other medications effective against the causative agent.	• Experiences control of infection
3. Instruct the patient and caregiver about signs and symptoms of infection and the need to report them early.	3. Early recognition of symptoms facilitates prompt treatment and avoids extra complications.	• Identifies signs and symptoms correctly and experiences no complications
		• Identifies signs and symptoms that are reportable to the physician
		• Takes medications as prescribed

#### Impaired Breathing

1. Monitor respiratory rate and pattern.	1. Rapid shallow breathing, diminished breath sounds, and shortness of breath may indicate respiratory failure resulting in hypoxia.	• Maintains stable respiratory rate and pattern within the normal limits
2. Auscultate the chest for breath sounds and abnormal lung sounds.	2. Crackles and wheezes may indicate fluid in the lungs, which disrupts respiratory function and alters the blood's oxygen-carrying capacity.	• Exhibits no adventitious lung sounds; normal breath sounds
3. Monitor pulse rate, blood pressure, and oxygen saturation levels.	3. Changes in pulse rate, blood pressure, and oxygen levels may indicate the development of respiratory or cardiac failure.	• Has stable pulse rate and blood pressure within normal limits, and exhibits no evidence of hypoxia
		• Oxygen saturation levels within acceptable range

(continued)

## Plan of Nursing Care

### Care of the Patient With AIDS (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Patient Outcomes

##### Wasting Syndrome and Fluid and Electrolyte Disturbances

1. Monitor weight and laboratory values for nutritional status.
2. Monitor intake and output and laboratory values for fluid and electrolyte imbalance (potassium, sodium, calcium, phosphorus, magnesium, and zinc).
3. Monitor for and report signs and symptoms of dehydration.

1. Weight loss, malnutrition, and anemia are common in HIV infection and increase risk for superinfection.
2. Chronic diarrhea, inadequate oral intake, vomiting, and profuse sweating deplete electrolytes. Small intestine inflammation may impair the absorption of fluids and electrolytes.
3. Fluid loss results in decreased circulating volume leading to tachycardia, dry skin and mucous membranes, poor skin turgor, elevated urine specific gravity, and thirst. Early detection allows early treatment.

- Maintains stable weight
- Eats a nutritious diet
- Attains and maintains hemoglobin, hematocrit, and ferritin levels within normal limits
- Sustains fluid–electrolytes balance within normal limits
- Exhibits no signs and symptoms of dehydration

##### Reactions to Medications

1. Monitor for medication interactions.
2. Monitor for and promptly report side effects from antiretroviral agents.
3. Instruct the patient and caregiver in the medication regimen.

1. People with HIV infection receive many medications for HIV and for disease complications. Early detection of medication interactions is necessary to prevent complications.
2. Side effects from antiretroviral agents can be life-threatening. Serious side effects include anemia, pancreatitis, peripheral neuropathy, mental confusion, and persistent nausea and vomiting. Corrective measures need to be instituted.
3. Knowledge of the medication purpose, correct administration, side effects, and strategies to manage or prevent side effects promote safety and greater compliance with treatment.

- Experiences no serious side effects or complications from medications
- Correctly describes medication regimen and complies with therapy, including adaptations in eating routines and type of food used with prescribed medications

### Chart 52-6 • ASSESSMENT

#### Mental Status in HIV Infection

Assessment	Function	Selected Descriptors
Appearance	Physical characteristics, grooming, dress	Obese, cachectic, emaciated, poor eye contact, clean, disheveled, inappropriate dress for weather, slumped posture
Behavior	Motor activity	Restless, agitated, lethargic, hyperactive, rigid, repetitive
Speech	Verbal communication	Intelligible, clear, slurred, rapid, slowed, pressured, repetitive, perseveration, mute
Mood	General feeling tone	Friendly, fearful, hostile, euphoric, despondent, labile
Affect	Emotional expression	Appropriate, bizarre, flat, blunted, apathetic, overly dramatic
Cognition	Memory and orientation	Oriented (to time, place, and person), confused, disoriented, distractible, short attention span, intact remote and immediate memory, forgetful
Comprehension	Intellectual functioning	Able to abstract, concrete, poor judgment, lacks insight, unable to compute, lacks general knowledge, able to learn
Thought process	Expression of thoughts	Goal oriented, tangential, delusional, looseness of associations, confabulation, obsessive, ritualistic
Perception	Perspective of world	Presence of auditory, visual, olfactory, or kinesthetic hallucinations

## Diagnosis

### NURSING DIAGNOSES

The list of potential nursing diagnoses is extensive because of the complex nature of this disease. Based on assessment data, however, major nursing diagnoses for the patient may include the following:

- Impaired skin integrity related to cutaneous manifestations of HIV infection, excoriation, and diarrhea
- Diarrhea related to enteric pathogens or HIV infection
- Risk for infection related to immunodeficiency
- Activity intolerance related to weakness, fatigue, malnutrition, impaired fluid and electrolyte balance, and hypoxia associated with pulmonary infections
- Disturbed thought processes related to shortened attention span, impaired memory, confusion, and disorientation associated with HIV encephalopathy
- Ineffective airway clearance related to PCP, increased bronchial secretions, and decreased ability to cough related to weakness and fatigue
- Pain related to impaired perianal skin integrity secondary to diarrhea, KS, and peripheral neuropathy
- Imbalanced nutrition, less than body requirements, related to decreased oral intake
- Social isolation related to stigma of the disease, withdrawal of support systems, isolation procedures, and fear of infecting others
- Anticipatory grieving related to changes in lifestyle and roles and unfavorable prognosis
- Deficient knowledge related to HIV infection, means of preventing HIV transmission, and self-care

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, possible complications may include the following:

- Opportunistic infections
- Impaired breathing or respiratory failure
- Wasting syndrome and fluid and electrolyte imbalance
- Adverse reaction to medications

## Planning and Goals

Goals for the patient may include achievement and maintenance of skin integrity, resumption of usual bowel habits, absence of infection, improved activity tolerance, improved thought processes, improved airway clearance, increased comfort, improved nutritional status, increased socialization, expression of grief, increased knowledge regarding disease prevention and self-care, and absence of complications.

## Nursing Interventions

### PROMOTING SKIN INTEGRITY

The skin and oral mucosa are assessed routinely for changes in appearance, location and size of lesions, and evidence of infection and breakdown. The patient is encouraged to maintain a balance between rest and mobility whenever possible. Patients who are immobile are assisted to change position every 2 hours. Devices such as alternating-pressure mattresses and low-air-loss beds are used to prevent skin breakdown. Patients are encouraged to avoid

scratching, to use nonabrasive, nondrying soaps, and to apply nonperfumed skin moisturizers to dry skin surfaces. Regular oral care is also encouraged.

Medicated lotions, ointments, and dressings are applied to affected skin surfaces as prescribed. Adhesive tape is avoided. Skin surfaces are protected from friction and rubbing by keeping bed linens free of wrinkles and avoiding tight or restrictive clothing. Patients with foot lesions are advised to wear cotton socks and shoes that do not cause the feet to perspire. Antipruritic, antibiotic, and analgesic agents are administered as prescribed.

The perianal region is assessed frequently for impairment of skin integrity and infection. The patient is instructed to keep the area as clean as possible. The perianal area is cleaned after each bowel movement with nonabrasive soap and water to prevent further excoriation and breakdown of the skin and infection. If the area is very painful, soft cloths or cotton sponges may prove to be less irritating than washcloths. In addition, sitz baths or gentle irrigation may facilitate cleaning and promote comfort. The area is dried thoroughly after cleaning. Topical lotions or ointments may be prescribed to promote healing. Wounds are cultured if infection is suspected so that the appropriate antimicrobial treatment can be initiated. Debilitated patients may require assistance in maintaining hygienic practices.

### PROMOTING USUAL BOWEL HABITS

Bowel patterns are assessed for diarrhea. The nurse monitors the frequency and consistency of stools and reports of abdominal pain or cramping associated with bowel movements. Factors that exacerbate frequent diarrhea are also assessed. The quantity and volume of liquid stools are measured to document fluid volume losses. Stool cultures are obtained to identify pathogenic organisms.

The patient is counseled about ways to decrease diarrhea. The physician may recommend restriction of oral intake to rest the bowel during periods of acute inflammation associated with severe enteric infections. As the patient's dietary intake is increased, foods that act as bowel irritants, such as raw fruits and vegetables, popcorn, carbonated beverages, spicy foods, and foods of extreme temperatures, should be avoided. Small, frequent meals help to prevent abdominal distention. The physician may prescribe medications such as anticholinergic antispasmodics or opioids, which decrease diarrhea by decreasing intestinal spasms and motility. Administering antidiarrheal agents on a regular schedule may be more beneficial than administering them on an as-needed basis. Antibiotics and antifungal agents may also be prescribed to combat pathogens identified by stool cultures. The nurse should also assess the self-care strategies being used by the patient to control diarrhea (Henry et al., 1999).

### PREVENTING INFECTION

The patient and caregivers are instructed to monitor for signs and symptoms of infection: fever; chills; night sweats; cough with or without sputum production; shortness of breath; difficulty breathing; oral pain or difficulty swallowing; creamy-white patches in the oral cavity; unexplained weight loss; swollen lymph nodes; nausea; vomiting; persistent diarrhea; frequency, urgency, or pain on urination; headache; visual changes or memory lapses; redness, swelling, or drainage from skin wounds; and vesicular lesions on the face, lips, or perianal area. The nurse also monitors laboratory values that indicate infection, such as the white blood cell count and differential. The physician may decide to culture specimens of wound drainage, skin lesions, urine, stool, sputum, mouth, and blood to identify pathogenic organisms and the most appro-

appropriate antimicrobial therapy. The patient is instructed to avoid others with active infections such as upper respiratory infections.

### IMPROVING ACTIVITY TOLERANCE

Activity tolerance is assessed by monitoring the patient's ability to ambulate and perform activities of daily living. Patients may be unable to maintain their usual levels of activity because of weakness, fatigue, shortness of breath, dizziness, and neurologic involvement. Assistance in planning daily routines that maintain a balance between activity and rest may be necessary. In addition, patients benefit from instructions about energy conservation techniques, such as sitting while washing or while preparing meals. Personal items that are frequently used should be kept within the patient's reach. Measures such as relaxation and guided imagery may be beneficial because they decrease anxiety, which contributes to weakness and fatigue.

Collaboration with other members of the health care team may uncover other factors associated with increasing fatigue and strategies to address them. For example, if fatigue is related to anemia, administering epoetin alfa (EpoGen) as prescribed may relieve fatigue and increase activity tolerance.

### MAINTAINING THOUGHT PROCESSES

The patient is assessed for alterations in mental status that may be related to neurologic involvement, metabolic abnormalities, infection, side effects of treatment, and coping mechanisms. Manifestations of neurologic impairment may be difficult to distinguish from psychological reactions to HIV infection, such as anger and depression.

Family members are instructed to speak to the patient in simple, clear language and give the patient sufficient time to respond to questions. Family members are instructed to orient the patient to the daily routine by talking about what is taking place during daily activities. They are encouraged to provide the patient with a regular daily schedule for medication administration, grooming, meal times, bedtimes, and awakening times. Posting the schedule in a prominent area (eg, on the refrigerator), providing nightlights for the bedroom and bathroom, and planning safe leisure activities allow the patient to maintain a regular routine in a safe manner. Activities that the patient previously enjoyed are encouraged. These should be easy to accomplish and fairly short in duration. The nurse encourages the family to remain calm and not to argue with the patient while protecting the patient from injury. Around-the-clock supervision may be necessary, and strategies can be implemented to prevent the patient from engaging in potentially dangerous activities, such as driving, using the stove, or mowing the lawn. Strategies for improving or maintaining functional abilities and for providing a safe environment are used for patients with HIV encephalopathy (Chart 52-7).

### IMPROVING AIRWAY CLEARANCE

Respiratory status, including rate, rhythm, use of accessory muscles, and breath sounds; mental status; and skin color must be assessed at least daily. Any cough and the quantity and characteristics of sputum are documented. Sputum specimens are analyzed for infectious organisms. Pulmonary therapy (coughing, deep breathing, postural drainage, percussion, and vibration) is provided as often as every 2 hours to prevent stasis of secretions and to promote airway clearance. Because of weakness and fatigue, many patients require assistance in attaining a position (such as a high Fowler's or semi-Fowler's position) that facilitates breathing and airway clearance. Adequate rest is essential to maximize energy expenditure and prevent excessive fatigue. The fluid

## NURSING RESEARCH PROFILE 52-2

### Assessing Fatigue in Persons Living With HIV/AIDS

Bormann, J., Shively, M., Smith, T. L., & Gifford, A. (2001). Measurement of fatigue in HIV-positive adults: Reliability and validity of the Global Fatigue Index. *Journal of Association of Nurses in AIDS Care*, 12(3), 75–83.

#### Purpose

Fatigue is often cited by people living with HIV/AIDS as one of the most bothersome and frequently reported symptoms. Fatigue is a complex construct that consists of cognitive, emotional, and physical components, so its assessment can be challenging. The purpose of this study was to refine an assessment tool that could be used by nurses in clinical practice and research.

#### Study Sample and Design

The Global Fatigue Index (GFI) was taken from the Multidimensional Assessment of Fatigue instrument, which was developed in patients with rheumatoid arthritis. The GFI consists of 15 items and assesses 5 dimensions of fatigue: degree; severity; distress; impact on activities of daily living; and timing, which addresses the frequency of fatigue and changes in degree of fatigue over the past week. A Likert scale is used for each item, and a single score of fatigue is calculated. Data were collected from 209 symptomatic HIV-positive persons living in San Diego, California, who were participating in an 8-week longitudinal descriptive study.

#### Findings

The nonrandom sample included 183 men and 26 women. Their mean age was  $40.8 \pm 8.3$ ; their ages ranged from 26 to 70 years. Fifty percent of the sample reported a diagnosis of AIDS; 71.8% of them reported taking highly active antiretroviral therapy (HAART). Almost 88% of the sample reported fatigue. Internal consistency reliability of the GFI was assessed at 0.96. Test–retest reliability of the assessment tool was demonstrated by lack of significant changes in scores over 8 weeks. Construct validity was analyzed through principal components factor analysis and demonstrated two factors. Construct validity was determined by examining the correlation of GFI scores and more established, widely used scales that assess health distress, depression, stress levels, and measures of physical and mental health. Significant correlations with these measures indicated construct validity of the GFI.

There were no significant bivariate correlations between GFI scores and patient characteristics (age, gender, ethnicity, education, employment, and types of antiretroviral therapy). There was no significant relationship between fatigue as measured by the GFI and viral load as measured by HIV-RNA levels or CD4T4 cell.

#### Nursing Implications

The GFI is a practical, patient-centered instrument with evidence of reliability and validity. It takes only about 5 minutes to complete and can be used by nurses to assess baseline fatigue, to monitor the course of fatigue over time and in relation to changes in patients' HIV disease status and treatment plans, and to identify the need for more in-depth assessments of psychosocial, physical, and sleep status. The GFI can also be used by patients to monitor their fatigue scores to assess the effectiveness of different strategies.

volume status is evaluated so that adequate hydration can be maintained. Unless contraindicated by renal or cardiac disease, an intake of 3 L of fluid daily is encouraged. Humidified oxygen may be prescribed, and nasopharyngeal or tracheal suctioning, intubation, and mechanical ventilation may be necessary to maintain adequate ventilation.

Chart  
52-7

## Care of the Patient With HIV Encephalopathy

**Disturbed Thought Processes**

- Assess mental status and neurologic functioning.
- Monitor for medication interactions, infections, electrolyte imbalance, and depression.
- Frequently orient the patient to time, place, person, reality, and the environment.
- Use simple explanations.
- Teach the patient to perform tasks in incremental steps.
- Provide memory aids (clocks and calendars).
- Provide memory aids for medication administration.
- Post activity schedule.
- Give positive feedback for appropriate behavior.
- Teach caretakers how to orient patient to time, place, person, reality, and the environment.
- Encourage the patient to designate a responsible person to assume power of attorney.

**Disturbed Sensory Perception**

- Assess sensory impairment.
- Decrease amount of stimuli in the patient's environment.
- Correct inaccurate perceptions.
- Provide reassurance and safety if the patient displays fear.
- Provide a secure and stable environment.
- Teach caregivers how to recognize inaccurate sensory perceptions.
- Teach caregivers techniques to correct inaccurate perceptions.
- Teach the patient and caregivers to report any changes in the patient's vision to the patient's health care provider.

**Risk for Injury**

- Assess the patient's level of anxiety, confusion, or disorientation.
- Assess the patient for delusions or hallucinations.
- Remove potentially dangerous objects from the patient's environment.
- Structure the environment for safety (ensure adequate lighting, avoid clutter, provide bed rails if needed).
- Supervise smoking.
- Do not let the patient drive a car if confusion is present.
- Instruct the patient and caregiver in home safety.
- Provide assistance as needed for ambulation and in getting in and out of bed.
- Pad headboard and side rails if the patient has seizures.

**Self-Care Deficits**

- Encourage activities of daily living within the patient's level of ability.
- Encourage independence but assist if the patient cannot perform an activity.
- Demonstrate any activity that the patient is having difficulty accomplishing.
- Monitor food and fluid intake.
- Weigh patient weekly.
- Encourage the patient to eat, and offer nutritious meals, snacks, and adequate fluids.
- If patient is incontinent, establish a routine toileting schedule.
- Teach caregivers how to meet the patient's self-care needs.

**RELIEVING PAIN AND DISCOMFORT**

The patient is assessed for the quality and severity of pain associated with impaired perianal skin integrity, the lesions of KS, and peripheral neuropathy. In addition, the effects of pain on elimination, nutrition, sleep, affect, and communication are explored, along with exacerbating and relieving factors. Cleaning the perianal area as previously described can promote comfort. Topical anesthetics or ointments may be prescribed. Use of soft cushions or foam pads may increase comfort while sitting. The patient is instructed to avoid foods that act as bowel irritants. Antispasmodics and antidiarrheal medications may be prescribed to reduce the discomfort and frequency of bowel movements. If necessary, systemic analgesic agents may also be prescribed.

Pain from KS is frequently described as a sharp, throbbing pressure and heaviness if lymphedema is present. Pain management may include using nonsteroidal anti-inflammatory drugs (NSAIDs) and opioids plus nonpharmacologic approaches such as relaxation techniques. When NSAIDs are used in patients receiving zidovudine, hepatic and hematologic status must be monitored.

The patient with pain related to peripheral neuropathy frequently describes it as burning, numbness, and "pins and needles." Pain management measures may include opioids, tricyclic antidepressants, and elastic compression stockings to equalize pressure. Tricyclic antidepressants have been found helpful in controlling the symptoms of neuropathic pain. They also potentiate the actions of opioids and can be used to relieve pain without increasing the dose of the opioid.

**IMPROVING NUTRITIONAL STATUS**

Nutritional status is assessed by monitoring weight; dietary intake; anthropometric measurements; and serum albumin, BUN, protein, and transferrin levels. The patient is also assessed for fac-

tors that interfere with oral intake, such as anorexia, oral and esophageal candidal infection, nausea, pain, weakness, fatigue, and lactose intolerance. Based on the results of assessment, the nurse can implement specific measures to facilitate oral intake. The dietitian is consulted to determine the patient's nutritional requirements.

Control of nausea and vomiting with antiemetic medications administered on a regular basis may increase the patient's dietary intake. Inadequate food intake resulting from pain caused by mouth sores or a sore throat may be managed by administering prescribed opioids and viscous lidocaine (the patient is instructed to rinse the mouth and swallow). Additionally, the patient is encouraged to eat foods that are easy to swallow and to avoid rough, spicy, or sticky food items and foods that are excessively hot or cold. Oral hygiene before and after meals is encouraged.

When fatigue and weakness interfere with intake, the nurse encourages the patient to rest before meals. If the patient is hospitalized, meals should be scheduled so that they do not occur immediately after painful or unpleasant procedures. The patient with diarrhea and abdominal cramping is encouraged to avoid foods that stimulate intestinal motility and abdominal distention (eg, fiber-rich food or lactose if the patient is intolerant to lactose). The patient is instructed about ways to enhance the nutritional value of meals. Adding eggs, butter, margarine, and fortified milk (powdered skim milk is added to milk to increase the caloric content) to gravies, soups, or milkshakes can provide additional calories and protein. Commercial supplements such as puddings, powders, milkshakes, and Advera (a nutritional product specifically designed for people with HIV infection or AIDS) may also be useful. Patients who cannot maintain their nutritional status through oral intake may require enteral feedings or parenteral nutrition.

## DECREASING THE SENSE OF ISOLATION

Individuals with AIDS are at risk for double stigmatization. They have what society refers to as a “dread disease,” and they may have a lifestyle that differs from what is considered acceptable by many people. Many people with AIDS are young adults at a developmental stage usually associated with establishing intimate relationships and personal and career goals and having and raising children. Their focus changes as they are faced with a disease that threatens their life expectancy with no cure. In addition, they may be forced to reveal hidden lifestyles or behaviors to family, friends, coworkers, and health care providers. As a result, people with HIV infection may be overwhelmed with emotions such as anxiety, guilt, shame, and fear. They also may be faced with multiple losses, such as rejection by family and friends and loss of sexual partners, family, and friends; financial security; normal roles and functions; self-esteem; privacy; ability to control bodily functions; ability to interact meaningfully with the environment; and sexual functioning. Some patients may harbor feelings of guilt because of their lifestyle or because they may have infected others in current or previous relationships. Other patients may feel anger toward sexual partners who transmitted the virus. Infection control measures used in the hospital or at home may further contribute to the patient’s emotional isolation. Any or all of these stressors may cause the patient with AIDS to withdraw both physically and emotionally from social contact.

Nurses are in a key position to provide an atmosphere of acceptance and understanding of people with AIDS and their families and partners. The patient’s usual level of social interaction is assessed as early as possible to provide a baseline for monitoring changes in behavior indicative of social isolation (eg, decreased interaction with staff or family, hostility, non-compliance). Patients are encouraged to express feelings of isolation and loneliness, with the assurance that these feelings are not unique or abnormal.

Providing information about how to protect themselves and others may help patients avoid social isolation. Patients, family, and friends must be assured that AIDS is not spread through casual contact. Educating ancillary personnel, nurses, and physicians will help to reduce factors that might contribute to patients’ feelings of isolation. Patient care conferences that address the psychosocial issues associated with AIDS may help sensitize the health care team to patients’ needs.

## COPING WITH GRIEF

The nurse can help patients verbalize feelings and explore and identify resources for support and mechanisms for coping, especially when the patient is grieving about anticipated losses. Patients are encouraged to maintain contact with family, friends, and coworkers and to use local or national AIDS support groups and hotlines. If possible, losses are identified and addressed. The patient is encouraged to continue usual activities whenever possible. Consultations with mental health counselors are useful for many patients.

## MONITORING AND MANAGING POTENTIAL COMPLICATIONS

### Opportunistic Infections

Patients who are immunosuppressed are at risk for OIs. Therefore, anti-infective agents may be prescribed and laboratory tests obtained to monitor their effect. Signs and symptoms of OIs, including fever, malaise, difficulty breathing, nausea or vomiting, diarrhea, difficulty swallowing, and any occurrences of swelling or discharge, should be reported.

## Respiratory Failure

Impaired breathing is a major complication that increases the patient’s discomfort and anxiety and may lead to respiratory and cardiac failure. The respiratory rate and pattern are monitored and the lungs are auscultated for abnormal breath sounds. The patient is instructed to report shortness of breath and increasing difficulty in carrying out usual activities. Pulse rate and rhythm, blood pressure, and oxygen saturation are monitored. Suctioning and oxygen therapy may be prescribed to ensure an adequate airway and to prevent hypoxia. Mechanical ventilation may be necessary for a patient who cannot maintain adequate ventilation as a result of pulmonary infection, fluid and electrolyte imbalance, or respiratory muscle weakness. Arterial blood gas values are used to guide ventilator settings. If the patient is intubated, a method must be established to allow communication with the nurse and others. Attention must be given to assisting the patient on mechanical ventilation to cope with the stress associated with intubation and ventilator assistance. The possible need for mechanical ventilation in the future should be discussed early in the course of the disease, when the patient is able to make his or her desires about treatment known. The use of mechanical ventilation should be consistent with the patient’s decisions about end-of-life treatment. (Further discussion of end-of-life care can be found in Chap. 17.)

## Cachexia and Wasting

Wasting syndrome and fluid and electrolyte disturbances, including dehydration, are common complications of HIV infection and AIDS. The patient’s nutritional and electrolyte status is evaluated by monitoring weight gains or losses, skin turgor, ferritin levels, hemoglobin and hematocrit values, and electrolyte levels. Fluid and electrolyte status is monitored on an ongoing basis; fluid intake and output and urine specific gravity may be monitored daily if the patient is hospitalized with complications. The skin is assessed for dryness and adequate turgor. Vital signs are monitored for decreased systolic blood pressure or increased pulse rate upon sitting or standing. Signs and symptoms of electrolyte disturbances, such as muscle cramping, weakness, irregular pulse, decreased mental status, nausea, and vomiting, are documented and reported to the physician. Serum electrolyte values are monitored and abnormalities reported.

The nurse helps the patient select foods that will replenish electrolytes, such as oranges and bananas (potassium) and cheese and soups (sodium). A fluid intake of 3 L or more, unless contraindicated, is encouraged to replace fluid lost with diarrhea, and measures to control diarrhea are initiated. If fluid and electrolyte imbalances persist, the nurse may administer IV fluids and electrolytes as prescribed. Effects of parenteral therapy are monitored.

## Side Effects of Medications

Adverse reactions are of concern in patients who receive many medications to treat HIV infection or its complications. Many medications can cause severe toxic effects. Information about the purpose of the medications, correct administration, side effects, and strategies to manage or prevent side effects is provided. Patients and their caregivers need to know which signs and symptoms of side effects should be reported immediately to their primary health care provider (see Table 52-3).

In addition to medications used to treat HIV infection, other medications that may be required include opioids, tricyclics, and NSAIDs for pain relief; medications for treatment of OIs; antihistamines (diphenhydramine) for relief of pruritus (itching); acetaminophen or aspirin for management of fever; and antiemetic agents for control of nausea and vomiting. Concurrent use of

many of these medications may cause many drug interactions, including hepatic and hematologic abnormalities. Therefore, careful laboratory monitoring for these abnormalities is warranted.

During each contact with the patient, it is important for the nurse to ask not only about side effects but also how well the patient is managing the medication regimen. The nurse may be able to assist the patient in organizing and planning the medication schedule to promote adherence to the medication regimen.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

Patients, families, and friends are instructed about the routes of transmission of HIV. The nurse discusses precautions to prevent transmitting HIV, including using condoms during vaginal or anal intercourse (Chart 52-8); using dental dams or avoiding oral contact with the penis, vagina, or rectum; avoiding sexual practices that might cut or tear the lining of the rectum, vagina, or penis; and avoiding sexual contact with multiple partners, individuals known to be HIV infected, people who use injection drugs, and sexual partners of people who inject drugs.

Patients and their families or caregivers must receive instructions about how to prevent disease transmission, including handwashing techniques, and in methods for safely handling items

soiled with body fluids. Caregivers in the home are taught how to administer medications, including IV preparations.

The medication regimens used for patients with HIV infection and AIDS are often complex and expensive. Patients receiving combination therapies for treatment of HIV infection and its complications require careful teaching about the importance of taking medications as prescribed and explanations and assistance in fitting the medication regimen into their lives (Chart 52-9).

Guidelines about infection and infection control, follow-up care, diet, rest, and activity are also necessary. Patient teaching also includes strategies to avoid infection. The importance of personal hygiene is emphasized. Kitchen and bathroom surfaces should be cleaned regularly with disinfectants to prevent fungal and bacterial growth. Patients with pets are instructed to have another person clean areas soiled by animals, such as bird cages and litter boxes. If this is not possible, the patient should use gloves to clean up after pets. Patients are advised to avoid exposure to others who are sick or who have been recently vaccinated. Patients with AIDS and their sexual partners are strongly urged to avoid exposure to body fluids during sexual activities and to use condoms for any form of sexual intercourse. Injection drug use is strongly discouraged because of the risk to the patient of other infections and transmission of HIV infection to others. Patients infected with HIV are urged to avoid exposure to bodily fluids (through sexual contact or injection drug use) to prevent exposure to other HIV strains. The importance of avoiding smoking and maintaining a balance between diet, rest, and exercise is also emphasized.

If the patient requires enteral or parenteral nutrition, instruction is provided to patients and families about how to administer nutritional therapies at home. Home care nurses provide ongoing teaching and support for the patient and family.

Patients who are HIV positive or who inject drugs are instructed not to donate blood. Injection drug users who are unwilling to stop using drugs are advised to avoid sharing drug equipment with others.

### Continuing Care

Many people with AIDS remain in their community and continue their usual daily activities, whereas others can no longer work or maintain their independence. Families or caregivers may need assistance in providing supportive care. There are many community-based organizations that provide a variety of services for people living with HIV infection and AIDS; nurses can help identify these services.

Community health nurses, home care nurses, and hospice nurses are in an excellent position to provide the support and guidance so often needed in the home setting. As hospital costs continue to rise and insurance coverage continues to decline, the complexity of home care increases. Home care nurses are key in the administration of parenteral antibiotics, chemotherapy, and nutrition in the home.

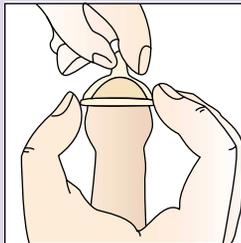

During home visits, the nurse assesses the patient's physical and emotional status and home environment. The patient's adherence to the therapeutic regimen is assessed, and strategies are suggested to assist with adherence. The patient is assessed for progression of disease and for adverse side effects of medications. Previous teaching is reinforced, and the importance of keeping follow-up appointments is stressed.

Complex wound care or respiratory care may be required in the home. Patients and families are often unable to meet these skilled care needs without assistance. Nurses may refer patients to community programs that offer a range of services for patients, friends, and families, including help with housekeeping, hygiene, and meals; transportation and shopping; individual and group

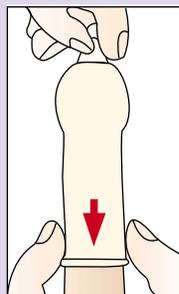

**Chart 52-8 • PATIENT EDUCATION**  
**The Right Way to Use a Male Condom**

1. Put on a new condom before any kind of sex.
2. Hold the condom by the tip to squeeze out the air.

3. Unroll the condom all the way over the erect penis.

4. Have sex.
5. Hold the condom so it cannot come off the penis.
6. Pull out.
7. Use a new condom if you want to have sex again or if you want to have sex in a different place (eg, in the anus and then in the vagina).

Keep condoms cool and dry. Never use skin lotions, baby oil, petroleum jelly, or cold cream with condoms. The oil in these products will cause the condom to break. You may use products made with water (like K-Y jelly or glycerin).

Chart 52-9

## Home Care Checklist • Adhering to Medication Therapy for HIV

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Verbalize knowledge of each medication name.	✓	✓
• State the action of each medication.	✓	✓
• State the correct times that medications are to be taken.	✓	✓
• Identify special guidelines to follow when taking medications (eg, with meals, on an empty stomach, medications that are not to be taken together).	✓	✓
• Demonstrate methods of keeping track of the medication regimen and storage of the prescribed medications.	✓	✓
• Identify specific laboratory tests that are necessary for the prescribed medication regimen.	✓	✓
• List expected side effects of each medication.	✓	✓
• Identify side effects that should be reported to health care providers.	✓	✓
• Explain the importance of and necessity for adherence with prescribed medication regimen.	✓	✓
• Demonstrate correct disposal of sharps and of parenteral medication according to Standard Precautions guidelines.	✓	✓
• Demonstrate correct administration of IM, SC, or IV medications.	✓	✓
• Demonstrate correct use and safe disposal of needles, syringes, and other IV equipment.	✓	✓
• Discuss with health care providers any problems that he or she is having with side effects and adherence.	✓	✓
• Report any episodes of nonadherence to the medication regimen.	✓	✓

therapy; support for caregivers; telephone networks for the homebound; and legal and financial assistance. These services are typically provided by both professional and nonprofessional volunteers. A social worker may be consulted to identify sources of financial support, if needed.

Home care and hospice nurses are increasingly called on to provide physical and emotional support to patients and families as patients with AIDS enter the terminal stages of disease. This support takes on special meaning when people with AIDS lose friends and when family members fear the disease or feel anger concerning the patient's lifestyle. The nurse encourages the patient and family to discuss end-of-life decisions and to ensure that care is consistent with those decisions, all comfort measures are employed, and the patient is treated with dignity at all times.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Maintains skin integrity
2. Resumes usual bowel habits
3. Experiences no infections
4. Maintains adequate level of activity tolerance
5. Maintains usual level of thought processes
6. Maintains effective airway clearance
7. Experiences increased sense of comfort, less pain
8. Maintains adequate nutritional status
9. Experiences decreased sense of social isolation
10. Progresses through grieving process
11. Reports increased understanding of AIDS and participates in self-care activities as possible
12. Remains free of complications

## Emotional and Ethical Concerns

Nurses in all settings will be called on to provide care for patients with HIV infection. In doing so, they encounter not only the physical challenges of this epidemic but also emotional and ethi-

cal concerns. The concerns raised by health care professionals involve issues such as fear of infection, responsibility for giving care, values clarification, confidentiality, developmental stages of patients and caregivers, and poor prognostic outcomes.

Many patients with HIV infection have engaged in "stigmatized" behaviors. Because these behaviors challenge some traditional religious and moral values, nurses may feel reluctant to care for these patients. In addition, health care providers may still have fear and anxiety about disease transmission despite education concerning infection control and the low incidence of transmission to health care providers (Chart 52-10). Nurses are encouraged to examine their personal beliefs and use the process of values clarification to approach controversial issues. The American Nurses Association's Code for Nurses can also be used to help resolve ethical dilemmas that might affect the quality of care given to HIV-infected patients.

Nurses are responsible for protecting the patient's right to privacy by safeguarding confidential information. Inadvertent disclosure of confidential patient information may result in personal, financial, and emotional hardships for HIV-infected individuals. The controversy surrounding confidentiality concerns the circumstances in which information can be disclosed to others. Health care team members need accurate patient information to conduct assessment, planning, implementation, and evaluation of patient care. Failure to disclose HIV status could compromise the quality of patient care. Sexual partners of HIV-infected patients should know about the potential for infection and the need to engage in safer sex practices, as well as the possible need for testing and medical care. Nurses are advised to discuss concerns about confidentiality with nurse administrators and professional nursing organizations such as the Association of Nurses in AIDS Care, and to consult legal experts in their state to identify the most appropriate course of action.

AIDS has had a high mortality rate, but advances in anti-retroviral and multidrug therapy have demonstrated promise in slowing or controlling disease progression. It is not known whether current treatment regimens will remain effective, because viral drug resistance has developed with most previous medications.

### Chart 52-10 • Ethics and Related Issues Revealing One's HIV Status

**Should all people who are infected with HIV be required to reveal this status to all their sexual and/or needle-sharing contacts?**

#### Situation

The human immunodeficiency virus (HIV) causes HIV infection, which progresses to AIDS, a disease that is currently incurable and ultimately fatal. Many HIV-positive people are aware that they carry the virus but refuse to share this information with others, especially their sexual partners or injecting drug contacts. Because sexual contacts and needle-sharing partners are at risk for developing the disease, would a policy that requires notification of contacts infringe on the liberty and privacy of the known HIV-infected person?

#### Dilemma

The person's right to privacy conflicts with notifying all people who are contacts either through sexual or needle-sharing behavior (autonomy versus justice). The person's right to privacy conflicts with society's need to contain the deadly virus and stem a deadly epidemic (autonomy versus justice).

#### Discussion

What arguments would you offer in favor of notifying all the person's contacts?

What arguments would you offer against notifying all or some of the person's contacts?

Each state has various laws that pertain to whether contacts can be notified and who is responsible for notifying contacts. Is there a law for contact notification in the state in which you live? If there is such a law in your state, who is responsible for contact notification?

What would you do if the person responsible for contact notification refuses to do so based on his own beliefs for confidentiality of HIV infection status?

Most nurses in the United States have never faced an epidemic in which young and middle-aged adults experience serious illness and may die during the usual course of the disease process. Nurses may struggle with the value and meaning of their professional roles as they witness repeated instances of deterioration. Exposure to so many deaths in a population that is at the same developmental stage as many nurses can create feelings of stress. Contributing to this stress are personal fears of contagion or disapproval of the patient's lifestyle and behaviors. Unlike cancer or other diseases, AIDS is associated with controversies challenging our legal and political systems as well as religious and personal beliefs. Nurses who feel stressed and overburdened may experience physical and mental distress in the form of fatigue, headache, changes in appetite and sleep patterns, helplessness, irritability, apathy, negativity, and anger.

Many strategies have been used by nurses to cope with the stress associated with caring for AIDS patients. Education and provision of up-to-date information help to alleviate apprehension and prepare nurses to deliver safe, high-quality patient care. Interdisciplinary meetings allow participants to support one another and provide comprehensive patient care. Staff support groups give nurses an opportunity to solve problems and explore values and feelings about caring for AIDS patients and their families; they also provide a forum for grieving. Other sources of support include nursing administrators, peers, and spiritual advisors.

### Critical Thinking Exercises

1. A 27-year-old man who was tested for HIV infection when he volunteered as a blood donor has been identified as HIV positive. He does not believe the results, says he cannot be HIV positive, and becomes angry when you attempt to explain the test results to him. How should you respond to the patient, and what further testing or treatment would you anticipate? How would you modify your approach if the patient seemed suicidal?
2. You are making a home visit to a patient with HIV encephalopathy. Describe the aspects of the home environment you would assess to ensure safety and adequate care. How would you modify your assessment if the patient lived alone in a third-floor apartment without an elevator? If the patient lived in a rural setting?
3. You are the nurse manager of a surgical department. A new graduate working in the operating room was inadvertently stuck with a needle used to administer medication to a patient who is HIV positive. She is frightened about contracting HIV infection. What actions should you take as nurse manager? What do you tell the new graduate about possible risks and consequences related to her needlestick? What testing, treatment, and counseling are warranted?
4. The partner of a patient hospitalized with AIDS asks you directly, "Does my partner have AIDS?" He demands a response, saying he has a legal right to know. How would you respond to him? What ethical and legal issues are involved here?
5. You are caring for a 26-year-old woman who is HIV positive and has two young children who are HIV negative. She tells you that she has recently remarried and that she and her new husband are considering having a child. She asks you what the likelihood is that her third child will also be HIV negative. What information and knowledge do you need to discuss pregnancy and childbearing with her? What counseling and teaching are warranted for the patient and her spouse?
6. One of your patients is hospitalized in the advanced stages of HIV disease with major complications and hepatitis C. The patient has brief episodes of disorientation. He has refused to prepare or even discuss an advance directive, although his family would like him to do so. What is the impact of lack of an advance directive on his care if he lapses into coma? If he cannot participate in making decisions about his health care?

# ● Assessment and Management of Patients With Allergic Disorders

## **LEARNING OBJECTIVES** ●

*On completion of this chapter, the learner will be able to:*

1. Explain the physiologic events involved with allergic reactions.
2. Describe the types of hypersensitivity.
3. Describe the management of patients with allergic disorders.
4. Describe measures to prevent and manage anaphylaxis.
5. Use the nursing process as a framework for care of the patient with allergic rhinitis.
6. Discuss the different allergic disorders according to type.

The human body is menaced by a host of potential invaders— allergens as well as microbial organisms—that constantly threaten its surface defenses. After penetrating those defenses, these allergens and organisms compete with the body for its nutrients and, if allowed to flourish unimpeded, disrupt its enzyme systems and destroy its vital tissues. To protect against these agents, the body is equipped with an elaborate defense system.

The epithelial cells coating the skin and making up the lining of the respiratory, gastrointestinal, and genitourinary tracts provide the first line of defense. The structure and continuity of these surfaces and the resistance to penetration are initial deterrents to invaders.

One of the most effective defense mechanisms is the body's capacity to equip itself rapidly with weapons (antibodies) individually designed to meet each new invader, namely specific protein antigens. Antibodies react with antigens in a variety of ways: (1) by coating the antigens' surfaces if they are particular substances, (2) by neutralizing the antigens if they are toxic, and (3) by precipitating the antigens out of solution if they are dissolved.

The antibodies prepare the antigens so that the phagocytic cells of the blood and the tissues can dispose of them. In some cases, however, the body produces inappropriate or exaggerated responses to specific antigens, and the result is an allergic or hypersensitivity disorder.

## Allergic Reaction: Physiologic Overview

An allergic reaction is a manifestation of tissue injury resulting from interaction between an antigen and an antibody. **Allergy** is an inappropriate and often harmful response of the immune system to normally harmless substances. In this case, the substance is termed an **allergen**. **Atopy** refers to allergic reactions characterized by the action of IgE antibodies and a genetic predisposition to allergic reactions.

When the body is invaded by an **antigen**, usually a protein that the body's defenses recognize as foreign, a series of events occurs in an attempt to render the invader harmless, destroy it, and remove it from the body. When lymphocytes respond to the antigen, **antibodies** (protein substances that protect against antigens) are produced. Common allergic reactions occur when the immune system of a susceptible person responds aggressively to a

substance that is normally harmless (eg, dust, weeds, pollen, dander). Chemical mediators released in allergic reactions may produce symptoms ranging from mild to life-threatening.

The many cells and organs of the immune system secrete various substances important in the immune response. These parts of the immune system must work together to ensure adequate defense against invaders (ie, virus, bacteria, other foreign substances) without destroying the body's own tissues by an overly aggressive reaction.

## FUNCTION AND PRODUCTION OF IMMUNOGLOBULINS

Antibodies formed by lymphocytes and plasma cells in response to an immunogenic stimulus constitute a group of serum proteins called **immunoglobulins**. Grouped into five classes (IgE, IgD, IgG, IgM, and IgA), antibodies can be found in the lymph nodes, tonsils, appendix, and Peyer's patches of the intestinal tract or circulating in the blood and lymph. Each antibody molecule is composed of two identical heavy (H) chains and two identical light (L) chains. Each chain contains one variable region and one or more constant regions. The constant regions determine the class (IgE, IgD, etc.) of each antibody and allow each class of antibody to interact with specific effector cells and molecules. The variable regions contain antigen-binding sites (Porth, 2002). Antibodies are capable of binding with a wide variety of antigens, which include macromolecules and small chemicals (Abbas & Lichtman, 2001). Antibodies of the IgM, IgG, and IgA classes have definite and well-established protective functions. These include neutralization of toxins and viruses and precipitation, agglutination, and lysis of bacteria and other foreign cellular material. (See Chap. 50 for further discussion of these functions.)

Immunoglobulins of the IgE class are involved in allergic disorders and some parasitic infections, evidenced by elevation of IgE levels. IgE-producing cells are located in the respiratory and intestinal mucosa. Two or more IgE molecules bind together to an allergen and trigger **mast cells** or basophils to release chemical mediators, such as histamine, serotonin, kinins, slow-reacting substance of anaphylaxis (SRS-A), and the neutrophil factor, which produces allergic skin reactions, asthma, and hay fever.

## Glossary

**allergen:** substance that causes manifestations of allergy

**allergy:** inappropriate and often harmful immune system response to substances that are normally harmless

**anaphylaxis:** clinical response to an immediate immunologic reaction between a specific antigen and antibody

**angioneurotic edema:** condition characterized by urticaria and diffuse swelling of the deeper layers of the skin

**antibody:** protein substance developed by the body in response to and interacting with a specific antigen

**antigen:** substance that induces the production of antibodies

**antihistamine:** medication that opposes the action of histamine

**atopic dermatitis:** type I hypersensitivity involving inflammation of the skin evi-

denced by itching, redness, and a variety of skin lesions

**atopy:** term often used to describe IgE-mediated diseases; genetically determined allergic disorders

**B lymphocyte:** cells that are important in producing circulating antibodies

**bradykinin:** polypeptide that stimulates nerve fibers and causes pain

**eosinophil:** granular leukocyte

**epitope:** an immunologically active site on an antigen; a single antigen can have several different epitopes that elicit responses from different antibodies

**erythema:** diffuse redness of the skin

**haptan:** incomplete antigen

**histamine:** substance in the body that causes increased gastric secretion, dilation of capillaries, and constriction of the bronchial smooth muscle

**hypersensitivity:** abnormal heightened reaction to a stimulus of any kind

**immunoglobulins:** a family of closely related proteins capable of acting as antibodies

**leukotrienes:** a group of chemical mediators that initiate the inflammatory response

**lymphokines:** substances released by sensitized lymphocytes when they contact specific antigens

**mast cell:** connective tissue cells that contain heparin and histamine in their granules

**prostaglandins:** unsaturated fatty acids that have a wide assortment of biologic activity

**rhinitis:** inflammation of the nasal mucosa

**serotonin:** chemical mediator that acts as a potent vasoconstrictor and bronchoconstrictor

**T lymphocyte:** cells that can cause graft rejection, kill foreign cells, or suppress production of antibodies

**urticaria:** hives

Antibodies combine with antigens in a special way, likened to keys fitting into a lock. Antigens (the keys) only fit certain antibodies (the locks). Hence, the term “specificity” refers to the specific reaction of an antibody to an antigen. There are many variations and complexities in these patterns. The strength with which one antigen-binding surface of an antibody binds to one **epitope**, an immunologically active site on an antigen, is known as the affinity of the interaction (Abbas & Lichtman, 2001).

Antibody molecules are bivalent; that is, they have two combining sites. Therefore, the antibody easily becomes a cross-link between two antigen groups, causing them to clump together (agglutination). By this action, foreign invaders are cleared from the bloodstream. Agglutination is the means for determining blood group in laboratory tests.

### Role of B Cells

The B cell, or **B lymphocyte**, is programmed to produce one specific antibody. On encountering a specific antigen, a B cell stimulates production of plasma cells, the site of antibody production. The result is the outpouring of antibodies for the purpose of destroying and removing the antigen.

### Role of T Cells

The T cell, or **T lymphocyte**, assists the B cells in producing antibodies. T cells secrete substances known as **lymphokines** that encourage cell growth, promote cell activation, direct the flow of cell activity, destroy target cells, and stimulate the macrophages. Macrophages present the antigen to the T cells and initiate the immune response. They also digest antigens and assist in removing cells and other debris. The antigen-binding site of a T cell has a structure much like that of an immunoglobulin. It recognizes epitopes through complementary interactions. Unlike a specific antibody, a T cell does not bind free antigens (Parslow, Stites, Terr & Imboden, 2001).

## FUNCTION OF ANTIGENS

Antigens are divided into two groups: complete protein antigens and low-molecular-weight substances. Complete protein antigens, such as animal dander, pollen, and horse serum, stimulate a complete humoral response. (See Chap. 50 for a discussion of humoral

immunity.) Low-molecular-weight substances, such as medications, function as **haptens** (incomplete antigens), binding to tissue or serum proteins to produce a carrier complex that initiates an antibody response. The term “haptens” is derived from the Greek word *haptien* (to fasten). The proteins or other immunogens that haptens are fastened to are known as carriers (Parslow et al., 2001).

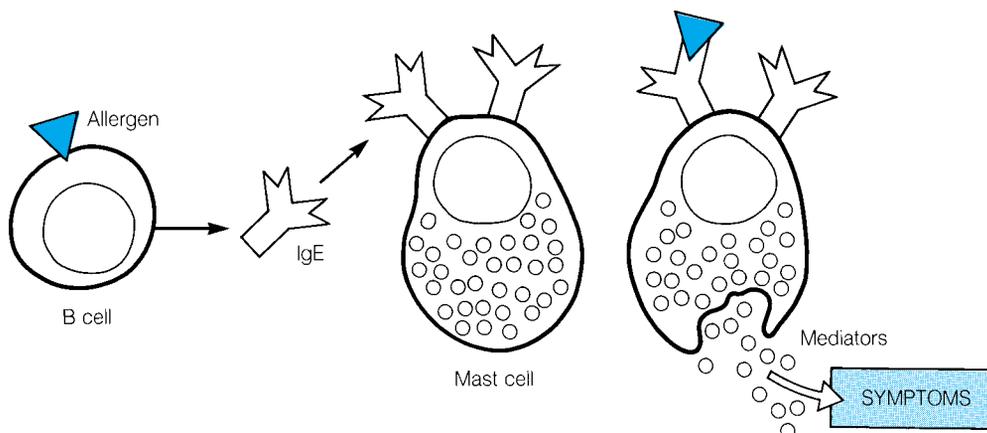

In an allergic reaction, the production of antigen-specific IgE antibodies requires active communication between macrophages, T cells, and B cells. When the allergen is absorbed through the respiratory tract, gastrointestinal tract, or skin, allergen sensitization occurs. The macrophage processes the antigen and presents it to the appropriate T cell. B cells that are influenced by the T cell mature into an allergen-specific IgE immunoglobulin-secreting plasma cell that synthesizes and secretes antigen-specific IgE antibody.

## FUNCTION OF CHEMICAL MEDIATORS

Mast cells, which have a major role in IgE-mediated immediate hypersensitivity, are located in the skin and mucous membranes. When mast cells are stimulated by antigens, powerful chemical mediators are released that cause a sequence of physiologic events resulting in symptoms of immediate hypersensitivity (Fig. 53-1). There are two types of chemical mediators: primary, which are preformed and found in mast cells or basophils, and secondary, which are inactive precursors formed or released in response to primary mediators. The most prevalent known primary and secondary mediators are described next. Table 53-1 summarizes the actions of primary and secondary chemical mediators.

### Primary Mediators

IgE-mediated inflammation occurs when an antigen binds to the IgE antibodies that occupy certain receptors on mast cells. Within minutes, this binding causes the mast cell to degranulate, releasing certain preformed mediators. A two-phase response results. There is an initial immediate effect on blood vessels, smooth muscle, and glandular secretion. This is followed a few hours later by cellular infiltration of the involved site. This type of inflammatory response is commonly known as an immediate hypersensitivity response (Parslow et al., 2001).

**FIGURE 53-1** Allergen triggers B cell to make IgE antibody, which attaches to mast cell. When that allergen reappears, it binds to the IgE and triggers the mast cell to release its chemicals. Courtesy of U.S. Dept. of Health and Human Services, National Institutes of Health.

Table 53-1 • Chemical Mediators of Hypersensitivity

MEDIATORS	ACTION
<b>Primary Mediators</b> (Preformed and found in mast cells or basophils)	
Histamine (preformed in mast cells)	Vasodilation Smooth muscle contraction, increased vascular permeability, increased mucus secretions Attracts eosinophils
Eosinophil chemotactic factor of anaphylaxis (ECF-A) (preformed in mast cells)	Attracts eosinophils
Platelet-activating factor (PAF) (requires synthesis by mast cells, neutrophils, and macrophages)	Smooth muscle contraction Incites platelets to aggregate and release serotonin and histamine
Prostaglandins (chemically derived from arachidonic acid; require synthesis by cells)	D and F series → bronchoconstriction E series → bronchodilation D, E, and F series → vasodilation
Basophil kallikrein (preformed in mast cells)	Frees bradykinin, which causes bronchoconstriction, vasodilation, and nerve stimulation
<b>Secondary Mediators</b> (Inactive precursors formed or released in response to primary mediators)	
Bradykinin (derived from precursor kininogen)	Smooth muscle contraction, increased vascular permeability, stimulates pain receptors, increased mucus production
Serotonin (preformed in platelets)	Smooth muscle contraction, increased vascular permeability
Heparin (preformed in mast cells)	Anticoagulant
Leukotrienes (derived from arachidonic acid and activated by mast cell degranulation) C, D, and E or slow-reacting substance of anaphylaxis (SRS-A)	Smooth muscle contraction, increased vascular permeability

## HISTAMINE

**Histamine** plays an important role in the immune response. Histamine is released from mast cell granules where it is stored. Maximal intensity is reached within about 15 minutes after antigen contact (Parslow et al., 2001). The effects of histamine release include erythema; localized edema in the form of wheals; pruritus; contraction of bronchial smooth muscle, resulting in wheezing and bronchospasm; dilation of small venules and constriction of larger vessels; and increased secretion of gastric and mucosal cells, resulting in diarrhea. Histamine action results from stimulation of histamine-1 ( $H_1$ ) and histamine-2 ( $H_2$ ) receptors found on different types of lymphocytes, particularly T-lymphocyte suppressor cells and basophils.  $H_1$  receptors are found predominantly on bronchiolar and vascular smooth muscle cells.  $H_2$  receptors are found on gastric parietal cells.

Certain medications are categorized by their action at these receptors. Diphenhydramine (Benadryl) is an example of an **anti-histamine**, which is a medication displaying an affinity for  $H_1$  receptors; cimetidine (Tagamet) and ranitidine (Zantac) are examples of other pharmacologic agents that target  $H_2$  receptors to inhibit gastric secretions in peptic ulcer disease.

## EOSINOPHIL CHEMOTACTIC FACTOR OF ANAPHYLAXIS

Preformed in the mast cells, this chemotactic factor, which affects movement of **eosinophils** (granular leukocytes) to the site of allergens, is released upon degranulation to inhibit the action of leukotrienes and histamine.

## PLATELET-ACTIVATING FACTOR

Platelet-activating factor (PAF) is responsible for initiating platelet aggregation at sites of immediate hypersensitivity reactions. It also causes bronchoconstriction and increased vascular permeability. PAF also activates factor XII, or Hageman factor, which induces the formation of bradykinin.

## PROSTAGLANDINS

**Prostaglandins**, composed of unsaturated fatty acids, produce smooth muscle contraction as well as vasodilation and increased capillary permeability. The fever and pain that occur with inflammation are due in part to the prostaglandins.

## Secondary Mediators

### LEUKOTRIENES

**Leukotrienes** are chemical mediators that initiate the inflammatory response. They are metabolites released by mucosal mast cells. They collectively make up what was once termed “slow-reacting substance of anaphylaxis” (SRS-A). Leukotrienes cause smooth muscle contraction, bronchial constriction, mucus secretion in the airways, and the typical wheal and flare reaction of the skin (Parslow et al., 2001). Compared with histamine, leukotrienes are 100 to 1,000 times more potent in causing bronchospasm. Many manifestations of inflammation can be attributed in part to leukotrienes. Medications categorized as leukotriene antagonists or modifiers (zileuton [Zyflo], zafirlukast [Accolate], montelukast [Singulair]) block the synthesis or action of leukotrienes and prevent the signs and symptoms associated with asthma.

### BRADYKININ

**Bradykinin** is a polypeptide with the ability to cause increased vascular permeability, vasodilation, hypotension, and contraction of many types of smooth muscle, such as the bronchi (Parslow et al., 2001). Increased permeability of the capillaries results in edema. Bradykinin stimulates nerve cell fibers and produces pain.

### SEROTONIN

**Serotonin** is released during platelet aggregation, acting as a potent vasoconstrictor and causing contraction of bronchial smooth muscle.

## HYPERSENSITIVITY

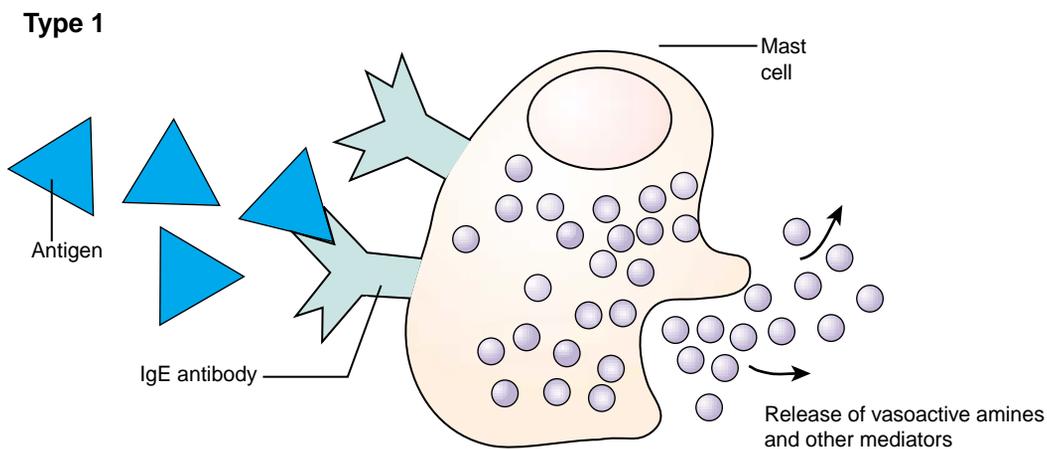

Although the immune system defends the host against infections and foreign antigens, immune responses can themselves cause tissue injury and disease. An immune response to an antigen may result in sensitivity to challenge with that antigen; **hypersensitivity** is a reflection of excessive or aberrant immune responses (Abbas & Lichtman, 2001).

A hypersensitivity reaction is an abnormal, heightened reaction to any type of stimuli. It usually does not occur with the first exposure to an allergen. Rather, the reaction follows a re-exposure after sensitization in a predisposed individual. Sensitization initiates the humoral response or buildup of antibodies. To promote understanding of the immunopathogenesis of disease, hypersensitivity reactions have been classified into four specific types of re-

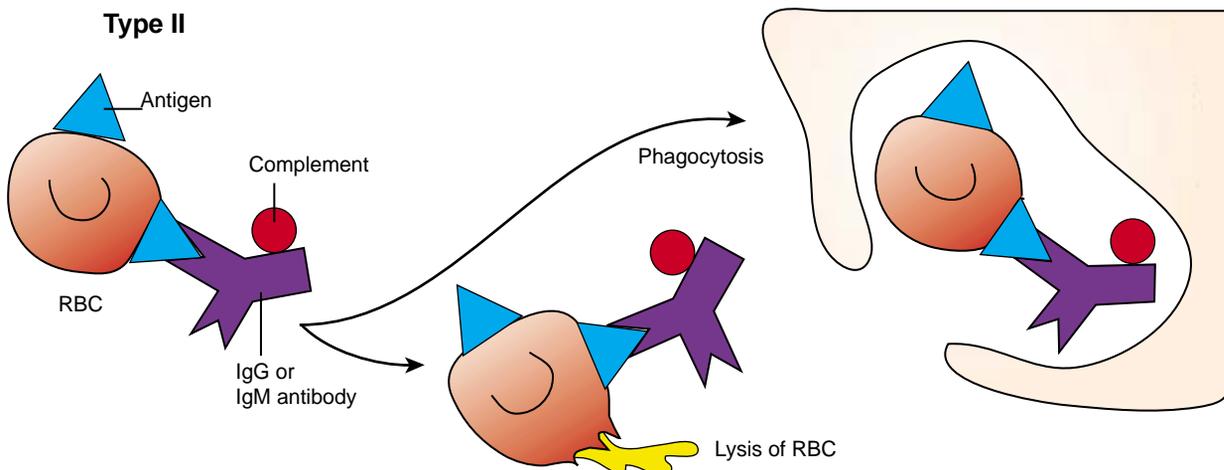

actions (Fig. 53-2). Most allergies are identified as either type I or type IV hypersensitivity reactions.

### Anaphylactic (Type I) Hypersensitivity

The most severe form of a hypersensitivity reaction is **anaphylaxis**. This systemic reaction is characterized by edema in many tissues, including the larynx, and is often accompanied by hypotension (Abbas & Lichtman, 2001). Type I or anaphylactic hypersensitivity is an immediate reaction beginning within minutes of exposure to an antigen. This reaction is mediated by IgE antibodies rather than IgG or IgM antibodies. Type I hypersensitivity requires previous exposure to the specific antigen. In turn, the plasma cells produce IgE antibodies in the lymph nodes, where helper T cells aid in promoting this reaction. The IgE antibodies

Type I. An anaphylactic reaction is characterized by vasodilation, increased capillary permeability, smooth muscle contraction, and eosinophilia. Systemic reactions may involve laryngeal stridor, angioedema, hypotension, and bronchial, GI, or uterine spasm; local reactions are characterized by hives. Examples of type I reactions include extrinsic asthma, allergic rhinitis, systemic anaphylaxis, and reactions to insect stings.

Type II. A cytotoxic reaction, which involves the binding of either the IgG or IgM antibody to a cell-bound antigen, may lead to eventual cell and tissue damage. The reaction is the result of mistaken identity when the system identifies a normal constituent of the body as foreign and activates the complement cascade. Examples of type II reactions are myasthenia gravis, Goodpasture's syndrome, pernicious anemia, hemolytic disease of the newborn, transfusion reaction, and thrombocytopenia.

**FIGURE 53-2** Four types of hypersensitivity reactions.

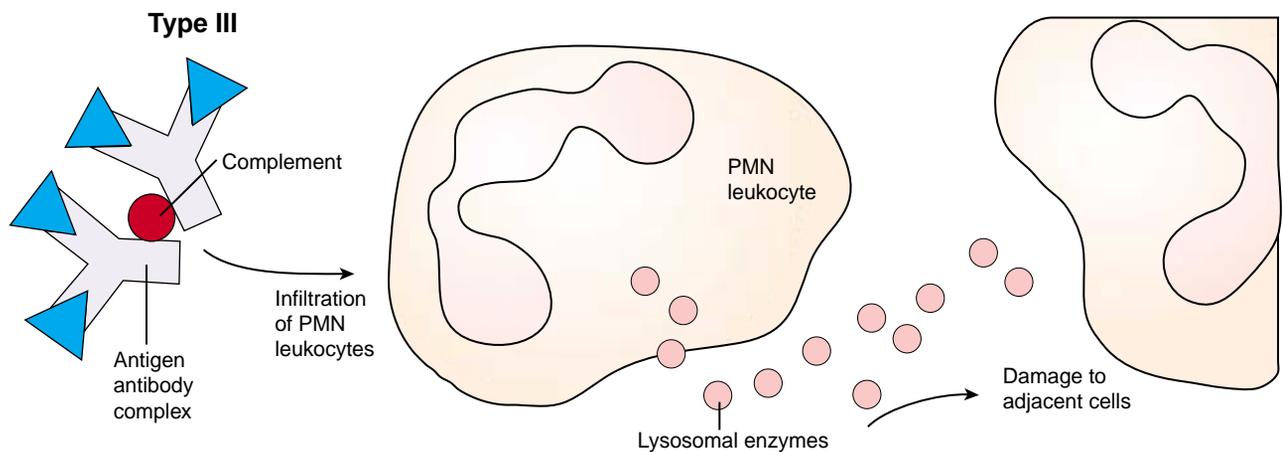

bind to membrane receptors on mast cells found in connective tissue and basophils. During re-exposure, the antigen binds to adjacent IgE antibodies, activating a cellular reaction that triggers degranulation and the release of chemical mediators (histamine, leukotrienes, and eosinophil chemotactic factor of anaphylaxis [ECF-A]).

Primary chemical mediators are responsible for the symptoms of type I hypersensitivity because of their effects on the skin, lungs, and gastrointestinal tract. When chemical mediators continue to be released, a delayed reaction may occur lasting for up to 24 hours. Clinical symptoms are determined by the amount of the allergen, the amount of mediator released, the sensitivity of the target organ, and the route of allergen entry. Type I hypersensitivity reactions may include both local and systemic anaphylaxis.

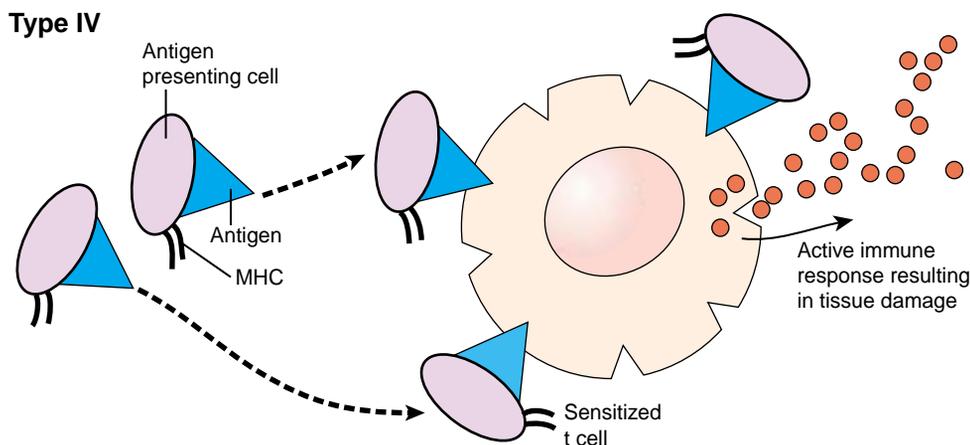

### Cytotoxic (Type II) Hypersensitivity

Type II, or cytotoxic, hypersensitivity occurs when the system mistakenly identifies a normal constituent of the body as foreign. This reaction may be a result of a cross-reacting antibody, possibly leading to cell and tissue damage. Type II hypersensitivity involves the binding of either IgG or IgM antibody to the cell-bound antigen. The result of antigen-antibody binding is activation of the complement cascade (see Chap. 50) and destruction of the cell to which the antigen is bound.

A type II hypersensitivity reaction is associated with several disorders. For example, in myasthenia gravis, the body mistakenly generates antibodies against normal nerve ending receptors. In Goodpasture syndrome, antibodies against lung and renal tissue are generated, producing lung damage and renal failure.

Type III. An immune complex reaction is marked by acute inflammation resulting from formation and deposition of immune complexes. The joints and kidneys are particularly susceptible to this kind of reaction, which is associated with systemic lupus erythematosus, serum sickness, nephritis and rheumatoid arthritis. Some signs and symptoms include urticaria, joint pain, fever, rash, and adenopathy (swollen glands).

Type IV. A delayed, or cellular, reaction occurs 1 to 3 days after exposure to an antigen. The reaction, which results in tissue damage, involves activity by lymphokines, macrophages, and lysozymes. Erythema and itching are common; a few examples include contact dermatitis, graft-versus-host disease, Hashimoto's thyroiditis, and sarcoidosis.

FIGURE 53-2 (Continued)

A type II hypersensitivity reaction resulting in red blood cell destruction is associated with drug-induced immune hemolytic anemia, Rh-hemolytic disease of the newborn, and incompatibility reactions in blood transfusions (see Chap. 33).

### Immune Complex (Type III) Hypersensitivity

Type III, or immune complex, hypersensitivity involves immune complexes formed when antigens bind to antibodies. These complexes are then cleared from the circulation by phagocytic action. When these type III complexes are deposited in tissues or vascular endothelium, two factors contribute to injury: the increased amount of circulating complexes and the presence of vasoactive amines. As a result, there is an increase in vascular permeability and tissue injury. The joints and kidneys are particularly susceptible to this type of injury. Type III hypersensitivity is associated with systemic lupus erythematosus, rheumatoid arthritis, certain types of nephritis, and some types of bacterial endocarditis. These are discussed elsewhere in this text.

### Delayed-Type (Type IV) Hypersensitivity

Type IV, or delayed-type hypersensitivity, also known as cellular hypersensitivity, occurs 24 to 72 hours after exposure to an allergen. It is mediated by sensitized T cells and macrophages. An example of this reaction is the effect of an intradermal injection of tuberculin antigen or purified protein derivative (PPD). Sensitized T cells react with the antigen at or near the injection site. Lymphokines are released and attract, activate, and retain macrophages at the site. These macrophages then release lysozymes, causing tissue damage. Edema and fibrin are responsible for the positive tuberculin reaction.

An example of a type IV hypersensitivity reaction is contact dermatitis resulting from exposure to allergens such as cosmetics, adhesive tape, topical medications, medication additives, and plant toxins. The primary exposure results in sensitization. Re-exposure causes a hypersensitivity reaction composed of low-molecular-weight molecules (haptens) that bind with proteins or carriers and are then processed by Langerhans cells in the skin. The symptoms that occur include itching, erythema, and raised lesions.

## Assessment

### HEALTH HISTORY AND CLINICAL MANIFESTATIONS

A comprehensive allergy history and a thorough physical examination provide useful data for the diagnosis and management of patients with allergic disorders. An assessment form is useful for obtaining and organizing this information (Chart 53-1).

The degree of difficulty and discomfort experienced by the patient because of allergic symptoms and the degree of improvement in those symptoms with and without treatment are assessed and documented. The relationship of symptoms to exposure to possible allergens is noted.

### Diagnostic Evaluation

Diagnostic evaluation of the patient with allergic disorders commonly includes blood tests, smears of body secretions, skin tests, and the radioallergosorbent test (RAST). Results of laboratory

blood studies provide supportive data for various diagnostic possibilities; however, they are not the major criteria for the diagnosis of allergic disease.

### COMPLETE BLOOD COUNT WITH DIFFERENTIAL

The white blood cell (WBC) count is usually normal except with infection. Eosinophils, granular leukocytes, normally make up 1% to 3% of the total number of WBCs. A level between 5% and 15% is nonspecific but does suggest allergic reaction. Higher levels are considered moderate and severe. In moderate eosinophilia, 15% to 40% of blood leukocytes as eosinophils are found in patients with allergic disorders as well as in patients with malignancy, immunodeficiencies, parasitic infections, and congenital heart disease, and those receiving peritoneal dialysis. In severe eosinophilia, 50% to 90% of blood leukocytes as eosinophils are found in the idiopathic hypereosinophilic syndrome.

### EOSINOPHIL COUNT

An actual count of eosinophils may be obtained from blood samples or smears of secretions. A total eosinophil count can be obtained from a blood sample by using special diluting fluids that hemolyze erythrocytes and stain the eosinophils. During symptomatic episodes, smears obtained from nasal secretions, conjunctival secretions, and sputum of atopic patients usually reveal eosinophils, indicative of an active allergic response.

### TOTAL SERUM IMMUNOGLOBULIN E LEVELS

High total serum IgE levels support the diagnosis of atopic disease. A normal IgE level, however, does not exclude the diagnosis of an allergic disorder. IgE levels are not as sensitive as the paper radioimmunosorbent test (PRIST) and the enzyme-linked immunosorbent assay (ELISA). Indications for determining IgE levels include the following:

- Evaluation of immunodeficiency
- Evaluation of drug reactions
- Initial laboratory screening for allergic bronchopulmonary aspergillosis
- Evaluation of allergy among children with bronchiolitis
- Differentiation of atopic and nonatopic eczema
- Differentiation of atopic and nonatopic asthma and rhinitis

### SKIN TESTS

Skin testing entails the intradermal injection or superficial application (epicutaneous) of solutions at several sites. Depending on the suspected cause of allergic signs and symptoms, several different solutions may be applied at several separate sites. These solutions contain individual antigens representing an assortment of allergens, including pollen, most likely to be implicated in the patient's disease. Positive reactions (wheal and flare) are clinically significant when correlated with the history, physical findings, and results of other laboratory tests.

The results of skin tests complement the data obtained from the history. They indicate which of several antigens are most likely to provoke symptoms and provide some clue to the intensity of the patient's sensitization. The dosage of the antigen (allergen) injected is also important. Most patients are hypersensitive

to more than one pollen. Under testing conditions, they may not react (although they usually do) to the specific pollens that induce their attacks.

In cases of doubt about the validity of the skin tests, a RAST or a provocative challenge test may be performed. If a skin test is indicated, there is a reasonable suspicion that a specific allergen is producing symptoms in an allergic patient. Several precautionary steps, however, must be observed before skin testing with allergens:

- Testing is not performed during periods of bronchospasm.
- Epicutaneous tests (scratch or prick tests) are performed before other testing methods in an effort to minimize the risk of systemic reaction.
- Emergency equipment must be readily available to treat anaphylaxis.

### Types of Skin Tests

The methods of skin testing include prick skin tests, scratch tests, and intradermal skin testing (Fig. 53-3). After prick or scratch tests, intradermal skin testing is performed with allergens that did not elicit positive reactions. Because a larger antigen challenge is being used, local or systemic reactions could occur if the same antigens that produced positive skin or scratch reactions are used. The back is the most suitable area of the body for skin testing because it permits the performance of many tests. The multitest applicator is a commercially available device with multiple test heads that allows simultaneous administration of antigens by multiple punctures at different sites.

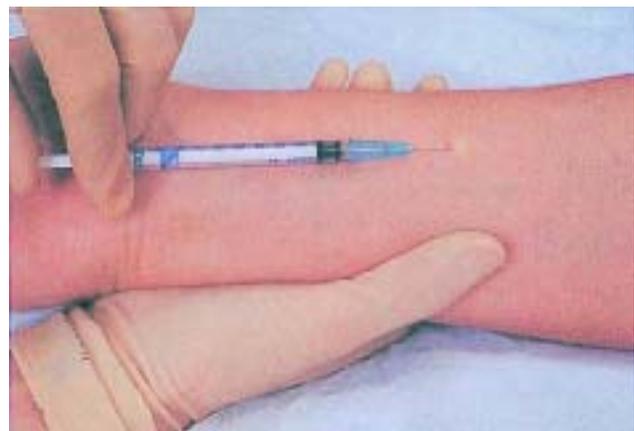

### Interpretation of Skin Test Results

Familiarity with and consistent use of a grading system are essential. The grading system used should be identified on a skin test sheet for later interpretation. A positive reaction, evidenced by the appearance of an urticarial wheal (round, reddened skin elevation) (Fig. 53-4), localized **erythema** (diffuse redness) in the area of inoculation or contact, or pseudopodia (irregular projec-

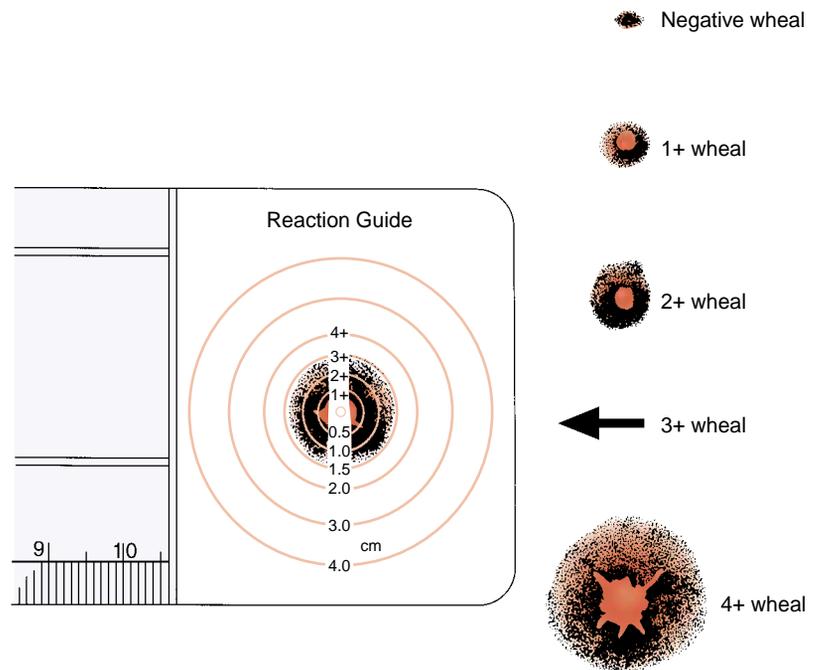

tion at the end of a wheal) with associated erythema is considered indicative of sensitivity to the corresponding antigen.

There may be false-negative results due to improper technique, outdated allergen solutions, and prior use of medications that suppress skin reactivity. Corticosteroids and antihistamines, including allergy medications, suppress skin test reactivity and are usually withheld 48 to 96 hours before testing, depending on the duration of their activity. False-positive skin tests may result from improper preparation or administration of allergen solutions.

Interpretation of positive or negative skin tests must be based on the history, physical examination, and other laboratory test

**FIGURE 53-3** Intradermal testing. A 0.5-mL or 1-mL sterile syringe with a 26/27 gauge intradermal needle is used to inject 0.02 to 0.03 mL of intradermal allergen. The needle is inserted with the bevel facing upward and the syringe parallel to the skin. The skin is penetrated superficially, and a small amount of the allergen solution is injected to create a bleb (raised area) approximately 5 mm in diameter. A separate sterile syringe and needle are used for each injection. From Taylor, C., Lillis C., & LeMone, P. (2001). *Fundamentals of nursing: The art and science of nursing care* (4th ed.). Philadelphia; Lippincott Williams & Wilkins.

**FIGURE 53-4** Interpretation of reactions: Negative = wheal soft with minimal erythema. 1+ = wheal present (5–8 mm) with associated erythema. 2+ = wheal (7–10 mm) with associated erythema. 3+ = wheal (9–15 mm), slight pseudopodia possible with associated erythema. 4+ = wheal (12 mm+) with pseudopodia and diffuse erythema.

results. The following guidelines are used for the interpretation of skin test results:

- Skin tests are more reliable for diagnosing atopic sensitivity in patients with allergic rhinoconjunctivitis than in patients with asthma.
- Positive skin tests correlate highly with food allergy.
- The use of skin tests to diagnose immediate hypersensitivity to medications is limited because metabolites of medications, not the medications themselves, are usually responsible for causing hypersensitivity.

## PROVOCATIVE TESTING

Provocative testing involves the direct administration of the suspected allergen to the sensitive tissue, such as the conjunctiva, nasal or bronchial mucosa, or gastrointestinal tract (by ingestion of the allergen) with observation of target organ response. This type of testing is helpful in identifying clinically significant allergens in patients with a large number of positive tests. Major disadvantages of this type of testing are the limitation of one antigen per session and the risk of producing severe symptoms, particularly bronchospasm, in patients with asthma.

## RADIOALLERGOSORBENT TEST

RAST is a radioimmunoassay that measures allergen-specific IgE. A sample of the patient's serum is exposed to a variety of suspected allergen particle complexes. If antibodies are present, they will combine with radiolabeled allergens. After the serum is centrifuged, radioimmunoassay detects the allergen-specific IgE antibody. Test results are then compared with control values. In addition to detecting an allergen, RAST indicates the quantity of allergen necessary to evoke an allergic reaction. Values are reported on a scale from 0 to 5. Values of 2+ or greater are considered significant. The major advantages of RAST over other tests include decreased risk of systemic reaction, stability of antigens, and lack of dependence on skin reactivity modified by medica-

tions. The major disadvantages include the limited allergen selection, reduced sensitivity compared with intradermal skin tests, lack of immediate results, and cost.

## Allergic Disorders

There are two types of IgE-mediated allergic reactions: atopic and nonatopic disorders. While the underlying immunologic reactions of the two types of disorders are the same, predisposing factors and manifestations are different. The atopic disorders are characterized by a hereditary predisposition and production of a local reaction to IgE antibodies produced in response to common environmental allergens (Kay, 2001a). The nonatopic disorders lack the genetic component and organ specificity of the atopic disorders (Porth, 2002). Examples of atopic disorders are allergic rhinitis, allergic asthma, and atopic dermatitis (Kay, 2001a).

A type I hypersensitivity response results in atopic (allergic) diseases, which affect 10% to 20% of the U.S. population. Genetic factors play a role in susceptibility to these diseases. Disorders characterized as atopic include anaphylaxis, allergic rhinoconjunctivitis, atopic dermatitis, urticaria and angioedema, gastrointestinal allergy, and asthma. Latex allergy may be a type I or type IV hypersensitivity reaction, although true latex allergy is considered to be a type I hypersensitivity reaction (Brehler & Kütting, 2001). Latex allergy is discussed later in this chapter. Contact dermatitis is considered a type IV hypersensitivity reaction.

## ANAPHYLAXIS

Anaphylaxis is a clinical response to an immediate (type I hypersensitivity) immunologic reaction between a specific antigen and an antibody. The reaction results from IgE antibody. An anaphylactic reaction can be triggered by exposure to an antigen through inhalation, injection, ingestion, or skin contact. It is a severe, life-threatening allergic reaction. It is estimated that 3.3 to 43 million persons in the United States (1.24% to 16.8% of the

population) are at risk for anaphylaxis (Neugut, Ghatak & Miller, 2001).

## Pathophysiology

Anaphylaxis is caused by the interaction of a foreign antigen with specific IgE antibodies found on the surface membrane of mast cells and peripheral blood basophils. The subsequent release of histamine and other bioactive mediators causes activation of platelets, eosinophils, and neutrophils and the coagulation cascade. Smooth muscle spasm, bronchospasm, mucosal edema and inflammation, and increased capillary permeability result. These systemic changes characteristically produce clinical manifestations within seconds or minutes of antigen exposure (Neugut et al., 2001). Closely related to anaphylaxis is an anaphylactoid (anaphylaxis-like) reaction, which is described in Chart 53-2.

Substances that most commonly cause anaphylaxis include foods, medications, insect stings, and latex (Chart 53-3). Foods that are common causes of anaphylaxis include peanuts, tree nuts, shellfish, fish, milk, eggs, soy, and wheat. Many medications have been implicated in anaphylaxis. Those that are most frequently reported include antibiotics (including penicillin), radiocontrast agents, intravenous anesthetics, aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), and opioids. Antibiotics and radiocontrast agents cause the most serious anaphylactic reactions, producing reactions in about 1 of every 5,000 exposures. Penicillin is the most common cause of anaphylaxis and accounts for about 75% of fatal anaphylactic reactions in the U.S. each year (Neugut et al., 2001).

## Clinical Manifestations

Anaphylactic reactions may be categorized as mild, moderate, and severe systemic reactions. The time from exposure to the antigen to onset of symptoms is a good indicator of the severity of the reaction: the faster the onset, the more severe the reaction (Neugut et al., 2001).

Mild systemic reactions consist of peripheral tingling and a sensation of warmth, possibly accompanied by fullness in the mouth and throat. Nasal congestion, periorbital swelling, pruritus, sneezing, and tearing of the eyes can also be expected. Onset of symptoms begins within the first 2 hours of exposure.

Moderate systemic reactions may include flushing, warmth, anxiety, and itching in addition to any of the above symptoms.

Chart  
53-2

### Anaphylactoid (Anaphylaxis-Like) Reaction

Closely related to anaphylaxis is an anaphylactoid (anaphylaxis-like) reaction, caused by the release of mast cell and basophil mediators triggered by non-IgE-mediated events. An anaphylactoid reaction may occur with medications, food, exercise, and cytotoxic antibody transfusions. The reaction may be local or systemic. Local reactions usually involve urticaria and angioedema at the site of the antigen exposure. Although possibly severe, anaphylactoid reactions are rarely fatal. Systemic reactions occur within about 30 minutes of exposure involving cardiovascular, respiratory, gastrointestinal, and integumentary organ systems. For the most part, an anaphylactoid reaction and its treatment are identical to that of anaphylaxis (Neugut et al., 2001).

Chart  
53-3

### Common Causes of Anaphylaxis

#### Foods

Peanuts, tree nuts (walnuts, pecans, cashews, almonds, etc.), shellfish (shrimp, lobster, crab, etc.), fish, milk, eggs, soy, wheat

#### Medications

Antibiotics, especially penicillin and sulfa antibiotics, allopurinol, radiocontrast agents, anesthetic agents (lidocaine, procaine), vaccines, hormones (insulin, vasopressin, ACTH), aspirin, nonsteroidal anti-inflammatory drugs (NSAIDs)

#### Other Pharmaceutical/Biologic Agents

Animal serums (tetanus antitoxin, snake venom antitoxin, rabies antitoxin), antigens used in skin testing

#### Insect Stings

Bees, wasps, hornets, yellow jackets, ants, including fire ants

#### Latex

Medical and nonmedical products containing latex

More serious reactions include bronchospasm and edema of the airways or larynx with dyspnea, cough, and wheezing. The onset of symptoms is the same as for a mild reaction.

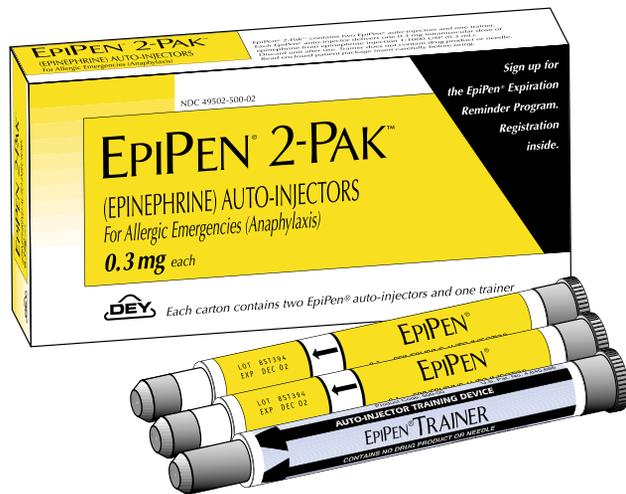

Severe systemic reactions have an abrupt onset with the same signs and symptoms described above. These progress rapidly to bronchospasm, laryngeal edema, severe dyspnea, cyanosis, and hypotension. Dysphagia (difficulty swallowing), abdominal cramping, vomiting, diarrhea, and seizures can also occur. Cardiac arrest and coma may follow.

## Prevention

Strict avoidance of potential allergens is an important preventive measure for the patient at risk for anaphylaxis (Neugut et al., 2001). Patients at risk for anaphylaxis from insect stings should avoid areas populated by insects and should use appropriate clothing, insect repellent, and caution to avoid further stings.

If avoidance of exposure to allergens is impossible, administration of epinephrine is a critical measure to prevent an anaphylactic reaction. People sensitive to insect bites and stings, those who have experienced food or medication reactions, and those who have experienced idiopathic or exercise-induced anaphylactic reactions should always carry an emergency kit that contains epinephrine. The EpiPen from Dey Pharmaceuticals is a commercially available first-aid device that delivers premeasured doses of 0.3 mg (EpiPen) and 0.15 mg (EpiPen Jr.) of epinephrine (Fig. 53-5). The autoinjection system requires no preparation, and the self-administration technique is uncomplicated. The patient must be given an opportunity to demonstrate the correct technique for use; an EpiPen training device is available. Verbal and written information about the emergency kit, as well as strategies to avoid exposure to threatening allergens, must also be provided.

Screening for allergies before a medication is prescribed or first administered is an important preventive measure. A careful history of any sensitivity to suspected antigens must be obtained before administering any medication, particularly in parenteral form, because this route is associated with the most severe anaphylaxis. Nurses caring for patients in any setting (hospital, home, outpatient diagnostic testing sites, long-term care facilities) must assess patients' risk for anaphylactic reactions. The patient is asked about previous exposure to contrast agents used for diag-

nostic tests and any allergic reactions, as well as reactions to any medications, foods, insect stings, and latex. Persons predisposed to anaphylaxis should wear some form of identification, such as a medical alert bracelet, naming allergies to medications, food, and other substances.

People who are allergic to insect venom may require venom immunotherapy, which is used as a control measure and not a cure. Immunotherapy following an insect sting is very effective in reducing the risk of anaphylaxis from future stings (Neugut et al., 2001). Insulin-allergic diabetic patients and penicillin-sensitive patients may require desensitization. Desensitization is based on controlled anaphylaxis, with a gradual release of mediators. Patients who undergo desensitization are cautioned that there should be no lapses in therapy, because this may lead to the reappearance of an allergic reaction when the medication is reinstated.

## Medical Management

Management depends on the severity of the reaction. Initially, respiratory and cardiovascular functions are evaluated. If the patient is in cardiac arrest, cardiopulmonary resuscitation is instituted. Oxygen is provided in high concentrations during cardiopulmonary resuscitation or when the patient is cyanotic, dyspneic, or wheezing. Epinephrine, in a 1 : 1,000 dilution, is administered subcutaneously in the upper extremity or thigh and may be followed by a continuous intravenous infusion. Antihistamines and corticosteroids may also be given to prevent recurrences of the reaction and to treat urticaria and angioedema. To maintain blood pressure and normal hemodynamic status, IV fluids (ie, normal saline solution), volume expanders, and vasopressor agents are given. In patients with episodes of bronchospasm or a history of bronchial asthma or chronic obstructive pulmonary disease, aminophylline and corticosteroids may also be administered to improve airway patency and function. If hypotension is unresponsive to vasopressors, intravenous glucagon may be given for its acute inotropic and chronotropic effects. Patients with severe reactions are observed closely for 12 to 14 hours. Because of the potential for recurrence, patients with even mild reactions must be educated concerning this risk.

## Nursing Management

If a patient is experiencing an allergic response, the nurse's initial action is to assess the patient for signs and symptoms of anaphylaxis. The nurse assesses the airway, breathing pattern, and other vital signs. The patient is observed for signs of increasing edema and respiratory distress. Prompt notification of the physician and preparation for initiation of emergency measures (intubation, administration of emergency medications, insertion of intravenous lines, fluid administration, oxygen administration) are important to reduce the severity of the reaction and to restore cardiovascular function. The nurse documents the interventions used and the patient's response to treatment, vital signs, and laboratory values.

The patient who has recovered from anaphylaxis needs an explanation of what occurred and instruction about avoiding future exposure to antigens and administering emergency medications to treat anaphylaxis. The patient must be instructed about antigens that should be avoided and about other strategies to prevent recurrence of anaphylaxis. All patients who have experienced an anaphylactic reaction should receive a prescription for preloaded syringes of epinephrine. The nurse instructs the patient and family in their use and has the patient and family demonstrate correct administration (Chart 53-4).

## ALLERGIC RHINITIS

Allergic **rhinitis** (inflammation of nasal mucosa; hay fever, chronic allergic rhinitis, pollinosis) is the most common form of respiratory allergy presumed to be mediated by an immediate (type I hypersensitivity) immunologic reaction. It affects about 8% to 10% of the U.S. population (20% to 30% of adolescents). The symptoms are similar to viral rhinitis but are usually more persistent and demonstrate seasonal variation (Tierney, McPhee & Papadakis, 2001). It often occurs with other conditions, such as allergic conjunctivitis, sinusitis, and asthma. Allergic rhinitis is associated with impaired work and school performance and decreased quality of life (Ratner, Ehrlich, Fineman et al., 2002). When untreated, many complications may result, such as allergic asthma, chronic nasal obstruction, chronic otitis media with hearing loss, anosmia (absence of the sense of smell), and, in children, orofacial dental deformities. Early diagnosis and adequate treatment are essential to reduce complications and relieve symptoms.

Because allergic rhinitis is induced by airborne pollens or molds, it is characterized by the following seasonal occurrences:

- Early spring—tree pollen (oak, elm, poplar)
- Early summer—rose pollen (rose fever), grass pollen (Timothy, red-top)
- Early fall—weed pollen (ragweed)

Each year, attacks begin and end at about the same time. Airborne mold spores require warm, damp weather. Although there is no rigid seasonal pattern, these spores appear in early spring, are rampant during the summer, and taper off and disappear by the first frost.

## Pathophysiology

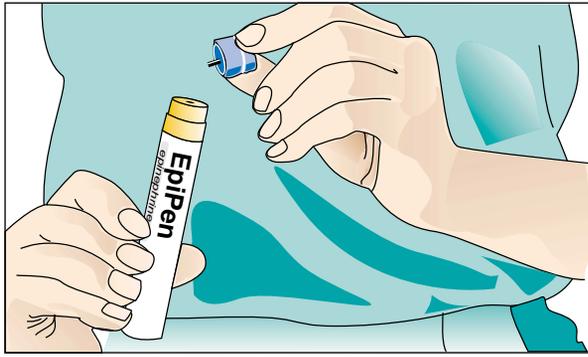

Sensitization begins by ingestion or inhalation of an antigen. On re-exposure, the nasal mucosa reacts by the slowing of ciliary action, edema formation, and leukocyte (primarily eosinophil) infiltration. Histamine is the major mediator of allergic reactions in the nasal mucosa. Tissue edema results from vasodilation and increased capillary permeability.

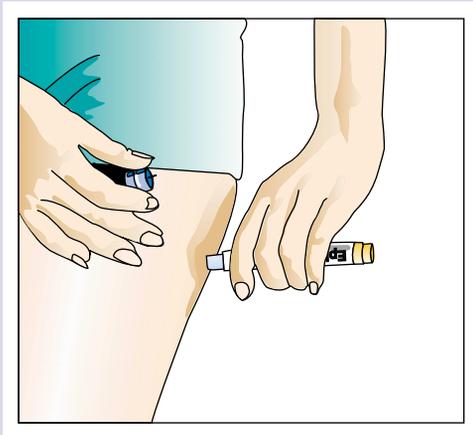

### Chart 53-4 • PATIENT EDUCATION Self-Administration of Epinephrine

The patient is taught how to inject epinephrine in the event of an anaphylactic reaction. The patient should be encouraged to practice this technique using a training device.

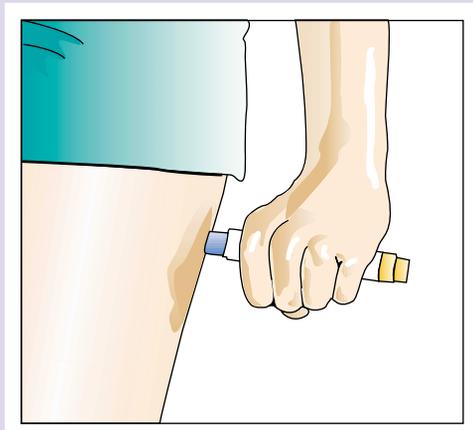

1. Carefully uncap the EpiPen device, holding it so that the injecting end is upright.

2. Position the device at the middle portion of the thigh.

3. Push the device into the thigh as far as possible. The EpiPen device will autoinject a premeasured dose of epinephrine into the subcutaneous tissue.

## Clinical Manifestations

Typical signs and symptoms of allergic rhinitis include nasal congestion; clear, watery nasal discharge; intermittent sneezing; and nasal itching. Itching of the throat and soft palate is common. Drainage of nasal mucus into the pharynx initiates multiple attempts to clear the throat and results in a dry cough or hoarseness. Headache, pain over the paranasal sinuses, and epistaxis can accompany allergic rhinitis. The symptoms of this chronic condition depend on environmental exposure and intrinsic host responsiveness. Allergic rhinitis may affect quality of life by also producing fatigue, loss of sleep, and poor concentration (Ratner et al., 2002).

## Assessment and Diagnostic Findings

Diagnosis of seasonal allergic rhinitis is based on history, physical examination, and diagnostic test results. Diagnostic tests include nasal smears, peripheral blood counts, total serum IgE, epicutaneous and intradermal testing, RAST, food elimination and challenge, and nasal provocation tests. Results indicative of allergy as the cause of rhinitis include increased IgE and eosinophil levels and positive reactions on allergen testing. False-positive and false-negative responses to these tests, particularly skin testing and provocation tests, may occur.

## Medical Management

The goal of therapy is to provide relief from symptoms. Therapy may include one or all of the following interventions: avoidance therapy, pharmacotherapy, and immunotherapy (Kay, 2001b). Verbal instructions must be reinforced by written information. Knowledge of general concepts regarding assessment and therapy in allergic diseases is important so that patients can learn to manage certain conditions as well as prevent severe reactions and illnesses.

### AVOIDANCE THERAPY

In avoidance therapy, every attempt is made to remove the allergens that act as precipitating factors. Simple measures and environmental controls are often effective in decreasing symptoms. Examples include use of air conditioners, air cleaners, humidifiers and dehumidifiers, and smoke-free environments. In many cases, it is impossible to avoid exposure to all environmental allergens, so pharmacologic therapy or immunotherapy is needed.

### PHARMACOLOGIC THERAPY

**Antihistamines.** Antihistamines, now classified as  $H_1$ -receptor antagonists (or  $H_1$ -blockers), are used in managing mild allergic disorders. ( $H_2$ -receptor antagonists are used to treat gastric and duodenal ulcers.)  $H_1$ -blockers bind selectively to  $H_1$  receptors, preventing the actions of histamines at these sites. They do not prevent the release of histamine from mast cells or basophils. The  $H_1$ -antagonists have no effect on  $H_2$ -receptors, but they do have the ability to bind to nonhistaminic receptors. The ability of certain antihistamines to bind to and block muscarinic receptors underlies several of the prominent anticholinergic side effects of these medications.

Oral antihistamines, which are readily absorbed, are most effective when given at the first occurrence of symptoms because they prevent the development of new symptoms by blocking the actions of histamine at the  $H_1$ -receptors. The effectiveness of these medications is limited to certain patients with hay fever, vasomotor rhinitis, **urticaria** (hives), and mild asthma. They are rarely effective in other conditions or in any severe conditions.

Antihistamines are the major class of medications prescribed for the symptomatic relief of allergic rhinitis. The major side effect is sedation, although histamine H<sub>1</sub> antagonists are less sedating than earlier antihistamines (Kay, 2001b). Additional side effects include nervousness, tremors, dizziness, dry mouth, palpitations, anorexia, nausea, and vomiting. Antihistamines are contraindicated during the third trimester of pregnancy; for nursing mothers and newborns; in children and elderly people; and in patients whose conditions can be aggravated by muscarinic blockade (ie, asthma, urinary retention, open-angle glaucoma, hypertension, and prostatic hyperplasia).

Newer antihistamines are called second-generation or non-sedating H<sub>1</sub>-receptor antagonists. Unlike first-generation H<sub>1</sub>-receptor antagonists, they do not cross the blood–brain barrier and do not bind to cholinergic, serotonin, or alpha-adrenergic receptors. They bind to peripheral rather than central nervous system H<sub>1</sub>-receptors, causing less sedation. Examples of these medications are loratadine (Claritin), cetirizine (Zyrtec), and fexofenadine (Allegra). These are summarized in Table 53-2.

**Adrenergic Agents.** Adrenergic agents, vasoconstrictors of mucosal vessels, are used topically (nasal and ophthalmic) in addition

to the oral route. The topical route (drops and sprays) causes fewer side effects than oral administration; however, the use of drops and sprays should be limited to a few days to avoid rebound congestion. Adrenergic nasal decongestants are used for the relief of nasal congestion when applied topically to the nasal mucosa. They activate the alpha-adrenergic receptor sites on the smooth muscle of the nasal mucosal blood vessels, reducing local blood flow, fluid exudation, and mucosal edema. Topical ophthalmic drops are used for symptomatic relief of eye irritations due to allergies. Potential side effects include hypertension, dysrhythmias, palpitations, central nervous system stimulation, irritability, tremor, and tachyphylaxis (acceleration of hemodynamic status). Examples of adrenergic decongestants and their routes of administration are found in Table 53-3.

**Mast Cell Stabilizers.** Intranasal cromolyn sodium (Nasal crom) is a spray that acts by stabilizing the mast cell membrane, thus reducing the release of histamine and other mediators of the allergic response. In addition, it inhibits macrophages, eosinophils, monocytes, and platelets involved in the immune response (Ratner et al., 2002). Cromolyn interrupts the physiologic response to nasal antigens and is used prophylactically before exposure to

**Table 53-2 • Chemical Classes of H<sub>1</sub> Antihistamines**

CLASSIFICATION AND EXAMPLE	MAJOR SIDE EFFECTS	NURSING IMPLICATIONS
<b>Sedating</b>		
Ethanolamines Ex: diphenhydramine (Benadryl)	Drowsiness, confusion  Dry mouth, nausea, vomiting	Teach patient to avoid alcohol, driving, or engaging in any hazardous activities until CNS response to drug treatment is stabilized. Suggest sucking on hard candy or ice chips for relief of dry mouth.
Piperazines Ex: hydroxyzine (Atarax)	Photosensitivity Urinary retention Dulls mental alertness; drowsiness	Encourage use of sunscreen and hat while outdoors. Assess for urinary retention; monitor urinary output. Teach patient to avoid alcohol, driving, or engaging in any hazardous activities until CNS response to drug treatment is stabilized.
Alkylamines Ex: chlorpheniramine (Chlor-Trimeton)	Dry mouth  Less CNS depression than other groups; best class for daytime use	Suggest sucking on hard candy or ice chips for relief of dry mouth.  Teach patient to avoid alcohol, driving, or engaging in any hazardous activities until CNS response to drug treatment is stabilized.
Ethylenediamines Ex: triproleamine (PBZ)	Gastrointestinal upset  Drowsiness	Administer medication with food or milk to decrease GI distress. Increase fluid intake. Teach patient to avoid alcohol, driving, or engaging in any hazardous activities until CNS response to drug treatment is stabilized.
Phenothiazines Ex: promethazine (Phenergan)	Palpitations  Heavy sedation and drowsiness	Instruct patient to sit and relax a few minutes before activity. Teach patient to avoid alcohol, driving, or engaging in any hazardous activities until CNS response to drug treatment is stabilized.
	Nasal congestion Hypotension	Encourage use of humidification at home. Instruct patient to rise from a sitting position slowly.
<b>Nonsedating</b>		
loratadine (Claritin)	Gastrointestinal upset	Counsel patient to take the medication on an empty stomach.
fexofenadine (Allegra)	Occasional drowsiness and fatigue	Teach patient to avoid alcohol, driving, or engaging in any hazardous activities until CNS response to drug treatment is stabilized.
cetirizine (Zyrtec)	Drowsiness, dry mouth	Teach patient to avoid alcohol, driving, or engaging in any hazardous activities until CNS response to drug treatment is stabilized.

**Table 53-3 • Adrenergic Decongestants and Their Routes of Administration**

ADRENERGIC DECONGESTANT	TRADE NAME	ROUTE OF ADMINISTRATION
naphazoline hydrochloride	Privine	Topical
oxymetazoline hydrochloride	Afrin, Dristan long-lasting, Neo-Synephrine 12 hour, Sinex long-lasting	Topical
phenylephrine hydrochloride	Neo-Synephrine	Topical
pseudoephedrine hydrochloride	Sudafed	Oral
tetrahydrozoline hydrochloride	Collyrium, Murine Plus, Visine	Topical ophthalmic and nasal preparations
xylometazoline hydrochloride	Neo-Synephrine II, Otrivin	Topical

allergens to prevent the onset of symptoms and to treat symptoms once they occur. It is also used therapeutically in chronic allergic rhinitis. This spray is as effective as antihistamines but less effective than intranasal corticosteroids in the treatment of seasonal allergic rhinitis. Patients must be informed that the beneficial effects of the medication may take a week or so to occur. The medication is of no benefit in the treatment of nonallergic rhinitis. Adverse effects (ie, sneezing, local stinging, and burning sensations) are usually mild.

**Corticosteroids.** Intranasal corticosteroids are indicated in more severe cases of allergic and perennial rhinitis that cannot be controlled by more conventional medications such as decongestants, antihistamines, and intranasal cromolyn. These medications include beclomethasone (Beconase, Vancenase), budesonide (Rhinocort), dexamethasone (Decadron Phosphate Turbinaire), flunisolide (Nasalide), fluticasone (Cutivate, Flonase), and triamcinolone (Nasacort).

Because of their anti-inflammatory actions, these medications are equally effective in preventing or suppressing the major symptoms of allergic rhinitis. Corticosteroids are administered by metered-spray devices. If the nasal passages are blocked, a topical decongestant can be used to clear the passages before the administration of the intranasal corticosteroid. Patients must be aware that full benefit may not be achieved for several days to 2 weeks. Adverse effects of intranasal corticosteroids are mild and include drying of the nasal mucosa and burning and itching sensations caused by the vehicle used to administer the medication. Systemic effects are more likely with dexamethasone. Recommended use of this medication is limited to 30 days. Beclomethasone, budesonide, flunisolide, fluticasone, and triamcinolone are deactivated rapidly after absorption, so they do not achieve significant blood levels. Corticosteroids suppress host defenses, so they must be used with caution in patients with tuberculosis or untreated bacterial infections of the lungs. Patients on corticosteroids are at risk for infection and for suppression of typical manifestations of inflammation because host defenses are compromised. Inhaled corticosteroids do not affect the immune system to the same degree as systemic corticosteroids (ie, oral corticosteroids). As corticosteroids are inhaled into the upper respiratory tract, tuberculosis or untreated bacterial infections of the lungs may become apparent and progress. Whenever possible, patients with tuberculosis and other bacterial infections of the lungs should avoid inhaled corticosteroids.

Oral and parenteral corticosteroids are used when conventional therapy has failed and symptoms are severe and of short duration. They can control symptoms of allergic reactions such as hay fever, medication-induced allergies, and allergic reactions to

insect stings. Because the response to corticosteroids is delayed, they have little or no value in acute therapy for severe reactions such as anaphylaxis. Patients who receive corticosteroids must be cautioned not to stop taking the medication suddenly or without specific instructions from the physician. The patient is also instructed about side effects, which include fluid retention, weight gain, hypertension, gastric irritation, glucose intolerance, and adrenal suppression. Further discussion of corticosteroids is provided in Chapter 42.

## IMMUNOTHERAPY

Allergen desensitization (allergen immunotherapy, hyposensitization) is primarily used to treat IgE-mediated diseases by injections of allergen extracts. This type of therapy provides an adjunct to symptomatic pharmacologic therapy and can be used when allergen avoidance is not possible (Parslow et al., 2001). Specific immunotherapy has been used in the treatment of allergic disorders for about 100 years. It consists of administering increasing concentrations of extracts of specific allergens over a long period (Kay, 2001b). Goals of immunotherapy include reducing the level of circulating IgE, increasing the level of blocking antibody IgG, and reducing mediator cell sensitivity. Immunotherapy has been most effective for ragweed pollen; however, treatment for grass, tree pollen, cat, and house dust mite allergens has also been effective.

Correlation of a positive skin test with a positive allergy history is an indication for immunotherapy if the allergen cannot be avoided. The value has been fairly well established in instances of allergic rhinitis and bronchial asthma that are clearly due to sensitivity to one of the common pollens, molds, and household dust. Although helpful in most patients, immunotherapy does not cure the condition. Before immunotherapy is initiated, the patient must understand what to expect and the importance of continuing therapy for several years. When skin tests are performed, the results are correlated with clinical manifestations; treatment is based on the patient's needs rather than on skin tests.

The most common method of treatment is the serial injection of one or more antigens that are selected in each particular case on the basis of skin tests. This method provides a simple and efficient technique for identifying IgE antibodies to specific antigens. Specific treatment consists of injecting extracts of the pollens or mold spores that cause symptoms in a particular patient. Injections begin with very small amounts and are gradually increased, usually at weekly intervals, until a maximum tolerated dose is attained. Maintenance booster injections are given at 2- to 4-week intervals, frequently for a period of several years, before maximum benefit is achieved.

There are three methods of injection therapy: coseasonal, pre-seasonal, and perennial. When treatment is given on a coseasonal basis, therapy is initiated during the season in which the patient experiences symptoms. This method has been proved ineffective and is used infrequently. Also, there is an increased risk of systemic reactions. Preseasonal therapy injections are given 2 to 3 months before symptoms are expected, allowing time for hypersensitization to occur. This treatment is discontinued after the season begins. Perennial therapy is administered all year round, usually on a monthly basis, and is the preferred method because it has more effective, longer-lasting results.

Any patient who receives specific immunotherapy is at risk for general, and potentially fatal, anaphylaxis. This occurs most frequently at the induction or “up-dosing” phase. Attempts have been made to minimize the risk of systemic reactions by pre-treating allergen extracts with agents such as formaldehyde. This approach decreases the binding of the allergen by IgE, but it also results in decreased immunogenicity (Kay, 2001b).

**NURSING ALERT** Because the injection of an allergen may induce systemic reactions, such injections are given only in a setting (ie, physician’s office, clinic) where epinephrine is immediately available.

Because of the risk for anaphylaxis, injections should not be given by a lay person or by the patient. The patient remains in the office or clinic for at least 30 minutes after the injection and is observed for possible systemic symptoms. If a large, local swelling develops at the injection site, the next dose should not be increased, because this may be a warning sign of a possible systemic reaction.

Therapeutic failure is evident when a patient does not experience a decrease of symptoms within 12 to 24 months, fails to develop increased tolerance to known allergens, and cannot decrease the use of medications to reduce symptoms. Potential causes of treatment failure include misdiagnosis of allergies, inadequate doses of allergen, newly developed allergies, and inadequate environmental controls.

## NURSING PROCESS: THE PATIENT WITH ALLERGIC RHINITIS

### Assessment

The examination and history of the patient reveal sneezing, often in paroxysms, thin and watery nasal discharge, itching eyes and nose, lacrimation, and occasionally headache. The health history includes a personal or family history of allergy. The allergy assessment identifies the nature of antigens, seasonal changes in symptoms, and medication history. The nurse also obtains subjective data about how the patient feels just before symptoms become obvious, such as the occurrence of pruritus, breathing problems, and tingling sensations. In addition to these symptoms, hoarseness, wheezing, hives, rash, erythema, and edema are noted. Any relationship between emotional problems or stress and the triggering of allergy symptoms is assessed.

### Diagnosis

#### NURSING DIAGNOSES

Based on the assessment data, the patient’s major nursing diagnoses may include the following:

- Ineffective breathing pattern related to allergic reaction

- Deficient knowledge about allergy and the recommended modifications in lifestyle and self-care practices
- Ineffective individual coping with chronicity of condition and need for environmental modifications

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on assessment data, potential complications may include the following:

- Anaphylaxis
- Impaired breathing
- Nonadherence to the therapeutic regimen

### Planning and Goals

The goals for the patient may include restoration of normal breathing pattern, increased knowledge about the causes and control of allergic symptoms, improved coping with alterations and modifications, and absence of complications.

### Nursing Interventions

#### IMPROVING BREATHING PATTERN

The patient is instructed and assisted to modify the environment to reduce the severity of allergic symptoms or to prevent their occurrence. The patient is instructed to reduce exposure to people with upper respiratory infections (URIs). If a URI occurs, the patient is encouraged to take deep breaths and cough frequently to ensure adequate gas exchange and prevent atelectasis. The patient is instructed to seek medical attention because allergy symptoms along with a URI may compromise adequate lung function. Compliance with medications and other treatment regimens is encouraged and reinforced.

#### PROMOTING UNDERSTANDING OF ALLERGY AND ALLERGY CONTROL

Instruction includes strategies to minimize exposure to allergens, desensitization procedures, and correct use of medications. The nurse informs and reminds the patient of the importance of keeping appointments for desensitization procedures because usually dosages are adjusted on a weekly basis, and missed appointments may interfere with the dosage adjustment.

Patients also need to understand that medications for allergy control should be used only when the allergy is apparent. This is usually on a seasonal basis. Continued use of medications when not required may cause an increased tolerance to the medication, with the result that the medication is not effective when needed.

#### COPING WITH A CHRONIC DISORDER

Although allergic reactions are infrequently life-threatening, they require constant vigilance to avoid allergens and modification of the lifestyle or environment to prevent recurrence of symptoms. Allergic symptoms are often present year-round and create discomfort and inconvenience for the patient. Although patients may not feel ill during allergy seasons, they often do not feel well either. The need to be alert for possible allergens in the environment may be tiresome, placing a burden on the patient’s ability to lead a normal life. Stress related to these difficulties may in turn increase the frequency or severity of symptoms.

To assist the patient in adjusting to these modifications, the nurse must have an appreciation of the difficulties encountered

by the patient. The patient is encouraged to verbalize feelings and concerns in a supportive environment and to identify strategies to deal with them effectively.

## MONITORING AND MANAGING POTENTIAL COMPLICATIONS

### Anaphylaxis and Impaired Breathing

Respiratory and cardiovascular functioning can be significantly altered during allergic reactions by the reaction itself or by the medications used to treat reactions. The respiratory status is evaluated by monitoring the respiratory rate and pattern and by assessing for breathing difficulties or abnormal lung sounds. The pulse rate and rhythm and blood pressure are monitored to assess cardiovascular status regularly or any time the patient reports symptoms such as itching or difficulty breathing. In the event of signs and symptoms suggestive of anaphylaxis, emergency medications and equipment must be available for immediate use.

### Nonadherence to Therapeutic Regimen

Knowing about the treatment regimen does not ensure adherence. Having the patient identify potential barriers and explore acceptable solutions for effective management of the condition (eg, installing tile floors rather than carpet, not gardening in the spring) can increase adherence to the treatment regimen.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

The patient is instructed about strategies to minimize exposure to allergens, the actions and adverse effects of medications, and the correct use of medications. The patient should know the names, dose, frequency, actions, and side effects of all medications taken.

Instruction about strategies to control allergic symptoms is based on the needs of the patient as determined by the results of tests, the severity of symptoms, and the motivation of the patient and family to deal with the condition. Suggestions for patients sensitive to dust and mold in the home are given in Chart 53-5.

If the patient is to undergo immunotherapy, the nurse reinforces the physician's explanation regarding the purpose and procedure. Instructions are given regarding the series of injections, usually given initially every week and then at 2- to 4-week intervals. These instructions include remaining in the physician's office or the clinic at least 30 minutes after the injection so that emergency treatment may be given if the patient has a reaction; avoiding rubbing or scratching the injection site; and continuing with the series for the period of time required. In addition, the patient and family are instructed about emergency treatment of severe allergic symptoms.

Because antihistamines often produce drowsiness, the patient is cautioned about this and other side effects of the particular medication. Operating machinery, driving a car, and performing activities requiring intense concentration should be postponed. The patient is also informed about the dangers of drinking alcohol when taking these medications because they tend to exaggerate the effects of alcohol.

The patient must be aware of the effects caused by overuse of the sympathomimetic agents in nose drops or sprays. A condition referred to as rhinitis medicamentosa may result (Fig. 53-6). After topical application of the medication, a rebound period may occur in which the nasal mucous membranes become more edematous and congested than they were before the medication was used. Such a reaction encourages the use of more medication, and a cyclical pattern results. The topical agent must be discontinued immediately and completely to correct this problem.

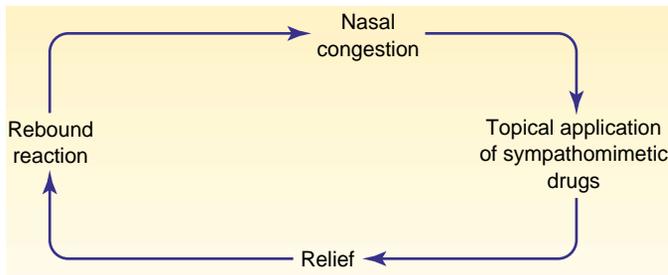

Chart 53-5

### Home Care Checklist • Allergy Management

At the completion of home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Verbalize how to maintain a dust-free environment by removing drapes, curtains, and venetian blinds and replacing them with pull shades; covering the mattress with a hypoallergenic cover that can be zipped; and removing rugs and replacing them with wood flooring or linoleum.	✓	✓
• Identify rationale for washing the floor and dusting and vacuuming daily.	✓	✓
• Identify rationale for replacing stuffed furniture with wood pieces that can easily be dusted.	✓	✓
• State rationale for wearing a mask whenever cleaning is being done.	✓	✓
• Identify rationale for avoiding use of tufted bedspreads, stuffed toys, and feather pillows and replacing them with washable cotton material.	✓	✓
• State rationale for avoiding the use of any clothing that causes itching.	✓	✓
• Verbalize ways to reduce dust in the house as a whole by using steam or hot water for heating rather than air and using air filters or air conditioning.	✓	✓
• Verbalize ways to reduce exposure to pollens or molds by identifying seasons of the year when pollen counts are high; wearing a mask at times of increased exposure (windy days and when grass is being cut); and avoiding contact with weeds, dry leaves, and freshly cut grass.	✓	✓
• State rationale for seeking air-conditioned areas at the height of the allergy season.	✓	✓
• State rationale for avoiding sprays and perfumes.	✓	✓
• State rationale for use of hypoallergenic cosmetics.	✓	✓
• State rationale for taking prescribed medications as ordered.	✓	✓
• Identify specific foods that may cause allergic symptoms. (Examples of foods that can cause allergic reactions are fish, nuts, eggs, and chocolate.)	✓	✓
• Develop a list of foods to avoid.	✓	✓

**FIGURE 53-6** Rhinitis medicamentosa. This cyclic pattern results from overuse of sympathomimetic nose drops or sprays.

### Continuing Care

Follow-up telephone calls to the patient are often reassuring to the patient and family and provide an opportunity for the nurse to answer any questions. The patient is reminded to keep follow-up appointments and is informed about the importance of continuing with treatment. The importance of participating in health promotion activities and health screening is emphasized to the patient.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Exhibits normal breathing patterns
  - a. Demonstrates lungs clear on auscultation
  - b. Exhibits absence of adventitious breath sounds (crackles, rhonchi, wheezing)
  - c. Has a normal respiratory rate and pattern
  - d. Reports no complaints of respiratory distress (shortness of breath, difficulty on inspiration or expiration)
2. Demonstrates knowledge about allergy and strategies to control symptoms
  - a. Identifies causative allergens, if known
  - b. States methods of avoiding allergens and controlling indoor and outdoor precipitating factors
  - c. Removes from the environment items that retain dust
  - d. Wears a dampened mask if dust or mold may be a problem
  - e. Avoids smoke-filled rooms and dust-filled or freshly sprayed areas
  - f. Uses air conditioning for a major part of the day
  - g. Takes antihistamines as prescribed; participates in hypo-sensitization program, if applicable
  - h. Describes name, purpose, side effects, and method of administration of prescribed medications
  - i. Identifies when to seek immediate medical attention for severe allergic responses
  - j. Describes activities that are possible, including ways to participate in activities without activating the allergies
3. Experiences relief of discomfort while adapting to the inconveniences of an allergy
  - a. Relates the emotional aspects of the allergic response
  - b. Demonstrates use of measures to cope positively with allergy
4. Absence of complications
  - a. Exhibits vital signs within normal limits

- b. Reports no symptoms or episodes of anaphylaxis (urticaria, itching, peripheral tingling, fullness in the mouth and throat, flushing, or difficulty swallowing) or coughing, wheezing, or difficulty breathing
- c. Demonstrates correct procedure to self-administer emergency medications to treat severe allergic reaction
- d. Correctly states medication names, dose and frequency of administration, and medication actions
- e. Correctly identifies side effects and untoward signs and symptoms to report to physician
- f. Discusses acceptable lifestyle changes and solutions for identified potential barriers for compliance with treatment and medication regimen

### CONTACT DERMATITIS

Contact dermatitis (dermatitis venenata), a type IV delayed hypersensitivity reaction, is an acute or chronic skin inflammation that results from direct skin contact with chemicals or allergens. There are four basic types: allergic, irritant, phototoxic, and photoallergic (Table 53-4). Eighty percent of cases are due to excessive exposure to or additive effects of irritants (eg, soaps, detergents, organic solvents) (Tierney et al., 2001). Skin sensitivity may develop after brief or prolonged periods of exposure, and the clinical picture may appear hours or weeks after the sensitized skin has been exposed.

#### Clinical Manifestations

Symptoms include itching, burning, erythema, skin lesions (vesicles), and edema, followed by weeping, crusting, and finally drying and peeling of the skin. In severe responses, hemorrhagic bullae may develop. Repeated reactions may be accompanied by thickening of the skin and pigmentary changes. Secondary invasion by bacteria may develop in skin abraded by rubbing or scratching. Usually, there are no systemic symptoms unless the eruption is widespread.

#### Assessment and Diagnostic Findings

The location of the skin eruption and the history of exposure aid in determining the condition. In cases of obscure irritants or an unobservant patient, however, diagnosis may be extremely difficult, often involving many trial-and-error procedures before the cause is determined. Patch tests on the skin with suspected offending agents may clarify the diagnosis.

### ATOPIC DERMATITIS

**Atopic dermatitis** is a type I immediate hypersensitivity disorder. A family history is common. The incidence of atopic dermatitis is highest in infants and children. Atopic dermatitis (eczema) affects 10% to 20% of children in Western populations (Kay, 2001b). Most patients have significant elevations of serum IgE and peripheral eosinophilia. Pruritus and hyperirritability of the skin are the most consistent features of atopic dermatitis and are related to large amounts of histamine in the skin. Excessive dryness of the skin with resultant itching is related to changes in lipid content, sebaceous gland activity, and sweating. In response to stroking of the skin, immediate redness appears on the skin and is followed in 15 to 30 seconds by pallor, which persists for

**Table 53-4 • Types, Testing, and Treatment of Contact Dermatitis**

TYPE	ETIOLOGY	CLINICAL PRESENTATION	DIAGNOSTIC TESTING	TREATMENT
Allergic	Results from contact of skin and allergenic substance. Has a sensitization period of 10–14 days.	Vasodilation and perivascular infiltrates on the dermis Intracellular edema Usually seen on dorsal aspects of hand	Patch testing (contraindicated in acute, widespread dermatitis)	Avoidance of offending material Burow's solution or cool water compress Systemic corticosteroids (prednisone) for 7–10 days Topical corticosteroids for mild cases Oral antihistamines to relieve pruritus
Irritant	Results from contact with a substance that chemically or physically damages the skin on a nonimmunologic basis. Occurs after first exposure to irritant or repeated exposures to milder irritants over an extended time.	Dryness lasting days to months Vesiculation, fissures, cracks Hands and lower arms most common areas	Clinical picture Appropriate negative patch tests	Identification and removal of source of irritation Application of hydrophilic cream or petrolatum to soothe and protect Topical corticosteroids and compresses for weeping lesions Antibiotics for infection and oral antihistamines for pruritus
Phototoxic	Resembles the irritant type but requires sun and a chemical in combination to damage the epidermis.	Similar to irritant dermatitis	Photopatch test	Same as for allergic and irritant dermatitis
Photoallergic	Resembles allergic dermatitis but requires light exposure in addition to allergen contact to produce immunologic reactivity.	Similar to allergic dermatitis	Photopatch test	Same as for allergic and irritant dermatitis

1 to 3 minutes. Lesions develop secondary to the trauma of scratching and appear in areas of increased sweating and hypervascularity. Atopic dermatitis is chronic, with remissions and exacerbations. This condition has a tendency to recur, with remission from adolescence to age 20 (Tierney et al., 2001). Treatment must be individualized.

### Medical Management

Guidelines for treatment include decreasing itching and scratching by wearing cotton fabrics, washing with a mild detergent, humidifying dry heat in winter, maintaining room temperature at 20°C to 22.2°C (68°F to 72°F), using antihistamines such as diphenhydramine (Benadryl), and avoiding animals, dust, sprays, and perfumes. Keeping the skin moisturized with daily baths to hydrate the skin and topical skin moisturizers is encouraged. Topical corticosteroids are used to prevent inflammation, and any infection is treated with antibiotics to eliminate *Staphylococcus aureus* when indicated. Use of low doses of cyclosporine (Neoral, Sandimmune), an immunosuppressive agent, may be effective (Kay, 2001b).

### Nursing Management

Patients who experience atopic dermatitis and their families require assistance and support from the nurse to cope with the disorder. The symptoms are often disturbing to the patient and

disruptive to the family. The appearance of the skin may affect the patient's self-esteem and may affect the patient's willingness to interact with others. Instructions and counseling about strategies to incorporate preventive measures and treatments into the lifestyle of the family may be helpful.

Patients and family members need to be aware of signs of secondary infection and of the need to seek treatment if infection occurs. The nurse also teaches the patient and family about the side effects of medications used in treatment.

### DERMATITIS MEDICAMENTOSA (DRUG REACTIONS)

Dermatitis medicamentosa, a type I hypersensitivity disorder, is the term applied to skin rashes induced by the internal administration of certain medications. Although individuals react differently to each medication, certain medications tend to induce eruptions of similar types. Rashes are among the most common adverse reactions to medications and occur in approximately 2% to 3% of hospitalized patients (Tierney et al., 2001).

In general, drug reactions appear suddenly, have a particularly vivid color, present with characteristics that are more intense than the somewhat similar eruptions of infectious origin, and, with the exception of bromide and the iodide rashes, disappear rapidly after the medication is withdrawn. Rashes may be accompanied by systemic or generalized symptoms. Upon discovery of a medication allergy, patients are warned that they have a hypersensi-

tivity to a particular medication and are advised not to take it again. Information identifying the hypersensitivity should be carried with them at all times.

Skin eruptions related to medication therapy suggest more serious hypersensitivities. Frequent assessment and prompt reporting of the appearance of any eruptions are important so that early treatment can be initiated. Some cutaneous drug reactions may be associated with a clinical complex that involves other organs. These are known as complex drug reactions (Tierney et al., 2001).

## URTICARIA AND ANGIONEUROTIC EDEMA

Urticaria (hives) is a type I hypersensitive allergic reaction of the skin characterized by the sudden appearance of pinkish, edematous elevations that vary in size and shape and itch and cause local discomfort. They may involve any part of the body, including the mucous membranes (especially those of the mouth), the larynx (occasionally with serious respiratory complications), and the gastrointestinal tract.

Each hive remains for a few minutes to several hours before disappearing. For hours or days, clusters of these lesions may come, go, and return episodically. If this sequence continues for longer than 6 weeks, the condition is called chronic urticaria (Tierney et al., 2001).

**Angioneurotic edema** involves the deeper layers of the skin, resulting in more diffuse swelling rather than the discrete lesions characteristic of hives. On occasion, this reaction covers the entire back. The skin over the reaction may appear normal but often has a reddish hue. The skin does not pit on pressure, as ordinary edema does. The regions most often involved are the lips, eyelids, cheeks, hands, feet, genitalia, and tongue; the mucous membranes of the larynx, the bronchi, and the gastrointestinal canal may also be affected, particularly in the hereditary type (see section that follows). Swellings may appear suddenly, in a few seconds or minutes, or slowly, in 1 or 2 hours. In the latter case, their appearance is often preceded by itching or burning sensations. Seldom does more than a single swelling appear at one time, although one may develop while another is disappearing. Infrequently, swelling recurs in the same region. Individual lesions usually last 24 to 36 hours. On rare occasions, swelling may recur with remarkable regularity at intervals of 3 to 4 weeks.

## HEREDITARY ANGIOEDEMA

Hereditary angioedema, although not an immunologic disorder in the usual sense, is included because of its resemblance to allergic angioedema and because of the seriousness of the condition. Symptoms are due to edema of the skin, the respiratory tract, or the digestive tract. Attacks may be precipitated by trauma or may seem to occur spontaneously.

### Clinical Manifestations

When skin is involved, the swelling is usually diffuse, does not itch, and is usually not accompanied by urticaria. Gastrointestinal edema may cause abdominal pain severe enough to suggest the need for surgery. Typically, attacks last 1 to 4 days and are gener-

ally harmless. Occasionally, attacks affect the subcutaneous and submucosal tissues in the region of the upper airway and can be associated with respiratory obstruction and asphyxiation. This disorder is inherited as an autosomal dominant trait. Approximately 85% of patients with this disorder have one nonproductive gene; the other 15% have a gene mutation (Parslow et al., 2001).

### Medical Management

Attacks usually subside within 3 to 4 days, but during this time the patient should be observed carefully for signs of laryngeal obstruction, which may necessitate tracheostomy as a life-saving measure. Epinephrine, antihistamines, and corticosteroids are usually used in treatment, but their success is limited.

## FOOD ALLERGY

IgE-mediated food allergy, a type I hypersensitivity reaction, occurs in 0.1% to 7.0% of the population. Almost any food can cause allergic symptoms. Any food can contain an allergen that results in anaphylaxis. The most common offenders are seafood (lobster, shrimp, crab, clams, fish), legumes (peanuts, tree nuts, peas, beans, licorice), seeds (sesame, cottonseed, caraway, mustard, flaxseed, and sunflower seeds), nuts, berries, egg white, buckwheat, milk, and chocolate (Parslow et al., 2001). Peanut and tree nut (ie, cashew, walnut) allergies are responsible for most severe food allergy reactions (Sicherer, Munoz-Furlong, Burks et al., 1999).

One of the dangers of food allergens is that they may be hidden in other foods and not apparent to those susceptible to the allergen. For example, peanuts and peanut butter are often used in salad dressings and Asian, African, and Mexican cooking and may result in severe allergic reactions, including anaphylaxis. Previous contamination of equipment with allergens (ie, peanuts) during preparation of another food product (ie, chocolate cake) is enough to produce anaphylaxis in those with severe allergy.

### Clinical Manifestations

Clinical symptoms are classic allergic symptoms (urticaria, atopic dermatitis, wheezing, cough, laryngeal edema, angioedema) and gastrointestinal symptoms (itching; swelling of lips, tongue, and palate; abdominal pain; nausea; cramps; vomiting; and diarrhea).

### Assessment and Diagnostic Findings

A careful diagnostic workup is required in any patient with a suspected food hypersensitivity. Included are a detailed allergy history, a physical examination, and pertinent diagnostic tests. When testing for allergy, skin testing is used to identify the source of symptoms and is useful in identifying specific foods as causative agents.

### Medical Management

Therapy for food hypersensitivity includes elimination of the food responsible for the hypersensitivity (Chart 53-6). Pharmacologic therapy is necessary in patients who cannot avoid exposure to offending foods or patients with multiple food sensitivities not responsive to elimination measures. Medication therapy involves the use of H<sub>1</sub>- and H<sub>2</sub>-blockers, antihistamines, adrenergic agents, corticosteroids, and cromolyn sodium.

Chart 53-6

## Home Care Checklist • Managing Food Allergies

At the completion of home care instruction, the patient or caregiver will be able to:

- Verbalize understanding of the need to maintain an allergen-free diet.
- Demonstrate reading of food labels to identify hidden allergens in food.
- Identify ways to manage an allergen-free diet when eating away from home.
- State the need to wear a medical alert medallion or bracelet.
- List symptoms of food allergy.
- Demonstrate emergency administration of epinephrine.
- State the importance of prompt treatment and health care follow-up.

	Patient	Caregiver
• Verbalize understanding of the need to maintain an allergen-free diet.	✓	✓
• Demonstrate reading of food labels to identify hidden allergens in food.	✓	✓
• Identify ways to manage an allergen-free diet when eating away from home.	✓	✓
• State the need to wear a medical alert medallion or bracelet.	✓	✓
• List symptoms of food allergy.	✓	✓
• Demonstrate emergency administration of epinephrine.	✓	✓
• State the importance of prompt treatment and health care follow-up.	✓	✓

Many food allergies disappear with time, particularly in children. About one third of proven allergies disappear in 1 to 2 years if the patient carefully avoids the offending food.

### Nursing Management

In addition to participating in management of the allergic reaction, the nurse focuses on preventing future exposure of the patient to the food allergen. If a severe allergic or anaphylactic reaction to food allergens has occurred, the nurse must instruct the patient and family about strategies to prevent its recurrence. The patient is instructed about the importance of carefully assessing food prepared by others for obvious as well as hidden sources of food allergens and of avoiding locations and facilities where those allergens are likely to be present. The patient and family must be knowledgeable about early signs and symptoms of allergic reactions and must be proficient in emergency administration of epinephrine if a reaction occurs. The nurse also advises the patient to wear a medical alert bracelet or to carry identification and emergency equipment at all times.

### SERUM SICKNESS

The illness known as serum sickness is an example of an immune complex type III hypersensitivity. It has traditionally resulted from the administration of therapeutic antisera of animal sources for the treatment or prevention of infectious diseases, such as tetanus, pneumonia, rabies, diphtheria, botulism, and venomous snake and black widow spider bites. With the advent of human antitetanus serum and antibiotics, classic serum sickness is much less common now. However, various medications (primarily penicillin) may cause a serum sickness-like reaction similar to that caused by foreign sera.

### Clinical Manifestations

Symptoms are due to a reaction and immunologic attack on the serum or medication. Antibodies appear to be of the IgE and IgM classes. Early manifestations, beginning 6 to 10 days after the administration of the medication, include an inflammatory reaction at the site of injection of the medication, followed by regional and generalized lymphadenopathy. There is usually a skin rash, which may be urticarial or purpuric. Joints are frequently tender and swollen. Vasculitis may occur in any organ but is most commonly observed in the kidney, resulting in proteinuria and, occasionally, casts in the urine. There may be mild to severe cardiac involvement. Peripheral neuritis may cause temporary paralysis of the upper extremities or may be widespread, causing Guillain-Barré syndrome.

### Medical Management

The usual course lasts for several days to a few weeks if untreated, but the patient responds promptly and completely if treated with antihistamines and corticosteroids. Aggressive therapy, including ventilator support, may be necessary if peripheral neuritis and Guillain-Barré syndrome occur.

### Nursing Management

See Chapter 64 for nursing management of Guillain-Barré syndrome.

### LATEX ALLERGY

Latex allergy, the allergic reaction to natural rubber proteins, has been implicated in rhinitis, conjunctivitis, contact dermatitis, urticaria, asthma, and anaphylaxis. Latex allergy and hypersensitivity were first reported in 1927 (Parslow et al., 2001). Although the prevalence of latex allergy is unknown, since 1989 the number of cases of latex allergy has steadily increased (Parslow et al., 2001). This increase may be due to the widespread use of latex gloves with implementation of universal and now standard precautions in response to the AIDS epidemic, changes in the manufacturing of gloves to speed the process to meet the increased demand for gloves, and greater awareness about latex allergy and its signs and symptoms.

Natural rubber latex is derived from the sap of the rubber tree (*Hevea brasiliensis*). The conversion of the liquid rubber latex into a finished product entails the addition of more than 200 chemicals. The proteins in the natural rubber latex (Hevea proteins) or the various chemicals that are used in the manufacturing process are thought to be the source of the allergic reactions. Not all objects composed of latex have the same ability to stimulate an allergic response. For example, the antigenicity of latex gloves can differ widely depending on their manufacturing method.

Populations at risk include health care workers, patients with atopic allergies or multiple surgeries, people working in factories manufacturing latex products, females, and patients with spina bifida. Because more food handlers, hairdressers, auto mechanics, and police are now wearing latex gloves, they may also be at risk for latex allergy. It is estimated that 1% to 3% of the general population has an allergy to latex and that 10% to 17% of health care workers are sensitized. Patients are at risk for anaphylactic reactions due to contact with latex during medical treatments, especially surgical procedures. About 19% of anaphylactic reactions associated with anesthesia are caused by allergy to latex (Brehler & Kütting, 2001).

Food that has been handled by individuals wearing latex gloves may stimulate an allergic response. Cross-reactions have been reported in people who are allergic to certain food products, such as kiwis, bananas, pineapples, passion fruits, avocados, and chestnuts.

Routes of exposure to latex products can be cutaneous, percutaneous, mucosal, parenteral, and aerosol. The most frequent source of exposure is cutaneous, which usually involves the wearing of natural latex gloves. The powder used to facilitate putting on latex gloves can become a carrier of latex proteins from the gloves; when the gloves are put on or removed, the particles become airborne and can be inhaled or can settle on skin, mucous membranes, or clothing. Mucosal exposure can occur from the use of latex condoms, catheters, airways, and nipples. Parenteral exposure can occur from intravenous lines or hemodialysis equipment. In addition to latex-derived medical devices, many household items also contain latex. Examples of medical and household items containing latex and a list of alternative products are found in Table 53-5. It is estimated that over 40,000 medical devices and nonmedical products contain latex (Brehler & Kütting, 2001).

## Clinical Manifestations

Several different types of reactions to latex are possible. Irritant contact dermatitis, a nonimmunologic response, may be due to mechanical skin irritation or an alkaline pH associated with latex gloves. Common symptoms of irritant dermatitis include erythema and pruritus. These symptoms can be eliminated by changing glove brands or using powder-free gloves. Use of hand lotion before donning latex gloves may worsen the symptoms because lotions may leach latex proteins from the gloves, increasing skin exposure and the risk of developing true allergic reactions (Burt, 1998).

Delayed hypersensitivity to latex, a type IV allergic reaction mediated by T cells in the immune system, is localized to the area of exposure and is characterized by symptoms of contact dermatitis, including vesicular skin lesions, papules, pruritus, edema, erythema, and crusting and thickening of the skin. These symptoms usually appear on the back of the hands. This reaction is thought to be due to chemicals that are used for manufacturing latex products. It is the most common allergic reaction to latex. Although not usually life-threatening, delayed hypersensitivity

**Table 53-5 • Selected Products Containing Natural Rubber Latex and Latex-Free Alternatives**

PRODUCTS CONTAINING LATEX	EXAMPLES OF LATEX-SAFE ALTERNATIVES*
<b>Hospital Environment</b>	
Ace bandage (brown)	Ace bandage, white all cotton
Adhesive bandages, Band-Aid dressing, Telfa	Cotton pads and plastic or silk tape, Active Strip (3M), Duoderm
Anesthesia equipment	Neoprene anesthesia kit (King)
Blood pressure cuff, tubing, and bladder	Clean Cuff, single-use nylon or vinyl blood pressure cuffs or wrap with stockinette or apply over clothing
Catheters	All-silicone or vinyl catheters
Catheter leg bag straps	Velcro straps
Crutch axillary pads and hand grips, tips	Cover with cloth, tape
ECG pads	Baxter, Red Dot 3M ECG pads
Elastic compression stockings	Kendall SCD stockings with stockinette
Gloves	Dermaprene, Neoprene, polymer, or vinyl gloves
IV catheters	Jelco, Deseret IV catheters
IV rubber injection ports	Cover Y-sites and ports; do not puncture. Use three-way stopcocks on plastic tubing.
Levin tube	Salem sump tube
Medication vials	Remove rubber stopper.
Penrose drains	Jackson-Pratt, Zimmer hemovac drains
Prepackaged enema kits	Theravac, Fleet Ready-to-use
Pulse oximeters	Nonin oximeters
Resuscitation bags	Laerdal, Puritan Bennett, <i>certain</i> Ambu
Stethoscope tubing	PVC tubing; cover with latex-free stockinette
Syringes—single use (Monoject, B & D)	Terumo syringes, Abbott PCA Abboject
Suction tubing	PVC (Davol, Laerdal)
Tapes	Dermicel, Micropore
Thermometer probes	Diatec probe covers
Tourniquets	X-Tourn straps (Avcor)
Theraband	New Thera-band Exercisers, plastic tubing
<b>Home Environment</b>	
Balloons	Mylar balloons
Diapers, incontinence pads	Huggies, Always, <i>some</i> Attends
Condoms, diaphragms	Polyurethane products, Durex/Avanti and Reality products (female condom)
Feminine hygiene pad	Kimberly-Clark products
Wheelchair cushions	ROHO cushions, Sof Care bed/chair cushions

\*Confirmation is essential to verify that all items are latex-free before using, especially if risk of latex allergy.

### NURSING RESEARCH PROFILE 53-1

#### Barrier Effectiveness of Latex and Non-latex Gloves

Korniewicz, D., el-Masri, M., Broyles, J. M., Martin, C. D., & O'Connell, K. P. (2002). Performance of latex and nonlatex medical examination gloves during simulated use. *American Journal of Infection Control, 30*(2), 133–138.

#### Purpose

In recent years, a variety of non-latex gloves have been used in health care in response to the increasing incidence of allergic reactions to latex, which has occurred with the increased use of gloves to protect health care personnel from exposure to body fluids. However, little research data about the barrier quality of these new synthetic gloves are available. The purpose of this study was to examine the effects of glove stress, type of material, and manufacturer on the barrier effectiveness of medical examination gloves.

#### Study Design and Sample

The sample consisted of 5,510 medical examination gloves: 1,464 nitrile, 1,052 latex, 1,006 copolymer, and 1,988 vinyl gloves. Eleven brands of gloves from five manufacturers were tested for barrier effectiveness. The gloves were divided into two groups: stressed and unstressed. Unstressed gloves were tested by the FDA 1989 water-leak test in which the gloves were filled with 1,000 mL of water, hung for 2 minutes, and observed for leaks. The gloves were rated as ineffective barriers if a water leak was detected. The remaining gloves were subjected to a laboratory and clinical stress protocol that mimics the stresses on gloves that occur during clinical use. Visible water leaks or leakage on the FDA water-leak test indicated barrier ineffectiveness. Chi-square analyses were used to test the differences between the fre-

quencies of failure across glove material, manufacturer, and the stressed vs. nonstressed conditions.

#### Findings

Nitrile gloves had the lowest rate of failure, followed by latex gloves. Copolymer and vinyl gloves had the highest rates of failure. The failure rates were significantly different ( $p < 0.001$ ). Subjecting gloves to the stress protocol increased the failure rate significantly ( $p < 0.002$ ). Failure rates were also significantly different by glove manufacturer ( $p < 0.001$ ). The data demonstrated that glove material, manufacturer, and stress are important factors that influence the barrier effectiveness of medical examination gloves.

#### Nursing Implications

The research findings suggest that nitrile medical examination gloves are an acceptable alternative to latex gloves and that vinyl and copolymer gloves provide less protection to the wearer. These findings suggest the need for health care providers and facilities to use care in selecting the type and manufacturer of gloves to protect the wearer during patient care. The researchers indicated that studies using larger samples are warranted and should address other variables that may affect the barrier effectiveness of gloves during use, including duration of use, presence of powder, glove size, hand dominance, complexity of tasks performed while wearing gloves, and the use of instruments.

reactions often require major changes in the patient's home and work environment to avoid further exposure.

Immediate hypersensitivity, a type I allergic reaction, is mediated by the IgE mast cell system. Symptoms can include rhinitis, conjunctivitis, asthma, and anaphylaxis. The term "latex allergy" is usually used to describe the type I reaction. Clinical manifestations have a rapid onset and can include urticaria, wheezing, dyspnea, laryngeal edema, bronchospasm, tachycardia, angioedema, hypotension, and cardiac arrest.

Localized itching, erythema, or local urticaria within minutes after exposure to latex are often the initial symptoms. Symptoms of subsequent reactions can include generalized urticaria, angioedema, rhinitis, conjunctivitis, asthma, and anaphylactic shock minutes after dermal or mucosal exposure to latex. An increasing number of individuals allergic to latex experience severe reactions characterized by generalized urticaria, bronchospasm, and hypotension (Brehler & Kütting, 2001).

### Diagnostic Testing

The diagnosis of latex allergy is based on the history and diagnostic test results (Parslow et al., 2001). Sensitization is detected by skin testing, RAST, or ELISA. Skin tests have been unreliable because of variability in the techniques used; however, a new standardized skin testing reagent is expected to be available in the near future. Skin tests should be done only by clinicians who have expertise in their administration and interpretation and who have the necessary equipment available to treat local or systemic allergic reactions to the reagent (Hamilton & Adkinson, 1998). Nasal challenge and dipstick tests may be useful in the future as screening tests for latex allergy.

### Medical Management

The best treatment available for latex allergy is the avoidance of latex products, but this is often difficult because of the widespread use of latex-based products. Patients who have experienced an anaphylactic reaction to latex should be instructed to wear medical identification. Antihistamines and an emergency kit containing epinephrine should be provided to these patients, along with instructions about emergency management of latex allergy symptoms. Patients should be counseled to notify all health care workers as well as local paramedic and ambulance companies about their allergy. Warning labels can be attached to car windows to alert police and paramedics about the driver's or passenger's latex allergy in case of a motor vehicle crash. Individuals with latex allergy should be provided with a list of alternative products and referred to local support groups; they are also urged to carry their own supply of nonlatex gloves.

People with type I latex sensitivity may be unable to continue to work if a latex-free environment is not possible. This may occur with surgeons, dentists, operating room personnel, or intensive care nurses. Occupational implications for employees with type IV latex sensitivity are usually easier to manage by changing to nonlatex gloves and avoiding direct contact with latex-based medical equipment. Although latex-specific immunotherapy has been reported, this method of treatment remains experimental (Brehler & Kütting, 2001).

### Nursing Management

The nurse can assume a pivotal role in the management of both patients and staff with latex allergies. All patients should be asked about latex allergy, although special attention should be given to

those at particularly high risk (eg, patients with spina bifida, patients who have undergone multiple surgical procedures). Every time an invasive procedure must be performed, the nurse should consider the possibility of latex allergies. Nurses working in operating rooms, intensive care units, short procedure units, and emergency departments need to pay particular attention to latex allergy. See Chapter 19 for a latex allergy screening form.

Although the type I reaction is the most significant of the reactions to latex, care must be taken in the presence of irritant contact dermatitis and delayed hypersensitivity reaction to avoid further exposure of the individual to latex. Patients with latex allergy are advised to notify their health care providers and to wear a medical information bracelet. Patients must become knowledgeable about what products contain latex and what products are safe, nonlatex alternatives. They must also become knowledgeable about signs and symptoms of latex allergy and emergency treatment and self-injection of epinephrine in case of allergic reaction.

Nurses can be instrumental in establishing and participating in multidisciplinary committees to address latex allergy and to promote a latex-free environment. Latex allergy protocols and education of staff about latex allergy and precautions are important strategies to reduce this growing problem and to ensure assessment and prompt treatment of affected individuals.

## New Approaches to Treatment of Allergic Diseases

Although allergen-specific immunotherapy reduces symptoms for several years after it is discontinued, this approach to management is limited in terms of usefulness because of its potential adverse effects, particularly anaphylaxis, and the relatively crude allergen extracts involved. Newer approaches to the treatment of allergic diseases to overcome these limitations are being evaluated and include the use of substances such as naturally occurring isoforms of allergens from plants and trees. These isoforms are less likely to stimulate anaphylactic reactions. Use of recombinant allergens is expected to eliminate variation between batches of allergen. Other experimental approaches include the use of DNA vaccines and monoclonal antibodies and other strategies to block IgE or its synthesis (Kay, 2001b).

### Critical Thinking Exercises

**1.** A 45-year-old man arrives at the emergency department where you are employed. He states that he is severely allergic to bees and was stung by a wasp approximately 10 minutes ago. He tells you that he has been in anaphylactic shock in the past as a result of bee stings. He tells you that he received allergy injections for bee allergy approximately 10 years ago. Upon assessing the patient, you note that he has generalized hives and urticaria on his body, and he is complaining of his throat swelling. What would be your immediate course of action?

**2.** A patient with severe allergies is to receive instructions about self-administration of epinephrine if she experiences anaphylaxis. Develop a teaching plan for this patient and identify outcomes to measure the effectiveness of your

teaching. How would you modify your teaching if the patient reports a severe fear of injection? If the patient has a profound hearing loss? If the patient is visually impaired?

**3.** A 28-year-old man has a surgical procedure for a varicocele. A Penrose drain is inserted into his scrotum during the surgical procedure in the operating room. The patient develops erythema and significant edema of the scrotum inconsistent with the procedure that was performed. The circulating nurse had noted on the operative checklist that the patient was allergic to latex. What would be your immediate course of action? How could you ensure that a similar situation would not occur in the future? What course of action could you take to ensure a latex-free environment for patients who require such an environment?

# ● Assessment and Management of Patients With Rheumatic Disorders

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Explain the processes of inflammation and degradation in the development of rheumatic diseases.
2. Describe the assessment and diagnostic findings that may be evidenced by patients with a suspected diagnosis of rheumatic disease.
3. Discuss appropriate nursing interventions based on nursing diagnoses and collaborative problems that commonly occur with rheumatic disorders.
4. Apply the nursing process as a framework for the care of the patient with a rheumatic disease, such as connective tissue disease or osteoarthritis.
5. Describe the systemic effects of a connective tissue disease.
6. Devise a teaching plan for the patient with newly diagnosed rheumatic disease.
7. Identify modifications in interventions to accommodate changes in patients' functional ability that may occur with disease progression.

**R**heumatic diseases include common disorders such as osteoarthritis or rarer conditions such as systemic lupus erythematosus or scleroderma. These conditions can be life-threatening or minor illnesses. The problems caused by the rheumatic diseases include not only the obvious limitations in mobility and activities of daily living but also the subtler systemic effects that can lead to organ failure and death or result in problems such as pain, fatigue, altered self-image, and sleep disturbances. The rheumatic disease may be the patient's primary health problem or a secondary diagnosis. Thus, thorough understanding of rheumatic diseases and their effects on the patient's function and well-being is the key to developing an appropriate plan of care.

## Rheumatic Diseases

Commonly called arthritis (inflammation of a joint) and thought of as one condition, the rheumatic diseases are actually more than 100 different types of disorders that primarily affect skeletal muscles, bones, cartilage, ligaments, tendons, and joints of males and females of all ages. Some disorders are more likely to occur at a particular time of life or to affect one gender more than the other. The onset of these conditions may be acute or insidious, with a course possibly marked by periods of remission (a period when disease symptoms are reduced or absent) and exacerbation (a period when symptoms occur or increase). Treatment can be simple, aimed at localized relief, or it can be complex, directed toward relieving systemic effects. Permanent changes may result from the disease.

There are several approaches to the classification of rheumatic diseases. One basic system is to classify disease as either monoarticular (affects a single joint) or polyarticular (affects multiple joints) and then to further classify it as either inflammatory or noninflammatory (Klippel, 2001). Conditions that may secondarily affect the musculoskeletal structure are also included, emphasizing the diversity of the rheumatic diseases.

### Pathophysiology

Understanding the normal anatomy and physiology of the **diarthrodial** or **synovial** joints is key to understanding the pathophysiology of the rheumatic diseases. The function of the synovial joints is movement. Each synovial joint has a given range of motion, although range of motion of movable joints varies between individuals.

In a normal synovial joint, a smooth, nearly friction-free, resilient surface for movement is provided by articular cartilage,

which covers the bone end of the joint. Lining the inner surface of the fibrous capsule is the synovial membrane, which secretes fluid into the space between the bone ends. The synovial fluid functions as a shock absorber and a lubricant, allowing the joint to move freely.

The joint is the area most commonly affected by the inflammation and degeneration seen in rheumatic diseases. Despite the diversity of rheumatic diseases, from localized involvement of one joint to systemic, multisystem disorders, they all involve some degree of inflammation and degeneration, which may occur simultaneously. Inflammation is manifested in the joints as synovitis. In inflammatory rheumatic diseases, the primary process is inflammation as a result of the immune response. Degeneration occurs as a secondary process, resulting from the effect of **pannus** (proliferation of newly formed synovial tissue infiltrated with inflammatory cells). The inflammation is a result of altered immune function.

Conversely, in degenerative rheumatic diseases, inflammation occurs as a secondary process. This synovitis is usually milder, is more likely to be seen in advanced disease, and represents a reactive process. The synovitis is thought to result from mechanical irritation from cartilage **matrix** products.

### INFLAMMATION

Inflammation involves a series of related steps. With the triggering event, the **antigen** stimulus activates monocytes and T lymphocytes (also called T cells). Next, the immunoglobulin antibodies form immune complexes with antigens. Phagocytosis of the immune complexes is initiated, generating an inflammatory reaction (joint effusion, pain, and edema) (Fig. 54-1).

During the next step, the normal immune response deviates. Phagocytosis produces chemicals such as leukotrienes and prostaglandins. **Leukotrienes** contribute to the inflammatory process by attracting other white blood cells to the area. **Prostaglandins** act as modifiers to inflammation. In some cases, they increase inflammation; in other cases, they slow it down. Leukotrienes and prostaglandins produce enzymes such as collagenase that break down collagen, a vital part of a normal joint. The release of these enzymes in the joint causes edema, proliferation of synovial membrane and pannus formation, destruction of cartilage, and erosion of bone.

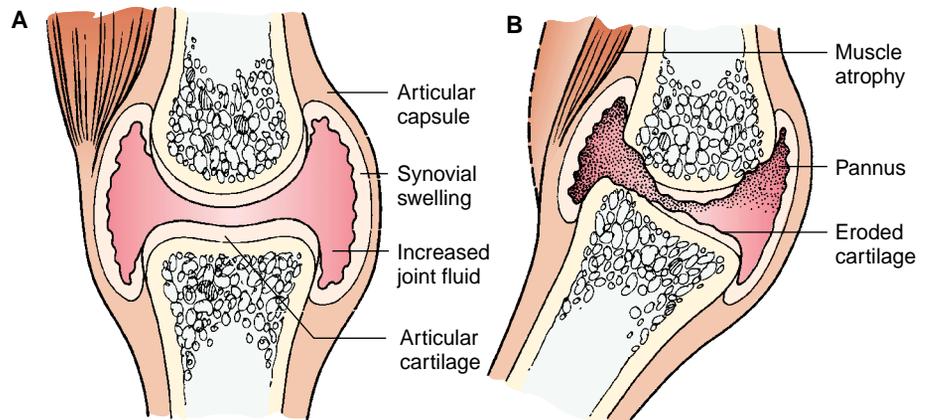

The immunologic inflammatory process begins when antigens are presented to T lymphocytes, leading to a proliferation of T and B cells. B cells are a source for **antibody**-forming cells, or plasma cells. In response to specific antigens, plasma cells produce and release antibodies. Antibodies combine with corresponding

## Glossary

**ankylosis:** fixation or immobility of a joint  
**antibody:** a protein substance developed by the body in response to and interacting with a specific antigen  
**antigen:** a substance that induces production of antibodies  
**arthroplasty:** replacement of a joint  
**complement:** a plasma protein associated with immunologic reactions  
**cytokines:** generic term for nonantibody proteins that act as intercellular mediators, as in the generation of immune response

**diarthrodial:** a joint with two freely movable parts  
**hemarthrosis:** bleeding into the joint  
**joint effusion:** the escape of fluid from the blood vessels or lymphatics into the joint space  
**leukotrienes:** chemical mediators formed from constituents (ie, arachidonic acid) of cell membranes; they initiate and mediate the inflammatory response  
**matrix:** noncellular component of tissue  
**osteophyte:** a bony outgrowth or protuberance; spur

**pannus:** newly formed synovial tissue infiltrated with inflammatory cells  
**prostaglandins:** lipid-soluble molecules synthesized from constituents (ie, arachidonic acid) from cell membranes; they mediate the inflammatory process  
**subchondral bone:** bony plate that supports the articular cartilage  
**synovial:** pertaining to the joint-lubricating fluid  
**tophi:** accumulation of crystalline deposits in articular surfaces, bones, soft tissue, and cartilage

**FIGURE 54-1** (A) Synovial swelling and fluid accumulation. (B) Pannus (a proliferation of synovial tissue), eroded articular cartilage, and joint space narrowing—all of which contribute to muscle atrophy and ankylosis (joint rigidity and immobility).

antigens to form pairs, or immune complexes. The immune complexes build up and are deposited in synovial tissue or other organs in the body, triggering the inflammatory reaction that can ultimately damage the involved tissue.

The systemic nature of the rheumatic disease category known as the diffuse connective tissue diseases is reflected in the resultant widespread inflammatory process. Although focused in the joints, inflammation also involves other areas. The blood vessels (vasculitis and arteritis), lungs, heart, and kidneys may also be affected by the inflammation. In the joints, this inflammatory response is manifested as pannus extending throughout the joint space and, if persistent, eroding the articular cartilage, causing secondary degenerative changes to the joint.

### DEGENERATION

Although the cause for degeneration of the articular cartilage is poorly understood, the process is known to be metabolically active and therefore more accurately called “degradation.” One theory of degradation is that genetic or hormonal influences, mechanical factors, or prior joint damage causes cartilage failure. Degradation of cartilage ensues and increased mechanical stress on bone ends causes stiffening of bone tissue. Another theory is that bone stiffening occurs and results in increased mechanical stress on cartilage, which in turn initiates the processes of degradation.

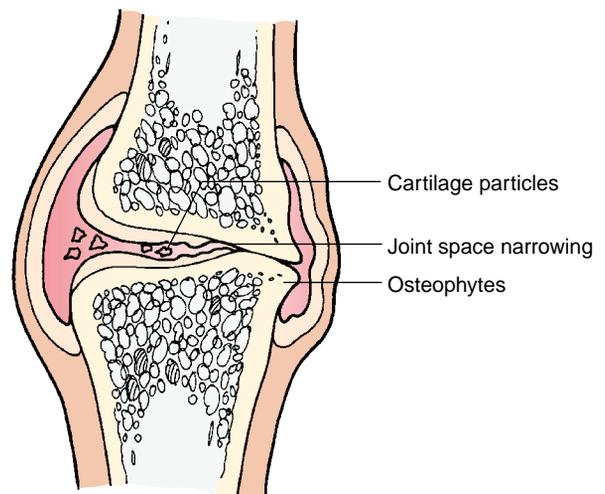

Articular cartilage plays two essential mechanical roles in joint physiology. First, the articular cartilage provides a remarkably smooth weight-bearing surface and, with synovial fluid, provides extremely low friction during movement. Second, the cartilage transmits load or pressure to the bone, dissipating the mechanical stress. Specific factors have been implicated in association with degenerative joint changes.

**Mechanical Stress.** Articular cartilage is highly resistant to wear under conditions of repeated movement. However, repetitive impact loading (velocity at which the force is applied) rapidly leads to joint failure at the cartilage level. When a person walks, three to four times the body weight is transmitted through the knee. A deep knee bend transmits up to nine times the body weight through the patellofemoral joint. As a joint undergoes repeated mechanical stress, the elasticity of the joint capsule, articular cartilage, and ligaments is reduced. The articular plate (**subchondral bone**) thins, and its ability to absorb shock decreases. The joint space narrows, accompanied by a loss of stability. When the articular plate disappears, bony spurs (**osteophytes**) form at the edges of the joint surfaces, and the capsule and synovial mem-

branes thicken. The joint cartilage degenerates and atrophies (shrinks), the bones harden and hypertrophy (thicken) at their articular surfaces, and the ligaments calcify. As a result, sterile **joint effusions** (fluid escaping from the blood vessels or lymphatics into the joint cavity) and secondary synovitis may be present (Fig. 54-2).

**Altered Lubrication.** In addition to the changes in the articular cartilage and subchondral bone, lubrication of the joint is also a factor in joint degeneration. With joint loading (forces carried through the joint), lubrication depends on a film of interstitial fluid squeezed out of the cartilage upon compression of the opposing surfaces of the joint. The mechanisms that normally operate under high weight loads to produce this lubricating film may be affected.

**Immobility.** Immobilization of a joint is another factor that can produce degenerative changes in articular cartilage. Although these changes are more marked and appear earlier in areas of contact, they also occur in areas not subject to mechanical compression. Cartilage degeneration due to joint immobility may result from loss of the pumping action of lubrication that occurs with joint movement. By 3 weeks after remobilization of the joint, the

**FIGURE 54-2** Joint space narrowing and osteophytes (bone spurs) are characteristic of degenerative changes in joints.

cartilage abnormalities are reversed. However, impact exercising (activities such as running) prevents reversal of the atrophy. Instead, slow, gradual range of motion is thought to be very important in preventing cartilage injury.

## Clinical Manifestations

Pain is the symptom of a rheumatic disease that most commonly causes a person to seek medical attention. Other common symptoms include joint swelling, limited movement, stiffness, weakness, and fatigue.

## Assessment and Diagnostic Findings

Assessment begins with a general health history, which includes the onset of symptoms and how they evolved, family history, past health history, and any other contributing factors. Because many of the rheumatic diseases are chronic conditions, the health history should also include information about the patient's perception of the problem, previous treatments and their effectiveness, the patient's support systems, and the patient's current knowledge base and the source of that information. A complete health history is followed by a complete physical assessment.

Assessment for rheumatic diseases combines the physical examination with a functional assessment. Inspection of the patient's general appearance occurs during initial contact. Gait, posture, and general musculoskeletal size and structure are observed. Gross deformities and abnormalities in movement are noted. The symmetry, size, and contour of other connective tissues, such as the skin and adipose tissue, are also noted and recorded. Chart 54-1 outlines the important areas for consideration during the physical assessment. The functional assessment is a combination of history (what the patient reports that he or she can and cannot do) and examination (observation of activities: the patient demonstrates what he or she can and cannot do, such as dressing and getting in and out of a chair). Observation also includes the adaptations and adjustments the patient may have made (sometimes without awareness); for example, with shoulder or elbow involvement, the individual may bend over to reach the fork to the mouth rather than raising the fork to the mouth.

The history and physical assessment data are supplemented by supportive or confirming diagnostic test findings. In some instances, tests are used to follow the course of the disease. For example, the erythrocyte sedimentation rate (ESR) reflects inflammatory activity and indirectly the progression or remission of disease. The following tests are most commonly used for patients with rheumatic diseases.

### ARTHROCENTESIS

Arthrocentesis (needle aspiration of synovial fluid) may be performed not only to obtain a sample of synovial fluid for analysis but also to relieve pain caused by pressure of increased fluid volume, usually in the knee or shoulder. Synovial fluid is usually analyzed in cases such as suspected joint infection to determine the presence of inflammatory cells and to identify crystals in suspected gout or the presence of blood following trauma.

After the joint is anesthetized locally, a large-bore needle is inserted into the joint space to obtain a fluid specimen. Because this procedure has the potential for introducing bacteria into the joint, aseptic technique is essential. After the procedure, the patient is observed for signs of infection and **hemarthrosis** (bleeding into the joint).

Normally, synovial fluid is clear, viscous, straw-colored, and scanty in volume, with few cells. In inflammatory joint disease, however, the fluid may become cloudy, milky, or dark yellow and may contain numerous inflammatory cells, such as leukocytes (white blood cells) and **complement** (a plasma protein associated with immunologic reactions). The viscosity is reduced in inflammatory disease, and copious amounts of fluid may be present. Arthrocentesis is diagnostically a valuable test, but arthrocentesis of small joints (ie, fingers or wrist) to obtain fluid may be difficult.

### X-RAY STUDIES

X-rays are often used in evaluating patients with rheumatic disease. The timing of the studies influences their usefulness: it is unlikely that a patient with a 2-month history of joint inflammation will have demonstrable changes on an x-ray study, but someone with long-standing disease may show severe joint degeneration. X-rays can also be used to monitor disease activity and progression, demonstrating the loss of cartilage and narrowing of the joint space over time. In addition, x-rays can demonstrate cartilage abnormalities, joint erosions, abnormal bony growth, and osteopenia (decreased bone mineralization).

**Arthrography.** Arthrography is a diagnostic procedure used to detect connective tissue disorders. A radiopaque substance or air is injected into the joint cavity, especially the knee or shoulder, to outline the contour of the joint. The joint is then put through passive range of motion while several x-rays are obtained. The radiopaque substance is absorbed systemically, and joint swelling consequently subsides. After the procedure, the patient is observed for signs of infection and hemarthrosis.

### BONE AND JOINT SCANS

A bone scan reflects the degree to which the crystal lattice of bone takes up or absorbs a bone-seeking radioactive isotope. An area demonstrating increased uptake, such as a joint, is considered abnormal. A joint scan, the most sensitive study, allows determination of joint damage throughout the body. Because bone and joint scans are not the most cost-effective methods for detecting early disease, they are not done routinely at the time of diagnosis.

### TISSUE BIOPSIES

A muscle biopsy, carried out to examine skeletal muscle, is useful in diagnosing myositis. Following administration of local anesthesia under sterile conditions in an outpatient setting or in an operating room, a surgical incision is made to obtain the desired specimen, which is sent to the laboratory for microscopic analysis. A pressure dressing is applied, and the affected extremity is immobilized for 12 to 24 hours.

An arterial biopsy may be performed to examine a specimen of an arterial wall using a procedure similar to that for a muscle biopsy. Most frequently the temporal artery is selected, but other arteries may be used as indicated. Arterial biopsy most often confirms inflammation of the vessel wall, or arteritis, a type of vasculitis.

A skin biopsy may be performed to confirm inflammatory connective tissue diseases such as lupus erythematosus or scleroderma. A specimen may be lightly scraped from the skin without causing discomfort. Deeper skin biopsies may be needed when scraping is insufficient.

### BLOOD TESTS

In general, laboratory studies in rheumatology are based on the assumption that most rheumatic diseases are autoimmune disorders. Although many of the tests are highly complex and

Rheumatic Diseases

In addition to the head-to-toe assessment or systems review, the following are important areas of consideration to be noted when performing the complete physical assessment of a patient with a known or suspected rheumatic disease.

Manifestation	Significance
<p>Skin (inquire and inspect)</p> <p>Rash, lesions</p> <p>Increased bruising</p> <p>Erythema</p> <p>Thinning</p> <p>Warmth</p> <p>Photosensitivity</p>	<ul style="list-style-type: none"> <li>• Associated with lupus erythematosus, vasculitis, adverse effect of medication</li> <li>• Associated with several rheumatic diseases and adverse effect of medication</li> <li>• Sign of inflammation</li> <li>• Adverse effect of medication</li> <li>• Sign of inflammation</li> <li>• Associated with systemic lupus erythematosus (SLE), dermatomyositis, adverse effect of medication</li> </ul>

<p>Musculoskeletal (inspect and palpate)</p> <p>Joint redness, warmth, swelling, tenderness, deformity—location of first joint involved, pattern of progression, symmetry, acute vs chronic nature</p> <p>Joint range of motion</p> <p>Surrounding tissue findings</p> <p>Muscle atrophy, subcutaneous nodules, popliteal cyst</p> <p>Muscle strength (grip)</p>	<ul style="list-style-type: none"> <li>• Signs of inflammation</li> <li>• Decreased range of motion may indicate severity or progression of disease.</li> <li>• Extra-articular manifestations</li> <li>• Muscle strength decreases with increased disease activity.</li> </ul>

technical, no single test used in isolation sufficiently supports a diagnosis of a rheumatic disease. Some of the most common blood studies are listed with their corresponding normal ranges and primary indications in Table 54-1. Because many of the tests require special laboratory techniques, they may not be used in every health care facility. The physician determines which tests are necessary based on the symptoms, stage of disease, and cost and likely benefit of the test.

### IMPLICATIONS

Diagnosis of a specific rheumatic disease may or may not be relatively simple and clear-cut. Commonly, observation of clinical signs and symptoms over time is needed to make the diagnosis. The combination of history, assessment, testing, and evolving manifestations of the disease may require explanation and interpretation to the patient with early disease. This is especially true for patients with multisystem rheumatic disease, such as one of the connective tissue diseases.

The presence of crystals or bacteria in the synovial fluid is specifically diagnostic for gout or infectious arthritis, respectively. Diagnosis, however, may be more presumptive in the case of the older person who is thought to have osteoarthritis (OA) based on single joint involvement, supportive x-ray findings, and no evidence of other disease processes (Altman et al., 2000).

Many forms of rheumatic disease can be accurately diagnosed by the primary health care provider, but patients with more complicated signs and symptoms may need referral to a rheumatologist (a physician who specializes in diagnosing and treating rheumatic disease). Patients should know which type of rheumatic disease they have, not just that they have “arthritis” or “arthritis of the knee.”

### Gerontologic Considerations

Although people of all ages, from infancy through childhood, adolescence, and maturity, may be affected, rheumatic disease is commonly thought of by the patient, family, and society as a whole as an inevitable consequence of aging. Many older people expect and accept the immobility and self-care problems related to the rheumatic diseases and do not seek help, thinking that nothing can be done. Careful diagnosis and appropriate treatment can improve the quality of life for older people. However, the rheumatic diseases do have some special implications for the older adult.

In elderly patients, other medical conditions may take precedence over the rheumatic disease, which commonly becomes a secondary diagnosis and concern. Identifying the effects of the rheumatic disease on the patient's lifestyle, independence, and other chronic or acute conditions is important.

The frequency, pattern of onset, clinical features, severity, and effects on function of the rheumatic disease in elderly patients may be different in very elderly patients. Some of the rheumatic diseases, such as OA, are more prevalent with aging (Altman et al., 2000). One disease, polymyalgia rheumatica, is exclusive to the elderly (Gonzalez-Gay et al., 1999), whereas some disorders may be less severe for elderly people than for younger patients. However, OA, the most prevalent activity-limiting condition among elderly people, may account for more total disability among elderly patients than many diseases, such as stroke or cancer, that are considered more serious.

In some instances, the age of the patient and coexisting health problems may make diagnosis difficult. A missed diagnosis is not unusual because of the assumption that most older people with joint problems have OA. In addition, it may be difficult to differentiate problems associated with aging from those caused by a

rheumatic disease. For example, rheumatoid arthritis (RA) that begins in the later years has been shown to differ prognostically and therapeutically from RA that begins in childhood or early adulthood. In the elderly patient with initial RA, the onset is more likely to be abrupt, but the clinical course does not appear to differ from that of RA with an insidious onset. Moreover, patients with elderly-onset RA are less likely to have subcutaneous nodules or rheumatoid factor at disease onset (Ruddy et al., 2001).

For the elderly person who has had a diffuse connective tissue disease, the risk for osteoporosis is increased. Pain, loss of mobility, diminished self-image, and increasing morbidity can result from progressive osteoporosis. Thus, diagnosis and treatment for osteoporosis should not be overlooked in this population. Exercise, postural assistance, analgesic agents, modification of activities of daily living, and psychological support can be useful.

Other conditions (eg, soft tissue problems such as bursitis) usually are not problematic by themselves. When combined with other health problems and the normal physiologic processes of aging, however, these conditions may significantly reduce the patient's quality of life. In fact, the effects of most forms of rheumatic disease may lead to considerable changes in the individual's lifestyle, possibly threatening his or her independence. Decreased vision and altered balance, often present in elderly people, may be problematic if rheumatic disease in the lower extremities affects locomotion. Also, the combination of poor hearing, diminished vision, memory loss, and depression contributes to nonadherence to the treatment regimen in elderly patients. Special techniques for promoting patient safety, self-management, and strategies such as memory aids for medications may be necessary.

Partly because of the more frequent contact of the elderly with the health care system for a variety of health issues, overtreatment or inappropriate treatment is possible. Complaints of pain may be met with a prescription for an opioid analgesic rather than instructions for rest, use of an assistive device, and local comfort measures such as heat or cold. Acetaminophen may be appropriate and worth trying before using other medications that pose a greater chance of side effects. Intra-articular corticosteroid injections, with their usually rapid relief of symptoms, may be requested by the patient who is unaware of the consequences of too-frequent use. In addition to these factors, exercise programs may not be instituted or may be ineffective because the patient expects results to occur quickly or fails to appreciate the effectiveness of a program of exercise.

Pharmacologic treatment of rheumatic disease in older patients is more difficult than it is in younger patients. If the medications used have an effect on the senses (hearing, cognition), this effect is intensified in the elderly. The cumulative effect of medications is accentuated because of the physiologic changes of aging. For example, decreased renal function in the elderly alters the metabolism of certain medications, such as nonsteroidal anti-inflammatory drugs (NSAIDs). Elderly patients are more prone to such side effects as gastroduodenal ulceration or bleeding, and they are more likely to use nonprescription remedies, to try many different medications (polypharmacy), and to be susceptible to unproven treatment methods (Michocki, 2001).

Elderly patients with rheumatic disease may accept or endure pain, loss of ambulation, and difficulty with activities of daily living unnecessarily. The need to view oneself as capable of managing life independently despite increasing age may take considerable energy. The body image and self-esteem of the elderly person with rheumatic disease, combined with underlying depression, may interfere with the use of assistive devices such as canes. Use of adaptive equipment such as long-handled reachers or tongs may be viewed as evidence of aging rather than as a means of increasing independence.

**Table 54-1 • Common Blood Studies for Rheumatic Diseases**

TEST	NORMAL VALUE	SIGNIFICANCE
<b>Serum</b>		
<b>Creatinine</b> Metabolic waste excreted through the kidneys	0.6–1.2 mg/dL (50–110 μmol/L)	Increase may indicate renal damage in SLE, scleroderma, and polyarteritis.
<b>Erythrocyte Sedimentation Rate (ESR)</b> Measures the rate at which red blood cells settle out of unclotted blood in 1 hour	Westergren = Men, 0–15 mm/h, Women, 0–25 mm/h Wintrobe = Men, 0–9 mm/h, Women 0–15 mm/h	Increase is usually seen in inflammatory connective tissue diseases. An increase indicates rising inflammation, resulting in clustering of RBCs, which makes them heavier than normal. The higher the ESR, the greater the inflammatory activity.
<b>Hematocrit</b> Measures the size, capacity, and number of cells present in blood	Men: 42–52% Women: 35–47%	Decrease can be seen in chronic inflammation (anemia of chronic disease); also, blood loss through bowel due to medication.
<b>Red Blood Cell Count</b> Measures circulating erythrocytes	Men: Average 4.8 million/μL Women: Average 4.3 million/μL	Decrease can be seen in RA, SLE.
<b>White Blood Cell Count</b> Measures circulating leukocytes	5,000–10,000 cells/mm <sup>3</sup>	Decrease may be seen in SLE.
<b>VDRL (Venereal Disease Research Laboratory)</b> Measures antibody to syphilis	Nonreactive	False-positive results are sometimes found with SLE.
<b>Uric Acid</b> Measures level of uric acid in serum	2.5–8 mg/dL (0.15–0.5 mmol/L)	Increase is seen with gout.
<b>Serum Immunology</b>		
<b>Antinuclear Antibody (ANA)</b> Measures antibodies that react with a variety of nuclear antigens If antibodies are present, further testing determines the type of ANA circulating in the blood (anti-DNA, anti-RNP).	Negative A few healthy adults have a positive ANA.	Positive test is associated with SLE, RA, scleroderma, Raynaud's disease, Sjögren's syndrome, necrotizing arteritis. The higher the titer, the greater the inflammation. The pattern of immunofluorescence (speckled, homogeneous, or nucleolar) helps determine the diagnosis.
<b>Anti-DNA, DNA binding</b> Titer measurement of antibody to double-stranded DNA	Negative	High titer is seen in SLE; increases in titer may indicate increase in disease activity.
<b>Complement levels—C<sub>3</sub>, C<sub>4</sub></b> Complement is a protein substance that binds with antigen–antibody complexes for the purpose of lysis. When the number of complexes increases markedly, complement is used for lysis, thus depleting the amount available in the blood.	C <sub>3</sub> : 55–120 mg/dL (550–1,200 mg/L) C <sub>4</sub> : 11–40 mg/dL (110–400 mg/L)	Decrease may be seen in RA and SLE. Decrease indicates autoimmune and inflammatory activity.
<b>C-Reactive Protein Test (CRP)</b> Shows presence of abnormal glycoprotein due to inflammatory process	Trace–6 μg/mL	A positive reading indicates active inflammation. Often is positive for RA, disseminated lupus erythematosus
<b>Immunoglobulin Electrophoresis</b> Measures the values of immunoglobulins	IgA 50–300 mg/dL (0.5–3 g/L) IgG 635–1,400 mg/dL (6.35–14 g/L) IgM 40–280 mg/dL (0.4–238 g/L)	Increased levels are found in people who have autoimmune disorders.
<b>Rheumatoid Factor (RF)</b> Determines the presence of abnormal antibodies seen in connective tissue disease	Negative	Positive titer > 1:80 Present in 80% of those with RA Positive RF may also suggest SLE, Sjögren's syndrome, or mixed connective tissue disease. The higher the titer (number at right of colon), the greater the inflammation.
<b>Tissue Typing</b>		
<b>HLA-B27 Antigen</b> Measures presence of HLA antigens, which are used for tissue recognition	Negative	Found in 80%–90% of those with ankylosing spondylitis and Reiter's syndrome.

The elderly person usually has a lifelong pattern of dealing with the stresses of daily life. Depending on the success of that pattern, the elderly person can often maintain a positive attitude and self-esteem when faced with a rheumatic disease, especially when support is available. Previous stress management strategies are assessed. If these strategies have been effective, the patient is encouraged and supported in their use. If the strategies were ineffective, the nurse assists the patient in identifying alternative strategies, encourages use of new strategies, and assesses their effectiveness.

## Medical Management

A treatment program involving the interdisciplinary team, including the patient, is the basis for managing the rheumatic diseases. The chronic nature of most of these diseases mandates that the patient understand the disease, have the information necessary to make good self-management decisions, and be presented with a therapeutic program that is compatible with his or her lifestyle. Table 54-2 outlines the goals and strategies of basic rheumatic disease management.

### PHARMACOLOGIC THERAPY

Medications are used with the rheumatic diseases to manage symptoms, control inflammation, and in some instances to modify the disease. Useful medications include the salicylates, NSAIDs, and disease-modifying antirheumatic drugs. Table 54-3 reviews the medications often used.

Controlling the inflammation related to the disease process will help in managing pain, but this is often a delayed response. Nonopioid medications are often used for pain management, especially early in the treatment program, until other measures can be instituted (Burckhardt, 2001a). Short-term use of low-dose antidepressant medications, such as amitriptyline, may be prescribed to reestablish adequate sleep patterns and improve pain management (Wegner, 2001).

### NONPHARMACOLOGIC PAIN MANAGEMENT

Nonpharmacologic methods of pain management are important. Methods used include therapeutic heat or cold and devices such

as a cane or a wrist splint to protect and support the joint. A combination of methods may be required because different methods often work better at different times.

## Exercise and Activity

The ongoing nature of most rheumatic diseases makes it important to maintain and, when possible, improve joint mobility and overall functional status. The individualized exercise program is crucial to movement. Table 54-4 summarizes the exercises appropriate for patients with rheumatic diseases. Appropriate programs of exercise have been shown to decrease pain and improve function. A mild analgesic may be suggested prior to exercise for a patient starting a program of exercise. Acute or prolonged pain associated with exercise should be reported to a health care provider for evaluation (Minor & Westby, 2001).

The major challenge for the patient and the health care provider is the need to adjust all aspects of treatment according to the activity of the disease. Especially for the patient with an active diffuse connective tissue disease, such as RA or systemic lupus erythematosus (SLE), activity levels may vary from day to day and even within the day itself.

## NURSING PROCESS: THE PATIENT WITH A RHEUMATIC DISEASE

### Assessment

The depth and focus of the nursing assessment depend on several factors: the health care setting (clinic or office, home, extended care facility, or hospital), the role of the nurse (home care nurse; nurse practitioner; hospital, clinic, or office nurse), and the needs of the patient. The nurse is often the first of the health care team members to come in contact with the patient. This enables the nurse to assess the patient's perceptions of the disorder and situation, actions taken to relieve symptoms, plans for treatment, and expectations. The nurse's assessment may lead to identifying issues and concerns that can be addressed by nursing interventions and, through collaboration with other team members, to achieving the expected patient outcomes.

The health history and physical assessment focus on current and past symptoms, such as fatigue, weakness, pain, stiffness, fever, or anorexia, and the effects of these symptoms on the patient's lifestyle and self-image. Because the rheumatic diseases affect many body systems, the history and physical assessment include a review and examination of all systems, with particular attention given to those areas most commonly affected, including the musculoskeletal system (see Chart 54-1).

The patient's psychological and mental status and social support systems are also assessed, as is his or her ability to participate in daily activities, comply with the treatment regimen, and manage self-care. The information obtained can give insight into the patient's understanding of the medication regimen and may reveal misuse of medications, noncompliance, or use of potentially harmful unproven remedies. Additional areas assessed include the patient's understanding, motivation, knowledge, coping abilities, past experiences, preconceptions, and fears. The effects of the disease on the patient's self-concept and coping abilities are also assessed. The patient's perception of the condition and its impact influences the decisions, choices, and actions associated with treatment recommendations.

**Table 54-2 • Goals and Strategies for Rheumatic Diseases**

MAJOR GOALS	MANAGEMENT STRATEGY
Suppress inflammation and the autoimmune response	Optimize pharmacologic therapy (anti-inflammatory and disease-modifying agents)
Control pain	Protect joints; ease pain with splints, thermal modalities, relaxation techniques
Maintain or improve joint mobility	Implement exercise programs for joint motion and muscle strengthening and overall health
Maintain or improve functional status	Make use of adaptive devices and techniques
Increase patient's knowledge of disease process	Provide and reinforce patient teaching
Promote self-management by patient compatible with the therapeutic regimen	Emphasize compatibility of therapeutic regimen and lifestyle

Table 54-3 • Medications Used in Rheumatic Diseases

MEDICATION	ACTION, USE, AND INDICATION	NURSING CONSIDERATIONS
<b>Salicylates</b>	<i>Action:</i> anti-inflammatory, analgesic, antipyretic	Administer with meals to prevent gastric irritation.
<i>Acetylated</i> aspirin	Acetylated salicylates are platelet aggregation inhibitors.	Assess for tinnitus, gastric intolerance, GI bleeding, and purpura.
<i>Nonacetylated</i> choline magnesium trisalicylate (Trilisate) choline salicylate (Arthropan) diflunisal (Dolobid) salsalate (Disalcid) sodium salicylate	Anti-inflammatory doses will produce blood salicylate levels of 20–30 mg/dL.	Monitor for possible confusion in the elderly.
<b>Nonsteroidal Anti-inflammatory Drugs (NSAIDs)</b>	<i>Action:</i> anti-inflammatory, analgesic, antipyretic, platelet aggregation inhibitor	Administer NSAIDs with food.
diclofenac (Voltaren)	Anti-inflammatory effect occurs 2–4 weeks after initiation.	Monitor for GI, CNS, cardiovascular, renal, hematologic, and dermatologic adverse effects.
etodolac (Lodine)	All NSAIDs are useful for short-term treatment of acute gout attack.	Avoid salicylates; use acetaminophen for additional analgesia.
flurbiprofen (Ansaid)	NSAIDs are alternative to salicylates for first-line therapy in several rheumatic diseases.	Watch for possible confusion in the elderly.
ibuprofen (Motrin)		
indomethacin (Indocin)		
ketoprofen (Orudis, Oruvail)		
meclofenamate (Meclomen)		
meloxicam (Mobic)		
nabumetone (Relafen)		
naproxen (Naprosyn)		
oxaprozin (DayPro)		
piroxicam (Feldene)		
sulindac (Clinoril)		
tolmetin sodium (Tolectin)		
COX-2 inhibitors	<i>Action:</i> Inhibit only cyclooxygenase-2 (COX-2) enzymes, which are produced during inflammation and spare COX-1 enzymes, which can be protective to the stomach and kidneys	Monitoring the same as for other NSAIDs
celecoxib (Celebrex)		Appropriate for the elderly and patients who are at high risk for gastric ulcers
rofecoxib (Vioxx)		
valdecoxib (Bextra)		
<b>Disease-Modifying Antirheumatic Drugs (DMARDs)</b>	<i>Action:</i> Anti-inflammatory, inhibits lysosomal enzymes	Administer concurrently with NSAIDs.
<b>Antimalarials</b>	Slow-acting, onset may take 2–4 months	Assess for visual changes, GI upset, skin rash, headaches, photosensitivity, bleaching of hair.
hydroxychloroquine (Plaquenil)	Useful in RA and SLE	Emphasize need for ophthalmologic exams (every 6–12 months).
chloroquine (Aralen)		Administer concurrently with NSAIDs.
<b>Gold-containing compounds</b>	<i>Action:</i> Inhibits T- and B-cell activity, suppresses synovitis during active stage of rheumatoid disease	Assess for stomatitis, diarrhea, dermatitis, proteinuria, hematuria, bone marrow suppression (decreased WBCs and/or platelets), CBC and urinalysis with every other injection
aurothioglucose (Solganol)		
gold sodium thiomalate (Myochrysin)		
auranofin (Ridaura)	Slow-acting, onset may take 3–6 months	
	IM preparations are given weekly for about 6 months, then every 2–4 weeks	
sulfasalazine (Azulfidine)	<i>Action:</i> Anti-inflammatory, reduces lymphocyte response, inhibits angiogenesis	Administer concurrently with NSAIDs.
	Useful in RA, seronegative spondyloarthropathies	Do not use in patients with allergy to sulfa medications or salicylates.
		Emphasize adequate fluid intake.
		Assess for GI upset, skin rash, headache, liver abnormalities, anemia.
penicillamine (Cuprimine)	<i>Action:</i> Anti-inflammatory, inhibits T-cell function, impairs antigen presentation	Administer concurrently with NSAIDs.
	Slow-acting, onset may take 2–3 months	Assess for GI irritation, decreased taste, skin rash or itching, bone marrow suppression, proteinuria with CBC, and urinalysis every 2–4 weeks.
	Useful in RA and systemic sclerosis	
<b>Immunosuppressives</b>	<i>Action:</i> Immune suppression, effects DNA synthesis and other cellular effects	Assess for bone marrow suppression, GI ulcerations, skin rashes, alopecia, bladder toxicity, increased infections.
methotrexate (Rheumatrex)	Have teratogenic potential; azathioprine and cyclophosphamide reserved for more aggressive or unresponsive disease	Monitor CBC, liver enzymes, creatinine every 2–4 weeks.
azathioprine (Imuran)	Methotrexate is “gold standard” for RA treatment; also useful in SLE.	Advise patient of contraceptive measures because of teratogenicity.
cyclophosphamide (Cytoxan)		

(continued)

Table 54-3 • Medications Used in Rheumatic Diseases (Continued)

MEDICATION	ACTION, USE, AND INDICATION	NURSING CONSIDERATIONS
cyclosporine (Neoval)	<i>Action:</i> Immunomodulator Used for severe, progressive RA, unresponsive to other DMARDs Used in combination with methotrexate	Assess slow dose titration upward until response noted or toxicity occurs. Assess for toxic effects: bleeding gums, fluid retention, hair growth, tremors. Monitor blood pressure and creatinine every 2 weeks until stable.
Immunomodulators leflunomide (Arava)	<i>Action:</i> Inhibit pyrimidine synthesis; anti-inflammatory May be used alone or in combination with other DMARDs. Used in moderate to severe RA.	Long half-life; requires loading dose followed by daily administration. Assess for diarrhea, nausea, rash, alopecia. Contraindicated in pregnancy. Monitor liver function tests.
etanercept (Enbrel)	<i>Action:</i> Binds to tumor necrosis factor, a cytokine involved in inflammatory and immune responses. Used in moderate to severe RA unresponsive to methotrexate. May be used in combination with methotrexate	Teach patient subcutaneous self-injection to be administered 2×/week. Monitor for injection site reactions. Educate patient about increased potential for infection and to withhold medication if fever occurs.
infliximab (Remicade)	<i>Action:</i> Anti-inflammatory, analgesic Used for shortest duration and at lowest dose possible to minimize adverse effects Useful for unremitting RA, SLE, polymyalgia rheumatica, myositis, arteritis Fast-acting; onset in days Injections useful for joints unresponsive to NSAIDs	Assess for toxicity: cataracts, GI irritation, hyperglycemia, hypertension, fractures, avascular necrosis, hirsutism, psychosis. Joints most amenable to injections include ankles, knees, hips, shoulders, and hands. Repeated injections can cause joint damage.
<b>Corticosteroids</b> prednisone prednisolone hydrocortisone intra-articular injections		
<b>Topical Analgesics</b> capsaicin (Zostrix)	<i>Action:</i> analgesic	Teach patient to apply sparingly, avoid areas of open skin, avoid contact with eyes and mucous membranes. Wash hands carefully after application. Assess for local skin irritation.

DMARDs, disease-modifying antirheumatic drugs.

## Diagnosis

### NURSING DIAGNOSES

Although many nursing diagnoses are appropriate for the patient with a rheumatic disease, a few of the most common include the following:

- Acute and chronic pain related to inflammation and increased disease activity, tissue damage, fatigue, or lowered tolerance level

- Fatigue related to increased disease activity, pain, inadequate sleep/rest, deconditioning, inadequate nutrition, emotional stress/depression
- Disturbed sleep pattern related to pain, depression, and medications
- Impaired physical mobility related to decreased range of motion, muscle weakness, pain on movement, limited endurance, lack of or improper use of ambulatory devices
- Self-care deficits related to contractures, fatigue, or loss of motion
- Disturbed body image related to physical and psychological changes and dependency imposed by chronic illness
- Ineffective coping related to actual or perceived lifestyle or role changes

Table 54-4 • Suggested Exercises to Promote Mobility

INFLAMMATORY PROCESS (PAIN)	RECOMMENDED EXERCISE	PATIENT PERFORMANCE LEVEL
Acute exacerbation; severe pain	Passive range of motion (ROM)	Unable to perform exercises alone
Subacute; moderate or minimal pain	Active assistive or active ROM within pain tolerance	Can perform with help from another person or an assistive mechanical device
Inactive; remission; minimal pain or absence of pain	Active ROM: isometrics	Can perform alone

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on assessment data, potential complications may include the following:

- Adverse effects of medications

### Planning and Goals

The major goals for the patient may include relief of pain and discomfort, relief of fatigue, increased mobility, maintenance of self-care, improved body image, effective coping, and absence of complications.

## Nursing Interventions

An understanding of the underlying disease process (ie, degeneration or inflammation, including degeneration resulting from inflammation or vice versa) guides the nurse's critical thinking processes. In addition, knowledge about whether the condition is localized or more widely systemic influences the scope of the nursing activity.

Some rheumatic diseases (eg, OA) are more localized alterations in which control of symptoms such as pain or stiffness is possible. Others (eg, gout) have a known cause and specific treatment to control the symptoms. The diseases that usually present the greatest challenge are those with systemic manifestations, such as the diffuse connective tissue diseases. The Plan of Nursing Care details the nursing interventions to be considered for each nursing diagnosis.

### RELIEVING PAIN AND DISCOMFORT

Medications are used on a short-term basis to relieve acute pain. Because the pain may be persistent, nonopioid analgesics such as acetaminophen are often used. After administering medications, the nurse needs to reassess pain levels at intervals. With persistent pain, assessment findings should be compared with baseline measurements and evaluations. Additional measures include exploring coping skills and strategies that have worked in the past.

The patient needs to understand the importance of taking medications, such as NSAIDs and disease-modifying agents, exactly as prescribed to achieve maximum benefits. These benefits include relief of pain and anti-inflammatory action as the disease is brought under control. Because disease control and pain relief are delayed, the patient may mistakenly believe the medication is ineffective or may think of the medication as merely "pain pills," taking them only sporadically and failing to achieve control over the disease activity. Alternately, the patient may not understand the need to continue the medication for its anti-inflammatory actions once pain control has been achieved.

A weight reduction program may be recommended to relieve stress on painful joints. Heat applications are also helpful in relieving pain, stiffness, and muscle spasm. Superficial heat may be applied in the form of warm tub baths or showers and warm moist compresses. Paraffin baths (dips), which offer concentrated heat, are helpful to patients with wrist and small-joint involvement. Maximum benefit is achieved within 20 minutes of application. More frequent use for shorter lengths of time is most beneficial. Therapeutic exercises can be carried out more comfortably and effectively after heat has been applied.

In some patients, however, heat may actually increase pain, muscle spasm, and synovial fluid volume. If the inflammatory process is acute, cold applications in the form of moist packs or an ice bag may be tried. Both heat and cold are analgesic to nerve pain receptors and can relax muscle spasms. Safe use of heat and cold must be evaluated and taught, particularly to patients with impaired sensation.

The use of braces, splints, and assistive devices for ambulation, such as canes, crutches, and walkers, eases pain by limiting movement or stress from weight bearing on painful joints. Acutely inflamed joints can be rested by applying splints to limit motion. Splints also support the joint to relieve spasm. Canes and crutches can relieve stress from inflamed and painful weight-bearing joints while promoting safe ambulation. Cervical collars may be used to support the weight of the head and limit cervical motion. A metatarsal bar or special pads may be put into shoes if foot pain or deformity is present.

Other strategies for decreasing pain include muscle relaxation techniques, imagery, self-hypnosis, and distraction.

### DECREASING FATIGUE

Fatigue related to rheumatic disease can be both acute (brief and relieved by rest or sleep) and chronic. Chronic fatigue, related to the disease process, is persistent, cumulative, and not eliminated by rest but is influenced by biologic, psychological, social, and personal factors.

Disease-related factors that may influence the amount and severity of fatigue include persistent pain, sleep disturbance, impaired physical activity, and disease duration. Pain increases fatigue by requiring additional physical and emotional energy to deal with it. It may also cause the patient to expend more energy to do tasks in a way that causes less pain. Pain may also interfere with sleep, thereby increasing the fatigue level (Aaronsen et al., 1999; Wolfe & Skevington, 2000).

Efforts are aimed at modifying and reducing the fatigue. Energy may be regained by using rest periods. The patient's needs determine the type and amount of rest needed. Naps or nighttime sleep can provide systemic rest. Splints can provide articular rest by limiting motion and stress on the joints. Relaxation techniques can provide emotional rest. Inactivity may lead to deconditioning and fatigue, so measures to build endurance should be instituted. Conditioning exercise, such as walking, swimming, or biking, requires gradual progression of activity and monitoring of disease activity.

Psychosocial factors with an effect on fatigue include depression, learned helplessness, and perceived social support (Belza, 2001; Parker et al., 2001). These factors affect the patient's perception and evaluation of the fatigue. Improvement of functional status can improve mood. The patient is taught strategies to conserve energy, such as planning and grouping activities to minimize the number of times the patient needs to climb the stairs each day and sitting down to prepare meals.

### PROMOTING RESTORATIVE SLEEP

Restful sleep is important in helping the patient to cope with pain, minimize physical fatigue, and deal with the changes necessitated by a chronic disease. In patients with acute disease, sleep time is frequently reduced and fragmented by prolonged awakenings. Stiffness, depression, and medications may also compromise the quality of sleep and increase daytime fatigue. A sleep-inducing routine, medication, and comfort measures may help improve the quality of sleep.

### INCREASING MOBILITY

Proper body positioning is essential to minimize stress on inflamed joints and prevent deformities that limit mobility. All joints should be supported in a position of optimal function. When in bed, the patient should lie flat on a firm mattress, with feet positioned against a footboard and with only one pillow under the head because of the risk of dorsal kyphosis. A pillow should not be placed under the knees because this promotes flexion contracture. The patient should lie prone several times daily to prevent hip flexion contracture.

Active range-of-motion exercises are encouraged because they prevent joint stiffness. If the patient cannot actively exercise the joints, passive range of motion should be performed.

Measures to reinforce proper body posture and increase mobility include walking erect and using chairs with straight backs. When seated, the patient should rest the feet flat on the floor and the shoulders and hips against the back of the chair.

*(text continues on page 1618)*

### Nursing Interventions

### Rationale

### Expected Patient Outcomes

**Nursing Diagnosis:** Acute and chronic pain related to inflammation and increased disease activity, tissue damage, or lowered tolerance level

**Goal:** Improvement in comfort level; incorporation of pain management techniques into daily life

<ol style="list-style-type: none"> <li>1. Provide variety of comfort measures               <ol style="list-style-type: none"> <li>a. Application of heat or cold</li> <li>b. Massage, position changes, rest</li> <li>c. Foam mattress, supportive pillow, splints</li> <li>d. Relaxation techniques, diversional activities</li> </ol> </li> <li>2. Administer anti-inflammatory, analgesic, and slow-acting antirheumatic medications as prescribed.</li> <li>3. Individualize medication schedule to meet patient's need for pain management.</li> <li>4. Encourage verbalization of feelings about pain and chronicity of disease.</li> <li>5. Teach pathophysiology of pain and rheumatic disease, and assist patient to recognize that pain often leads to unproved treatment methods.</li> <li>6. Assist in identification of pain that leads to use of unproven methods of treatment.</li> <li>7. Assess for subjective changes in pain.</li> </ol>	<ol style="list-style-type: none"> <li>1. Pain may respond to non-pharmacologic interventions such as joint protection, exercise, relaxation, and thermal modalities.</li> <li>2. Pain of rheumatic disease responds to individual or combination medication regimens.</li> <li>3. Previous pain experiences and management strategies may be different from those needed for persistent pain.</li> <li>4. Verbalization promotes coping.</li> <li>5. Knowledge of rheumatic pain and appropriate treatment may help patient avoid unsafe, ineffective therapies.</li> <li>6. The impact of pain on an individual's life often leads to misconceptions about pain and pain management techniques.</li> <li>7. The individual's description of the pain sensation is a more reliable indicator than objective measurements such as change in vital signs, body movement, and facial expression.</li> </ol>	<ul style="list-style-type: none"> <li>• Identifies factors that exacerbate or influence pain response</li> <li>• Identifies and uses pain management strategies</li> <li>• Verbalizes decrease in pain</li> <li>• Reports signs and symptoms of side effects in timely manner to prevent additional problems</li> <li>• Verbalizes that pain is characteristic of rheumatic disease</li> <li>• Establishes realistic pain-relief goals</li> <li>• Verbalizes that pain often leads to the use of nontraditional and unproved self-treatment methods</li> <li>• Identifies changes in quality or intensity of pain</li> </ul>
--	---	---

**Nursing Diagnosis:** Fatigue related to increased disease activity, pain, inadequate sleep/rest, deconditioning, inadequate nutrition, and emotional stress/depression

**Goal:** Incorporates as part of daily activities strategies necessary to modify fatigue

<ol style="list-style-type: none"> <li>1. Provide instruction about fatigue               <ol style="list-style-type: none"> <li>a. Describe relationship of disease activity to fatigue.</li> <li>b. Describe comfort measures while providing them.</li> <li>c. Develop and encourage a sleep routine (warm bath and relaxation techniques that promote sleep).</li> <li>d. Explain importance of rest for relieving systematic, articular, and emotional stress.</li> <li>e. Explain how to use energy conservation techniques (pacing, delegating, setting priorities).</li> <li>f. Identify physical and emotional factors that can cause fatigue.</li> </ol> </li> <li>2. Facilitate development of appropriate activity/rest schedule.</li> <li>3. Encourage adherence to the treatment program.</li> <li>4. Refer to and encourage a conditioning program.</li> <li>5. Encourage adequate nutrition, including source of iron from food and supplements.</li> </ol>	<ol style="list-style-type: none"> <li>1. The patient's understanding of fatigue will affect his or her actions.               <ol style="list-style-type: none"> <li>a. The amount of fatigue is directly related to the activity of the disease.</li> <li>b. Relief of discomfort can relieve fatigue.</li> <li>c. Effective bedtime routine promotes restorative sleep.</li> <li>d. Different kinds of rest are needed to relieve fatigue and are based on patient need and response.</li> <li>e. A variety of measures can be used to conserve energy.</li> <li>f. Awareness of the various causes of fatigue provides the basis for measures to modify the fatigue.</li> </ol> </li> <li>2. Alternating rest and activity conserves energy while allowing most productivity.</li> <li>3. Overall control of disease activity can decrease the amount of fatigue.</li> <li>4. Deconditioning resulting from lack of mobility, understanding, and disease activity contributes to fatigue.</li> <li>5. A nutritious diet can help counteract fatigue.</li> </ol>	<ul style="list-style-type: none"> <li>• Self-evaluates and monitors fatigue pattern</li> <li>• Verbalizes the relationship of fatigue to disease activity</li> <li>• Uses comfort measures as appropriate</li> <li>• Practices effective sleep hygiene and routine</li> <li>• Makes use of various assistive devices (splints, canes) and strategies (bed rest, relaxation techniques) to ease different kinds of fatigue</li> <li>• Incorporates time management strategies in daily activities</li> <li>• Uses appropriate measures to prevent physical and emotional fatigue</li> <li>• Has an established plan to ensure well-paced, therapeutic activity schedule</li> <li>• Adheres to therapeutic program</li> <li>• Follows a planned conditioning program</li> <li>• Consumes a nutritious diet consisting of appropriate food groups and recommended daily allowance of vitamins and minerals</li> </ul>

## Plan of Nursing Care

### Care of the Patient With a Rheumatic Disease (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Patient Outcomes

**Nursing Diagnosis:** Impaired physical mobility related to decreased range of motion, muscle weakness, pain on movement, limited endurance, lack of or improper use of ambulatory devices

**Goal:** Attains and maintains optimal functional mobility

- |   |  |  |
|---|--|--|
| <ol style="list-style-type: none"> <li>1. Encourage verbalization regarding limitations in mobility.</li> <li>2. Assess need for occupational or physical therapy consultation:               <ol style="list-style-type: none"> <li>a. Emphasize range of motion of affected joints.</li> <li>b. Promote use of assistive ambulatory devices.</li> <li>c. Explain use of safe footwear.</li> <li>d. Use individual appropriate positioning/posture.</li> </ol> </li> <li>3. Assist to identify environmental barriers.</li> <li>4. Encourage independence in mobility and assist as needed.               <ol style="list-style-type: none"> <li>a. Allow ample time for activity</li> <li>b. Provide rest period after activity.</li> <li>c. Reinforce principles of joint protection and work simplification.</li> </ol> </li> <li>5. Initiate referral to community health agency.</li> </ol> | <ol style="list-style-type: none"> <li>1. Mobility is not necessarily related to deformity. Pain, stiffness, and fatigue may temporarily limit mobility. The degree of mobility is not synonymous with the degree of independence. Decreased mobility may influence a person's self-concept and lead to social isolation.</li> <li>2. Therapeutic exercises, proper footwear, and/or assistive equipment may improve mobility. Correct posture and positioning are necessary for maintaining optimal mobility.</li> <li>3. Furniture and architectural adaptations may enhance mobility.</li> <li>4. Changes in mobility may lead to a decrease in personal safety.</li> <li>5. The degree of mobility may be slow to improve or may not improve with intervention.</li> </ol> | <ul style="list-style-type: none"> <li>• Identifies factors that interfere with mobility</li> <li>• Describes and uses measures to prevent loss of motion</li> <li>• Identifies environmental (home, school, work, community) barriers to optimal mobility</li> <li>• Uses appropriate techniques and/or assistive equipment to aid mobility</li> <li>• Identifies community resources available to assist in managing decreased mobility</li> </ul> |
|---|--|--|

**Nursing Diagnosis:** Self-care deficits related to contractures, fatigue, or loss of motion

**Goal:** Achieves self-care independently or with the use of resources

- |   |   |   |
|---|---|---|
| <ol style="list-style-type: none"> <li>1. Assist patient to identify self-care deficits and factors that interfere with ability to perform self-care activities.</li> <li>2. Develop a plan based on the patient's perceptions and priorities on how to establish and achieve goals to meet self-care needs, incorporating joint protection, energy conservation, and work simplification concepts.               <ol style="list-style-type: none"> <li>a. Provide appropriate assistive devices.</li> <li>b. Reinforce correct and safe use of assistive devices.</li> <li>c. Allow patient to control timing of self-care activities.</li> <li>d. Explore with the patient different ways to perform difficult tasks or ways to enlist the help of someone else.</li> </ol> </li> <li>3. Consult with community health care agencies when individuals have attained a maximum level of self-care yet still have some deficits, especially regarding safety.</li> </ol> | <ol style="list-style-type: none"> <li>1. The ability to perform self-care activities is influenced by the disease activity and the accompanying pain, stiffness, fatigue, muscle weakness, loss of motion, and depression.</li> <li>2. Assistive devices may enhance self-care abilities. Effective planning for changes must include the patient who must accept and adopt the plan.</li> <li>3. Individuals differ in ability and willingness to perform self-care activities. Changes in ability to care for self may lead to a decrease in personal safety.</li> </ol> | <ul style="list-style-type: none"> <li>• Identifies factors that interfere with the ability to perform self-care activities</li> <li>• Identifies alternative methods for meeting self-care needs</li> <li>• Uses alternative methods for meeting self-care needs</li> <li>• Identifies and uses other health care resources for meeting self-care needs</li> </ul> |
|---|---|---|

(continued)

## Plan of Nursing Care

### Care of the Patient With a Rheumatic Disease (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Patient Outcomes

**Nursing Diagnosis:** Disturbed body image related to physical and psychological changes and dependency imposed by chronic illness

**Goal:** Adapts to physical and psychological changes imposed by the rheumatic disease

- |   |  |  |
|---|--|--|
| <ol style="list-style-type: none"> <li>1. Help patient identify elements of control over disease symptoms and treatment.</li> <li>2. Encourage patient's verbalization of feelings, perceptions, and fears.               <ol style="list-style-type: none"> <li>a. Help to assess present situation and identify problems.</li> <li>b. Assist to identify past coping mechanisms.</li> <li>c. Assist to identify effective coping mechanisms.</li> </ol> </li> </ol> | <ol style="list-style-type: none"> <li>1. The individual's self-concept may be altered by the disease or its treatment.</li> <li>2. The individual's coping strategies reflect the strength of his or her self-concept.</li> </ol> | <ul style="list-style-type: none"> <li>• Verbalizes an awareness that changes taking place in self-concept are normal responses to rheumatic disease and other chronic illnesses</li> <li>• Identifies strategies to cope with altered self-concept</li> </ul> |
|---|--|--|

**Nursing Diagnosis:** Ineffective coping related to actual or perceived lifestyle or role changes

**Goal:** Use of effective coping behaviors for dealing with actual or perceived limitations and role changes

|--|--|---|

Care must be taken so that splinting for comfort does not restrict mobility later. The knee is splinted at full extension and the wrist at slight dorsiflexion. Because of the predominant strength of flexor muscles, the joints should not be permitted to "freeze" in positions of flexion. This can be prevented by regularly removing the splint and exercising the joint through a range of motion. Splint modification may be needed when changes occur in joint structure.

Additionally, assistive devices may be necessary for mobility. They should be properly fitted and the patient should be instructed in their correct and safe use. A cane, long enough to allow for only a slight bend of the elbow, should be held in the hand opposite the affected side. Forearm-trough style crutches (platform crutches) may be needed to protect the upper extremities if the disease also involves the hands and wrists. This is especially important for the patient undergoing rehabilitation after

lower extremity joint reconstructive surgery. Assistive devices can mean the difference between dependence and independence in mobility; however, they may also alter the patient's body image, which can become a barrier to compliance with treatment.

#### FACILITATING SELF-CARE

Adaptive equipment may increase the patient's independence. When introducing adaptive equipment, however, the nurse should be sensitive to the patient's feelings by demonstrating acceptance and positive attitudes about using these devices. The nurse needs to keep in mind that a patient's deformity does not necessarily equate with the severity of limitations or disability. For example, swollen hands may be more limiting than deformed hands. The nurse in the hospital or in the extended care facility can help preserve the patient's independence in these settings by making available adaptive equipment for eating, toileting,

bathing, and dressing. In the home, the nurse can encourage use of these devices. Again, by relieving pain, stiffness, and fatigue, the nurse may increase the patient's ability to perform self-care (Luck, 2001).

### IMPROVING BODY IMAGE AND COPING

All aspects of the patient's life, including perception of self, work role, social life, sexual function, and financial status, may be altered because of the unpredictability and uncertainty of the course of a rheumatic disease. Body image changes may cause social isolation and depression. The nurse and the family need to empathize with the patient's emotional reactions to the disease. Communication should be encouraged so that the patient and family verbalize feelings, perceptions, and fears related to the disease. The nurse helps the patient and family identify areas in which they have some control over disease symptoms and treatment. The nurse also encourages commitment to the treatment program, which is a key to positive outcomes, as well as use of effective coping strategies.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Medications used for treating rheumatic diseases have the potential for serious and adverse effects. Thus, an important aspect of care is avoiding medication-induced complications. The physician bases the prescribed medication regimen on clinical findings and past medical history, then monitors for side effects with periodic clinical assessments and laboratory testing. The nurse has a major role in working with the physician and pharmacist to help the patient recognize and deal with side effects from medications. These side effects may include gastrointestinal bleeding or irritation, bone marrow suppression, kidney or liver toxicity, infection, mouth sores, rashes, and changes in vision. Other signs and symptoms include bruising, breathing problems, dizziness, jaundice, dark urine, black or bloody stools, diarrhea, nausea and vomiting, and headaches. Systemic and local infections, which can often be masked by high doses of corticosteroids, need close monitoring (see Table 54-3 for more information about administration considerations).

Patient instruction also includes teaching correct techniques of self-administration of medications, methods of reducing side effects, and measures to ensure regular monitoring. The nurse can be available for consultation between physician visits. If side

effects occur, the medication may need to be stopped or the dose reduced. The patient may experience an increase in symptoms while the complication is being resolved or a new medication is being initiated. In such cases, the nurse's counseling regarding symptom management may relieve potential anxiety and distress.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

Patient teaching is an essential aspect of nursing care of the patient with rheumatic disease to enable the patient to maintain as much independence as possible, to take medications accurately and safely, and to use adaptive devices correctly. Patient teaching focuses on the disorder itself, the possible changes related to the disorder, the therapeutic regimen prescribed to treat it, the side effects of medications, strategies to maintain independence and function, and patient safety in the home (Chart 54-2).

The patient and family are encouraged to verbalize their concerns and ask questions. Pain, fatigue, and depression can interfere with the patient's ability to learn and should be addressed before initiating teaching. Various educational strategies may then be used, depending on the patient's previous knowledge base, interest level, degree of comfort, social or cultural influences, and readiness to learn. The nurse instructs the patient about basic disease management and necessary adaptations in lifestyle. Because suppression of inflammation and autoimmune responses requires the use of anti-inflammatory, disease-modifying antirheumatic and immunosuppressive agents, the patient is taught about prescribed medications, including type, dosage, rationale, side effects, self-administration, and required monitoring procedures. If hospitalized, the patient is encouraged to practice new self-management skills with support from caregivers and significant others. The nurse then reinforces disease management skills during each patient contact. Barriers to compliance are assessed and measures are taken to promote adherence to medications and the treatment program.

#### Continuing Care

Depending on the severity of the disorder and the patient's resources and supports, referral for home care may or may not be warranted. However, the patient who is elderly or frail, has a rheumatic disorder that limits function significantly, and lives alone may need a referral for home care.

Chart 54-2

#### Home Care Checklist • The Patient with Rheumatic Disease

*At the completion of the home care instruction, the patient or caregiver will be able to:*

	Patient	Caregiver
• Explain the nature of the disease and principles of disease management.	✓	✓
• Describe the medication regimen (name of medications, dosage, schedule of administration, precautions, side effects, and desired effects).	✓	✓
• Identify monitoring procedures and strategies that should be implemented.	✓	✓
• Identify sources of additional information, if necessary.	✓	✓
• Demonstrate accurate and safe self-administration of medications.	✓	✓
• Describe and demonstrate use of pain management techniques.	✓	✓
• Demonstrate use of joint protection techniques in activities of daily living (ADLs).	✓	✓
• Demonstrate ability to perform self-care activities independently or with assistive devices.	✓	
• Demonstrate a safe exercise program.	✓	
• Demonstrate a relaxation technique.	✓	

The impact of rheumatic disease on everyday life is not always evident when the patient is seen in the hospital or an ambulatory care setting. The increased frequency with which nurses see patients in the home provides opportunities for recognizing problems and implementing interventions aimed at improving the quality of life of patients with rheumatic disorders. The patient encountered in the home setting often has a rheumatic disease that is secondary to the primary reason for the visit. In such cases, the problems caused by the rheumatic disease may interfere with the treatment of the primary condition. For example, the patient who is recovering from coronary artery surgery may have been instructed to exercise but is unable or only partially able to do so because of the rheumatic disease. Conversely, treatment of the primary condition may cause or increase problems related to the rheumatic disease. For example, the cardiac patient who has been instructed to walk long distances every day may find that doing so increases the symptoms of OA in the knees.

During home visits, the nurse has the opportunity to assess the home environment and its adequacy for patient safety and management of the disorder. Compliance with the treatment program can be more easily monitored in the home setting, where physical and social barriers to adherence are more readily identified. For example, the patient with diabetes who requires insulin may be unable to fill the syringe accurately or administer the insulin because of impaired joint mobility. Appropriate adaptive equipment needed for increased independence is often identified more readily when the nurse sees how the patient functions in the home. Any barriers to compliance can be identified and appropriate referrals made.

For patients at risk for impaired skin integrity, the home care nurse can closely monitor skin status and also instruct, provide, or supervise the patient and family in preventive skin care measures. The nurse also assesses the patient's need for assistance in the home and supervises home health aides, who may meet many of the needs of the patient with a rheumatic disease. Referrals to physical and occupational therapists may be made as problems are identified and limitations increase. A home care nurse can visit the home to make sure the patient can function as independently as possible despite mobility problems and can safely manage treatments and pharmacotherapy. The patient and family should be alerted to support services such as Meals on Wheels and local Arthritis Foundation chapters.

Because many of the medications to suppress inflammation are injectable, the nurse may administer the medication to the patient or teach self-injection procedure. These frequent contacts allow the nurse to reinforce other disease management techniques.

The nurse also assesses the patient's physical and psychological status, adequacy of symptom management, and adherence to the management plan. Previous teaching is reinforced with emphasis on side effects of medications and changes in physical status indicating disease progression and the need to contact the health care provider for reevaluation; otherwise, patients may wait until their next appointment. The importance of follow-up appointments is emphasized to the patient and family.

Patients with chronic disorders often neglect general health issues if they are focused on their chronic disorder; therefore, the patient and family should be reminded about the importance of participating in other health promotion activities and health screening (eg, immunizations, cholesterol screening, bone density testing, gynecologic examinations, mammography, colonoscopy).

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Experiences relief of pain or improved comfort level
  - a. Identifies factors that cause or increase pain
  - b. Identifies realistic goals for pain relief
  - c. Uses pain management strategies safely and effectively
  - d. Reports decreased pain and increased comfort level
2. Experiences reduction in level of fatigue
  - a. Identifies factors that contribute to fatigue
  - b. Verbalizes the relationship of fatigue to disease activity
  - c. Schedules periodic rest periods and identifies and uses other measures to prevent or modify fatigue
  - d. Reports decreased level of fatigue
  - e. Practices energy conservation strategies
3. Improves sleep patterns
  - a. Reports fewer night-time awakenings
  - b. Adheres to sleep-inducing routine
  - c. Reports feeling rested upon awakening
4. Increases or maintains level of mobility
  - a. Identifies factors that impede mobility
  - b. Participates in activities and exercises that promote or maintain mobility
  - c. Uses assistive devices appropriately and safely
  - d. Demonstrates normal or acceptable body alignment and posture
5. Maintains self-care activities
  - a. Participates in self-care activities within capabilities
  - b. Uses adaptive equipment and alternative methods to increase participation in self-care activities
  - c. Maintains self-care at highest possible level
6. Experiences improved body image and coping
  - a. Verbalizes concerns about the impact of rheumatic disease on appearance and function
  - b. Sets and achieves meaningful goals
  - c. States acceptance of self-worth
  - d. Adapts to body image changes caused by disease
  - e. Identifies and uses effective coping strategies
7. Experiences absence of complications
  - a. Takes medications as prescribed
  - b. States potential side effects of medications and names reportable side effects
  - c. Verbalizes understanding of rationale for monitoring
  - d. Complies with recommendations for monitoring
  - e. Identifies strategies to reduce risks of side effects

## Diffuse Connective Tissue Diseases

Diffuse connective tissue disease refers to a group of disorders that are chronic in nature and characterized by diffuse inflammation and degeneration in the connective tissues. These disorders share similar clinical features and may affect some of the same organs. The characteristic clinical course is one of exacerbations and remissions. Although the diffuse connective tissue diseases have unknown causes, they are thought to be the result of immunologic abnormalities. They include RA, SLE, scleroderma, polymyositis, and polymyalgia rheumatica.

## RHEUMATOID ARTHRITIS

### Pathophysiology

RA is commonly used as the prototype for inflammatory arthritis. The incidence rate is approximately 3%, with a two to three times greater incidence in women (Ruddy et al., 2001). In RA, the autoimmune reaction (Fig. 54-3) primarily occurs in the synovial tissue. Phagocytosis produces enzymes within the joint. The enzymes break down collagen, causing edema, proliferation of the synovial membrane, and ultimately pannus formation. Pannus destroys cartilage and erodes the bone. The consequence is loss of articular surfaces and joint motion. Muscle fibers undergo degenerative changes. Tendon and ligament elasticity and contractile power are lost.

### Clinical Manifestations

Clinical manifestations of RA vary, usually reflecting the stage and severity of the disease. Joint pain, swelling, warmth, erythema, and lack of function are classic. Palpation of the joints reveals spongy or boggy tissue. Often fluid can be aspirated from

the inflamed joint. Characteristically, the pattern of joint involvement begins with the small joints in the hands, wrists, and feet. As the disease progresses, the knees, shoulders, hips, elbows, ankles, cervical spine, and temporomandibular joints are involved. The onset of symptoms is usually acute. Symptoms are usually bilateral and symmetric. In addition to joint pain and swelling, another classic sign of RA is joint stiffness, especially in the morning, lasting for more than 30 minutes (Klippel, 2001).

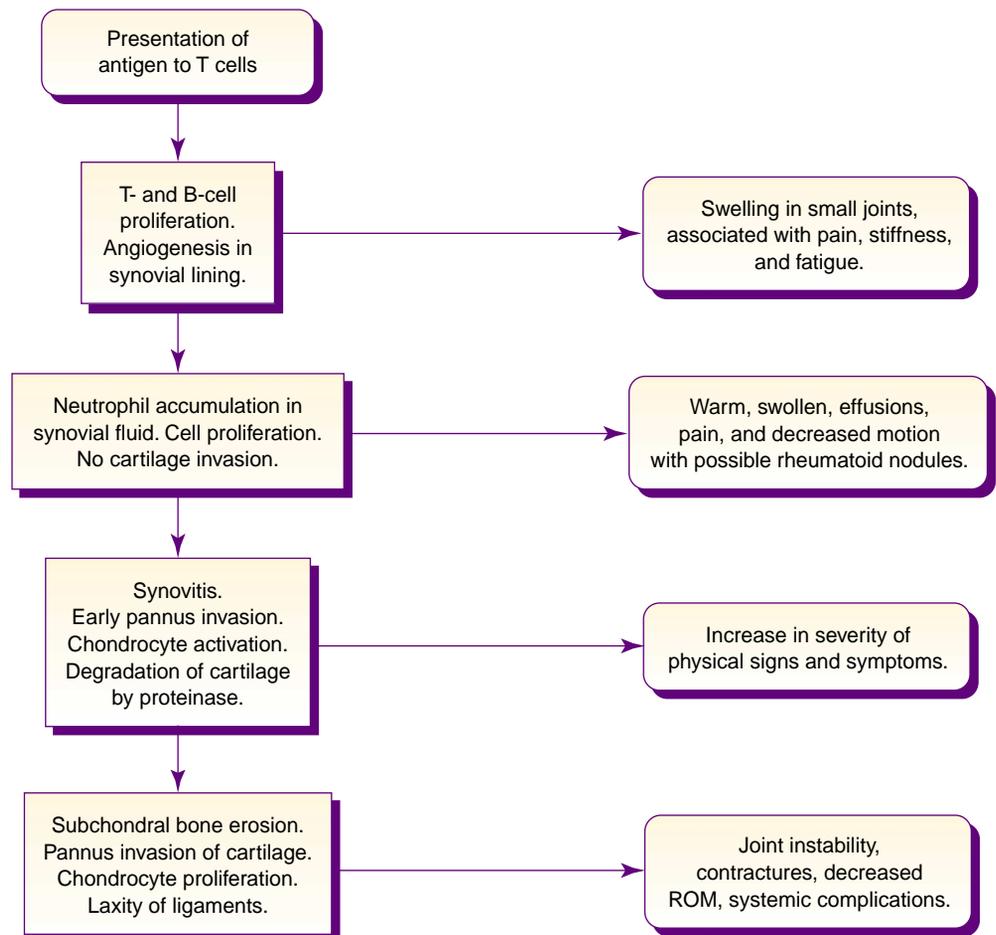

In the early stages of disease, even before bony changes occur, limitation in function can occur when there is active inflammation in the joints. Joints that are hot, swollen, and painful are not easily moved. The patient tends to guard or protect these joints through immobilization. Immobilization for extended periods can lead to contractures, creating soft tissue deformity.

Deformities of the hands and feet are common in RA (Fig. 54-4). The deformity may be caused by misalignment resulting from swelling, progressive joint destruction, or the subluxation (partial dislocation) that occurs when a bone slips over another and eliminates the joint space.

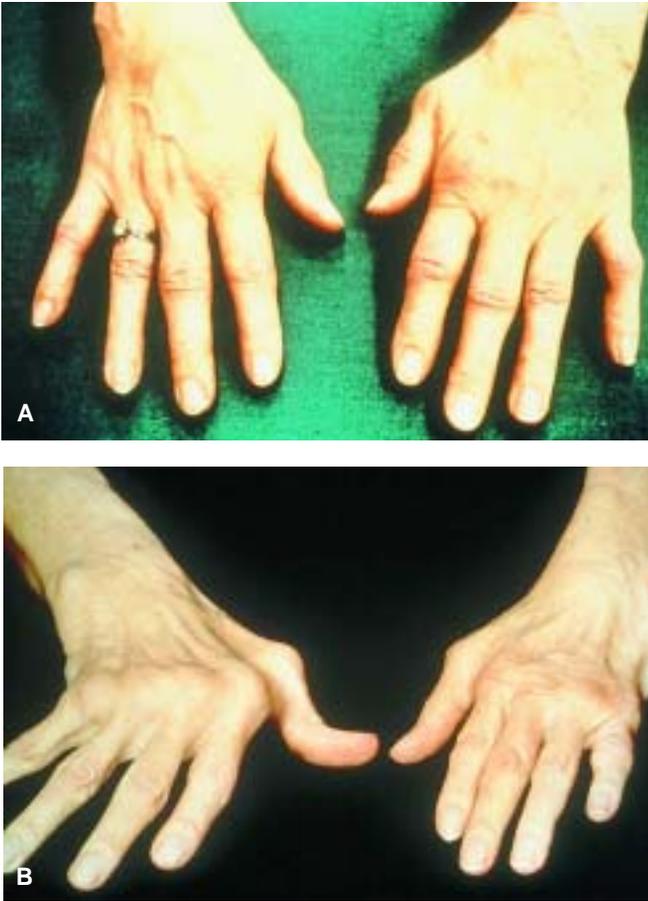

RA is a systemic disease with multiple extra-articular features. Most common are fever, weight loss, fatigue, anemia, lymph node enlargement, and Raynaud's phenomenon (cold- and

### Physiology/Pathophysiology

**FIGURE 54-3** Pathophysiology and associated physical signs of rheumatoid arthritis.

**FIGURE 54-4** Rheumatoid arthritis. (A) Early. (B) Advanced.

stress-induced vasospasm causing episodes of digital blanching or cyanosis). Rheumatoid nodules may be noted in patients with more advanced RA and develop at some time in up to half of patients (Klippel, 2001). These nodules are usually nontender and movable in the subcutaneous tissue. They usually appear over bony prominences such as the elbow, are varied in size, and can disappear spontaneously. Nodules occur only in individuals who have rheumatoid factor. The nodules often are associated with rapidly progressive and destructive disease. Other extra-articular features include arteritis, neuropathy, scleritis, pericarditis, splenomegaly, and Sjögren's syndrome (dry eyes and dry mucous membranes).

### Assessment and Diagnostic Findings

Several factors can contribute to a diagnosis of RA: rheumatoid nodules, joint inflammation detected on palpation, and certain laboratory findings. The history and physical examination address manifestations such as bilateral and symmetric stiffness, tenderness, swelling, and temperature changes in the joints. The patient is also assessed for extra-articular changes; these often include weight loss, sensory changes, lymph node enlargement, and fatigue. Rheumatoid factor is present in more than 80% of patients with RA, but its presence alone is not diagnostic of RA. The erythrocyte sedimentation rate (ESR) is significantly elevated with RA. The red blood cell count and C4 complement component are decreased. C-reactive protein and antinuclear antibody test results may also be positive. Arthrocentesis shows synovial

fluid that is cloudy, milky, or dark yellow and contains numerous inflammatory components, such as leukocytes and complement.

X-ray studies, performed to help diagnose and monitor the progression of disease, show characteristic bony erosions and narrowed joint spaces occurring later in the disease.

## Medical Management

### EARLY-STAGE RA

In patients with early RA, treatment begins with education, a balance of rest and exercise, and referral to community agencies for support. Medical management begins with therapeutic doses of salicylates or NSAIDs. When used in full therapeutic dosages, these medications provide both anti-inflammatory and analgesic effects. Taking medications as prescribed to maintain a consistent blood level is necessary to optimize the effectiveness of the anti-inflammatory medication.

Several COX-2 inhibitors, another class of NSAIDs, have been approved for treatment of RA. COX (cyclo-oxygenase) is an enzyme involved in the inflammatory process. COX-2 inhibitors block the enzyme involved in inflammation while leaving intact the enzyme involved in protecting the stomach lining. As a result, COX-2 inhibitors are less likely to cause gastric irritation and ulceration than other NSAIDs (Bombardier et al., 2000).

The trend in management is toward a more aggressive pharmacologic approach earlier in the disease. A window of opportunity for symptom control and improved disease management occurs within the first 2 years of disease onset. Therefore, the disease-modifying antirheumatic agents (antimalarials, gold, penicillamine, or sulfasalazine) are initiated early in treatment. If symptoms appear to be aggressive (ie, early bony erosions as seen on x-rays), methotrexate may be considered. Methotrexate is currently the gold standard in the treatment of RA because of its success in improving disease parameters (ie, pain, tender and swollen joints, quality of life). The goals are to control symptoms and prevent destruction of the joints (Koopman, 2001).

An alternative treatment approach for RA has emerged in the area of biologic therapies. Biologic response modifiers are a group of agents that consist of molecules produced by cells of the immune system or by cells that participate in the inflammatory reactions (Koopman, 2001). Recent studies (Moreland et al., 1999; Weinblatt et al., 1999) using tumor necrosis factor-alpha inhibitors, both alone and in combination with other medications, have shown that patients demonstrate significant improvement based on American College of Rheumatology criteria (Felson et al., 1995). Two examples of biologic response modifiers that are currently available are enatercept (Enbrel) and infliximab (Remicade). These agents inhibit the function of tumor necrosis factor-alpha, a key **cytokine** known to play a role in the disease process in RA (Miller, 2001). Research in this area is ongoing.

Additional analgesia may be prescribed for periods of extreme pain. Opioid analgesics are avoided because of the potential for continuing need for pain relief. Nonpharmacologic pain management techniques (eg, relaxation techniques, heat and cold applications) are taught.

### MODERATE, EROSIIVE RA

For moderate, erosive RA, a formal program with occupational and physical therapy is prescribed to educate the patient about principles of joint protection, pacing activities, work simplification, range of motion, and muscle-strengthening exercises. The patient is encouraged to participate actively in the management program. The medication program is reevaluated periodically, and appropriate changes are made if indicated. Cyclosporine,

an immunomodulator, may be added to enhance the disease-modifying effect of methotrexate.

### PERSISTENT, EROSIIVE RA

For persistent, erosive RA, reconstructive surgery and corticosteroids are often used. Reconstructive surgery is indicated when pain cannot be relieved by conservative measures. Surgical procedures include synovectomy (excision of the synovial membrane), tenorrhaphy (suturing a tendon), arthrodesis (surgical fusion of the joint), and **arthroplasty** (surgical repair and replacement of the joint). Surgery is not performed during disease flares.

Systemic corticosteroids are used when the patient has unremitting inflammation and pain or needs a “bridging” medication while waiting for the slower disease-modifying antirheumatic agent (eg, methotrexate) to begin working. Low-dose corticosteroid therapy is prescribed for the shortest time necessary to minimize side effects. Joints that are severely inflamed and fail to respond promptly to the measures outlined previously may be treated by local injection of a corticosteroid (Ruddy et al., 2001).

### ADVANCED, UNREMITTING RA

For advanced, unremitting RA, immunosuppressive agents are prescribed because of their ability to affect the production of antibodies at the cellular level. These include high-dose methotrexate (Rheumatrex), cyclophosphamide (Cytosan), and azathioprine (Imuran). These medications, however, are highly toxic and can produce bone marrow suppression, anemia, gastrointestinal disturbances, and rashes.

Through all stages of RA, depression and sleep deprivation may require the short-term use of low-dose antidepressant medications, such as amitriptyline (Elavil), paroxetine (Paxil), or sertraline (Zoloft), to reestablish an adequate sleep pattern and to manage chronic pain better.

The FDA has approved a medical device for use in treating patients with more severe and longstanding cases of RA who have failed to respond to or are intolerant of disease-modifying antirheumatic drugs. The device, a protein A Immunoabsorption column (Prozorba), is used in 12 weekly 2-hour apheresis treatments to bind IgG (ie, circulating immune complex). In this unique population of patients, a significant improvement using the American College of Rheumatology Criteria for Improvement has been demonstrated in several studies using the Prozorba column (Felson et al., 1999; Gendreau, 2001).

### Nutrition Therapy

Patients with RA frequently experience anorexia, weight loss, and anemia. A dietary history identifies usual eating habits and food preferences. Food selection should include the daily requirements from the basic food groups, with emphasis on foods high in vitamins, protein, and iron for tissue building and repair. For the extremely anorexic patient, small, frequent feedings with increased protein supplements may be prescribed. Some medications (ie, oral corticosteroids) used in RA treatment stimulate the appetite and, when combined with decreased activity, may lead to weight gain. Therefore, patients may need to be counseled about eating a healthy, calorie-restricted diet.

### Nursing Management

Nursing care of the patient with RA follows the basic plan of care presented earlier in the chapter. The most common issues for the patient with RA include pain, sleep disturbance, fatigue,

altered mood, and limited mobility. The patient with newly diagnosed RA needs information about the disease to make daily self-management decisions and to cope with having a chronic disease.

Because of repeated contact with the patient, the nurse has the opportunity to assess and intervene in patient concerns and issues that occur with the diagnosis of a chronic illness such as RA. Because the disease commonly affects young women, major concerns may be related to the effects of the disease on childbearing potential, caring for family, or work responsibilities. The patient with a chronic illness may seek a “cure” or have questions about alternative therapies. Frequently, however, patients are hesitant to share their concerns with health care professionals (American College of Rheumatology, 1998).

## SYSTEMIC LUPUS ERYTHEMATOSUS

The overall prevalence of SLE is estimated to be 100 per 100,000 persons. It occurs 10 times more frequently in women than in men and approximately three times more frequently in the African-American population than in Caucasians (Ruddy et al., 2001).

### Pathophysiology

SLE is a result of disturbed immune regulation that causes an exaggerated production of autoantibodies. This immunoregulatory disturbance is brought about by some combination of genetic, hormonal (as evidenced by the usual onset during the childbearing years), and environmental factors (sunlight, thermal burns). Certain medications, such as hydralazine (Apresoline), procainamide (Pronestyl), isoniazid (INH), chlorpromazine (Thorazine), and some antiseizure medications, have been implicated in chemical or drug-induced SLE.

In SLE, the increase in autoantibody production is thought to result from abnormal suppressor T-cell function, leading to immune complex deposition and tissue damage. Inflammation stimulates antigens, which in turn stimulate additional antibodies, and the cycle repeats.

### Clinical Manifestations

The onset of SLE may be insidious or acute. For this reason, SLE may remain undiagnosed for many years. Clinical features of SLE involve multiple body systems.

### SYSTEMIC MANIFESTATIONS

SLE is an autoimmune systemic disease that can affect any body system. Involvement of the musculoskeletal system, with arthralgias and arthritis (synovitis), is a common presenting feature of SLE. Joint swelling, tenderness, and pain on movement are also common. Frequently, these are accompanied by morning stiffness.

Several different types of skin manifestations may occur in patients with SLE, including subacute cutaneous lupus erythematosus, which involves papulosquamous or annular polycyclic lesions, and discoid lupus erythematosus, which is a chronic rash that has erythematous papules or plaques and scaling and can cause scarring and pigmentation changes. The most familiar skin manifestation (but occurring in fewer than half of patients with SLE) is an acute cutaneous lesion consisting of a butterfly-shaped rash across the bridge of the nose and cheeks (Fig. 54-5). In some cases of discoid lupus erythematosus, only skin involvement may occur. In some SLE patients, the initial skin involvement may be

**FIGURE 54-5** The characteristic butterfly rash of systemic lupus erythematosus.

the precursor to more systemic involvement. The lesions often worsen during exacerbations (flares) of the systemic disease and possibly are provoked by sunlight or artificial ultraviolet light. Oral ulcers, which may accompany skin lesions, may involve the buccal mucosa or the hard palate. The ulcers occur in crops and are often associated with exacerbations.

Pericarditis is the most common cardiac manifestation. Women who have SLE are also at risk for early atherosclerosis.

Serum creatinine levels and urinalysis are used in screening for renal involvement. Early detection allows for prompt treatment so that renal damage can be prevented. Renal involvement may lead to hypertension, which also requires careful monitoring and management.

Central nervous system involvement is widespread, encompassing the entire range of neurologic disease. The varied and frequent neuropsychiatric presentations of SLE are now widely recognized. These are generally demonstrated by subtle changes in behavior patterns or cognitive ability. Depression and psychosis are common (Klippel, 2001; Petri, 2000; Ruddy et al., 2001).

## Assessment and Diagnostic Findings

Diagnosis of SLE is based on a complete history, physical examination, and blood tests. In addition to the general assessment performed for any patient with a rheumatic disease, assessment for known or suspected SLE has special features. The skin is inspected for erythematous rashes. Cutaneous erythematous plaques with an adherent scale may be observed on the scalp, face, or neck. Areas of hyperpigmentation or depigmentation may be noted, depending on the phase and type of the disease. The patient should be questioned about skin changes (because these may be transitory) and specifically about sensitivity to sunlight or artificial ultraviolet light. The scalp should be inspected for alopecia and the mouth and throat for ulcerations reflecting gastrointestinal involvement.

Cardiovascular assessment includes auscultation for pericardial friction rub, possibly associated with myocarditis and accompanying pleural effusions. The pleural effusions and infiltrations, which reflect respiratory insufficiency, are demonstrated by abnormal lung sounds. Papular, erythematous, and purpuric lesions developing on the fingertips, elbows, toes, and extensor surfaces of the forearms or lateral sides of the hand that may become necrotic suggest vascular involvement.

Joint swelling, tenderness, warmth, pain on movement, stiffness, and edema may be detected on physical examination. The joint involvement is often symmetric and similar to that found in RA.

Typically, assessment reveals classic symptoms, including fever, fatigue, and weight loss and possibly arthritis, pleurisy, and pericarditis. Interactions with the patient and family may provide further evidence of systemic involvement. The neurologic assessment is directed at identifying and describing any central nervous system changes. The patient and family members are asked about any behavioral changes, including manifestations of neuroses or psychosis. Signs of depression are noted, as are reports of seizures, chorea, or other central nervous system manifestations.

No single laboratory test confirms SLE; rather, blood testing reveals moderate to severe anemia, thrombocytopenia, leukocytosis, or leukopenia and positive antinuclear antibodies. Other diagnostic immunologic tests support but do not confirm the diagnosis. Hematuria may be found on urinalysis.

## Medical Management

Treatment of SLE includes management of acute and chronic disease. Although SLE can be life-threatening, advances in its treatment have led to improved survival and reduced morbidity. Acute disease requires interventions directed at controlling increased disease activity or exacerbations that may involve any organ system. Disease activity is a composite of clinical and laboratory features that reflect active inflammation secondary to SLE. Management of the more chronic condition involves periodic monitoring and recognition of meaningful clinical changes requiring adjustments in therapy (Ruddy et al., 2001).

The goals of treatment include preventing progressive loss of organ function, reducing the likelihood of acute disease, minimizing disease-related disabilities, and preventing complications from therapy. Management of SLE involves regular monitoring to assess disease activity and therapeutic effectiveness.

## PHARMACOLOGIC THERAPY

Medication therapy for SLE is based on the concept that local tissue inflammation is mediated by exaggerated or heightened immune responses, which can vary widely in intensity and require different therapies at different times. The NSAIDs used for minor clinical manifestations are often used along with corticosteroids in an effort to minimize corticosteroid requirements.

Corticosteroids are the single most important medication available for treatment. They are used topically for cutaneous manifestations, in low oral doses for minor disease activity, and in high doses for major disease activity. Intravenous administration of corticosteroids is an alternative to traditional high-dose oral use. Antimalarial medications are effective for managing cutaneous, musculoskeletal, and mild systemic features of SLE. Immunosuppressive agents (alkylating agents and purine analogs) are used because of their effect on immune function. These medications are generally reserved for patients who have serious forms

of SLE and who have not responded to conservative therapies (Kimberly, 2001; National Institutes of Health, 1998; Ruddy et al., 2001).

## Nursing Management

The nursing care of the patient with SLE is based on the basic plan presented earlier in the chapter. The most common problems include fatigue, impaired skin integrity, body image disturbance, and lack of knowledge for self-management decisions. The disease or its treatment may produce dramatic changes in appearance and considerable distress for the patient. The changes and the unpredictable course of SLE necessitate expert assessment skills and nursing care and sensitivity to the psychological reactions of the patient. Patients may benefit from participation in support groups by receiving disease information, daily management tips, and social support. Because sun and ultraviolet light exposure can increase disease activity or cause an exacerbation, patients should be taught to avoid exposure or to protect themselves with sunscreen and clothing.

Because of the increased risk for involvement of multiple organ systems, patients should understand the need for routine periodic screenings as well as health promotion activities. A dietary consultation may be indicated to ensure that the patient is knowledgeable about dietary recommendations, given the increased risk for cardiovascular disease, including hypertension and atherosclerosis. The nurse instructs the patient about the importance of continuing prescribed medications and addresses the changes and side effects that are likely with their use. The patient is reminded of the importance of monitoring because of the increased risk for systemic involvement, including renal and cardiovascular effects.

## SCLERODERMA

Scleroderma (“hard skin”) is a relatively rare disease that is poorly understood; the cause is unknown. Its incidence is 18 to 20 persons per million per year (Ruddy et al., 2001).

## Pathophysiology

Like other diffuse connective tissue diseases, scleroderma (also known as systemic sclerosis) has a variable course with remissions and exacerbations. Its prognosis is not as optimistic as that of SLE. The disease commonly begins with skin involvement. Mononuclear cells cluster on the skin and stimulate lymphokines to stimulate procollagen. Insoluble collagen is formed and accumulates excessively in the tissues. Initially, the inflammatory response causes edema formation, with a resulting taut, smooth, and shiny skin appearance. The skin then undergoes fibrotic changes, leading to loss of elasticity and movement. Eventually, the tissue degenerates and becomes nonfunctional. This chain of events, from inflammation to degeneration, also occurs in blood vessels, major organs, and body systems (Klippel, 2001).

## Clinical Manifestations

Scleroderma starts insidiously with Raynaud’s phenomenon and swelling in the hands. The skin and the subcutaneous tissues become increasingly hard and rigid and cannot be pinched up from the underlying structures. Wrinkles and lines are obliterated. The skin is dry because sweat secretion over the involved region is suppressed. The extremities stiffen and lose mobility. The condition

spreads slowly; for years, these changes may remain localized in the hands and the feet. The face appears masklike, immobile, and expressionless, and the mouth becomes rigid.

The changes within the body, although not visible directly, are vastly more important than the visible changes. The left ventricle of the heart is involved, resulting in heart failure. The esophagus hardens, interfering with swallowing. The lungs become scarred, impeding respiration. Digestive disturbances occur because of hardening (sclerosing) of the intestinal mucosa. Progressive renal failure may occur.

The patient may manifest a variety of symptoms referred to as the CREST syndrome. CREST stands for calcinosis (calcium deposits in the tissues), Raynaud’s phenomenon, esophageal hardening and dysfunctioning, sclerodactyly (scleroderma of the digits), and telangiectasis (capillary dilation that forms a vascular lesion).

## Assessment and Diagnostic Findings

Assessment focuses on the sclerotic changes in the skin, contractures in the fingers, and color changes or lesions in the fingertips. Assessment of systemic involvement requires a systems review with special attention to gastrointestinal, pulmonary, renal, and cardiac symptoms. Limitations in mobility and self-care activities should be assessed, along with the impact the disease has had (or will have) on body image.

There is no one conclusive test to diagnose scleroderma. A skin biopsy is performed to identify cellular changes specific to scleroderma. Pulmonary studies show ventilation-perfusion abnormalities. Echocardiography identifies pericardial effusion (often present with cardiac involvement). Esophageal studies demonstrate decreased motility in 75% of patients with scleroderma. Blood tests may detect antinuclear antibodies, indicating a connective tissue disorder and possibly distinguishing the subgroup of scleroderma. A positive antinuclear antibody test result is common in patients with scleroderma.

## Medical Management

Treatment of scleroderma depends on the clinical manifestations. All patients require counseling, during which realistic individual goals may be determined. Support measures include strategies to decrease pain and limit disability. A moderate exercise program is encouraged to prevent joint contractures. Patients are advised to avoid extreme temperatures and to use lotion to minimize skin dryness.

## PHARMACOLOGIC THERAPY

No medication regimen has proved effective in modifying the disease process in scleroderma, but various medications are used to treat organ system involvement. Calcium channel blockers and other antihypertensive agents may provide improvement in symptoms of Raynaud’s phenomenon. Anti-inflammatory medications can be used to control arthralgia, stiffness, and general musculoskeletal discomfort (Klippel, 2001; Ramsey-Goldman, 2001).

## Nursing Management

The nursing care of the patient with scleroderma is based on the basic plan of nursing care presented earlier in the chapter. The most common nursing diagnoses of the patient with scleroderma include impaired skin integrity; self-care deficits; imbalanced nutrition, less than body requirements; and disturbed body image. The patient with advanced disease may also have problems with

impaired gas exchange, decreased cardiac output, impaired swallowing, and constipation.

Providing meticulous skin care and preventing the effects of Raynaud's phenomenon are major nursing challenges. Patient teaching must include the importance of avoiding cold and protecting the fingers with mittens in cold weather and when shopping in the frozen-food section of the grocery store. Warm socks and properly fitting shoes are helpful in preventing ulcers. Careful, frequent inspection for early ulcers is important. Smoking cessation is critical.

## POLYMYOSITIS

Polymyositis is one of a group of diseases termed idiopathic inflammatory myopathies. It is a rare condition with an incidence that is estimated to be from fewer than one to eight cases per million (Ruddy et al., 2001).

### Pathophysiology

Polymyositis is classified as autoimmune because autoantibodies are present. However, these antibodies do not cause damage to muscle cells, indicating only an indirect role in tissue damage. The pathogenesis is multifactorial, and a genetic predisposition is likely. Drug-induced disease is rare. Some evidence suggests a viral link.

### Clinical Manifestations

The onset varies from sudden onset with rapid progression to a very slow, insidious onset. Proximal muscle weakness is typically a first symptom. Muscle weakness is usually symmetric and diffuse. Dermatomyositis, a related condition, is most commonly identified by an erythematous smooth or scaly lesion found over the joint surface.

### Assessment and Diagnostic Findings

A complete history and physical examination help to exclude other muscle-related disorders. As with other diffuse connective tissue disorders, no one test confirms polymyositis. An electromyogram is performed to rule out degenerative muscle disease. A muscle biopsy may reveal inflammatory infiltrate in the tissue. Serum studies indicate increased muscle enzyme activity.

### Medical Management

Management involves high-dose corticosteroid therapy initially, followed by a gradual dosage reduction over several months as muscle enzyme activity decreases. Patients who do not respond to corticosteroids require the addition of an immunosuppressive agent. For patients who are unresponsive to corticosteroids and immunosuppressive medications, plasmapheresis, lymphapheresis, and total-body irradiation have been used. Skin rashes may respond to the antimalarial drug hydroxychloroquine. Physical therapy is initiated slowly with range-of-motion exercises to maintain joint mobility, followed by gradual strengthening exercises (Klippel, 2001).

### Nursing Management

Nursing care is based on the basic plan of nursing care presented earlier in the chapter. The most frequent nursing diagnoses for the patient with polymyositis include impaired physical mobility,

fatigue, self-care deficit, and insufficient knowledge of self-management techniques.

Patients with polymyositis may have symptoms similar to those of other inflammatory diseases. However, proximal muscle weakness is characteristic, making activities such as combing hair, reaching overhead, and using stairs difficult. Therefore, use of assistive devices may be recommended and referral to occupational or physical therapy may be warranted.

## POLYMYALGIA RHEUMATICA

### Pathophysiology

The underlying mechanism involved with polymyalgia rheumatica is unknown. This disease occurs predominately in Caucasians and often in first-degree relatives. An association with the genetic marker HLA-DR4 suggests a familial predisposition. Immunoglobulin deposits in the walls of inflamed temporal arteries also suggest an autoimmune process.

### Clinical Manifestations

Polymyalgia rheumatica is characterized by severe proximal muscle discomfort with mild joint swelling. Severe aching in the neck, shoulder, and pelvic muscles is common. Stiffness is noticeable most often in the morning and after periods of inactivity. Systemic features include low-grade fever, weight loss, malaise, anorexia, and depression. Because polymyalgia rheumatica generally occurs in people 50 years of age and older, it may be confused with, or disregarded as, an inevitable consequence of aging.

Giant cell arteritis, sometimes associated with polymyalgia rheumatica, may cause headaches, changes in vision, and jaw claudication. These symptoms should be evaluated immediately because of the potential for a sudden and permanent loss of vision if untreated. Polymyalgia rheumatica and giant cell arteritis generally have a self-limited course, lasting several months to several years (Paget, 2001).

### Assessment and Diagnostic Findings

Polymyalgia rheumatica and giant cell arteritis are found almost exclusively in people over 50 years of age. Giant cell arteritis has a reported incidence of 18 cases per 100,000, and polymyalgia rheumatica has an annual incidence rate of 52 cases per 100,000 over age 50 (Loeslie, 2000; Ruddy et al., 2001).

Assessment focuses on musculoskeletal tenderness, weakness, and decreased function. Careful attention should be directed toward assessing the head (for changes in vision, headaches, and jaw claudication).

Often diagnosis is difficult because of the lack of specificity of tests. A markedly high ESR is a screening test but is not definitive. Diagnosis is more likely to be made by eliminating other potential diagnoses, but this is highly dependent on the skills and experience of the diagnostician. The dramatic and immediate response to treatment with corticosteroids is considered by some to be diagnostic.

### Medical Management

Polymyalgia rheumatica (without giant cell arteritis) is treated with moderate doses of corticosteroids. NSAIDs are sometimes used for mild disease. For patients with giant cell arteritis, rapid initiation of and strict adherence to a regimen of corticosteroids are essential to avoid the complication of blindness.

## Nursing Management

The nursing care of the patient with polymyalgia rheumatica is based on the basic plan of nursing care presented earlier in the chapter. The most common nursing diagnoses include pain and insufficient knowledge of the medication regimen.

A management concern is that the patient will take the prescribed medication, frequently corticosteroids, until symptoms improve and then discontinue the medication. The decision to discontinue the medication should be based on clinical and laboratory findings. Nursing implications are related to helping the patient prevent and monitor side effects from medications (eg, infections, diabetes mellitus, gastrointestinal problems, and depression) and adjust to side effects that cannot be prevented (eg, increased appetite and altered body image).

**NURSING ALERT** The nurse must emphasize to the patient the need for continued adherence to the prescribed medication regimen to avoid complications of giant cell arteritis such as blindness.

The loss of bone mass with corticosteroid use increases the risk for osteoporosis in this already at-risk population. Interventions to promote bone health such as adequate dietary calcium and vitamin D, weight-bearing exercise, and smoking cessation, if indicated, should be emphasized (Buckley et al., 2001; Loeslie, 2000).

## Degenerative Joint Disease (Osteoarthritis)

OA, also known as degenerative joint disease or osteoarthrosis (even though inflammation may be present), is the most common and frequently disabling of the joint disorders. OA is both overdiagnosed and trivialized; it is frequently overtreated or undertreated. The functional impact of OA on quality of life, especially for elderly patients, is often ignored.

OA has been classified as primary (idiopathic), with no prior event or disease related to the OA, and secondary, resulting from previous joint injury or inflammatory disease. The distinction between primary and secondary OA is not always clear.

Increasing age directly relates to the degenerative process in the joint, as the ability of the articular cartilage to resist microfracture with repetitive low loads diminishes. OA often begins in the third decade of life and peaks between the fifth and sixth decades. By age 75 years, 85% of the population has either x-ray or clinical evidence of OA, but only 15% to 25% of these people experience significant symptoms (Ruddy et al., 2001).

## Pathophysiology

OA may be thought of as the end result of many factors combining in a generalized predisposition to the disease. OA affects the articular cartilage, subchondral bone (the bony plate that supports the articular cartilage), and synovium. A combination of cartilage degradation, bone stiffening, and reactive inflammation of the synovium occurs. The basic degenerative process in the joint exemplified in OA is presented in Figure 54-6. Understanding of OA has been greatly expanded beyond what previously was thought of as simply “wear and tear” related to aging. Risk factors for OA are summarized in Chart 54-3.

Congenital and developmental disorders of the hip are well known for predisposing a person to OA of the hip. These include congenital subluxation–dislocation of the hip, acetabular dysplasia, Legg-Calvé-Perthes disease, and slipped capital femoral epiphysis.

## Physiology/Pathophysiology

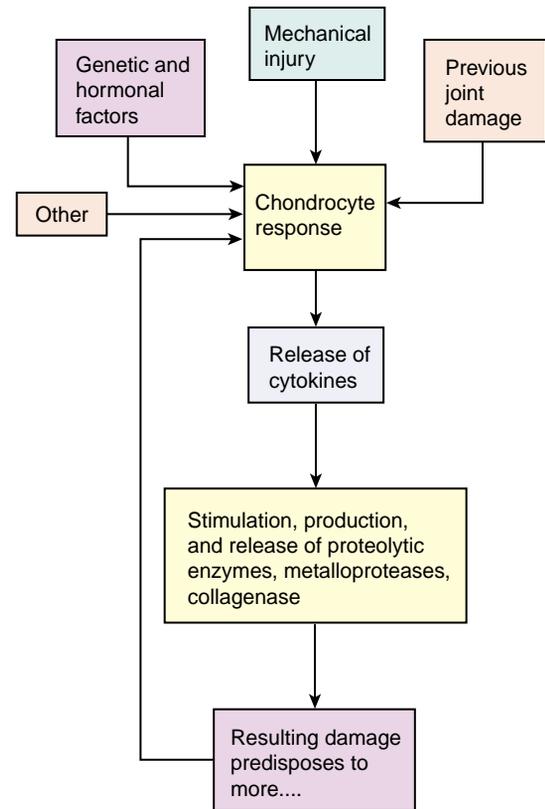

FIGURE 54-6 Pathophysiology of osteoarthritis.

Obesity is now a well-recognized risk factor for the development of OA (USDHHS, 2001). Being overweight or obese also increases the pain and discomfort associated with the disease (Altman et al., 2000; Coggon et al., 2001).

## Clinical Manifestations

The primary clinical manifestations of OA are pain, stiffness, and functional impairment. The pain is due to an inflamed synovium, stretching of the joint capsule or ligaments, irritation of nerve endings in the periosteum over osteophytes, trabecular microfracture, intraosseous hypertension, bursitis, tendinitis, and muscle spasm. Stiffness, which is most commonly experienced in the morning or after awakening, usually lasts less than 30 minutes

### Chart 54-3

### Risk Factors for Osteoarthritis

- Increased age
- Obesity
- Previous joint damage
- Repetitive use (occupational or recreational)
- Anatomic deformity
- Genetic susceptibility

and decreases with movement. Functional impairment is due to pain on movement and limited motion caused by structural changes in the joints.

Although OA occurs most often in weight-bearing joints (hips, knees, cervical and lumbar spine), the proximal and distal finger joints are also often involved. Characteristic bony nodes may be present; on inspection and palpation, these are usually painless, unless inflammation is present.

### Assessment and Diagnostic Findings

Diagnosis of OA is complicated because only 30% to 50% of patients with changes seen on x-rays report symptoms. Physical assessment of the musculoskeletal system reveals tender and enlarged joints. Inflammation, when present, is not the destructive type seen in the connective tissue diseases such as RA. OA is characterized by a progressive loss of the joint cartilage, which appears on x-ray as a narrowing of joint space. In addition, reactive changes occur at the joint margins and on the subchondral bone in the form of osteophytes (or spurs) as the cartilage attempts to regenerate. Neither the presence of osteophytes nor joint space narrowing alone is specific for OA; however, when combined, these are sensitive and specific findings. In early or mild OA, there is only a weak correlation between joint pain and synovitis. Blood tests are not useful in the diagnosis of OA.

### Medical Management

Although no treatment halts the degenerative process, certain preventive measures can slow the progress if undertaken early enough. These include weight reduction, prevention of injuries, perinatal screening for congenital hip disease, and ergonomic modifications.

Conservative treatment measures include the use of heat, weight reduction, joint rest and avoidance of joint overuse, orthotic devices to support inflamed joints (splints, braces), isometric and postural exercises, and aerobic exercise. Occupational and physical therapy can help the patient adopt self-management strategies.

### PHARMACOLOGIC THERAPY

Pharmacologic management of OA is directed toward symptom management and pain control. Medications are used in conjunction with nonpharmacologic strategies, which are the mainstay of OA management (Altman et al., 2000). In most patients with OA, the initial analgesic therapy is acetaminophen. Some patients respond to the nonselective NSAIDs, and patients who are at increased risk for gastrointestinal complications, especially gastrointestinal bleeding, have been managed effectively with COX-2 inhibitors (Altman et al., 2000; Beehrle & Evans, 1999; Bombardier et al., 2000; Pasero & McCaffery, 2001; Ruddy et al., 2001). Selection of medication is based on the patient's needs, the stage of disease, and the risk for side effects. Other medications that may be considered are the opioids and intra-articular corticosteroids. Topical analgesics such as capsaicin and methylsalicylate are also recommended (Altman et al., 2000; Ruddy et al., 2001).

Newer therapeutic approaches include glucosamine and chondroitin, which are thought to improve tissue function and retard breakdown of cartilage (Altman et al., 2000; McAlindon et al., 2000). Viscosupplementation, the intra-articular injection of hyaluronic acid, is thought to improve cartilage function and retard degradation; it may also have some anti-inflammatory effects (Huskinson & Donnelly, 1999; Watterson & Esdaile, 2000; Wright et al., 2000). Glucosamine and chondroitin and visco-

supplementation, although approved by the FDA, are still undergoing intensive investigation for safety and efficacy (Brandt et al., 2000).

### SURGICAL MANAGEMENT

In moderate to severe OA, when pain is severe or because of loss of function, surgical intervention may be used. Procedures most commonly used are osteotomy (to alter the force distribution in the joint) and arthroplasty. In arthroplasty, diseased joint components are replaced with artificial products (see Chap. 67).

Other procedures include viscosupplementation (the reconstitution of synovial fluid viscosity). Hyaluronic acid (Hyalgan, Synvisc), a glycosaminoglycan that acts as a lubricant and shock-absorbing fluid in the joint, may be used in this procedure. Hyaluronic acid stimulates the production of synoviocytes, possibly providing better and more prolonged pain control. A series of three to five weekly intra-articular injections are given. Pain relief may last for 6 months (Kellick et al., 1998).

Tidal irrigation (lavage) of the knee involves the introduction and then removal of a large volume of saline into the joint through cannulas. In some cases it provides pain relief for up to 6 months (Klippel, 2001; Lozada & Altman, 2001).

### Nursing Management

The nursing management of the patient with OA includes both pharmacologic and nonpharmacologic approaches. The nonpharmacologic interventions are used first and continued with the addition of pharmacologic agents. Pain management and optimizing functional ability are major goals of nursing intervention. Patients' understanding of their disease process and symptom pattern is critical to a plan of care. Because patients with OA are older, they may have other health problems. Commonly they are overweight, and they may have a sedentary lifestyle. Weight loss and an increase in aerobic activity such as walking, with special attention to quadriceps strengthening, are important approaches to pain management (Altman et al., 2000; Bautch et al., 1997; Ettinger et al., 1997). A referral for physical therapy or to an exercise program for individuals with similar problems may be very helpful. Canes or other assistive devices for ambulation should be considered. Exercises such as walking should be begun in moderation and increased gradually. Patients should plan their daily exercise for a time when the pain is least severe or should plan to use an analgesic, if appropriate, before exercising. Adequate pain management is important for the success of an exercise program.

## Spondyloarthropathies

The spondyloarthropathies are another category of systemic inflammatory disorders of the skeleton. The spondyloarthropathies include ankylosing spondylitis, reactive arthritis (Reiter's syndrome), and psoriatic arthritis. Spondyloarthritis is also associated with inflammatory bowel diseases such as regional enteritis (Crohn's disease) and ulcerative colitis.

These rheumatic diseases share several clinical features. The inflammation tends to occur peripherally at the sites of attachment—at tendons, joint capsules, and ligaments. Periosteal inflammation may be present. Many patients have arthritis of the sacroiliac joints. Onset tends to occur during young adulthood, with the disease affecting men more often than women. There is a strong tendency for these conditions to occur in families. Frequently, the HLA-B27 genetic marker is found.

### NURSING RESEARCH PROFILE 54-1

#### Older Women With Osteoarthritis

Baird, C. L. (2000). Living with hurting and difficulty doing: Older women with osteoarthritis. *Clinical Excellence for Nurse Practitioners*, 4(4), 231–237.

#### Purpose

Osteoarthritis (OA), the most common rheumatic disorder in older adults, presents a major challenge to individuals' independence. A greater understanding of patient experiences is necessary to develop appropriate needs-based interventions to help patients maintain independence. The purpose of this study was to develop an understanding of how OA affects individuals' lives and to provide data on which to base nursing interventions.

#### Study Sample And Design

A qualitative research design was used. After informed written consent was obtained from eligible participants, semistructured interviews were conducted. The interviews were recorded for transcription and analysis. Data analyzed included the transcriptions of the interviews and the investigator's field notes of observations and impressions.

The sample comprised 18 women, 65 to 92 years of age, who reported having OA and who participated in an Area Council on Aging Center or were referred by other study participants. Data were continuously compared throughout data gathering and analysis. A process of deconstructing and reconstructing the data into several levels of categories was carried out.

#### Findings

Subjects reported a continuous condition of "living with OA" and "living with hurting." Hurting characterized the participants' experience because of its chronicity and the participants' persistent discomfort and pain. The hurting was reported as being prominent during activities such as walking, attending to personal care, and managing tasks for independent living. This finding resulted in a second category: "living with difficulty doing." The state of "living with difficulty doing" was characterized by being unable to carry out activities because of pain, stiffness, and instability. Personal care and completing household tasks became difficult and often impossible to accomplish.

#### Nursing Implications

The findings of this study demonstrate the need for health care providers to understand the problems associated with living with OA and to assess the impact of OA on activities of daily living. Further, the findings emphasize the need to help patients with OA to obtain pain relief and to develop alternative strategies to deal with pain and to accomplish tasks important to them. These strategies include helping patients to learn how to pace themselves and to use nonpharmacologic modalities along with pharmacologic therapies for pain relief.

## ANKYLOSING SPONDYLITIS

Ankylosing spondylitis affects the cartilaginous joints of the spine and surrounding tissues. Occasionally, the large synovial joints, such as hips, knees, or shoulders, may be involved. Ankylosing spondylitis is usually diagnosed in the second or third decade of life. The disease is not usually as severe in females as in males, in whom the disease is more prevalent and likely to include significant systemic involvement. Back pain is the characteristic feature. As the disease progresses, ankylosis of the entire spine may occur, leading to respiratory compromise and complications.

## REACTIVE ARTHRITIS (REITER'S SYNDROME)

This disease process is called reactive because the arthritis occurs following an infection. It affects young adult males and is characterized primarily by urethritis, arthritis, and conjunctivitis. Dermatitis and ulcerations of the mouth and penis may also be present. Low back pain is common.

## PSORIATIC ARTHRITIS

Psoriatic arthritis is characterized by synovitis, polyarthritis, and spondylitis. Both psoriasis and arthritis are common conditions, and one theory suggests that the overlap of the two conditions is a chance occurrence. However, epidemiologic data suggest that the prevalence of arthritis in patients with psoriasis is 7% to 42%, exceeding the rate in the general population. Similarly, the prevalence of psoriasis in persons with arthritis is 2.6% to 7.0%, compared with 0.1% to 2.8% in the general population, supporting the theory that these two processes occur together in a unique disease process (Ruddy et al., 2001).

## Medical Management of Spondyloarthropathies

Medical management of spondyloarthropathies focuses on treating pain and maintaining mobility by suppressing inflammation. For the patient with ankylosing spondylitis, good body positioning and posture are essential, so that if **ankylosis** (fixation) does occur, the patient is in the most functional position. Maintaining range of motion with a regular exercise and muscle-strengthening program is especially important.

### PHARMACOLOGIC THERAPY

Salicylates, NSAIDs, and corticosteroids often produce marked improvement in back, skin, and joint symptoms. Methotrexate is also used to control psoriasis as well as joint inflammation.

### SURGICAL MANAGEMENT

Surgical management may include total hip replacement (see Chap. 67).

## Nursing Management of Spondyloarthropathies

Major nursing interventions in the spondyloarthropathies are related to symptom management and maintaining optimal functioning. This population is unique in rheumatology, because patients are primarily young men. Their major concerns are often related to prognosis and job modification, especially among those who perform physical work.

## Metabolic and Endocrine Diseases Associated With Rheumatic Disorders

Metabolic and endocrine diseases may be associated with rheumatic disorders. These include biochemical abnormalities (amyloidosis and scurvy), endocrine diseases (diabetes mellitus and acromegaly), immunodeficiency diseases (HIV infection, AIDS), and other hereditary disorders (hypermobility syndromes). The most common conditions, however, are the crystal-induced

arthropathies in which crystals, such as monosodium urate (gout) or calcium pyrophosphate (calcium pyrophosphate dihydrate disease [CPPD] or pseudogout), are deposited within joints and other tissues.

## GOUT

Gout is a heterogeneous group of conditions related to a genetic defect of purine metabolism resulting in hyperuricemia. Oversecretion of uric acid or a renal defect resulting in decreased excretion of uric acid, or a combination of both, occurs. The prevalence of gout is reported to be 1.6 to 13.6 per thousand. The incidence increases with age and body mass index. It occurs more commonly in males than females (Ruddy et al., 2001).

In primary hyperuricemia, elevated serum urate levels or manifestations of urate deposition appear to be consequences of faulty uric acid metabolism. Primary hyperuricemia may be due to severe dieting or starvation, excessive intake of foods that are high in purines (shellfish, organ meats), or heredity. In secondary hyperuricemia, gout is a clinical feature secondary to any of a number of genetic or acquired processes, including conditions in which there is an increase in cell turnover (leukemia, multiple myeloma, some types of anemias, psoriasis) and an increase in cell breakdown. Altered renal tubular function, either as a major action or as an unintended side effect of certain pharmacologic agents (diuretics such as thiazides and furosemide), low-dose salicylates, and ethanol can contribute to uric acid underexcretion.

## Pathophysiology

Hyperuricemia (serum concentration greater than 7 mg/dL [0.4 mmol/L]) can but does not always cause monosodium urate crystal deposition. However, as uric acid levels rise, risk increases (Ruddy et al., 2001). Attacks of gout appear to be related to sudden increases or decreases of serum uric acid levels. When the urate crystals precipitate within a joint, an inflammatory response occurs and an attack of gout begins. With repeated attacks, accumulations of sodium urate crystals, called **tophi**, are deposited in peripheral areas of the body, such as the great toe, the hands, and the ear. Renal urate lithiasis (kidney stones) with chronic renal disease secondary to urate deposition may develop.

The finding of urate crystals in the synovial fluid of asymptomatic joints suggests that factors other than crystals may be related to the inflammatory reaction. Recovered monosodium urate crystals are coated with immunoglobulins that are mainly immunoglobulin G (IgG). IgG enhances crystal phagocytosis, thereby demonstrating immunologic activity.

## Clinical Manifestations

Manifestations of the gout syndrome include acute gouty arthritis (recurrent attacks of severe articular and periarticular inflammation), tophi (crystalline deposits accumulating in articular tissue, osseous tissue, soft tissue, and cartilage), gouty nephropathy (renal impairment), and uric acid urinary calculi. Four stages of gout can be identified: asymptomatic hyperuricemia, acute gouty arthritis, intercritical gout, and chronic tophaceous gout. The subsequent development of gout is directly related to the duration and magnitude of the hyperuricemia. Therefore, the commitment to lifelong pharmacologic treatment of hyperuricemia is deferred until there is an initial attack of gout.

For hyperuricemic people who are going to develop gout, acute arthritis is the most common early clinical manifestation. The metatarsophalangeal joint of the big toe is the most commonly affected (75% of patients). The tarsal area, ankle, or knee may also be affected. Less commonly, the wrists, fingers, and elbows may be affected. The acute attack may be triggered by trauma, alcohol ingestion, dieting, medications, surgical stress, or illness. The abrupt onset often occurs at night, awakening the patient with severe pain, redness, swelling, and warmth of the affected joint. Early attacks tend to subside spontaneously over 3 to 10 days even without treatment. The attack is followed by a symptom-free period (the intercritical stage) until the next attack, which may not come for months or years. With time, however, attacks tend to occur more frequently, involve more joints, and last longer.

Tophi are generally associated with more frequent and severe inflammatory episodes. Higher serum concentrations of uric acid are also associated with more extensive tophus formation. Tophi most commonly occur in the synovium, olecranon bursa, subchondral bone, infrapatellar and Achilles tendons, subcutaneous tissue on the extensor surface of the forearms, and overlying joints. They have also been found in the aortic walls, heart valves, nasal and ear cartilage, eyelids, cornea, and sclerae. Joint enlargement may cause a loss of joint motion. Uric acid deposits may cause renal stones and kidney damage.

## Medical Management

A definitive diagnosis of gouty arthritis is established by polarized light microscopy of the synovial fluid of the involved joint. Uric acid crystals are seen within the polymorphonuclear leukocytes within the fluid. Colchicine (oral or parenteral) or an NSAID such as indomethacin is used to relieve an acute attack of gout. Management of hyperuricemia, tophi, joint destruction, and renal disorders is usually initiated after the acute inflammatory process has subsided. Uricosuric agents, such as probenecid, correct hyperuricemia and dissolve deposited urate. Allopurinol is also effective, but its use is limited because of the risk for toxicity. When reduction of the serum urate level is indicated, the uricosuric agents are the medications of choice. When the patient has, or is at risk for, renal insufficiency or renal calculi (kidney stones), allopurinol is the medication of choice. Corticosteroids may be used in resistant cases. If the individual experiences several acute episodes or there is evidence of tophi formation, prophylactic treatment is considered. Specific treatment is based on serum uric acid level, 24-hour urinary uric acid excretion, and renal function (Table 54-5).

## Nursing Management

Historically, gouty arthritis was thought to be a condition of the royalty and the very rich, with the disease attributed to “high living.” This has not been shown to be entirely true. While severe dietary restriction is not necessary, patients should be encouraged to restrict consumption of foods high in purines, especially organ meats, and to limit alcohol intake. Maintenance of normal body weight should be encouraged. In an acute episode of gouty arthritis, pain management is essential. During the intercritical period, the patient feels well and may abandon preventive behaviors, which may result in an acute attack. Acute attacks are most effectively treated if therapy is begun early in the course.

Table 54-5 • Medications Used to Treat Gout

MEDICATION	ACTIONS AND USE	NURSING IMPLICATIONS
colchicine	Lowers the deposition of uric acid and interferes with leukocytes and kinin formation, thus reducing inflammation; does not alter serum or urine levels of uric acid; used in acute and chronic management	<i>Acute management:</i> Administer when attack begins; dosage increased until pain relieved or diarrhea develops <i>Chronic management:</i> Prolonged use may decrease vitamin B <sub>12</sub> absorption; causes GI upset in most patients
probenecid (Benemid)	Uricosuric agent; inhibits renal reabsorption of urates and increases the urinary excretion of uric acid; prevents tophi formation	Be alert for nausea, rash, and constipation.
allopurinol (Zyloprim)	Xanthine oxidase inhibitor; interrupts the breakdown of purines before uric acid is formed; inhibits xanthinase because it blocks uric acid formation	Monitor for side effects, including bone marrow depression, vomiting, and abdominal pain.

## Fibromyalgia

Fibromyalgia is a common syndrome that involves chronic fatigue, generalized muscle aching, and stiffness. Two percent of the U.S. population, primarily women of childbearing age, are affected by this syndrome (American College of Rheumatology Fact Sheet, 2000). Although criteria for the classification of fibromyalgia have been established (Wolfe & Skevington, 1990), controversy exists as to whether this diagnosis represents a unique syndrome. The cause is unknown and no pathologic characteristics have been identified that are specific for the condition. Treatment consists of attention to the specific symptoms reported by the patient. NSAIDs may be used to treat the diffuse muscle aching and stiffness. Tricyclic antidepressants are used to improve or restore normal sleep patterns, and individualized programs of exercise are used to decrease muscle weakness and discomfort and to improve the general deconditioning that occurs in these individuals (American College of Rheumatology Fact Sheet, 2000; Burckhardt, 2001b; Clark et al., 2001).

### Nursing Management

Typically, patients with fibromyalgia have endured their symptoms for a long period of time. They may feel as if their symptoms have not been taken seriously. Nurses need to pay special attention to supporting these individuals and providing encouragement as they begin their program of therapy. Patient support groups may be helpful. Careful listening to patients' descriptions of their concerns and symptoms is essential to helping them make changes necessary to improve their quality of life (Anderson & Burckhardt, 1999).

## Arthritis Associated With Infectious Organisms

Arthritis, tenosynovitis, and bursitis can be associated with infectious organisms. Some inflammation of joints, tendons, and bursae is directly related to infection caused by bacterial, viral, fungal, or parasitic agents. Bacterial arthritis is the most rapidly destructive form of infectious arthritis. There are two major classes of bacterial arthritis: arthritis caused by *Neisseria gonorrhoeae* and nongonococcal bacterium. The most prevalent of the nongonococcal organisms include *Staphylococcus aureus* and the various

streptococcal variants. Less common pathogens are related to syphilis, tuberculosis, leprosy, fungi (particularly coccidioidomycosis), mycoplasmas, and viral agents, such as rubella, parvovirus, and hepatitis B.

### Clinical Manifestations

The characteristic symptom is acute onset of a warm, swollen joint. Culture of the bacterium from the synovial fluid confirms the diagnosis. The patient often immobilizes the joint and elevates the affected extremity because of pain and swelling. Fever may be high or it may be absent. Signs of systemic infection may be lacking in elderly patients, those with diabetes, and those with suppressed immune systems. Diagnosis and treatment may be delayed by patients with pre-existing arthritic conditions if they attribute the symptoms to a flare-up of arthritis.

### Management

This condition is a medical emergency necessitating early diagnosis and appropriate treatment to eliminate the causative organism; otherwise, the joint may be destroyed relatively quickly. Treatment consists of parenteral antibiotics and drainage of the joint. The results of cultures are used to determine the appropriate antibiotic therapy. Immobilization of the joint and repeated joint aspirations may be necessary along with intravenous antibiotics. Nursing management focuses on providing pain relief, administering antibiotics, and assisting the patient with self-care activities. If the patient is sent home on intravenous antibiotics, the nurse arranges home care and instructs the patient and care providers in safe administration and changes to report to a health care provider.

## Neoplasms and Neurovascular, Bone, and Extra-Articular Disorders

Primary neoplasms of joints, tendon sheaths, and bursae are rare. Most neoplasms are benign, arising from the synovium. These benign tumors include lipoma, hemangioma, and fibroma and tumor-like lesions such as ganglion, bursitis, and synovial cyst. Malignant tumors include primary tumors, such as synovial and bone sarcomas, and secondary involvement as manifestations of

joint invasion by leukemia, lymphoma, and myeloma or metastasis. Neoplasms may present as back or neck pain.

Neurovascular disorders include the compression syndromes, such as those with peripheral entrapment (carpal tunnel syndrome), radiculopathy, and spinal stenosis. Raynaud's phenomenon or disease and erythromelalgia (throbbing and burning pain often affecting the hands and feet) are also included in this category.

Bone and cartilage disorders include osteoporosis, osteomalacia, hypertrophic osteoarthropathy, diffuse idiopathic skeletal hyperostosis, Paget's disease, osteonecrosis, avascular necrosis, costochondritis, osteolysis or chondrolysis, and biomechanical or anatomic abnormalities. Notably, these conditions involve resorption, destruction, infection, or remodeling of bone.

Extra-articular rheumatism is a descriptive term for a group of conditions affecting structures other than the joints. Included are general and regional pain syndromes, low back pain and intervertebral disk disorders, tendonitis and bursitis, and ganglion cysts.

## Miscellaneous Disorders

The last category in the classification of the rheumatic diseases is aptly labeled miscellaneous disorders because it contains a mix of disorders frequently associated with arthritis and other conditions. These disorders include the direct result of trauma (including internal derangement and loose bodies of joints), pancreatic disease (related to avascular necrosis or osteonecrosis), sarcoidosis (a multisystem disorder particularly of the lymph nodes and lungs), and palindromic rheumatism (an uncommon variety of recurring and acute arthritis and periartthritis that in some may progress to RA but is characterized by symptom-free periods of days to months). Other conditions include villonodular synovitis, chronic active hepatitis, and drug-related rheumatic syndromes. The nursing interventions related to these varied conditions are specific to the multisystemic problems experienced by the patient. However, the musculoskeletal components should not be neglected or overlooked. Further information about these rare disorders can be found in specialty references.

### Critical Thinking Exercises

1. Your 28-year-old, newly married patient has recently been informed that she has SLE. Although she is undergoing extensive testing to determine the systemic effects of SLE, she states that she feels fine and cannot understand the reasons for the testing. What explanations would you provide? Explain the relationship of SLE to possible systemic effects of the disorder.
2. A 68-year-old woman is admitted for surgery to treat a bowel obstruction; it is anticipated that she will have a colostomy. She has advanced rheumatoid arthritis that has affected all four extremities and her cervical spine. How will the rheumatoid arthritis affect her immediate postoperative care? What modifications are necessary to enable her to manage her colostomy, given the effects of arthritis on her hands?
3. A 57-year-old patient with a long history of osteoarthritis comes to the emergency department with severe pain and swelling of his right knee of 10 days' duration. His knee is

hot to the touch and he has a fever. He explains that he thought his symptoms were due to a flare-up of his osteoarthritis. It is suspected that he has infectious arthritis.

Explain the possible consequences of this form of arthritis and the medical and nursing interventions you would anticipate. What are the possible consequences of the delay in seeking treatment?

4. NSAIDs and corticosteroids have been prescribed for your patient's rheumatic disorder. How do the actions of these medications differ, and what instructions and recommendations would you give to the patient to ensure their safe administration?

# ● Assessment of Integumentary Function

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Identify the structures and functions of the skin.
2. Differentiate the composition and function of each skin layer: epidermis, dermis, and subcutaneous tissue.
3. Identify and describe primary and secondary skin lesions and their pattern and distribution.
4. Recognize common skin eruptions and manifestations associated with systemic disease.
5. Describe the normal aging process of the skin and skin changes common to elderly patients.
6. List appropriate questions that will help elicit information during an assessment of the skin.
7. Describe the components of physical assessment most useful when examining the skin, hair, and nails.
8. Discuss common skin tests and procedures used in diagnosing skin and related disorders.

Skin disorders are encountered frequently in nursing practice. Skin-related disorders account for up to 10% of all ambulatory patient visits in this country. Because the skin mirrors the general condition of the patient, many systemic conditions may be accompanied by dermatologic manifestations (Fleischer et al., 2000).

The psychological stress of illness or various personal and family problems is commonly exhibited outwardly as dermatologic problems. Any hospitalized patient may suddenly develop itching and a rash from the treatment regimen. In certain systemic conditions, such as hepatitis and some cancers, dermatologic manifestations may be the first sign of the disorder.

## Anatomic and Physiologic Overview

The largest organ system of the body, the skin is indispensable for human life. Skin forms a barrier between the internal organs and the external environment and participates in many vital body functions. The skin is contiguous with the mucous membrane at the external openings of the digestive, respiratory, and urogenital systems. Because skin disorders are readily visible, dermatologic complaints are commonly the primary reason for a patient to seek health care.

### ANATOMY OF THE SKIN, HAIR, NAILS, AND GLANDS OF THE SKIN

The skin is composed of three layers: epidermis, dermis, and subcutaneous tissue (Fig. 55-1). The epidermis is an outermost layer of stratified epithelial cells and composed predominantly of keratinocytes. It ranges in thickness from about 0.1 mm on the eyelids to about 1 mm on the palms of the hands and soles of the feet. Four distinct layers compose the epidermis, from innermost to outermost: stratum germinativum, stratum granulosum, stratum lucidum, and stratum corneum. Each layer becomes more differentiated (ie, mature and with more specific functions) as it rises from the basal stratum germinativum layer to the outermost stratum corneum layer.

#### Epidermis

The epidermis, which is contiguous with the mucous membranes and the lining of the ear canals, consists of live, continuously dividing cells covered on the surface by dead cells that were origi-

nally deeper in the dermis but were pushed upward by the newly developing, more differentiated cells underneath. This external layer is almost completely replaced every 3 to 4 weeks. The dead cells contain large amounts of **keratin**, an insoluble, fibrous protein that forms the outer barrier of the skin and has the capacity to repel pathogens and prevent excessive fluid loss from the body. Keratin is the principal hardening ingredient of the hair and nails.

**Melanocytes** are the special cells of the epidermis that are primarily involved in producing the pigment **melanin**, which colors the skin and hair. The more melanin in the tissue, the darker is the color. Most of the skin of dark-skinned people and the darker areas of the skin on light-skinned people (eg, the nipple) contain larger amounts of this pigment. Normal skin color depends on race and varies from pale; almost ivory, to deep brown, almost pure black. Systemic disease affects skin color as well. For example, the skin appears bluish when there is insufficient oxygenation of the blood, yellow-green in people with jaundice, or red or flushed when there is inflammation or fever (Table 55-1).

Production of melanin is controlled by a hormone secreted from the hypothalamus of the brain called *melanocyte-stimulating hormone*. It is believed that melanin can absorb ultraviolet light in sunlight.

Two other cells are common to the epidermis: Merkel and Langerhans cells. **Merkel cells** are receptors that transmit stimuli to the axon through a chemical synapse. Langerhans cells are believed to play a significant role in cutaneous immune system reactions. These accessory cells of the afferent immune system process invading antigens and transport the antigens to the lymph system to activate the T lymphocytes.

The epidermis is modified in different areas of the body. It is thickest over the palms of the hands and soles of the feet and contains increased amounts of keratin. The thickness of the epidermis can increase with use and can result in calluses forming on the hands or corns forming on the feet.

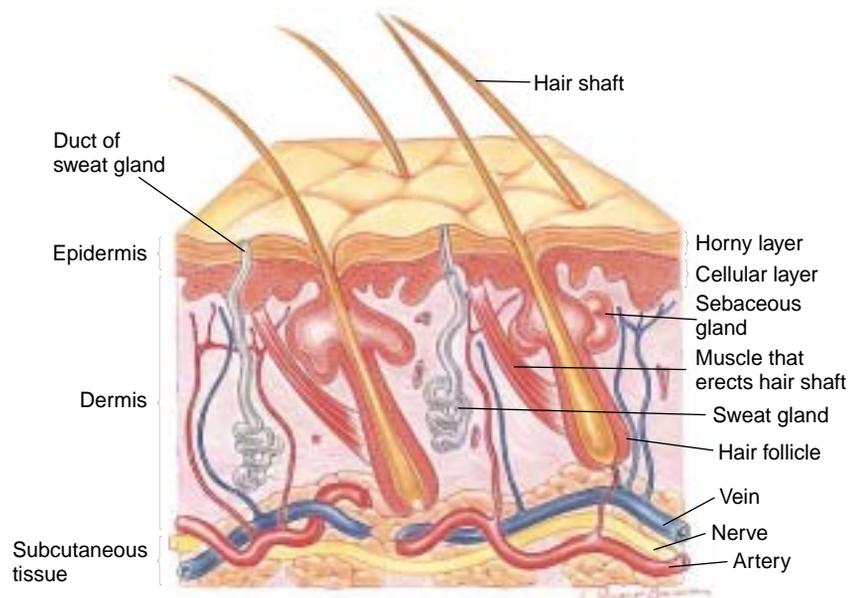

The junction of the epidermis and dermis is an area of many undulations and furrows called **rete ridges**. This junction anchors the epidermis to the dermis and permits the free exchange of essential nutrients between the two layers. This interlocking between the dermis and epidermis produces ripples on the surface of the skin. On the fingertips, these ripples are called *fingerprints*. They are a person's most individual characteristic, and they rarely change.

## Glossary

**alopecia:** loss of hair from any cause  
**anagen phase:** active phase of hair growth  
**dermatosis:** any abnormal skin condition  
**erythema:** redness of the skin caused by congestion of the capillaries  
**hirsutism:** the condition of having excessive hair growth  
**hyperpigmentation:** increase in the melanin of the skin, resulting in an increase in pigmentation  
**hypopigmentation:** decrease in the melanin of the skin, resulting in a loss of pigmentation  
**keratin:** an insoluble, fibrous protein that forms the outer layer of skin  
**lichenification:** leathery thickening of the skin

**Merkel cells:** cells of the epidermis that play a role in transmission of sensory messages  
**melanin:** the substance responsible for coloration of the skin  
**melanocytes:** cells of the skin that produce melanin  
**petechiae:** pinpoint red spots that appear on the skin as a result of blood leakage into the skin  
**rete ridges:** undulations and furrows that appear at the dermis–epidermis junction and are responsible for cementing together the two layers  
**sebaceous glands:** glands that exist within the epidermis and secrete sebum to keep the skin soft and pliable

**sebum:** fatty secretion of the sebaceous glands  
**striae:** bandlike streaks on the skin, distinguished by color, texture, depression, or elevation from the tissue in which they are found; usually purplish or white  
**telangiectases:** red marks on the skin caused by distention of the superficial blood vessels  
**vitiligo:** a localized or widespread condition characterized by destruction of the melanocytes in circumscribed areas of the skin, resulting in white patches  
**Wood's light:** a blue light used for diagnosing skin conditions

**FIGURE 55-1** Anatomic structures of the skin. From Bickley, L. S., & Hoekelman, R. A. (2003). *Bates' guide to physical examination and history taking*, 8th ed. Philadelphia: Lippincott Williams & Wilkins.

## Dermis

The dermis makes up the largest portion of the skin, providing strength and structure. It is composed of two layers: papillary and reticular. The papillary dermis lies directly beneath the epidermis and is composed primarily of fibroblast cells capable of producing one form of collagen, a component of connective tissue. The reticular layer lies beneath the papillary layer and also produces collagen and elastic bundles. The dermis is also made up of blood and lymph vessels, nerves, sweat and sebaceous glands, and hair roots. The dermis is often referred to as the “true skin.”

## Subcutaneous Tissue

The subcutaneous tissue, or hypodermis, is the innermost layer of the skin. It is primarily adipose tissue, which provides a cushion between the skin layers, muscles, and bones. It promotes skin mobility, molds body contours, and insulates the body. Fat is deposited and distributed according to the person's gender and in part accounts for the difference in body shape between men and women. Overeating results in increased deposition of fat beneath the skin. The subcutaneous tissues and amount of fat deposited are important factors in body temperature regulation.

## Hair

An outgrowth of the skin, hair is present over the entire body except for the palms and soles. The hair consists of a root formed in the dermis and a hair shaft that projects beyond the skin. It grows in a cavity called a *hair follicle*. Proliferation of cells in the bulb of the hair causes the hair to form (see Fig. 55-1).

Hair follicles undergo cycles of growth and rest. The rate of growth varies; beard growth is the most rapid, followed by hair on the scalp, axillae, thighs, and eyebrows. The growth or **anagen phase** may last up to 6 years for scalp hair, whereas the telogen or resting phase lasts for approximately 4 months. During telogen, hair sheds from the body. The hair follicle recycles into the growing phase spontaneously, or it can be induced by plucking out hairs. Growing and resting hair can be found side by side on all parts of the body. About 90% of the 100,000 hair follicles on a

normal scalp are in the growing phase at any one time, and 50 to 100 scalp hairs are shed each day.

There is a small bulge on the side of the hair follicle that houses the stem cells that migrate down to the follicle root and begin the cycle of reproducing the hair shaft. It was discovered that these bulges also contain the stem cells that migrate upward to reproduce skin (Jaworski & Gilliam, 1999). The location of these cells on the side of the hair shaft rather than at the base is a factor in hair loss. In conditions in which inflammation causes damage to the root of the hair, regrowth is possible. However, if inflammation causes damage to the bulge on the side, stem cells are destroyed and hair does not grow.

In certain locations on the body, hair growth is controlled by sex hormones. The most vivid example is the growth of hair on the face (ie, beard and mustache), chest, and back, which is controlled by the male hormones known as androgens. Some women with higher levels of testosterone have hair in the areas generally thought of as masculine, such as the face, chest, and lower abdomen. This is often a normal genetic variation; if it appears along with irregular menses and weight changes it may indicate a hormonal imbalance.

Hair in different parts of the body serves different functions. The hairs of the eyes (ie, eyebrows and lashes), nose, and ears filter out dust, bugs, and airborne debris. The hair of the skin provides thermal insulation in lower animals. This function is enhanced during cold or fright by piloerection (ie, hairs standing on end), caused by contraction of the tiny erector muscles attached to the hair follicle. The piloerection response that occurs in humans is probably vestigial (ie, rudimentary).

Hair color is supplied by various amounts of melanin within the hair shaft. Gray or white hair reflects the loss of pigment. Hair quantity and distribution can be affected by endocrine conditions. For example, Cushing's syndrome causes **hirsutism** (ie, excessive hair growth, especially in women), and hypothyroidism (ie, underactive thyroid) causes changes in hair texture. In many cases, chemotherapy and radiation therapy cause hair thinning or weakening of the hair shaft, resulting in partial or complete **alopecia** (ie, hair loss) from the scalp and other parts of the body.

## Nails

On the dorsal surface of the fingers and toes, a hard, transparent plate of keratin, called the *nail*, overlies the skin. The nail grows from its root, which lies under a thin fold of skin called the cuticle. The nail protects the fingers and toes by preserving their highly developed sensory functions, such as for picking up small objects.

Nail growth is continuous throughout life, with an average growth of 0.1 mm daily. Growth is faster in fingernails than toenails and tends to slow with aging. Complete renewal of a fingernail takes about 170 days, whereas toenail renewal takes 12 to 18 months.

## Glands of the Skin

There are two types of skin glands: sebaceous glands and sweat glands (see Fig. 55-1). The **sebaceous glands** are associated with hair follicles. The ducts of the sebaceous glands empty **sebum** (ie, oily secretion) onto the space between the hair follicle and the hair shaft. For each hair there is a sebaceous gland, the secretions of which lubricate the hair and render the skin soft and pliable.

Sweat glands are found in the skin over most of the body surface. They are heavily concentrated in the palms of the hands and soles of the feet. Only the glans penis, the margins of the lips, the external ear, and the nail bed are devoid of sweat glands. Sweat glands are subclassified into two categories: eccrine and apocrine.

The eccrine sweat glands are found in all areas of the skin. Their ducts open directly onto the skin surface. The thin, watery secretion called *sweat* is produced in the basal coiled portion of the eccrine gland and is released into its narrow duct. Sweat is composed of predominantly water and contains about one half of the salt content of the blood plasma. Sweat is released from eccrine glands in response to elevated ambient temperature and elevated body temperature. The rate of sweat secretion is under the control of the sympathetic nervous system. Excessive sweating of the palms and soles, axillae, forehead, and other areas may occur in response to pain and stress.

The apocrine sweat glands are larger, and unlike eccrine glands, their secretion contains parts of the secretory cells. They are located in the axillae, anal region, scrotum, and labia majora. Their ducts generally open onto hair follicles. The apocrine glands become active at puberty. In women, they enlarge and recede with each menstrual cycle. Apocrine glands produce a milky sweat that is sometimes broken down by bacteria to produce the characteristic underarm odor. Specialized apocrine glands called *ceruminous glands* are found in the external ear, where they produce cerumen (ie, wax).

## FUNCTIONS OF THE SKIN

### Protection

The skin covering most of the body is no more than 1 mm thick, but it provides very effective protection against invasion by bacteria and other foreign matter. The thickened skin of the palms and soles protects against the effects of the constant trauma that occurs in these areas.

The epidermis is the outermost layer of the skin and is composed of several layers of keratinocytes that change character as they migrate to the surface. The stratum corneum, the outer layer

of the epidermis, provides the most effective barrier to epidermal water loss and penetration of environmental factors such as chemicals, microbes, and insect bites.

Various lipids are synthesized in the stratum corneum and are the basis for the barrier function of this layer. These are long-chain lipids that are better suited than phospholipids for water resistance. The presence of these lipids in the stratum corneum creates a relatively impermeable barrier for water egress and for the entry of toxins, microbes, and other substances that come in contact with the surface of the skin.

Some substances do penetrate the skin but meet resistance in trying to move through the channels between the cell layers of the stratum corneum. Microbes and fungi, which are part of the body's normal flora, cannot penetrate unless there is a break in the skin barrier.

The dermis–epidermis junction is the basal layer, which is composed of collagen. The basal layer serves four functions. It acts as a scaffold for tissue organization and a template for regeneration; it provides selective permeability for filtration of serum; it is a physical barrier between different types of cells; and it adheres the epithelium to underlying cell layers.

### Sensation

The receptor endings of nerves in the skin allow the body to constantly monitor the conditions of the immediate environment. The primary functions of the receptors in the skin are to sense temperature, pain, light touch, and pressure (or heavy touch). Different nerve endings respond to each of the different stimuli. Although the nerve endings are distributed over the entire body, they are more concentrated in some areas than in others. For example, the fingertips are more densely innervated than the skin on the back.

### Fluid Balance

The stratum corneum (ie, outermost layer of the epidermis) has the capacity to absorb water, thereby preventing an excessive loss of water and electrolytes from the internal body and retaining moisture in the subcutaneous tissues. When skin is damaged, as occurs with a severe burn, large quantities of fluids and electrolytes may be lost rapidly, possibly leading to circulatory collapse, shock, and death.

The skin is not completely impermeable to water. Small amounts of water continuously evaporate from the skin surface. This evaporation, called *insensible perspiration*, amounts to approximately 600 mL daily in a normal adult. Insensible water loss varies with the body and ambient temperature. In a person with a fever, the loss can increase. During immersion in water, the skin can accumulate water up to three or four times its normal weight, such as swelling of the skin that occurs after prolonged bathing.

### Temperature Regulation

The body continuously produces heat as a result of the metabolism of food, which produces energy. This heat is dissipated primarily through the skin. Three major physical processes are involved in loss of heat from the body to the environment. The first process, radiation, is the transfer of heat to another object of

lower temperature situated at a distance. The second process, conduction, is the transfer of heat from the body to a cooler object in contact with it. Heat transferred by conduction to the air surrounding the body is removed by the third process, convection, which consists of movement of warm air molecules away from the body.

Evaporation from the skin aids heat loss by conduction. Heat is conducted through the skin into water molecules on its surface, causing the water to evaporate. The water on the skin surface may be from insensible perspiration, sweat, or the environment.

Normally, all of these mechanisms for heat loss are used. When the ambient temperature is very high, however, radiation and convection are ineffective, and evaporation becomes the only means for heat loss.

Under normal conditions, metabolic heat production is balanced by heat loss, and the internal temperature of the body is maintained constant at approximately 37°C (98.6°F). The rate of heat loss depends primarily on the surface temperature of the skin, which is a function of the skin blood flow. Under normal conditions, the total blood circulated through the skin is approximately 450 mL per minute, or 10 to 20 times the amount of blood required to provide necessary metabolites and oxygen. Blood flow through these skin vessels is controlled primarily by the sympathetic nervous system. Increased blood flow to the skin results in more heat delivered to the skin and a greater rate of heat loss from the body. In contrast, decreased skin blood flow decreases the skin temperature and helps conserve heat for the body. When the temperature of the body begins to fall, as occurs on a cold day, the blood vessels of the skin constrict, thereby reducing heat loss from the body.

Sweating is another process by which the body can regulate the rate of heat loss. Sweating does not occur until the core body temperature exceeds 37°C, regardless of skin temperature. In extremely hot environments, the rate of sweat production may be as high as 1 L per hour. Under some circumstances (eg, emotional stress), sweating may occur as a reflex and may be unrelated to the need to lose heat from the body.

## Vitamin Production

Skin exposed to ultraviolet light can convert substances necessary for synthesizing vitamin D (cholecalciferol). Vitamin D is essential for preventing rickets, a condition that causes bone deformities and results from a deficiency of vitamin D, calcium, and phosphorus.

## Immune Response Function

Research findings (Demis, 1998) indicate that several dermal cells (ie, Langerhans cells, interleukin-1–producing keratinocytes, and subsets of T lymphocytes) and three varieties of human leukocyte antigen (ie, protein marker on white blood cells indicating the type of cell) are important components of the immune system. Ongoing research is expected to more clearly define the role of these dermal cells in immune function.

## Gerontologic Considerations

The skin undergoes many physiologic changes associated with normal aging. A lifetime of excessive sun exposure, systemic diseases, poor nutrition, and certain medications (eg, antihistamines, diuretics) can enhance the range of skin problems and the

rapidity with which they appear. The outcome is an increasing vulnerability to injury and to certain diseases. Skin problems are common among older people.

Before conducting a skin assessment, the nurse needs to be aware of significant changes that occur with aging. The major changes in the skin of older people include dryness, wrinkling, uneven pigmentation, and various proliferative lesions. Cellular changes associated with aging include a thinning at the junction of the dermis and epidermis. This results in fewer anchoring sites between the two skin layers, so that even minor injury or stress to the epidermis can cause it to shear away from the dermis. This phenomenon of aging may account for the increased vulnerability of aged skin to trauma. With increasing age, the epidermis and dermis thin and flatten, causing wrinkles, sags, and overlapping skin folds (Fig. 55-2).

Loss of the subcutaneous tissue substances of elastin, collagen, and subcutaneous fat diminishes the protection and cushioning of underlying tissues and organs, decreases muscle tone, and results in the loss of the insulating properties of fat.

Cellular replacement slows as a result of aging. As the dermal layers thin, the skin becomes fragile and transparent. The blood supply to the skin also changes with age. Vessels, especially the capillary loops, decrease in number and size. These vascular changes contribute to the delayed wound healing commonly seen in the elderly patient. Sweat and sebaceous glands decrease in number and functional capacity, leading to dry and scaly skin. Reduced hormonal levels of androgens are thought to contribute to declining sebaceous gland function.

Hair growth gradually diminishes, especially over the lower legs and dorsum of the feet. Thinning is common in the scalp, axilla, and pubic areas. Other functions affected with normal aging include the barrier function of skin, sensory perception, and thermoregulation.

Photoaging, or damage from excessive sun exposure, has detrimental effects on the normal aging of skin. A lifetime of outdoor work or outdoor activities (eg, construction work, lifeguarding, sunbathing) without prudent use of sunscreens can lead to profound wrinkling; increased loss of elasticity; mottled, pigmented areas; cutaneous atrophy; and benign or malignant lesions.

Many skin lesions are part of normal aging. Recognizing these lesions enables the examiner to assist the patient to feel less anx-

**FIGURE 55-2** Hands with wrinkling and overlapping folds common to aging skin.

Chart  
55-1**Benign Changes in Elderly Skin**

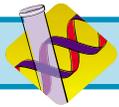

- Cherry angiomas (bright red “moles”)
- Diminished hair, especially on scalp and pubic area
- Dyschromias (color variations)
  - Solar lentigo (liver spots)
  - Melasma (dark discoloration of the skin)
  - Lentiginos (freckles)
- Neurodermatitis (itchy spots)
- Seborrheic keratoses (crusty brown “stuck-on” patches)
- Spider angiomas
- Telangiectasias (red marks on skin caused by stretching of the superficial blood vessels)
- Wrinkles
- Xerosis (dryness)
- Xanthelasma (yellowish waxy deposits on upper and lower eyelids)

ious about changes in skin. Chart 55-1 summarizes some skin lesions that are expected to appear as the skin ages. These are normal and require no special attention unless the skin becomes infected or irritated.

**Assessment****HEALTH HISTORY AND CLINICAL MANIFESTATIONS**

When caring for patients with dermatologic disorders, the nurse obtains important information through the health history and direct observations. The nurse’s skill in physical assessment and an understanding of the anatomy and function of the skin can ensure that deviations from normal are recognized, reported, and documented.

During the health history interview, the nurse asks about any family and personal history of skin allergies, allergic reactions to

**GENETICS IN NURSING PRACTICE—Integumentary Conditions**

Examples of integumentary conditions influenced by genetic factors include the following:

- Albinism
- Eczema
- Hypohidrotic ectodermal dysplasia
- Incontinentia pigmenti
- Neurofibromatosis type 1
- Pseudoxanthoma elasticum
- Psoriasis

**NURSING ASSESSMENTS****FAMILY HISTORY ASSESSMENT**

- Assess for other closely related family members with integumentary impairment or abnormalities.
- Inquire about the nature and type of skin lesions and age at onset (eg, skin involvement with incontinentia pigmenti occurs in the first few weeks of life with blistering of the skin, whereas lesions of neurofibromatosis type 1 may appear in early childhood through adulthood).
- Note gender of affected individuals (eg, mostly females with incontinentia pigmenti, mostly males with hypohidrotic ectodermal dysplasia).
- Inquire about the presence of other clinical features, such as unusual hair, teeth, or nails; thrombocytopenia; recurrent infections.

**PHYSICAL ASSESSMENT**

- Assess for related clinical features, such as sparse eyebrows and eyelashes, abnormally shaped teeth, alopecia, nail abnormalities (eg, hypohidrotic ectodermal dysplasia).
- Assess for related alterations in vision, such as nystagmus, strabismus; albinism; retinal abnormalities (eg, pseudo-

xanthoma elasticum); Lisch nodules and/or optic glioma (neurofibromatosis type 1).

**MANAGEMENT ISSUES SPECIFIC TO GENETICS**

- Inquire whether DNA mutation or other genetic testing has been performed on affected family members.
- If indicated, refer for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, availability of genetic testing, and gene-based interventions.
- Offer appropriate genetics information and resources.
- Assess patient’s understanding of genetics information.
- Provide support to families with newly diagnosed genetic-related integumentary conditions.
- Participate in management and coordination of care for patients with genetic conditions and for individuals predisposed to develop or pass on a genetic condition.

**GENETICS RESOURCES FOR NURSES AND THEIR PATIENTS ON THE WEB**

Genetic Alliance—a directory of support groups for patients and families with genetic conditions; <http://www.geneticalliance.org>

Gene Clinics—a listing of common genetic disorders with clinical summaries, genetic counseling and testing information; <http://www.geneclinics.org>

National Organization of Rare Disorders—a directory of support groups and information for patients and families with rare genetic disorders; <http://www.rarediseases.org>

Online Mendelian Inheritance in Man (OMIM)—a complete listing of inherited genetic conditions; <http://www.ncbi.nlm.nih.gov/omim/stats/html>

food, medications, chemicals, previous skin problems, and skin cancer. The names of cosmetics, soaps, shampoos, and other personal hygiene products are obtained if there have been any recent skin problems noticed with the use of these products. The health history contains specific information about the onset, signs and symptoms, location, and duration of any pain, itching, rash, or other discomfort experienced by the patient. The accompanying assessment chart lists selected questions useful in obtaining appropriate information (Chart 55-2).

## PHYSICAL ASSESSMENT

Assessment of the skin involves the entire skin area, including the mucous membranes, scalp, hair, and nails. The skin is a reflection of a person's overall health, and alterations commonly correspond to disease in other organ systems. Inspection and palpation are techniques commonly used in examining the skin. The room must be well lighted and warm. A penlight may be used to highlight lesions. The patient completely disrobes and is adequately draped. Gloves are worn during skin examination if rash or lesions are to be palpated. However, it is important to avoid making the patient feel as if he or she cannot be touched. Touching skin lesions indicates a level of acceptance of the patient.

### Chart 55-2 • ASSESSMENT

#### Patient History of Skin Disorders

Patient history relevant to skin disorders may be obtained by asking the following questions:

- When did you first notice this skin problem? (Also investigate duration and intensity.)
- Has it occurred previously?
- Are there any other symptoms?
- What site was first affected?
- What did the rash or lesion look like when it first appeared?
- Where and how fast did it spread?
- Do you have any itching, burning, tingling, or crawling sensations?
- Is there any loss of sensation?
- Is the problem worse at a particular time or season?
- How do you think it started?
- Do you have a history of hay fever, asthma, hives, eczema, or allergies?
- Who in your family has skin problems or rashes?
- Did the eruptions appear after certain foods were eaten?
  - Which foods?
- When the problem occurred, had you recently consumed alcohol?
- What relation do you think there may be between a specific event and the outbreak of the rash or lesion?
- What medications are you taking?
- What topical medication (ointment, cream, salve) have you put on the lesion (including over-the-counter medications)?
- What skin products or cosmetics do you use?
- What is your occupation?
- What in your immediate environment (plants, animals, chemicals, infections) might be precipitating this disorder?
  - Is there anything new, or are there any changes in the environment?
- Does anything touching your skin cause a rash?
- How has this affected you (or your life)?
- Is there anything else you wish to talk about in regard to this disorder?

## Assessing General Appearance

The general appearance of the skin is assessed by observing color, temperature, moisture or dryness, skin texture (rough or smooth), lesions, vascularity, mobility, and the condition of the hair and nails. Skin turgor, possible edema, and elasticity are assessed by palpation.

Skin color varies from person to person and ranges from ivory to deep brown to almost pure black. The skin of exposed portions of the body, especially in sunny, warm climates, tends to be more pigmented than the rest of the body. The vasodilation that occurs with fever, sunburn, and inflammation produces a pink or reddish hue to the skin. Pallor is an absence of or a decrease in normal skin color and vascularity and is best observed in the conjunctivae or around the mouth.

The bluish hue of cyanosis indicates cellular hypoxia and is easily observed in the extremities, nail beds, lips, and mucous membranes. Jaundice, a yellowing of the skin, is directly related to elevations in serum bilirubin and is often first observed in the sclerae and mucous membranes (Fig. 55-3).

## Erythema

**Erythema** is redness of the skin caused by the congestion of capillaries. In light-skinned people, it is easily observed at any location where it appears. To determine possible inflammation, the skin is palpated for increased warmth and for smoothness (ie, edema) or hardness (ie, intracellular infiltration). Because dark skin tends to assume a purple-gray cast when an inflammatory process is present, it may be difficult to detect erythema.

## Rash

In instances of pruritus (ie, itching), the patient should be asked to indicate which areas of the body are involved. The skin is then stretched gently to decrease the reddish tone and make the rash stand out. Pointing a penlight laterally across the skin may effectively highlight the rash. The differences in skin texture are then assessed by running the tips of the fingers lightly over the skin. The borders of the rash may be palpable. The patient's mouth and ears are included in the examination. (Sometimes rubeola, or measles, causes a red cast to appear on the tip of the ears.) The patient's temperature is assessed, and the lymph nodes are palpated.

**FIGURE 55-3** Examples of skin color changes: the bluish tint of cyanosis (*left*) and the yellow hue of jaundice (*right*).

## Cyanosis

Cyanosis is the bluish discoloration that results from a lack of oxygen in the blood. It appears with shock or with respiratory or circulatory compromise. In people with light skin, cyanosis manifests as a bluish hue to the lips, fingertips, and nail beds. Other indications of decreased tissue perfusion include cold, clammy skin; a rapid, thready pulse; and rapid, shallow respirations. The conjunctivae of the eyelids are examined for pallor and **petechiae** (ie, pinpoint red spots that appear on the skin as a result of blood leakage into the skin).

In a person with dark skin, the skin usually assumes a grayish cast. To detect cyanosis, the areas around the mouth and lips and over the cheekbones and earlobes should be observed.

## Color Changes

Almost every process that occurs on the skin causes some color change. For example, **hypopigmentation** (ie, decrease in the melanin of the skin, resulting in a loss of pigmentation) may be caused by a fungal infection, eczema, or **vitiligo** (ie, condition characterized by destruction of the melanocytes in circumscribed areas of the skin, resulting in white patches). **Hyperpigmentation** (ie, increase in the melanin of the skin, resulting in increased pigmentation) may occur after disease or injury to the skin (ie, postinflammatory), after sun injury, or as a result of aging.

Changes in skin color in people with dark skin are more noticeable and may cause more concern because the discoloration is more readily visible. Some variation in skin pigment levels is considered normal. Examples include the pigmented crease across the bridge of the nose, pigmented streaks in the nails, and pigmented spots on the sclera of the eye. Many variations of color are genetically determined.

### ASSESSING PATIENTS WITH DARK SKIN

The color gradations that occur in people with dark skin are largely determined by genetic transmission; they may be described as light, medium, or dark. In people with dark skin, melanin is produced at a faster rate and in larger quantities than in people with light skin. Healthy dark skin has a reddish base or undertone. The buccal mucosa, tongue, lips, and nails normally are pink. The degree of pigmentation of the patient's skin may affect the appearance of a lesion. Lesions may be black, purple, or gray instead of the tan or red seen in patients with light skin. Dark pigment responds with discoloration after injury or inflammation, and patients with dark skin more often experience post-inflammatory hyperpigmentation than those with lighter skin. The hyperpigmentation eventually fades but may require months to a year to do so.

In general, people with dark skin suffer the same skin conditions as those with light skin. They are less likely to have skin cancer but more likely to have keloid or scar formation and disorders resulting from occlusion or blockage of hair follicles.

Table 55-2 provides an overview of color changes in light-skinned and dark-skinned people, and the following section provides specific guidelines for assessing dark and light skin.

### ASSESSING SKIN LESIONS

Skin lesions are the most prominent characteristics of dermatologic conditions. They vary in size, shape, and cause and are classified according to their appearance and origin. Skin lesions can

be described as primary or secondary. Primary lesions are the initial lesions and are characteristic of the disease itself. Secondary lesions result from external causes, such as scratching, trauma, infections, or changes caused by wound healing. Depending on the stage of development, skin lesions are further categorized according to type and appearance (Chart 55-3).

A preliminary assessment of the eruption or lesion should help to identify the type of **dermatosis** (ie, abnormal skin condition) and indicate whether the lesion is primary or secondary. At the same time, the anatomic distribution of the eruption should be observed, because certain diseases affect certain sites of the body and are distributed in characteristic patterns and shapes (Figs. 55-4 and 55-5). To determine the extent of the regional distribution, the left and right sides of the body should be compared while the color and shape of the lesions are assessed. After observation, the lesions are palpated to determine their texture, shape, and border and to see if they are soft and filled with fluid or hard and fixed to the surrounding tissue.

A metric ruler is used to measure the size of the lesions so that any further extension can be compared with this baseline measurement. The dermatosis is documented on the patient's health record; it should be described clearly and in detail, using precise terminology.

After the characteristic distribution of the lesions has been determined, the following information should be obtained and described clearly and in detail:

- Color of the lesion
- Any redness, heat, pain, or swelling
- Size and location of the involved area
- Pattern of eruption (eg, macular, papular, scaling, oozing, discrete, confluent)
- Distribution of the lesion (eg, bilateral, symmetric, linear, circular)

If acute open wounds or lesions are found on inspection of the skin, a comprehensive assessment should be made and documented in the patient's record. This assessment should address several issues:

- Wound bed: Inspect for necrotic and granulation tissue, epithelium, exudate, color, and odor.
- Wound edges and margins: Observe for undermining (ie, extension of the wound under the surface skin), and evaluate for condition.
- Wound size: Measure in millimeters or centimeters, as appropriate, to determine diameter and depth of the wound and surrounding erythema.
- Surrounding skin: Assess for color, suppleness and moisture, irritation, and scaling.

### Assessing Vascularity and Hydration

After the color of the skin has been evaluated and lesions have been inspected, an assessment of vascular changes in the skin is performed. A description of vascular changes includes location, distribution, color, size, and the presence of pulsations. Common vascular changes include petechiae, ecchymoses, **telangiectases** (ie, red marks on the skin caused by stretching of the superficial blood vessels), angiomas, and venous stars.

Skin moisture, temperature, and texture are assessed primarily by palpation. The elasticity (ie, turgor) of the skin, which decreases in normal aging, may be a factor in assessing the hydration status of a patient.

Table 55-2 • Color Changes in Light and Dark Skin

ETIOLOGY	LIGHT SKIN	DARK SKIN
<b>Pallor</b>		
Anemia—decreased hematocrit Shock—decreased perfusion, vasoconstriction	Generalized pallor	Brown skin appears yellow-brown, dull; black skin appears ashen gray, dull. (Observe areas with least pigmentation: conjunctivae, mucous membranes.)
Local arterial insufficiency	Marked localized pallor (lower extremities, especially when elevated)	Ashen gray, dull; cool to palpation
Albinism—total absence of pigment melanin	Whitish pink	Tan, cream, white
Vitiligo—a condition characterized by destruction of the melanocytes in circumscribed areas of the skin (may be localized or widespread)	Patchy, milky white spots, often symmetric bilaterally	Same
<b>Cyanosis</b>		
Increased amount of unoxygenated hemoglobin:	Dusky blue	Dark but dull, lifeless; only severe cyanosis is apparent in skin. (Observe conjunctivae, oral mucosa, nail beds.)
Central—chronic heart and lung disease cause arterial desaturation	Nail beds dusky	
Peripheral—exposure to cold, anxiety		
<b>Erythema</b>		
Hyperemia—increased blood flow through engorged arterial vessels, as in inflammation, fever, alcohol intake, blushing	Red, bright pink	Purplish tinge, but difficult to see. (Palpate for increased warmth with inflammation, taut skin, and hardening of deep tissues.)
Polycythemia—increased red blood cells, capillary stasis	Ruddy blue in face, oral mucosa, conjunctivae, hands and feet	Well concealed by pigment. (Observe for redness in lips.)
Carbon monoxide poisoning	Bright, cherry red in face and upper torso	Cherry red nail beds, lips, and oral mucosa
Venous stasis—decreased blood flow from area, engorged venules	Dusky rubor of dependent extremities (a prelude to necrosis with pressure ulcer)	Easily masked. (Use palpation to identify warmth or edema.)
<b>Jaundice</b>		
Increased serum bilirubin concentration (>2–3 mg/100 mL) due to liver dysfunction or hemolysis, as after severe burns or some infections	Yellow first in sclerae, hard palate, and mucous membranes; then over skin	Check sclerae for yellow near limbus; do not mistake normal yellowish fatty deposits in the periphery under eyelids for jaundice. (Jaundice is best noted at junction of hard and soft palate, on palms.)
Carotenemia—increased level of serum carotene from ingestion of large amounts of carotene-rich foods	Yellow-orange tinge in forehead, palms and soles, and nasolabial folds, but no yellowing in sclerae or mucous membranes	Yellow-orange tinge in palms and soles
Uremia—renal failure causes retained urochrome pigments in the blood	Orange-green or gray overlying pallor of anemia; may also have ecchymoses and purpura	Easily masked. (Rely on laboratory and clinical findings.)
<b>Brown-Tan</b>		
Addison's disease—cortisol deficiency stimulates increased melanin production	Bronzed appearance, an “external tan”; most apparent around nipples, perineum, genitalia, and pressure points (inner thighs, buttocks, elbows, axillae)	Easily masked. (Rely on laboratory and clinical findings.)
<i>Café-au-lait</i> spots—caused by increased melanin pigment in basal cell layer	Tan to light brown, irregularly shaped, oval patch with well-defined borders often not visible in the very dark skinned person	

## Assessing the Nails and Hair

A brief inspection of the nails includes observation of configuration, color, and consistency. Many alterations in the nail or nail bed reflect local or systemic abnormalities in progress or resulting from past events (Fig. 55-6). Transverse depressions known as Beau's lines in the nails may reflect retarded growth of the nail matrix because of severe illness or, more commonly, local trauma. Ridging, hypertrophy, and other changes may also be visible with

local trauma. Paronychia, an inflammation of the skin around the nail, is usually accompanied by tenderness and erythema. The angle between the normal nail and its base is 160 degrees. When palpated, the nail base is usually firm. Clubbing is manifested by a straightening of the normal angle (180 degrees or greater) and softening of the nail base. The softened area feels spongelike when palpated.

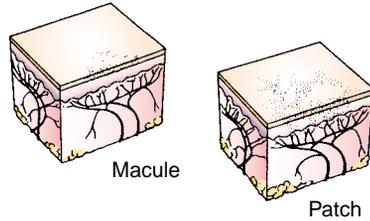

(text continues on page 1650)

Chart  
55-3

## Primary and Secondary Skin Lesions

## PRIMARY SKIN LESIONS

Primary skin lesions are original lesions arising from previously normal skin. Secondary lesions can originate from primary lesions and are the progression of the primary disease to a different appearance.

Macule

Patch

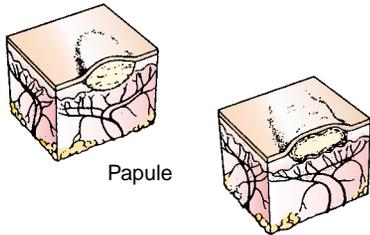

**Macule, Patch**

Flat, nonpalpable skin color change (color may be brown, white, tan, purple, red)

- *Macule*: <1 cm, circumscribed border
- *Patch*: >1 cm, may have irregular border

**Examples:**

Freckles, flat moles, petechia, rubella, vitiligo, port wine stains, ecchymosis

Papule

Plaque

**Papule, Plaque**

Elevated, palpable, solid mass  
Circumscribed border

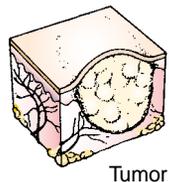

Plaque may be coalesced papules with flat top

- *Papule*: <0.5 cm
- *Plaque*: >0.5 cm

**Examples:**

*Papules*: Elevated nevi, warts, lichen planus

*Plaques*: Psoriasis, actinic keratosis

Tumor

**Nodule, Tumor**

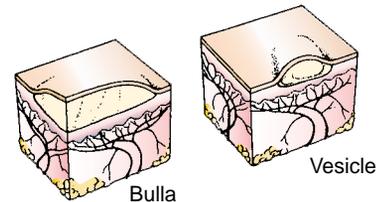

Elevated, palpable, solid mass  
Extends deeper into the dermis than a papule

- *Nodule*: 0.5–2 cm; circumscribed
- *Tumor*: >1–2 cm; tumors do not always have sharp borders

**Examples:**

*Nodules*: Lipoma, squamous cell carcinoma, poorly absorbed injection, dermatofibroma

*Tumors*: Larger lipoma, carcinoma

Bulla

Vesicle

**Vesicle, Bulla**

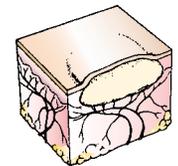

Circumscribed, elevated, palpable mass containing serous fluid

- *Vesicle*: <0.5 cm
- *Bulla*: >0.5 cm

**Examples:**

*Vesicles*: Herpes simplex/zoster, chickenpox, poison ivy, second-degree burn (blister)

*Bulla*: Pemphigus, contact dermatitis, large burn blisters, poison ivy, bullous impetigo

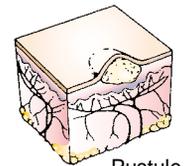

Wheal

**Wheal**

- Elevated mass with transient borders
- Often irregular
- Size and color vary
- Caused by movement of serous fluid into the dermis
- Does not contain free fluid in a cavity (as, for example, a vesicle does)

**Examples:**

Urticaria (hives), insect bites

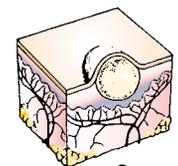

Pustule

**Pustule**

- Pus-filled vesicle or bulla

**Examples:**

Acne, impetigo, furuncles, carbuncles

Cyst

**Cyst**

- Encapsulated fluid-filled or semisolid mass
- In the subcutaneous tissue or dermis

**Examples:**

Sebaceous cyst, epidermoid cysts

(continued)

Chart  
55-3

## Primary and Secondary Skin Lesions (Continued)

**SECONDARY SKIN LESIONS**

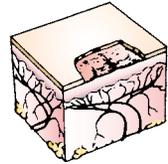

Secondary skin lesions result from changes in primary lesions.

**Erosion**

- Loss of superficial epidermis
- Does not extend to dermis
- Depressed, moist area

**Examples:**

Ruptured vesicles, scratch marks

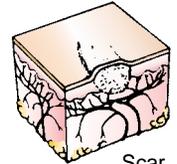

Erosion

**Scar (Cicatrix)**

- Skin mark left after healing of a wound or lesion
- Represents replacement by connective tissue of the injured tissue
- Young scars: red or purple
- Mature scars: white or glistening

**Examples:**

Healed wound or surgical incision

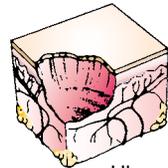

Scar

**Ulcer**

- Skin loss extending past epidermis
- Necrotic tissue loss
- Bleeding and scarring possible

**Examples:**

Stasis ulcer of venous insufficiency, pressure ulcer

Ulcer

**Keloid**

- Hypertrophied scar tissue
- Secondary to excessive collagen formation during healing
- Elevated, irregular, red
- Greater incidence among African Americans

**Example:**

Keloid of ear piercing or surgical incision

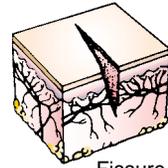

Keloid

**Fissure**

- Linear crack in the skin
- May extend to dermis

**Examples:**

Chapped lips or hands, athlete's foot

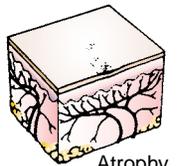

Fissure

**Atrophy**

- Thin, dry, transparent appearance of epidermis
- Loss of surface markings
- Secondary to loss of collagen and elastin
- Underlying vessels may be visible

**Examples:**

Aged skin, arterial insufficiency

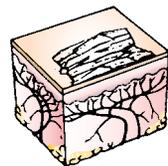

Atrophy

**Scales**

- Flakes secondary to desquamated, dead epithelium
- Flakes may adhere to skin surface
- Color varies (silvery, white)
- Texture varies (thick, fine)

**Examples:**

Dandruff, psoriasis, dry skin, pityriasis rosea

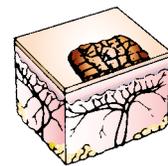

Scales

**Lichenification**

- Thickening and roughening of the skin
- Accentuated skin markings
- May be secondary to repeated rubbing, irritation, scratching

**Example:**

Contact dermatitis

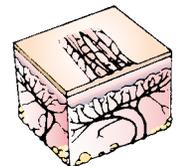

Crust

**Crust**

- Dried residue of serum, blood, or pus on skin surface
- Large, adherent crust is a scab

**Examples:**

Residue left after vesicle rupture: impetigo, herpes, eczema

Lichenification

(continued)

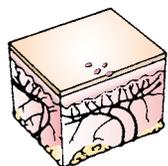

Chart  
55-3

## Primary and Secondary Skin Lesions (Continued)

## VASCULAR SKIN LESIONS

**Petechia (pl. petechiae)**

- Round red or purple macule
- Small: 1–2 mm
- Secondary to blood extravasation
- Associated with bleeding tendencies or emboli to skin

Petechiae

**Ecchymosis (pl. ecchymoses)**

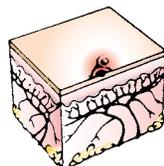

- Round or irregular macular lesion
- Larger than petechia
- Color varies and changes: black, yellow, and green hues
- Secondary to blood extravasation
- Associated with trauma, bleeding tendencies

Ecchymoses

**Cherry Angioma**

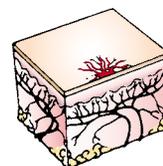

- Papular and round
- Red or purple
- Noted on trunk, extremities
- May blanch with pressure
- Normal age-related skin alteration
- Usually not clinically significant

Cherry angioma

**Spider Angioma**

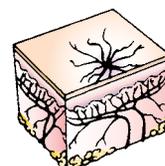

- Red, arteriole lesion
- Central body with radiating branches
- Noted on face, neck, arms, trunk
- Rare below the waist
- May blanch with pressure
- Associated with liver disease, pregnancy, vitamin B deficiency

Spider angioma

**Telangiectasia (Venous Star)**

- Shape varies: spider-like or linear
- Color bluish or red
- Does not blanch when pressure is applied
- Noted on legs, anterior chest
- Secondary to superficial dilation of venous vessels and capillaries
- Associated with increased venous pressure states (varicosities)

Telangiectasia

The hair assessment is carried out by inspecting and palpating. Gloves are worn, and the examination room should be well lighted. Separating the hair so that the condition of the skin underneath can be easily seen, the nurse assesses color, texture, and distribution. Any abnormal lesions, evidence of itching, inflammation, scaling, or signs of infestation (ie, lice or mites) are documented.

**COLOR AND TEXTURE**

Natural hair color ranges from white to black. Hair color begins to gray with age, initially appearing during the third decade of life, when the loss of melanin begins to become apparent. However, it is not unusual for the hair of younger people to turn gray as a result of hereditary traits. The person with albinism (ie, partial or complete absence of pigmentation) has a genetic predisposition to white hair from birth. The natural state of the hair can be altered by using hair dyes, bleaches, and curling or relaxing products. The types of products used are identified during the assessment.

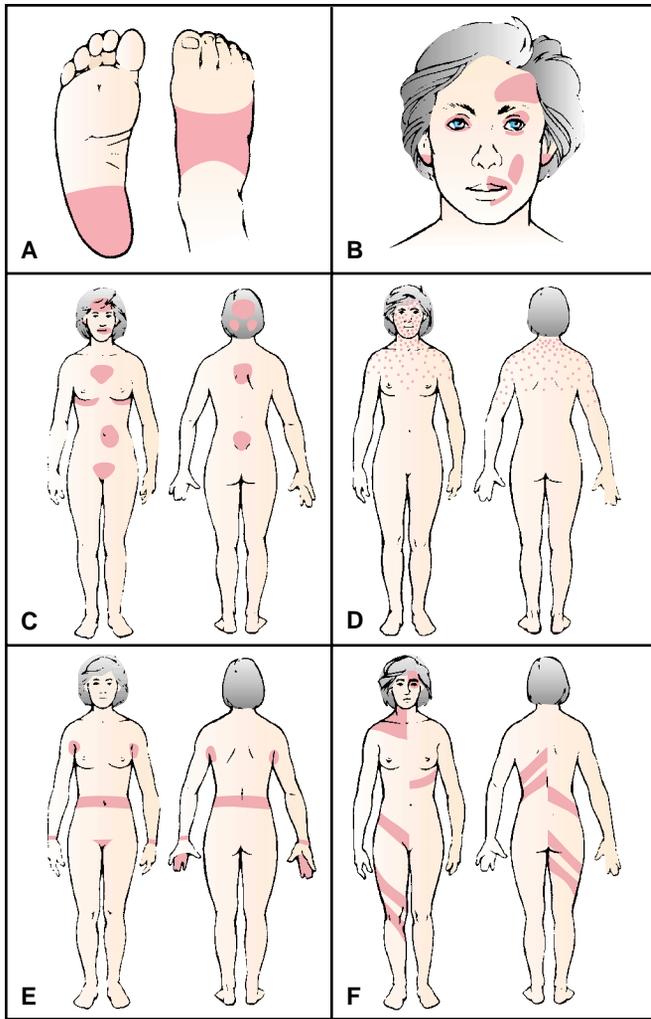

The texture of scalp hair ranges from fine to coarse, silky to brittle, oily to dry, and shiny to dull, and hair can be straight, curly, or kinky. Dry, brittle hair may result from overuse of hair dyes, hair dryers, and curling irons or from endocrine disorders,

such as thyroid dysfunction. Oily hair is usually caused by increased secretion from the sebaceous glands close to the scalp. If the patient reports a recent change in hair texture, the underlying reason is pursued; the alteration may arise simply from the overuse of commercial hair products or from changing to a new shampoo.

**DISTRIBUTION**

Body hair distribution varies with location. Hair over most of the body is fine, except in the axillae and pubic areas, where it is coarse. Pubic hair, which develops at puberty, forms a diamond shape extending up to the umbilicus in boys and men. Female pubic hair resembles an inverted triangle. If the pattern found is more characteristic of the opposite gender, it may indicate an endocrine problem and further investigation is in order. Racial differences in hair are expected, such as straight hair in Asians and curly, coarser hair in people of African descent.

Men tend to have more body and facial hair than women. Loss of hair, or alopecia, can occur over the entire body or be confined to a specific area. Scalp hair loss may be localized to patchy areas or may range from generalized thinning to total

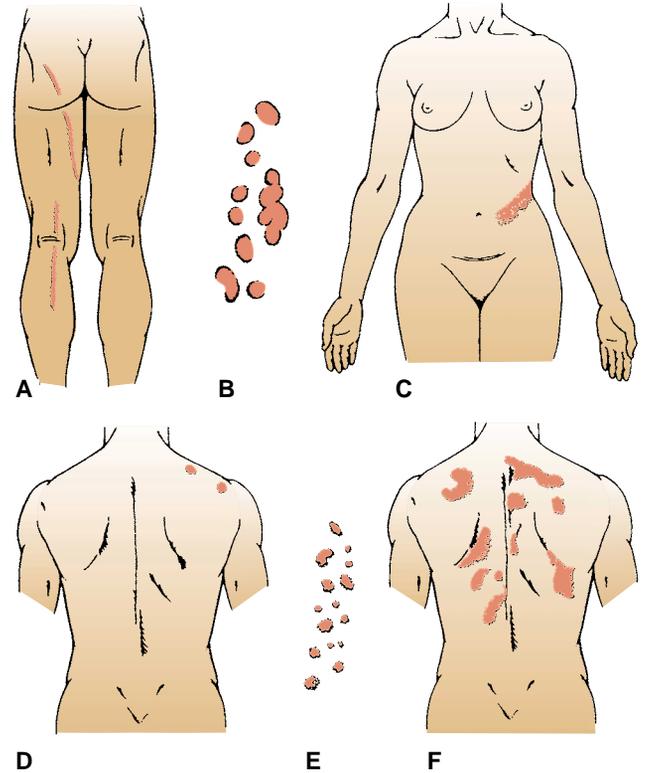

**FIGURE 55-4** Anatomic distribution of common skin disorders. (A) Contact dermatitis (shoes). (B) Contact dermatitis (cosmetics, perfumes, earrings). (C) Seborrheic dermatitis. (D) Acne. (E) Scabies. (F) Herpes zoster (shingles).

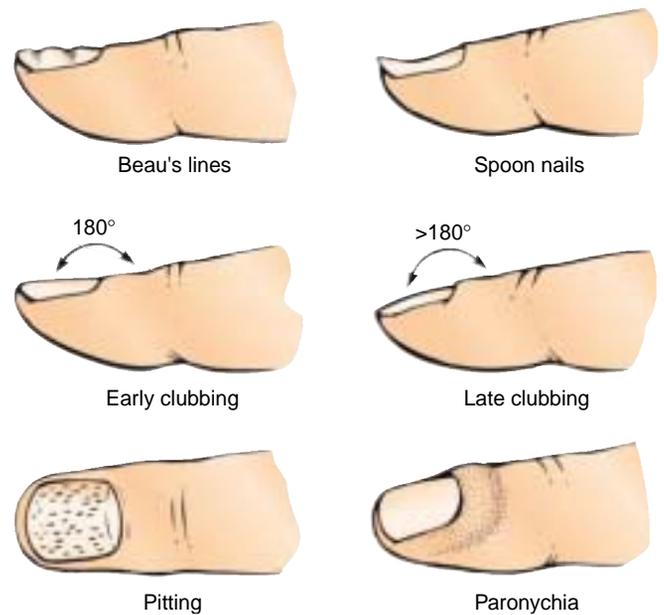

baldness. When assessing scalp hair loss, it is important to investigate the underlying cause with the patient. Patchy hair loss may be from habitual hair pulling or twisting; from excessive traction on the hair (eg, braiding too tightly); excessive use of dyes, straighteners, and oils; chemotherapeutic agents (eg, doxorubicin, cyclophosphamide); fungal infection; or moles or lesions on the scalp. Regrowth may be erratic, and distribution may never attain the previous thickness.

**HAIR LOSS**

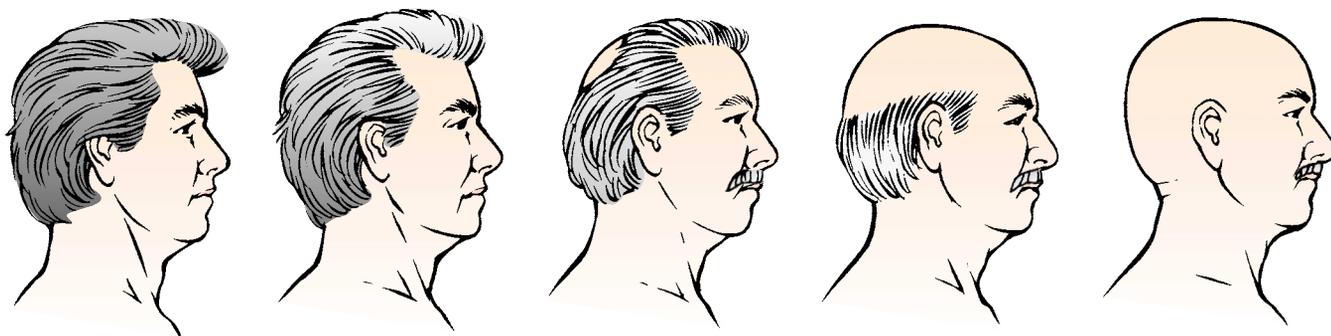

The most common cause of hair loss is male pattern baldness, which affects more than one half of the male population and is believed to be related to heredity, aging, and androgen (male hormone) levels. Androgen is necessary for male pattern baldness to develop. The pattern of hair loss begins with receding of the hairline in the frontal-temporal area and progresses to gradual thinning and complete loss of hair over the top of the scalp and crown. Figure 55-7 illustrates the typical male pattern hair loss.

**FIGURE 55-5** Skin lesion configurations. (A) Linear (in a line). (B) Annular and arciform (circular or arcing). (C) Zosteriform (linear along a nerve route). (D) Grouped (clustered). **FIGURE 55-7** The progression of male pattern baldness.

### OTHER CHANGES

Male pattern hair distribution may be seen in some women at the time of menopause, when the hormone estrogen is no longer produced by the ovaries. In women with hirsutism, excessive hair may grow on the face, chest, shoulders, and pubic area. When menopause is ruled out as the underlying cause, hormonal abnormalities related to pituitary or adrenal dysfunction must be investigated.

Because patients with skin conditions may be viewed negatively by others, these patients may become distraught and avoid interaction with people. Skin conditions can lead to disfigurement, isolation, job loss, and economic hardship.

Some conditions may subject the patient to a protracted illness, leading to feelings of depression, frustration, self-consciousness, poor self-image, and rejection. Itching and skin irritation, features of many skin diseases, may be a constant annoyance. The results of these discomforts may be loss of sleep, anxiety, and depression, all of which reinforce the general distress and fatigue that frequently accompany skin disorders.

For patients suffering such physical and psychological discomforts, the nurse needs to provide understanding, explanations of the problem, appropriate instructions related to treatment, nursing support, patience, and encouragement. It takes time to help patients gain insight into their problems and resolve their difficulties. It is imperative to overcome any aversion that may be felt when caring for patients with unattractive skin disorders. The nurse should show no sign of hesitancy when approaching patients with skin disorders. Such hesitancy only reinforces the psychological trauma of the disorder.

## Diagnostic Evaluation

In addition to obtaining the patient's history, the examiner inspects the primary and secondary lesions and their configuration and distribution. Certain diagnostic procedures may also be used to help identify skin conditions.

### SKIN BIOPSY

Performed to obtain tissue for microscopic examination, a skin biopsy may be obtained by scalpel excision or by a skin punch instrument that removes a small core of tissue. Biopsies are per-

formed on skin nodules, plaques, blisters, and other lesions to rule out malignancy and to establish an exact diagnosis.

### IMMUNOFLUORESCENCE

Designed to identify the site of an immune reaction, immunofluorescence testing combines an antigen or antibody with a fluorochrome dye. Antibodies can be made fluorescent by attaching them to a dye. Direct immunofluorescence tests on skin are techniques to detect autoantibodies directed against portions of the skin. The indirect immunofluorescence test detects specific antibodies in the patient's serum.

### PATCH TESTING

Performed to identify substances to which the patient has developed an allergy, patch testing involves applying the suspected allergens to normal skin under occlusive patches. The development of redness, fine bumps, or itching is considered a weak positive reaction; fine blisters, papules, and severe itching indicate a moderately positive reaction; and blisters, pain, and ulceration indicate a strong positive reaction (see Chap. 53).

### SKIN SCRAPINGS

Tissue samples are scraped from suspected fungal lesions with a scalpel blade moistened with oil so that the scraped skin adheres to the blade. The scraped material is transferred to a glass slide, covered with a coverslip, and examined microscopically.

### TZANCK SMEAR

The Tzanck smear is a test used to examine cells from blistering skin conditions, such as herpes zoster, varicella, herpes simplex, and all forms of pemphigus. The secretions from a suspected lesion are applied to a glass slide, stained, and examined.

### WOOD'S LIGHT EXAMINATION

**Wood's light** is a special lamp that produces long-wave ultraviolet rays, which result in a characteristic dark purple fluorescence. The color of the fluorescent light is best seen in a darkened room, where it is possible to differentiate epidermal from dermal

lesions and hypopigmented and hyperpigmented lesions from normal skin. The patient is reassured that the light is not harmful to skin or eyes. Lesions that still contain melanin almost disappear under ultraviolet light, whereas lesions that are devoid of melanin increase in whiteness with ultraviolet light.

## CLINICAL PHOTOGRAPHS

Photographs are taken to document the nature and extent of the skin condition and are used to determine progress or improvement resulting from treatment.

### Critical Thinking Exercises

1. In thinking about the skin as the first line of defense for homeostasis, identify some of the threats to skin integrity that should be assessed when admitting a patient to the hospital. What impact does the type of skin care delivered have on skin integrity? How would skin assessment of an elderly patient differ from that of a young adult?

2. An elderly African American woman is admitted to the hospital for treatment of diabetes. What concerns should be addressed relative to the skin and circulation in a patient with diabetes? How will your assessment of the skin of this patient differ from the assessment of the skin of a Caucasian patient?

# ● Management of Patients With Dermatologic Problems

## **LEARNING OBJECTIVES**

*On completion of this chapter, the learner will be able to:*

1. Describe the general management of the patient with an abnormal skin condition.
2. Use the nursing process as a framework for care of the patient with psoriasis.
3. Describe the health education needs of the patient with infections of the skin and parasitic skin diseases.
4. Use the nursing process as a framework for care of patients with noninfectious, inflammatory dermatoses.
5. Describe the management and nursing care of the patient with skin cancer.
6. Use the nursing process as a framework for care of the patient with malignant melanoma.
7. Describe characteristics of the various types of Kaposi's sarcoma.
8. Compare the various types of dermatologic and plastic reconstructive surgeries.
9. Use the nursing process as a framework for care of the patient undergoing facial reconstructive surgery.

**N**ursing care for patients with dermatologic problems includes administering topical and systemic medications, managing wet dressings and other special dressings, and providing therapeutic baths. The four major objectives of therapy are to prevent additional damage, prevent secondary infection, reverse the inflammatory process, and relieve the symptoms.

## Skin Care for Patients With Skin Conditions

Some skin problems are markedly aggravated by soap and water, and bathing routines are modified according to the condition. Denuded skin, whether the area of desquamation is large or small, is excessively prone to damage by chemicals and trauma. The friction of a towel, if applied with vigor, is sufficient to produce a brisk inflammatory response that causes any existing lesion to flare up and extend.

### Protecting the Skin

The essence of skin care and protection in bathing a patient with skin problems is as follows: a mild, lipid-free soap or soap substitute is used; the area is rinsed completely and blotted dry with a soft cloth; and deodorant soaps are avoided.

Special care is necessary when changing dressings. Pledgets saturated with oil, sterile saline, or another prescribed solution help to loosen crusts, remove exudates, or free an adherent dry dressing.

### Preventing Secondary Infection

Potentially infectious skin lesions should be regarded strictly as such, and proper precautions should be observed until the diagnosis is established. Most lesions with pus contain infectious material. The nurse and physician must adhere to standard precautions and wear gloves when inspecting the skin or changing the dressing. Proper disposal of any contaminated dressing is carried out according to Occupational Safety and Health Administration (OSHA) regulations.

### Reversing the Inflammatory Process

The type of skin lesion (eg, oozing, infected, or dry) usually determines the type of local medication or treatment that is prescribed. As a rule, if the skin is acutely inflamed (ie, hot, red, and

swollen) and oozing, it is best to apply wet dressings and soothing lotions. For chronic conditions in which the skin surface is dry and scaly, water-soluble emulsions, creams, ointments, and pastes are used. The therapy is modified as the responses of the skin indicate. The patient and the nurse should note whether the medication or dressings seem to irritate the skin. The success or failure of therapy usually depends on adequate instruction and motivation of the patient and the interest of and support by the health care personnel.

## Wound Care for Skin Conditions

There are three major classifications of dressings for skin conditions: wet, moisture-retentive, and occlusive. During the 1980s and 1990s, new product development quadrupled the available choices for wound care, especially within the moisture-retentive dressing classification. Products classified as moisture-retentive dressings include hydrogels, foams, and alginates. Biologicals and biosynthetics containing collagen and growth factor are being researched and will soon be available. Chart 56-1 lists generic wound care products. Consultation with a wound care specialist can be very helpful in choosing the product most appropriate for the patient.

### Dressings and Rules of Wound Care

Even with the increased availability of dressings, an appropriate selection can be made if certain principles are maintained, referred to as the five rules of wound care (Krastner, et al, 2002).

**Rule 1: Categorization.** The nurse should learn about dressings by generic category and compare new products with those that already make up the category. As hundreds of choices become available, the nurse should become familiar with the generic categories and develop a systematic approach to product selection. The nurse should become familiar with indications, contraindications, and side effects. The best dressing may be created by combining products in different categories to achieve several goals at the same time. These categories are discussed in subsequent sections.

**Rule 2: Selection.** The nurse should select the safest and most effective, user-friendly, and cost-effective dressing possible. In

## Glossary

**acantholysis:** separation of epidermal cells from each other due to damage or abnormality of the intracellular substance  
**balneotherapy:** a bath with therapeutic additives  
**carbuncle:** localized skin infection involving several hair follicles  
**cheilitis:** dry, cracking, inflamed skin at the corners of the mouth  
**comedones:** the primary lesions of acne, caused by sebum blockage in the hair follicle  
**débridement:** removal of necrotic or dead tissue by mechanical, surgical, or autolytic means

**dermatitis:** any inflammation of the skin  
**dermatosis:** any abnormal skin lesion  
**epidermopoiesis:** development of epidermal cells  
**furuncle:** localized skin infection of a single hair follicle  
**hydrophilic:** a material that absorbs moisture  
**hydrophobic:** a material that repels moisture  
**hygroscopic:** a material that absorbs moisture from the air  
**lichenification:** thickening of the horny layer of the skin  
**liniments:** lotions with added oil for increased softening of the skin

**plasmapheresis:** removal of whole blood from the body, separation of its cellular elements by centrifugation, and reinfusion of them suspended in saline or some other plasma substitute, thereby depleting the body's own plasma without depleting its cells  
**Propionibacterium acnes:** bacteria that live on the skin; the primary causative agent of acne  
**pyoderma:** bacterial skin infections  
**suspensions:** liquid preparations in which powder is suspended, requiring shaking before use  
**tinea:** a superficial fungal infection on the skin or scalp

Chart  
56-1

## Wound Care Products

adhesives	creams or skin protectant	lubricating, stimulating sprays
adhesive removers	pastes	moisturizers
adhesive skin closures	dressing covers	moisture barrier ointments
adhesive tapes	enzyme débriding agents	ointments
alginate dressings	foam dressings	ointments
antibiotics	gauze dressings	perineal cleansers
antimicrobials	growth factors	skin sealants
antiseptics	hydrocolloid dressings	transparent film dressings
bandages	hydrogel dressings	wound fillers:
biosynthetic dressings	leg ulcer wraps, compression bandages or wraps	pastes, powders, beads, etc.
cleansers		wound pouches
collagen dressings		
composite dressings		
contact layers		

many cases, nurses carry out the physician's prescriptions for dressings, but they should be prepared to give the physician feedback about the dressing's effect on the wound, ease of use for the patient, and other considerations when applicable.

**Rule 3: Change.** The nurse changes dressings based on patient, wound, and dressing assessments, not on standardized routines. Traditional nursing care plans recommended changing dressings on a routine schedule, often three or four times each day.

**NURSING ALERT** It is believed that the natural wound-healing process should not be disrupted. Unless the wound is infected or has a heavy discharge, it is common to leave chronic wounds covered for 48 to 72 hours and acute wounds for 24 hours.

**Rule 4: Evolution.** As the wound progresses through the phases of wound healing, the dressing protocol is altered to optimize wound healing. It is rare, especially in cases of chronic wounds, that the same dressing material is appropriate throughout the healing process. The rule assumes that the nurse and the patient or family have access to a wide variety of products and knowledge about their use. The nurse teaches the patient or family caregiver about wound care and ensures that the family has access to appropriate dressing choices.

**Rule 5: Practice.** Practice with dressing material is required for the nurse to learn the performance parameters of the particular dressing. Refining the skills of applying appropriate dressings correctly and learning about new dressing products are essential nursing responsibilities. Dressing changes should not be delegated to assistive personnel; these techniques require the knowledge base and assessment skills of professional nurses.

## Wet Dressings

Wet dressings (ie, wet compresses applied to the skin) were traditionally used for acute, weeping, inflammatory lesions. They have become almost obsolete in light of the many newer products available for wound care. Wet dressings are sterile or nonsterile (clean), depending on the skin disorder. They are used to reduce inflammation by producing constriction of the blood vessels

(thereby decreasing vasodilation and local blood flow in inflammation); to clean the skin of exudates, crusts, and scales; to maintain drainage of infected areas; and to promote healing by facilitating the free movement of epidermal cells across the involved skin so that new granulation tissue forms. Wet dressings can be used for vesicular, bullous, pustular, and ulcerative disorders, as well as for inflammatory conditions.

Before applying these dressings, the nurse performs hand hygiene and puts on sterile or clean gloves. The open dressing requires frequent changes because evaporation is rapid. The closed dressing is changed less frequently, but there is always a danger that the closed dressing may cause not only softening and but actual maceration of the underlying skin. Wet-to-dry dressings are used to remove exudate from erosions or ulcers. The dressing remains in place until it dries. It is then removed without soaking so that crusts, exudate, or pus from the skin lesion adhere to the dressing and are removed with it.

## Moisture-Retentive Dressings

Newer, commercially produced moisture-retentive dressings can perform the same functions as wet compresses but are more efficient at removing exudate because of their higher moisture-vapor transmission rate; some have reservoirs that can hold excessive exudate. There is also evidence that moist wound healing results in wound resurfacing 40% faster than with air exposure. A number of moisture-retentive dressings are already impregnated with saline solution, petrolatum, zinc-saline solution, hydrogel, or antimicrobial agents, thereby eliminating the need to coat the skin to avoid maceration. The main advantages of moisture-retentive dressings over wet compresses are reduced pain, fewer infections, less scar tissue, gentle autolytic débridement, and decreased frequency of dressing changes. Depending on the product used and the type of dermatologic problem encountered, most moisture-retentive dressings may remain in place from 12 to 24 hours; some can remain in place as long as a week. Table 56-1 is a guide to wound dressing functions and categories.

Hydrogels are polymers with a 90% to 95% water content. They are available in impregnated sheets or as gel in a tube. Their high moisture content makes them ideal for autolytic débridement of wounds. They are semitransparent, allowing for wound inspection without dressing removal. They are comfortable and soothing for the painful wound. They have no inherent adhesive and require a secondary dressing to keep them in place. Hydrogels are appropriate for superficial wounds with high serous output, such as abrasions, skin graft sites, and draining venous ulcers.

Hydrocolloids are composed of a water-impermeable, polyurethane outer covering separated from the wound by a hydrocolloid material. They are adherent and nonpermeable to water vapor and oxygen. As it evaporates over the wound, water is absorbed into the dressing, which softens and discolors with the increased water content. The dressing can be removed without damage to the wound. As the dressing absorbs water, it produces a foul-smelling, yellowish covering over the wound. This is a normal chemical interaction between the dressing and wound exudate and should not be confused with purulent drainage from the wound. Unfortunately, most of the hydrocolloid dressings are opaque, limiting inspection of the wound without removal of the dressing.

Available in sheets and in gels, hydrocolloids are a good choice for exudative wounds and for acute wounds. Easy to use and comfortable, hydrocolloid dressings promote débridement and formation of granulation tissue. They do not have to be removed for bathing. Most can be left in place for up to 7 days.

Table 56-1 • Quick Guide to Wound Dressing Function and Categories

FUNCTION	ACTION	EXAMPLE
Absorption	Absorbs exudate	Alginates, composite dressings, foams, gauze, hydrocolloids, hydrogels
Cleansing	Removes purulent drainage, foreign debris, and devitalized tissue	Wound cleansers
Débridement	<i>Autolytic</i> ; covers a wound and allows enzymes to self-digest sloughed skin  <i>Chemical or enzymatic</i> ; applied topically to break down devitalized tissue <i>Mechanical</i> ; removes devitalized tissue with mechanical force	Absorption beads, pastes, powders; alginates; composite dressings; foams; hydrate gauze; hydrogels; hydrocolloids; transparent films; wound care systems  Enzymatic débridement agents  Wound cleansers, gauze (wet to dry), whirlpool
Diathermy	Produces electrical current to promote warmth and new tissue growth	
Hydration	Adds moisture to a wound	Gauze (saturated with saline) solution, hydrogels, wound care systems, fibrous fleece dressings
Maintain moist environment	Manages moisture levels in a wound and maintains a moist environment	Composites, contact layers, foams, gauze (impregnated or saturated), hydrogels, hydrocolloids, transparent films, wound care systems
Manage high-output wounds	Manages excessive quantities of exudate	Pouching systems
Pack or fill dead space	Prevents premature wound closure or fills shallow areas and provides absorption	Absorbent beads, powders, pastes; alginates, composites, foams, gauze (impregnated and non-impregnated)
Protect and cover wound	Provides protection from the external environment	Composites, compression bandages/wraps, foams, gauze dressings, hydrogels, hydrocolloids, transparent film dressings
Protect periwound skin	Prevents moisture and mechanical trauma from damaging delicate tissue around wound	Composites, foams, hydrocolloids, pouching systems, skin sealants, transparent film dressings
Provide therapeutic compression	Provides appropriate levels of support to the lower extremities in venous stasis disease	Compression bandages, wraps

Foam dressings consist of microporous polyurethane with an absorptive **hydrophilic** (ie, water-absorbing) surface that covers the wound and a **hydrophobic** (ie, water-resistant) backing to block leakage of exudate. They are nonadherent and require a secondary dressing to keep them in place. Moisture is absorbed into the foam layer, decreasing maceration of surrounding tissue. A moist environment is maintained, and removal of the dressing does not damage the wound. The foams are opaque and must be removed for wound inspection. Foams are a good choice for exudative wounds. They are especially helpful over bony prominences because they provide contoured cushioning.

Calcium alginates are derived from seaweed and consist of tremendously absorbent calcium alginate fibers. They are hemostatic and bioabsorbable and can be used as sheets, mats, or ropes of absorbent material. As the exudate is absorbed, the fibers turn into a viscous hydrogel. They are quite useful in areas where the tissue is more irritated or macerated. The alginate dressing forms a moist pocket over the wound while the surrounding skin stays dry. They also react with wound fluid to form a foul-smelling coating. Alginates work well when packed into a deep cavity, wound, or sinus tract with heavy drainage (Kraestner et al, 2002). They are nonadherent and require a secondary dressing.

## Occlusive Dressings

Occlusive dressings may be commercially produced or made inexpensively from sterile or nonsterile gauze squares or wrap. Occlusive dressings cover topical medication that is applied to a **dermatosis** (ie, abnormal skin lesion). The area is kept airtight by using plastic film (eg, plastic wrap). Plastic film is thin and readily adapts to all sizes, body shapes, and skin surfaces. Plastic surgical tape containing a corticosteroid in the adhesive layer can be cut to size and applied to individual lesions. Generally, plastic wrap should be used no more than 12 hours each day.

## AUTOLYTIC DÉBRIDEMENT

Autolytic **débridement** is a process that uses the body's own digestive enzymes to break down necrotic tissue. The wound is kept moist with occlusive dressings. Eschar and necrotic debris are softened, liquefied, and separated from the bed of the wound.

Several commercially available products contain the same enzymes that the body produces naturally. These are called enzymatic débriding agents; examples include Accu Zyme, collagenase (Santyl), Granulex, and Zymase. Application of these products speeds the rate at which necrotic tissue is removed. This method is still slower and no more effective than surgical débridement. When enzymatic débridement is being used under an occlusive

dressing, a foul odor is produced by the breakdown of cellular debris. This odor does not indicate that the wound is infected. The nurse should expect this reaction, and help the patient understand the reason for the odor.

## Advances in Wound Treatment

Increasing understanding of how skin heals has led to several advances in therapy. Growth factors are cytokines or proteins that have potent mitogenic activity (Valencia et al., 2001). Low levels of cytokines circulate in the blood continuously, but activated platelets release increased amounts of preformed growth factors into a wound. This increase in cytokines in the wound stimulates cellular growth and granulation of skin. Regranex gel contains bcaplermin, a platelet-derived growth factor, which is applied to the wound to stimulate healing. Apligraf is a skin construct (ie, bio-engineered skin substitute) imbedded in a dressing that also contains cytokines and fibroblasts. When applied to wounds, these agents stimulate platelet activity and potentially decrease wound healing time (Paquette & Falanga, 2002).

Some oral medications are being investigated for their benefits in healing chronic venous ulcers of the lower legs. Pentoxifylline (Trental) increases peripheral blood flow by decreasing the viscosity of blood. It has some fibrinolytic action and decreases leukocyte adhesion to the wall of the blood vessels. Enteric-coated aspirin has also been shown to be of value, although its exact mechanism is still not clear (Valencia et al., 2001).

## Medical Management

### THERAPEUTIC BATHS (BALNEOTHERAPY) AND MEDICATIONS

Baths or soaks, known as **balneotherapy**, are useful when large areas of skin are affected. The baths remove crusts, scales, and old medications and relieve the inflammation and itching that accompany acute dermatoses. The water temperature should be comfortable, and the bath should not exceed 20 to 30 minutes because of the tendency of baths and soaks to produce skin maceration. Table 56-2 lists the different types of therapeutic baths and their uses.

## PHARMACOLOGIC THERAPY

Because skin is easily accessible and therefore easy to treat, topical medications are often used. High concentrations of some medications can be applied directly to the affected site with little systemic absorption and therefore with few systemic side effects. However, some medications are readily absorbed through the skin and can produce systemic effects. Because topical preparations may induce allergic contact **dermatitis** (ie, inflammation of the skin) in sensitive patients, any untoward response should be reported immediately and the medication discontinued.

Medicated lotions, creams, ointments, and powders are frequently used to treat skin lesions. In general, moisture-retentive dressings, with or without medication, are used in the acute stage; lotions and creams are reserved for the subacute stage; and ointments are used when inflammation has become chronic and the skin is dry with scaling or **lichenification** (ie, leathery thickening).

With all types of topical medication, the patient is taught to apply the medication gently but thoroughly and, when necessary, to cover the medication with a dressing to protect clothing. Table 56-3 lists some commonly used topical preparations.

**Lotions.** Lotions are of two types: suspensions and liniments. **Suspensions** consist of a powder in water, requiring shaking before application, and clear solutions, containing completely dissolved active ingredients. Lotions are usually applied directly to the skin, but a dressing soaked in the lotion can be placed on the affected area. A suspension such as calamine lotion provides a rapid cooling and drying effect as it evaporates, leaving a thin, medicinal layer of powder on the affected skin. Lotions are frequently used to replenish lost skin oils or to relieve pruritus. Lotions must be applied every 3 or 4 hours for sustained therapeutic effect. If left in place for a longer period, they may crust and cake on the skin. **Liniments** are lotions with oil added to prevent crusting. Because lotions are easy to use, therapeutic compliance is generally high.

**Powders.** Powders usually have a talc, zinc oxide, bentonite, or cornstarch base and are dusted on the skin with a shaker or with cotton sponges. Although their therapeutic action is brief, powders act as **hygroscopic** agents that absorb and retain moisture from the air and reduce friction between skin surfaces and clothing or bedding.

Table 56-2 • Types of Therapeutic Baths

BATH SOLUTION	EFFECTS AND USES	NURSING INTERVENTIONS
Water	Same effect as wet dressings	• Fill the tub half full.
Saline	Used for widely disseminated lesions	• Keep the water at a comfortable temperature.
Colloidal (Aveeno, oatmeal)	Antipruritic, soothing	• Do not allow the water to cool excessively.
Sodium bicarbonate (baking soda)	Cooling	• Use a bath mat— <i>medications added to bath can cause the tub to be slippery.</i>
Starch	Soothing	• Apply an emollient cream to damp skin after the bath if lubrication is desired.
Medicated tars	Psoriasis and chronic eczema	• Because tars are volatile, the bath area should be well ventilated.
Bath oils	Antipruritic and emollient action; acute and subacute generalized eczematous eruptions	• Dry by gently blotting with a towel.
		• Keep room warm to minimize temperature fluctuations.
		• Encourage the patient to wear light, loose clothing after the bath.

**Table 56-3 • Common Topical Preparations and Medications**

PREPARATION	PRODUCT NAME
Bath preparations	
With tar	Balnetar, Doak Oil, Lavatar
With colloidal oatmeal	Aveeno Oilated Bath Powder
With oatmeal and mineral oil	Aveeno Bath Oil, Nutra Soothe
With mineral oil	Nutraderm Bath Oil, Lubath, Alpha-Keri Bath Oil
Moisturizer creams	Acid Mantle Cream, Curel Cream, Dermasil, Eucerin, Lubriderm, Noxzema Skin Cream
Moisturizer ointments	Aquaphor Ointment, Eutra Swiss Skin Cream, Vaseline Ointment
Topical anesthetics	lidocaine (Xylocaine) of various strengths in the form of spray, ointment, gel; EMLA cream (lidocaine 2.5% and prilocaine 2.5%)
Topical antibiotics	bacitracin, Polysporin (bacitracin and polymixin B), Bactroban ointment or cream (mupirocin 2%), erythromycin 2% (Emgel, Eryderm Solution), clindamycin phosphate 1% (Cleocin cream, gel, solution), gentamicin sulfate 1% (Garamycin cream or ointment), 1% silver sulfadiazine cream (Silvadene)

**Creams.** Creams may be suspensions of oil in water or emulsions of water in oil, with additional ingredients to prevent bacterial and fungal growth. Both may cause an allergic reaction such as contact dermatitis. Oil-in-water creams are easily applied and usually are the most cosmetically acceptable to the patient. Although they can be used on the face, they tend to have a drying effect. Water-in-oil emulsions are greasier and are preferred for drying and flaking dermatoses. Creams usually are rubbed into the skin by hand. They are used for their moisturizing and emollient effects.

**Gels.** Gels are semisolid emulsions that become liquid when applied to the skin or scalp. They are cosmetically acceptable to the patient because they are not visible after application, and they are greaseless and nonstaining. The newer water-based gels appear to penetrate the skin more effectively and cause less stinging on application. They are especially useful for acute dermatitis in which there is weeping exudate (eg, poison ivy).

**Pastes.** Pastes are mixtures of powders and ointments and are used in inflammatory blistering conditions. They adhere to the skin and may be difficult to remove without using an oil (eg, olive oil, mineral oil). Pastes are applied with a wooden tongue depressor or gloved hand.

**Ointments.** Ointments retard water loss and lubricate and protect the skin. They are the preferred vehicle for delivering medication to chronic or localized dry skin conditions, such as eczema or psoriasis. Ointments are applied with a wooden tongue depressor or by hand (gloved).

**Sprays and Aerosols.** Spray and aerosol preparations may be used on any widespread dermatologic condition. They evaporate on contact and are used infrequently.

**Corticosteroids.** Corticosteroids are widely used in treating dermatologic conditions to provide anti-inflammatory, antipruritic, and vasoconstrictive effects. The patient is taught to apply this medication according to strict guidelines, using it sparingly but rubbing it into the prescribed area thoroughly. Absorption of topical corticosteroid is enhanced when the skin is hydrated or the affected area is covered by an occlusive or moisture-retentive dressing. Inappropriate use of topical corticosteroids can result in local and systemic side effects, especially when the medication is absorbed through inflamed and excoriated skin, under occlusive dressings, or when used for long periods on sensitive areas. Local side effects may include skin atrophy and thinning, striae (ie, band-like streaks), and telangiectasia. Thinning of the skin results from the ability of corticosteroids to inhibit skin collagen synthesis (Odom et al., 2000). The thinning process can be reversed by discontinuing the medication, but striae and telangiectasia are permanent. Systemic side effects may include hyperglycemia and symptoms of Cushing's syndrome. Caution is required when applying corticosteroids around the eyes because long-term use may cause glaucoma or cataracts, and the anti-inflammatory effect of corticosteroids may mask existing viral or fungal infections.

Concentrated (fluorinated) corticosteroids are never applied on the face or intertriginous areas (ie, axilla and groin), because these areas have a thinner stratum corneum and absorb the medication much more quickly than areas such as the forearm or legs. Persistent use of concentrated topical corticosteroids in any location may produce acnelike dermatitis, known as steroid-induced acne, and hypertrichosis (ie, excessive hair growth). Because some topical corticosteroid preparations are available without prescription, patients should be cautioned about prolonged and inappropriate use. Table 56-4 lists topical corticosteroid preparations according to potency.

**Intralesional Therapy.** Intralesional therapy consists of injecting a sterile suspension of medication (usually a corticosteroid) into or just below a lesion. Although this treatment may have an anti-inflammatory effect, local atrophy may result if the medication is injected into subcutaneous fat. Skin lesions treated with intralesional therapy include psoriasis, keloids, and cystic acne. Occasionally, immunotherapeutic and antifungal agents are administered as intralesional therapy.

**Systemic Medications.** Systemic medications are also prescribed for skin conditions. These include corticosteroids for short-term therapy for contact dermatitis or for long-term treatment of a chronic dermatosis, such as pemphigus vulgaris. Other frequently used systemic medications include antibiotics, antifungals, antihistamines, sedatives, tranquilizers, analgesics, and cytotoxic agents.

## Nursing Management

Management begins with a health history, direct observation, and a complete physical examination. Chapter 55 provides a description of integumentary assessment. Because of its visibility, a skin condition is usually difficult to ignore or conceal from others and may therefore cause the patient some emotional distress. The major goals for the patient may include maintenance of skin integrity, relief of discomfort, promotion of restful sleep, self-acceptance, knowledge about skin care, and avoidance of complications.

Table 56-4 • Potency: Topical Corticosteroids

POTENCY	TOPICAL CORTICOSTEROID	PREPARATIONS
OTC	0.5–1.0% hydrocortisone	cr, lot, oint*
Lowest	dexamethasone 0.1% (Decaderm)	cr, oint, aerosol, gel
	alclometasone 0.05% (Aclovate)	cr, oint
	hydrocortisone 2.5% (Hytone)	cr, lot, oint
Low–medium	desonide 0.05% (DesOwen, Tridesilon)	cr, lot, oint
	fluocinolone acetonide 0.025% (Synalar)	cr, solution
	hydrocortisone valerate 0.2% (Westcort)	cr, solution
	betamethasone valerate 0.1% (Valisone)	cr, oint
	fluticasone propionate 0.05% (Cutivate)	cr, oint
Medium–high	triamcinolone acetonide 0.1–0.5% (Aristocort)	cr, oint, lot
	fluocinonide 0.05% (Lidex)	cr, oint, gel
	desoximetasone 0.05–0.25% (Topicort)	cr, oint, gel
	fluocinolone 0.2% (Synalar)	cr, oint
	diflorasone diacetate 0.05% (Psorcon)	cr, oint
Very high	clobetasol propionate 0.05% (Temovate)	cr, oint, gel
	betamethasone dipropionate 0.05% (Diprolene)	cr, oint, gel
	halobetasole propionate 0.05% (Ultravate)	cr, oint

\*cr, cream; lot, lotion; oint, ointment; OTC, over the counter

Nursing management for patients who must perform self-care for skin problems, such as applying medications and dressings, focuses mainly on teaching the patient how to wash the affected area and pat it dry, apply medication to the lesion while the skin is moist, cover the area with plastic (eg, Telfa pads, plastic wrap, vinyl gloves, plastic bag) if recommended, and cover it with an elastic bandage, dressing, or paper tape to seal the edges. Dressings that contain or cover a topical corticosteroid should be removed for 12 of every 24 hours to prevent skin thinning (ie, atrophy), striae, and telangiectasia (ie, small, red lesions caused by dilation of blood vessels).

Other forms of dressings, such as those used to cover topical medications, include soft cotton cloth and stretchable cotton dressings (eg, Surgitube, TubeGauz) that can be used for fingers, toes, hands, and feet. The hands can be covered with disposable polyethylene or vinyl gloves sealed at the wrists; the feet can be wrapped in plastic bags covered by cotton socks. Gloves and socks that are already impregnated with emollients, making application to the hands and feet more convenient, are also available. When large areas of the body must be covered, cotton cloth topped by an expandable stockinette can be used. Disposable diapers or cloths folded in diaper fashion are useful for dressing the groin and the

perineal areas. Axillary dressings can be made of cotton cloth, or a commercially prepared dressing may be used and taped in place or held by dress shields. A turban or plastic shower cap is useful for holding dressings on the scalp. A face mask, made from gauze with holes cut out for the eyes, nose, and mouth, may be held in place with gauze ties looped through holes cut in the four corners of the mask. See the Plan of Nursing Care 56-1 for more information.

## Pruritus

### GENERAL ITCHING

Pruritus (ie, itching) is one of the most common symptoms of patients with dermatologic disorders. Itch receptors are unmyelinated, penicillate (ie, brushlike) nerve endings that are found exclusively in the skin, mucous membranes, and cornea. Although pruritus is usually caused by primary skin disease with resultant rash or lesions, it may occur without a rash or lesion. This is referred to as essential pruritus, which generally has a rapid onset, may be severe, and interferes with normal daily activities.

Pruritus may be the first indication of a systemic internal disease such as diabetes mellitus, blood disorders, or cancer. It may also accompany renal, hepatic, and thyroid diseases (Chart 56-2). Some common oral medications such as aspirin, antibiotics, hormones (ie, estrogens, testosterone, or oral contraceptives), and opioids (ie, morphine or cocaine) may cause pruritus directly or by increasing sensitivity to ultraviolet light. Certain soaps and chemicals, radiation therapy, prickly heat (ie, miliaria), and contact with woolen garments are also associated with pruritus. Pruritus may also be caused by psychological factors, such as excessive stress in family or work situations.

### Pathophysiology

Scratching the itchy area causes the inflamed cells and nerve endings to release histamine, which produces more pruritus, generating a vicious itch–scratch cycle. If the patient responds to an itch by scratching, the integrity of the skin may be altered, and excoriation, redness, raised areas (ie, wheals), infection, or changes in pigmentation may result. Pruritus usually is more severe at night and is less frequently reported during waking hours, probably because the person is distracted by daily activities. At night, when there are few distractions, the slightest pruritus cannot be easily ignored. Severe itching is debilitating.

### Gerontologic Considerations

Pruritus occurs frequently in elderly people as a result of dry skin. Elderly people are also more likely to have a systemic illness that triggers pruritus, are at higher risk for occult malignancy, and are more likely to be on multiple medications than is the younger population. All of these factors increase the incidence of pruritus.

### Medical Management

A thorough history and physical examination usually provide clues to the underlying cause of the pruritus, such as hay fever, allergy, recent administration of a new medication, or a change of cosmetics or soaps. After the cause has been identified, treatment of the condition should relieve the pruritus. Signs of infection and environmental clues, such as warm, dry air or irritating bed linens, should be identified. In general, washing with soap and hot water

(text continues on page 1664)

## Plan of Nursing Care

### Patients With Dermatoses (Abnormal Skin Conditions)

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Impaired skin integrity related to changes in the barrier function of the skin

**Goal:** Maintenance of skin integrity

- |  |  |   |
|--|--|---|
| <ol style="list-style-type: none"> <li>1. Protect healthy skin from maceration (excessive hydration of stratum corneum) when applying wet dressings.</li> <li>2. Remove moisture from skin by blotting gently and avoiding friction.</li> <li>3. Guard carefully against risks of thermal injuries from excessively hot wet dressings and from subtle heat injuries (heating pads, radiators).</li> <li>4. Advise patient to use sunscreens agents.</li> </ol> | <ol style="list-style-type: none"> <li>1. Maceration of healthy skin can cause skin breakdown and extension of the primary condition.</li> <li>2. Friction and maceration play a major role in some skin diseases.</li> <li>3. Patients with dermatoses may have decreased sensitivity to heat.</li> <li>4. Many cosmetic problems and virtually all cutaneous malignancies can be attributed to chronic skin damage.</li> </ol> | <ul style="list-style-type: none"> <li>• Maintains skin integrity</li> <li>• Absence of maceration</li> <li>• No signs of thermal injury</li> <li>• Absence of infection</li> <li>• Applies prescribed topical medication</li> <li>• Takes prescribed medication on schedule</li> </ul> |
|--|--|---|

**Nursing Diagnosis:** Acute pain and itching related to skin lesions

**Goal:** Relief of discomfort

- |   |  |   |
|---|--|---|
| <ol style="list-style-type: none"> <li>1. Examine area of involvement.               <ol style="list-style-type: none"> <li>a. Attempt to discover cause of discomfort.</li> <li>b. Record observations in detail, using descriptive terminology.</li> <li>c. Anticipate possible allergic reaction; obtain a medication history.</li> </ol> </li> <li>2. Control environmental and physical factors.               <ol style="list-style-type: none"> <li>a. Keep humidity about 60%; use a humidifier.</li> <li>b. Maintain a cool environment.</li> <li>c. Use mild soap for sensitive skin (Dove, Cataphyl, Aveeno).</li> <li>d. Remove excess clothing or bedding.</li> <li>e. Wash bed linens and clothing with mild fragrance-free soap.</li> <li>f. Stop repeated exposures to detergents, cleansers, and solvents.</li> </ol> </li> <li>3. Use skin care measures to maintain skin integrity and promote comfort.               <ol style="list-style-type: none"> <li>a. Provide tepid cooling baths or cool dressings for itching.</li> <li>b. Treat dryness (xerosis) as prescribed.</li> <li>c. Apply skin lotion or cream immediately after bathing.</li> </ol> </li> </ol> | <ol style="list-style-type: none"> <li>1. Understanding the extent and characteristics of the skin involved helps in planning interventions.               <ol style="list-style-type: none"> <li>a. Helps to identify appropriate comfort measures.</li> <li>b. An accurate description of a cutaneous lesion is necessary for diagnosis and treatment. Many skin conditions appear similar but have different etiologies. Cutaneous inflammatory response may be muted in elderly patients.</li> <li>c. A generalized rash, particularly of sudden onset, may indicate a medication allergy.</li> </ol> </li> <li>2. Itching is aggravated by heat, chemicals, and physical irritants.               <ol style="list-style-type: none"> <li>a. At low humidity, the skin loses water.</li> <li>b. Coolness deters itching.</li> <li>c. These contain no detergents, dyes, fragrances, or hardening agents.</li> <li>d. Promotes cool environment.</li> <li>e. Strong soaps and laundry additives can cause skin irritation.</li> <li>f. Any substance that removes water, lipids, or protein from the epidermis alters the skin's barrier function.</li> </ol> </li> <li>3. The skin is an important barrier that must be maintained intact to function properly.               <ol style="list-style-type: none"> <li>a. Gradual evaporation of water from dressings cools the skin and relieves pruritus.</li> <li>b. Dry skin can produce areas of dermatitis with redness, itching, scaling, and, in more severe forms, swelling, blistering, cracking, and weeping.</li> <li>c. Effective hydration of the stratum corneum prevents compromise of the barrier layer of the skin.</li> </ol> </li> </ol> | <ul style="list-style-type: none"> <li>• Achieves relief of discomfort</li> <li>• Verbalizes that itching has been relieved</li> <li>• Demonstrates absence of skin excoriation from scratching</li> <li>• Complies with prescribed treatment</li> <li>• Keeps skin hydrated and lubricated</li> <li>• Demonstrates intact skin; skin regaining healthy appearance</li> </ul> |
|---|--|---|

(continued)

## Plan of Nursing Care

### Patients With Dermatoses (Abnormal Skin Conditions) (Continued)

#### Nursing Interventions

- d. Keep nails trimmed.
- e. Apply prescribed topical therapy.
- f. Help the patient accept possibly prolonged treatment.
- g. Advise the patient to refrain from using salves or lotions that are commercially available.

#### Rationale

- d. Trimming decreases skin damage from scratching.
- e. This helps to relieve symptoms.
- f. Effective coping measures usually promote comfort.
- g. The patient's problem may be aggravated by self-medication.

#### Expected Outcomes

#### Nursing Diagnosis: Disturbed sleep pattern related to pruritus

##### Goal: Achievement of restful sleep

- |   |   |   |
|---|---|---|
| <ol style="list-style-type: none"> <li>1. Prevent and treat dry skin.               <ol style="list-style-type: none"> <li>a. Advise patient to keep bedroom well ventilated and humidified.</li> <li>b. Keep skin moisturized.</li> <li>c. Bathe/shower only as necessary if skin is excessively dry. Use no soap or only mild soap. Apply skin lotion/cream immediately after bathing while skin is damp.</li> </ol> </li> <li>2. Advise patient of the following measures that may be helpful in promoting sleep:               <ol style="list-style-type: none"> <li>a. Keep a regular schedule for sleeping. Go to bed at the same time; get up at the same time.</li> <li>b. Avoid caffeinated drinks in the evening.</li> <li>c. Exercise regularly, particularly in late afternoon.</li> <li>d. Use a bedtime routine or ritual.</li> <li>e. Use an antihistamine at bedtime if prescribed.</li> </ol> </li> </ol> | <ol style="list-style-type: none"> <li>1. Nocturnal pruritus interferes with normal sleep.               <ol style="list-style-type: none"> <li>a. Dry air will make skin feel itchy. A comfortable environment promotes relaxation.</li> <li>b. This prevents water loss. Dry, itchy skin can usually be controlled but not cured.</li> <li>c. These measures preserve skin moisture.</li> </ol> </li> <li>a. Regularity of sleep schedule is important in maintaining sleep.</li> <li>b. Caffeine has peak effect 2–4 hours after being consumed.</li> <li>c. Exercise at this time appears to have beneficial sleep effect.</li> <li>d. This eases transition from wakefulness to sleep.</li> <li>e. Antihistamines decrease itching and promote sleep.</li> </ol> | <ul style="list-style-type: none"> <li>• Achieves restful sleep</li> <li>• Reports relief of itching</li> <li>• Maintains appropriate environmental conditions</li> <li>• Avoids caffeine in late afternoon and evening</li> <li>• Identifies measures to promote sleep</li> <li>• Experiences satisfactory rest/sleep pattern</li> </ul> |
|---|---|---|

#### Nursing Diagnosis: Disturbed body image related to unsightly skin appearance

##### Goal: Development of increasing self-acceptance

- |   |   |   |
|---|---|---|
| <ol style="list-style-type: none"> <li>1. Assess patient for disturbance of self-image (avoidance of eye contact, self-negating verbalizations, expression of disgust about skin condition).</li> <li>2. Identify psychosocial stage of development.</li> <li>3. Provide opportunity for expression. Listen (in an open, nonjudgmental way) to expressions of grief/anxiety about changes in body image.</li> </ol> | <ol style="list-style-type: none"> <li>1. Disturbance of body image may accompany any disease or condition that is apparent to the patient. An impression of one's own body has an effect on self-concept.</li> <li>2. There is a relationship between development stage, self-image, and the patient's reaction to and understanding of skin condition.</li> <li>3. The patient needs the experience of being heard and understood.</li> </ol> | <ul style="list-style-type: none"> <li>• Develops increasing acceptance of own body</li> <li>• Follows through and participates in self-care measures</li> <li>• Reports feeling in control of situation</li> <li>• Gives self positive reinforcement</li> <li>• Verbalizes a more healthful self-regard</li> <li>• Appears less self-conscious; is not afraid to socialize and be seen by others</li> <li>• Uses concealing and highlighting techniques to enhance appearance</li> </ul> |
|---|---|---|

(continued)

## Plan of Nursing Care

### Patients With Dermatoses (Abnormal Skin Conditions) (Continued)

#### Nursing Interventions

4. Assess the patient's concerns and fears. Assist anxious patient to develop insight and identify and cope with problems.
5. Support patient's efforts to improve body image (participation in skin treatments; grooming), develop self-acceptance, socialize with others, and use cosmetics to conceal disfigurement.

#### Rationale

4. This gives health care personnel opportunity to neutralize undue anxiety and restore reality to the situation. Fear is destructive to adaptation.
5. A positive approach and suggestions about cosmetic techniques are often helpful in promoting self-acceptance and socialization.

#### Expected Outcomes

**Nursing Diagnosis:** Deficient knowledge about skin care and methods of treating skin ailment

**Goal:** Understanding of skin care

- |   |  |  |
|---|--|--|
| <ol style="list-style-type: none"> <li>1. Determine what the patient knows (understands and misunderstands) about the condition.</li> <li>2. Keep the patient informed; correct misconceptions/misinformation.</li> <li>3. Demonstrate application of prescribed therapy (wet compresses; topical medication).</li> <li>4. Advise the patient to keep skin moist and flexible with hydration and application of skin cream and lotion.</li> <li>5. Encourage the patient to attain a healthy nutritional status.</li> </ol> | <ol style="list-style-type: none"> <li>1. Provides baseline data for developing the teaching plan.</li> <li>2. Patients need to have a sense that there is something they can do. Most patients benefit from explanations and reassurance.</li> <li>3. Allows patient the opportunity to observe the correct way to perform therapies.</li> <li>4. The stratum corneum needs water to stay flexible. Application of skin cream or lotion to damp skin prevents dry, rough, cracked, and scaly skin.</li> <li>5. The appearance of the skin reflects a person's general health. Changes may signal abnormal nutrition.</li> </ol> | <ul style="list-style-type: none"> <li>• Acquires understanding of skin care</li> <li>• Follows treatment as prescribed and can verbalize rationale for measures taken</li> <li>• Carries out prescribed baths, soaks, wet dressings</li> <li>• Uses topical medication appropriately</li> <li>• Understands importance of nutrition to skin health</li> </ul> |
|---|--|--|

**Collaborative Problems:** Infection

**Goal:** Absence of complications

- |  |   |   |
|--|---|---|
| <ol style="list-style-type: none"> <li>1. Have a high index of suspicion for an infection in patients with compromised immune systems.</li> <li>2. Instruct the patient clearly and in detail about the therapeutic regimen.</li> <li>3. Apply intermittent wet dressings as prescribed to reduce intensity of inflammation.</li> <li>4. Provide tub baths and soaks as prescribed.</li> <li>5. Administer prescribed antimicrobial agents.</li> </ol> | <ol style="list-style-type: none"> <li>1. Any condition that compromises the immune status increases the risk of cutaneous infection.</li> <li>2. Effective patient education is dependent on the interpersonal skills of the health professionals and on giving clear instructions reinforced through written instructions.</li> <li>3. A wet dressing produces evaporative cooling, causing constriction of superficial cutaneous vessels and thereby decreasing erythema and serum production. Wet dressings help in débridement of vesicles and crusts and control inflammatory processes.</li> <li>4. Loosens exudates and scales.</li> <li>5. Kills or prevents the growth of the infectious organism.</li> </ol> | <ul style="list-style-type: none"> <li>• Remains free of infection</li> <li>• Describes skin care measures that promote cleanliness and prevent skin breakdown</li> <li>• Identifies signs and symptoms of infection to report</li> <li>• Identifies adverse effects of medications that should be reported to health care personnel</li> <li>• Participates in skin care measures (eg, dressing changes, soaks)</li> </ul> |
|--|---|---|

(continued)

## Plan of Nursing Care

### Patients With Dermatoses (Abnormal Skin Conditions) (Continued)

Nursing Interventions	Rationale	Expected Outcomes
6. Use topical medications containing corticosteroids as prescribed and as indicated. <ol style="list-style-type: none"> <li>Observe lesion periodically for changes in response to therapy.</li> <li>Instruct the patient about possible adverse effects of long-term use of fluorinated topical corticosteroids.</li> </ol> 7. Advise patient to stop using any skin agent that makes the problem worse.	6. Corticosteroids have an anti-inflammatory action, resulting in part from their ability to induce vasoconstriction of the small vessels in the upper dermis. Extensive prolonged use of topical corticosteroids can lead to antiproliferative effects on epidermal cells (loss of hair in area used; thinning of the skin). 7. A contact dermatitis or allergic reaction may develop from any ingredient in the medication.	

is avoided. Bath oils (eg, Lubath, Alpha-Keri) containing a surfactant that makes the oil mix with bath water may be sufficient for cleaning. However, an elderly patient or a patient with unsteady balance should avoid adding oil because it increases the danger of slipping in the bathtub. A warm bath with a mild soap followed by application of a bland emollient to moist skin can control xerosis (ie, dry skin). Applying a cold compress, ice cube, or cool agents that contain menthol and camphor (which constrict blood vessels) may also help relieve pruritus.

#### PHARMACOLOGIC THERAPY

Topical corticosteroids may be beneficial as anti-inflammatory agents to decrease itching. Oral antihistamines are even more effective because they can overcome the effects of histamine release from damaged mast cells. An antihistamine, such as diphenhydramine (Benadryl) or hydroxyzine (Atarax), prescribed in a sedative dose at bedtime is effective in producing a restful and comfortable sleep. Nonsedating antihistamine medications such

as fexofenadine (Allegra) should be used to relieve daytime pruritus. Tricyclic antidepressants, such as doxepin (Sinequan), may be prescribed for pruritus of neuropsychogenic origin. If pruritus continues, further investigation of a systemic problem is advised.

#### Nursing Management

The nurse reinforces the reasons for the prescribed therapeutic regimen and counsels the patient on specific points of care. If baths have been prescribed, the patient is reminded to use tepid (not hot) water and to shake off the excess water and blot between intertriginous areas (ie, body folds) with a towel. Rubbing vigorously with the towel is avoided because this overstimulates the skin and causes more itching. It also removes water from the stratum corneum. Immediately after bathing, the skin should be lubricated with an emollient to trap moisture.

The patient is instructed to avoid situations that cause vasodilation (ie, expansion of the blood vessels). Examples include exposure to an overly warm environment and ingestion of alcohol or hot foods and liquids. All can induce or intensify itching. Using a humidifier is helpful if environmental air is dry. Activities that result in perspiration should be limited because perspiration may irritate and promote pruritus. If the patient is troubled at night with itching that interferes with sleep, the nurse can advise wearing cotton clothing next to the skin rather than synthetic materials. The room should be kept cool and humidified. Vigorous scratching should be avoided, and nails kept trimmed to prevent skin damage and infection. When the underlying cause of pruritus is unknown and further testing is required, the nurse explains each test and the expected outcome.

#### PERINEAL AND PERIANAL ITCHING

Pruritus of the genital and anal regions may be caused by small particles of fecal material lodged in the perianal crevices or attached to anal hairs or by perianal skin damage caused by scratching, moisture, and decreased skin resistance as a result of corticosteroid or antibiotic therapy. Other possible causes of perianal itching include local irritants such as scabies and lice, local lesions such as hemorrhoids, fungal or yeast infections, and pinworm infestation. Conditions such as diabetes mellitus, anemia, hyperthyroidism, and pregnancy may also result in pruritus. Occasionally, no cause can be identified.

Chart  
56-2

#### Systemic Disorders Associated With Generalized Pruritus

Chronic renal disease  
 Obstructive biliary disease (primary biliary cirrhosis, extrahepatic biliary obstruction, drug-induced cholestasis)  
 Endocrine disease (thyrotoxicosis, hypothyroidism, diabetes mellitus)  
 Psychiatric disorders (emotional stress, anxiety, neurosis, phobias)  
 Malignancies (polycythemia vera, Hodgkin's disease, lymphoma, leukemia, multiple myeloma, mycosis fungoides, and cancers of the lung, breast, central nervous system, and gastrointestinal tract)  
 Neurologic disorders (multiple sclerosis, brain abscess, brain tumor)  
 Infestations (scabies, lice, other insects)  
 Pruritus of pregnancy (pruritic urticarial papules of pregnancy [PUPP], cholestasis of pregnancy, pemphigoid of pregnancy)  
 Folliculitis (bacterial, candidiasis, dermatophyte)  
 Skin conditions (seborrheic dermatitis, folliculitis, iron deficiency anemia, atopic dermatitis)

## Management

The patient is instructed to follow proper hygiene measures and to discontinue home and over-the-counter remedies. The perineal or anal area should be rinsed with lukewarm water and blotted dry with cotton balls. Premoistened tissues may be used after defecation. Cornstarch can be applied in the skinfold areas to absorb perspiration.

As part of health teaching, the nurse instructs the patient to avoid bathing in water that is too hot and to avoid using bubble baths, sodium bicarbonate, and detergent soaps, all of which aggravate dryness. To keep the perineal or perianal skin area as dry as possible, patients should avoid wearing underwear made of synthetic fabrics. Local anesthetic agents should not be used because of possible allergic effects. The patient should also avoid vasodilating agents or stimulants (eg, alcohol, caffeine) and mechanical irritants such as rough or woolen clothing. A diet that includes adequate fiber may help maintain soft stools and prevent minor trauma to the anal mucosa.

## Secretory Disorders

The main secretory function of the skin is performed by the sweat glands, which help to regulate body temperature. These glands excrete perspiration that evaporates, thereby cooling the body. The sweat glands are located in various parts of the body and respond to different stimuli. Those on the trunk generally respond to thermal stimulation; those on the palms and soles respond to nervous stimulation; and those in the axillae and on the forehead respond to both kinds of stimulation. Normal perspiration has no odor. Body odor is produced by the increase in bacteria on the skin and the interaction of bacterial waste products with the chemicals of perspiration.

As a rule, moist skin is warm, and dry skin is cool, but this is not always true. It is not unusual to observe warm, dry skin in a dehydrated patient and very hot, dry skin in some febrile states.

Normally, sweat can be controlled with the use of antiperspirants and deodorants. Most antiperspirants are aluminum salts that block the opening to the sweat duct. Pure deodorants inhibit bacterial growth and block the metabolism of sweat; they have no antiperspirant effect. Fragrance-free deodorants are available for those with sensitive skin (Odom et al., 2000).

## HYDRADENITIS SUPPURATIVA

A condition called hidradenitis suppurativa can occur in certain individuals. The cause is unknown.

### Pathophysiology

Abnormal blockage of the sweat glands causes recurring inflammation, nodules, and draining sinus tracts. Eventually, hypertrophic bands of scar tissue form in the area of the sweat glands.

### Clinical Manifestations

The condition occurs more frequently in the axilla but also appears in inguinal folds, on the mons pubis, and around the buttocks. The patients can be extremely uncomfortable with multiple suppurative lesions within a small area. This condition does not appear before puberty and does appear to have a genetic basis.

## Management

Management is difficult. Hot compresses and oral antibiotics are used frequently. Isotretinoin (Accutane) or etretinate can be tried; careful monitoring for side effects is important. Incision and drainage of large suppurating areas with gauze packs inserted to facilitate drainage is often necessary. Rarely, the entire area is excised, removing the scar tissue and any infection. This surgery is drastic and attempted only as a last resort (Hall, 2000).

## SEBORRHEIC DERMATOSES

Seborrhea is excessive production of sebum (ie, secretion of sebaceous glands) in areas where sebaceous glands are normally found in large numbers, such as the face, scalp, eyebrows, eyelids, sides of the nose and upper lip, malar regions (ie, cheeks), ears, axillae, under the breasts, groin, and gluteal crease of the buttocks. Seborrheic dermatitis is a chronic inflammatory disease of the skin with a predilection for areas that are well supplied with sebaceous glands or lie between skin folds, where the bacteria count is high.

### Clinical Manifestations

Two forms of seborrheic dermatoses can occur, an oily form and a dry form. Either form may start in childhood and continue throughout life. The oily form appears moist or greasy. There may be patches of sallow, greasy skin, with or without scaling, and slight erythema (ie, redness), predominantly on the forehead, nasolabial fold, beard area, scalp, and between adjacent skin surfaces in the regions of the axillae, groin, and breasts. Small pustules or papulopustules resembling acne may appear on the trunk. The dry form, consisting of flaky desquamation of the scalp with a profuse amount of fine, powdery scales, is commonly called dandruff. The mild forms of the disease are asymptomatic. When scaling occurs, it is often accompanied by pruritus, which may lead to scratching and secondary infections and excoriation.

Seborrheic dermatitis has a genetic predisposition. Hormones, nutritional status, infection, and emotional stress influence its course. The remissions and exacerbations of this condition should be explained to the patient. If a person has not previously been diagnosed with this condition and suddenly appears with a severe outbreak, a complete history and physical examination should be considered.

### Medical Management

Because there is no known cure for seborrhea, the objective of therapy is to control the disorder and allow the skin to repair itself. Seborrheic dermatitis of the body and face may respond to a topically applied corticosteroid cream, which allays the secondary inflammatory response. However, this medication should be used with caution near the eyelids, because it can induce glaucoma and cataracts in predisposed patients. Patients with seborrheic dermatitis may develop a secondary candidal (yeast) infection in body creases or folds. To avoid this, patients should be advised to ensure maximum aeration of the skin and to clean carefully areas where there are creases or folds in the skin. Patients with persistent candidiasis should be evaluated for diabetes.

The mainstay of dandruff treatment is proper, frequent shampooing (daily or at least three times weekly) with medicated shampoos. Two or three different types of shampoo should be used in rotation to prevent the seborrhea from becoming resistant to a particular shampoo. The shampoo is left on at least 5 to 10 minutes. As the condition of the scalp improves, the treatment

can be less frequent. Antiseborrheic shampoos include those containing selenium sulfide suspension, zinc pyrithione, salicylic acid or sulfur compounds, and tar shampoo that contains sulfur or salicylic acid.

## Nursing Management

A person with seborrheic dermatitis is advised to avoid external irritants, excessive heat, and perspiration; rubbing and scratching prolong the disorder. To avoid secondary infection, the patient should air the skin and keep skin folds clean and dry.

Instructions for using medicated shampoos are reinforced for those with dandruff that requires treatment. Frequent shampooing is contrary to some cultural practices; the nurse should be sensitive to these differences when teaching the patient about home care.

The patient is cautioned that seborrheic dermatitis is a chronic problem that tends to reappear. The goal is to keep it under control. Patients need to be encouraged to adhere to the treatment program. Those who become discouraged and disheartened by the effect on body image should be treated with sensitivity and an awareness of their need to express their feelings.

## ACNE VULGARIS

Acne vulgaris is a common follicular disorder affecting susceptible hair follicles, most commonly found on the face, neck, and upper trunk. It is characterized by **comedones** (ie, primary acne lesions), both closed and open, and by papules, pustules, nodules, and cysts.

Acne is the most commonly encountered skin condition in adolescents and young adults between ages 12 and 35. Both genders are affected equally, although onset is slightly earlier for girls. This may be because girls reach puberty at a younger age than boys. Acne becomes more marked at puberty and during adolescence because the endocrine glands that influence the secretions of the sebaceous glands are functioning at peak activity. Acne appears to stem from an interplay of genetic, hormonal, and bacterial factors. In most cases, there is a family history of acne.

## Pathophysiology

During childhood, the sebaceous glands are small and virtually nonfunctioning. These glands are under endocrine control, especially by the androgens. During puberty, androgens stimulate the sebaceous glands, causing them to enlarge and secrete a natural oil, sebum, which rises to the top of the hair follicle and flows out onto the skin surface. In adolescents who develop acne, androgenic stimulation produces a heightened response in the sebaceous glands so that acne occurs when accumulated sebum plugs the pilosebaceous ducts. This accumulated material forms comedones.

## Clinical Manifestations

The primary lesions of acne are comedones. Closed comedones (ie, whiteheads) are obstructive lesions formed from impacted lipids or oils and keratin that plug the dilated follicle. They are small, whitish papules with minute follicular openings that generally cannot be seen. These closed comedones may evolve into open comedones, in which the contents of the ducts are in open communication with the external environment. The color of open comedones (ie, blackheads) results not from dirt, but from an accumulation of lipid, bacterial, and epithelial debris.

Although the exact cause is unknown, some closed comedones may rupture, resulting in an inflammatory reaction caused by leakage of follicular contents (eg, sebum, keratin, bacteria) into the dermis. This inflammatory response may result from the action of certain skin bacteria, such as *Propionibacterium acnes*, that live in the hair follicles and break down the triglycerides of the sebum into free fatty acids and glycerin. The resultant inflammation is seen clinically as erythematous papules, inflammatory pustules, and inflammatory cysts. Mild papules and cysts drain and heal on their own without treatment. Deeper papules and cysts may result in scarring of the skin. Acne is usually graded as mild, moderate, or severe based on the number and type of lesions (eg, comedones, papules, pustules, cysts).

## Assessment and Diagnostic Findings

The diagnosis of acne is based on the history and physical examination, evidence of lesions characteristic of acne, and age. Acne does not occur until puberty. The presence of the typical comedones (ie, whiteheads and blackheads) along with excessively oily skin is characteristic. Oiliness is more prominent in the midfacial area; other parts of the face may appear dry. When there are numerous lesions, some of which are open, the person may exude a distinct sebaceous odor. Women may report a history of flare-ups a few days before menses. Biopsy of lesions is seldom necessary for a definitive diagnosis.

## Medical Management

The goals of management are to reduce bacterial colonies, decrease sebaceous gland activity, prevent the follicles from becoming plugged, reduce inflammation, combat secondary infection, minimize scarring, and eliminate factors that predispose the person to acne. The therapeutic regimen depends on the type of lesion (eg, comedonal, papular, pustular, cystic).

There is no predictable cure for the disease, but combinations of therapies are available that can effectively control its activity. Topical treatment may be all that is needed to treat mild to moderate lesions and superficial inflammatory lesions (ie, papular or pustular).

## NUTRITION AND HYGIENE THERAPY

Although food restrictions have been recommended from time to time in treating acne, diet is not believed to play a major role in therapy. However, the elimination of a specific food or food product associated with a flare-up of acne, such as chocolate, cola, fried foods, or milk products, should be promoted. Maintenance of good nutrition equips the immune system for effective action against bacteria and infection.

For mild cases of acne, washing twice each day with a cleansing soap may be all that is required. These soaps can remove the excessive skin oil and the comedo in most cases. Providing positive reassurance, listening attentively, and being sensitive to the feelings of the patient with acne are essential contributors to the patient's psychological well-being and understanding of the disease and treatment plan. Over-the-counter acne medications contain salicylic acid and benzoyl peroxide, both of which are very effective at removing the sebaceous follicular plugs. However, the skin of some people is sensitive to these products, which can cause irritation or excessive dryness, especially when used with some prescribed topical medications. The patient should be instructed to discontinue their use if severe irritation occurs. Oil-free cosmetics and creams should be chosen. These products are usually designated as useful

for acne-prone skin. The duration of treatment depends on the extent and severity of the acne. In severe cases, treatment may extend over years.

### TOPICAL PHARMACOLOGIC THERAPY

**Benzoyl Peroxide.** Benzoyl peroxide preparations are widely used because they produce a rapid and sustained reduction of inflammatory lesions. They depress sebum production and promote breakdown of comedo plugs. They also produce an antibacterial effect by suppressing *P. acnes*. Initially, benzoyl peroxide causes redness and scaling, but the skin usually adjusts quickly to its use. Typically, the patient applies a gel of benzoyl peroxide once daily. In many instances, this is the only treatment needed. Benzoyl peroxide, benzoyl erythromycin, and benzoyl sulfur combinations are available over the counter and by prescription. Vitamin A acid (tretinoin) applied topically is used to clear the keratin plugs from the pilosebaceous ducts. Vitamin A acid speeds the cellular turnover, forces out the comedones, and prevents new comedones.

The patient should be informed that symptoms may worsen during early weeks of therapy because inflammation may occur during the process. Erythema and peeling also frequently result. Improvement may take 8 to 12 weeks. Some patients cannot tolerate this therapy. The patient is cautioned against sun exposure while using this topical medication because it may cause an exaggerated sunburn. Package insert directions should be followed carefully.

**Topical Antibiotics.** Topical antibiotic treatment for acne is common. Topical antibiotics suppress the growth of *P. acnes*; reduce superficial free fatty acid levels; decrease comedones, papules, and pustules; and produce no systemic side effects. Common topical preparations include tetracycline, clindamycin, and erythromycin.

### SYSTEMIC PHARMACOLOGIC THERAPY

**Antibiotics.** Oral antibiotics, such as tetracycline, doxycycline, and minocycline, administered in small doses over a long period are very effective in treating moderate and severe acne, especially when the acne is inflammatory and results in pustules, abscesses, and scarring. Therapy may continue for months to years. The tetracycline family of antibiotics is contraindicated in children younger than age 12 and in pregnant women. Although these medications are considered safe for long-term use in most cases, administration during pregnancy can affect the development of teeth, causing enamel hypoplasia and permanent discoloration of teeth in infants. Side effects of tetracyclines include photosensitivity, nausea, diarrhea, cutaneous infection in either gender, and vaginitis in women. In some women, broad-spectrum antibiotics may suppress normal vaginal bacteria and predispose the patient to candidiasis, a fungal infection.

**Oral Retinoids.** Synthetic vitamin A compounds (ie, retinoids) are used with dramatic results in patients with nodular cystic acne unresponsive to conventional therapy. One compound is isotretinoin (Accutane). Isotretinoin is also used for active inflammatory papular pustular acne that has a tendency to scar. Isotretinoin reduces sebaceous gland size and inhibits sebum production. It also causes the epidermis to shed (ie, epidermal desquamation), thereby unseating and expelling existing comedones.

The most common side effect, experienced by almost all patients, is **cheilitis** (ie, inflammation of the lips). Dry and chafed skin and mucous membranes are frequent side effects. These

changes are reversible with the withdrawal of the medication. Most important, isotretinoin, like other vitamin A metabolites, is teratogenic in humans, meaning that it can have an adverse effect on a fetus, causing central nervous system and cardiovascular defects and structural abnormalities of the face. Contraceptive measures for women of childbearing age are mandatory during treatment and for about 4 to 8 weeks thereafter. To avoid additive toxic effects, patients are cautioned not to take vitamin A supplements while taking isotretinoin (Odom et al., 2000).

**Hormone Therapy.** Estrogen therapy (including progesterone-estrogen preparations) suppresses sebum production and reduces skin oiliness. It is usually reserved for young women when the acne begins somewhat later than usual and tends to flare up at certain times in the menstrual cycle. Estrogen in the form of estrogen-dominant oral contraceptive compounds may be administered on a prescribed cyclic regimen. Estrogen is not administered to male patients because of undesirable side effects such as enlargement of the breasts and decrease in body hair.

### SURGICAL MANAGEMENT

Surgical treatment of acne consists of comedo extraction, injections of corticosteroids into the inflamed lesions, and incision and drainage of large, fluctuant (ie, moving in palpable waves), nodular cystic lesions. Cryosurgery (ie, freezing with liquid nitrogen) may be used for nodular and cystic forms of acne. Patients with deep scars may be treated with deep abrasive therapy (ie, dermabrasion), in which the epidermis and some superficial dermis are removed down to the level of the scars.

Comedones may be removed with a comedo extractor. The site is first cleaned with alcohol. The opening of the extractor is then placed over the lesion, and direct pressure is applied to cause extrusion of the plug through the extractor. Removal of comedones leaves erythema, which may take several weeks to subside. Recurrence of comedones after extraction is common because of the continuing activity of the pilosebaceous glands.

Table 56-5 summarizes the treatment modalities for acne vulgaris.

### Nursing Management

Nursing care of patients with acne consists largely of monitoring and managing potential complications of skin treatments. Major nursing activities include patient education, particularly in proper skin care techniques, and managing potential problems related to the skin disorder or therapy.

### PREVENTING SCARRING

Prevention of scarring is the ultimate goal of therapy. The chance of scarring increases as the grade of acne increases. Grades III and IV (25 to more than 50 comedones, papules, or pustules) usually require longer-term therapy with systemic antibiotics or isotretinoin. Patients should be warned that discontinuing these medications can exacerbate acne, lead to more flare-ups, and increase the chance of deep scarring. Moreover, manipulation of the comedones, papules, and pustules increases the potential for scarring.

When acne surgery is prescribed to extract deep-seated comedones or inflamed lesions or to incise and drain cystic lesions, the intervention itself may result in further scarring. Dermabrasion, which levels existing scar tissue, can also increase scar formation. Hyperpigmentation or hypopigmentation also may affect the tis-

**Table 56-5 • Commonly Prescribed Treatments of Acne Vulgaris**

TYPE OF THERAPY	PRESCRIBED TREATMENT AGENT
Topical	benzoyl peroxide wash, gel benzoyl peroxide and erythromycin (Benzamycin gel) benzoyl peroxide and sulfur (Benzulfoid cream) resorcinol (as ingredient in other preparations) salicylic acid (as ingredient in other preparations) sulfur (as ingredient in other preparations) tretinoin (Retin A, Avita) other comedogenics (adapalene [Differen], azelaic acid [Azelex], tazorotene [Tazorac]) topical antibiotics
Systemic	oral antibiotics (erythromycin, tetracycline, doxycycline, minocin, penicillins) isotretinoin (Accutane) hormones: corticosteroids high dose for anti-inflammatory action low dose to suppress androgenic action intralesional for anti-inflammatory action antiandrogens oral contraceptives (women only)
Surgical	extraction of comedo contents drainage of pustules and cysts excision of sinus tracts and cysts intralesional corticosteroids for anti-inflammatory action cryotherapy dermabrasion for scars laser resurfacing of scars

Treatments listed are common but do not include all available forms of therapy.

sue involved. The patient should be informed of these potential outcomes before choosing surgical intervention for acne.

### PREVENTING INFECTION

Female patients receiving long-term antibiotic therapy with tetracycline should be advised to watch for and report signs and symptoms of oral or vaginal candidiasis, a yeastlike fungal infection.

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** In addition to receiving instructions for taking prescribed medications, patients are instructed to wash the face and other affected areas with mild soap and water twice each day to remove surface oils and prevent obstruction of the oil glands. They are cautioned to avoid scrubbing the face; acne is not caused by dirt and cannot be washed away.

Mild abrasive soaps and drying agents are prescribed to eliminate the oily feeling that troubles many patients. At the same time, patients are cautioned to avoid excessive abrasion because it makes acne worse. Excessive abrasion causes minute scratches on the skin surface and increases possible bacterial contamination. Soap itself can irritate the skin.

All forms of friction and trauma are avoided, including propping the hands against the face, rubbing the face, and wearing

tight collars and helmets. Patients are instructed to avoid manipulation of pimples or blackheads. Squeezing merely worsens the problem, because a portion of the blackhead is pushed down into the skin, which may cause the follicle to rupture. Because cosmetics, shaving creams, and lotions can aggravate acne, these substances are best avoided unless the patient is advised otherwise. There is no evidence that a particular food can cause or aggravate acne. In general, eating a nutritious diet helps the body maintain a strong immune system.

## Bacterial Infections: Pyodermas

Also called **pyodermas**, pus-forming bacterial infections of the skin may be primary or secondary. Primary skin infections originate in previously normal-appearing skin and are usually caused by a single organism. Secondary skin infections arise from a pre-existing skin disorder or from disruption of the skin integrity from injury or surgery. In either case, several microorganisms may be implicated (eg, *Staphylococcus aureus*, group A streptococci). The most common primary bacterial skin infections are impetigo and folliculitis. Folliculitis may lead to furuncles or carbuncles.

### IMPETIGO

Impetigo is a superficial infection of the skin caused by staphylococci, streptococci, or multiple bacteria. Bullous impetigo, a more deep-seated infection of the skin caused by *S. aureus*, is characterized by the formation of bullae (ie, large, fluid-filled blisters) from original vesicles. The bullae rupture, leaving raw, red areas.

The exposed areas of the body, face, hands, neck, and extremities are most frequently involved. Impetigo is contagious and may spread to other parts of the patient's skin or to other members of the family who touch the patient or use towels or combs that are soiled with the exudate of the lesions.

Although impetigo is seen at all ages, it is particularly common among children living in poor hygienic conditions. It often follows pediculosis capitis (head lice), scabies (itch mites), herpes simplex, insect bites, poison ivy, or eczema. Chronic health problems, poor hygiene, and malnutrition may predispose an adult to impetigo. Some people have been identified as asymptomatic carriers of *S. aureus*, usually in the nasal passages.

### Clinical Manifestations

The lesions begin as small, red macules, which quickly become discrete, thin-walled vesicles that soon rupture and become covered with a loosely adherent honey-yellow crust (Fig. 56-1). These crusts are easily removed to reveal smooth, red, moist surfaces on which new crusts soon develop. If the scalp is involved, the hair is matted, which distinguishes the condition from ringworm.

### Medical Management

Systemic antibiotic therapy is the usual treatment. It reduces contagious spread, treats deep infection, and prevents acute glomerulonephritis (ie, kidney infection), which may occur as an aftermath of streptococcal skin diseases. In nonbullous impetigo, benzathine penicillin or oral penicillin may be prescribed. Bullous impetigo is treated with a penicillinase-resistant penicillin (eg, cloxacillin,

**FIGURE 56-1** Impetigo of the nostril.

dicloxacillin). In penicillin-allergic patients, erythromycin is an effective alternative.

Topical antibacterial therapy (eg, mupirocin) may be prescribed when the disease is limited to a small area. However, topical therapy requires that the medication be applied to the lesions several times daily for a week. The treatment regimen may be impossible for some patients or their caregivers to follow. Topical antibiotics generally are not as effective as systemic therapy in eradicating or preventing the spread of streptococci from the respiratory tract, thereby increasing the risk for developing glomerulonephritis.

When topical therapy is prescribed, lesions are soaked or washed with soap solution to remove the central site of bacterial growth, giving the topical antibiotic an opportunity to reach the infected site. After the crusts are removed, a topical medication (eg, Polysporin, bacitracin) may be applied. Gloves are worn when providing patient care. An antiseptic solution, such as povidone-iodine (Betadine) may be used to clean the skin, reduce bacterial content in the infected area, and prevent spread.

## Nursing Management

The nurse instructs the patient and family members to bathe at least once daily with bactericidal soap. Cleanliness and good hygiene practices help prevent the spread of the lesions from one skin area to another and from one person to another. Each person should have a separate towel and washcloth. Because impetigo is a contagious disorder, infected people should avoid contact with other people until the lesions heal.

## FOLLICULITIS, FURUNCLES, AND CARBUNCLES

Folliculitis is an infection of bacterial or fungal origin that arises within the hair follicles. Lesions may be superficial or deep. Single or multiple papules or pustules appear close to the hair follicles. Folliculitis commonly affects the beard area of men who shave and women's legs. Other areas include the axillae, trunk, and buttocks.

Pseudofolliculitis barbae (ie, shaving bumps) are an inflammatory reaction that occurs predominately on the faces of African American and other curly-haired men as a result of shaving. The sharp ingrowing hairs have a curved root that grows at a more acute angle and pierces the skin, provoking an irritative reaction. The only entirely effective treatment is to avoid shaving. Other treatments include using special lotions or antibiotics or using a hand brush to dislodge the hairs mechanically. If the patient must

remove facial hair, a depilatory cream or electric razor may be more appropriate than a straight razor.

A **furuncle** (ie, boil) is an acute inflammation arising deep in one or more hair follicles and spreading into the surrounding dermis. It is a deeper form of folliculitis. Furunculosis refers to multiple or recurrent lesions. Furuncles may occur anywhere on the body but are more prevalent in areas subjected to irritation, pressure, friction, and excessive perspiration, such as the back of the neck, the axillae, and the buttocks.

A furuncle may start as a small, red, raised, painful pimple. Frequently, the infection progresses and involves the skin and subcutaneous fatty tissue, causing tenderness, pain, and surrounding cellulitis. The area of redness and induration represents an effort of the body to keep the infection localized. The bacteria (usually staphylococci) produce necrosis of the invaded tissue. The characteristic pointing of a boil follows in a few days. When this occurs, the center becomes yellow or black, and the boil is said to have "come to a head."

A **carbuncle** is an abscess of the skin and subcutaneous tissue that represents an extension of a furuncle that has invaded several follicles and is large and deep seated. It is usually caused by a staphylococcal infection. Carbuncles appear most commonly in areas where the skin is thick and inelastic. The back of the neck and the buttocks are common sites. In carbuncles, the extensive inflammation frequently prevents a complete walling off of the infection; absorption may occur, resulting in high fever, pain, leukocytosis, and even extension of the infection to the bloodstream.

Furuncles and carbuncles are more likely to occur in patients with underlying systemic diseases, such as diabetes or hematologic malignancies, and in those receiving immunosuppressive therapy for other diseases. Both are more prevalent in hot climates, especially on skin beneath occlusive clothing.

## Medical Management

In treating staphylococcal infections, it is important not to rupture or destroy the protective wall of induration that localizes the infection. The boil or pimple should never be squeezed.

Follicular disorders, including folliculitis, furuncles, and carbuncles, are usually caused by staphylococci; although if the immune system is impaired, the causative organisms may be gram-negative bacilli. Systemic antibiotic therapy, selected by sensitivity study, is generally indicated. Oral cloxacillin, dicloxacillin, and flucloxacillin are first-line medications. Cephalosporins and erythromycin are also effective. Bed rest is advised for patients who have boils on the perineum or in the anal region, and a course of systemic antibiotic therapy is indicated to prevent the spread of the infection.

When the pus has localized and is fluctuant, a small incision with a scalpel can speed resolution by relieving the tension and ensuring direct evacuation of the pus and slough. The patient is instructed to keep the draining lesion covered with a dressing.

## Nursing Management

Intravenous fluids, fever reduction, and other supportive treatments are indicated for patients who are very ill or suffering with toxicity. Warm, moist compresses increase vascularization and hasten resolution of the furuncle or carbuncle. The surrounding skin may be cleaned gently with antibacterial soap, and an antibacterial ointment may be applied. Soiled dressings are handled according to standard precautions. Nursing personnel should carefully follow isolation precautions to avoid becoming carriers

of staphylococci. Disposable gloves are worn when caring for these patients.

**NURSING ALERT** Nurses must take special precautions in caring for boils on the face, because the skin area drains directly into the cranial venous sinuses. Sinus thrombosis with fatal pyemia can develop after manipulating a boil in this location. The infection can travel through the sinus tract and penetrate the brain cavity, causing brain abscess.

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** To prevent and control staphylococcal skin infections such as boils and carbuncles, the staphylococcal pathogen must be eliminated from the skin and environment. Efforts must be made to increase the patient's resistance and provide a hygienic environment. If lesions are actively draining, the mattress and pillow should be covered with plastic material and wiped off with disinfectant daily; the bed linens, towels, and clothing should be laundered after each use; and the patient should use an antibacterial soap and shampoo for an indefinite period, often for several months.

Recurrent infection is prevented with the use of prescribed antibiotic therapy (eg, a daily dose of oral clindamycin to be taken continuously for about 3 months). The patient must take the full dose for the time prescribed. The purulent exudate (ie, pus) is a source of reinfection or transmission of infection to caregivers. When the patient has a history of recurrent infections, a carrier state may exist, which should be investigated and treated with an antibacterial cream such as mupirocin.

## Viral Skin Infections

### HERPES ZOSTER

Herpes zoster, also called shingles, is an infection caused by the varicella-zoster virus, a member of a group of DNA viruses. The viruses causing chickenpox and herpes zoster are indistinguishable, hence the name varicella-zoster virus. The disease is characterized by a painful vesicular eruption along the area of distribution of the sensory nerves from one or more posterior ganglia. It is assumed that herpes zoster represents a reactivation of latent varicella virus infection and reflects lowered immunity. After a case of chickenpox runs its course, it is thought that the varicella-zoster viruses responsible for the outbreak lie dormant inside nerve cells near the brain and spinal cord. Later, when these latent viruses are reactivated, they travel by way of the peripheral nerves to the skin, where the viruses multiply and create a red rash of small, fluid-filled blisters. About 10% of adults get shingles during their lifetimes, usually after age 50 years. There is an increased frequency of herpes zoster infections among patients with weakened immune systems and cancers, especially leukemias and lymphomas (Odom et al., 2000).

### Clinical Manifestations

The eruption is usually accompanied or preceded by pain, which may radiate over the entire region supplied by the affected nerves. The pain may be burning, lancinating (ie, tearing or sharply cutting), stabbing, or aching. Some patients have no pain, but itching and tenderness may occur over the area. Sometimes, malaise and gastrointestinal disturbances precede the eruption. The

patches of grouped vesicles appear on the red and swollen skin. The early vesicles, which contain serum, later may become purulent, rupture, and form crusts. The inflammation is usually unilateral, involving the thoracic, cervical, or cranial nerves in a bandlike configuration. The blisters are usually confined to a narrow region of the face or trunk (Fig. 56-2). The clinical course varies from 1 to 3 weeks. If an ophthalmic nerve is involved, the patient may have eye pain. Inflammation and a rash on the trunk may cause pain with the slightest touch. The healing time varies from 7 to 26 days.

Herpes zoster in healthy adults is usually localized and benign. However, in immunosuppressed patients, the disease may be severe and the clinical course acutely disabling.

### Medical Management

The goals of herpes zoster management are to relieve the pain and to reduce or avoid complications, which include infection, scarring, and postherpetic neuralgia and eye complications. Pain is controlled with analgesics, because adequate pain control during the acute phase helps prevent persistent pain patterns. Systemic corticosteroids may be prescribed for patients older than age 50 years to reduce the incidence and duration of postherpetic neuralgia (ie, persistent pain of the affected nerve after healing). Healing usually occurs sooner in those who have been treated with corticosteroids. Triamcinolone (Aristocort, Kenacort, Kenalog) injected subcutaneously under painful areas is effective as an anti-inflammatory agent.

There is evidence that infection is arrested if oral antiviral agents such as acyclovir (Zovirax), valacyclovir (Valtrex), or famciclovir (Famvir) are administered within 24 hours of the initial eruption. Intravenous acyclovir, if started early, is effective in significantly reducing the pain and halting the progression of the disease. In older patients, the pain from herpes zoster may persist as postherpetic neuralgia for months after the skin lesions disappear (Hall, 2000).

Ophthalmic herpes zoster occurs when an eye is involved. This is considered an ophthalmic emergency, and the patient should be referred to an ophthalmologist immediately to prevent the possible sequelae of keratitis, uveitis, ulceration, and blindness.

**FIGURE 56-2** Herpes zoster (shingles).

People who have been exposed to varicella (ie, chicken pox) by primary infection or by vaccination are not at risk for infection after exposure to patients with herpes zoster.

## Nursing Management

The nurse assesses the patient's discomfort and response to medication and collaborates with the physician to make necessary adjustments to the treatment regimen. The patient is taught how to apply wet dressings or medication to the lesions and to follow proper hand hygiene techniques to avoid spreading the virus.

Diversionary activities and relaxation techniques are encouraged to ensure restful sleep and to alleviate discomfort. A caregiver may be required to assist with dressings, particularly if the patient is elderly and unable to apply them. Relatives, neighbors, or a home care nurse may need to help with dressing changes and food preparation for patients who cannot care for themselves or prepare nourishing meals.

## HERPES SIMPLEX

Herpes simplex is a common skin infection. There are two types of the causative virus, which are identified by viral typing. Generally, herpes simplex type 1 occurs on the mouth and type 2 in the genital area, but both viral types can be found in both locations. About 85% of adults worldwide are seropositive for herpes type 1. The prevalence of type 2 is lower; type 2 usually appears at the onset of sexual activity. Serologic testing shows that many more people are infected than have a history of clinical disease.

Herpes simplex is classified as a true primary infection, a non-primary initial episode, or a recurrent episode. True primary infection is the initial exposure to the virus. A nonprimary initial episode is the initial episode of type 1 or type 2 in a person previously infected with the other type. Recurrent episodes are subsequent episodes of the same viral type.

## OROLABIAL HERPES

Orolabial herpes, also called fever blisters or cold sores, consists of erythematous-based clusters of grouped vesicles on the lips. A prodrome of tingling or burning with pain may precede the appearance of the vesicles by up to 24 hours. Certain triggers, such as sunlight exposure or increased stress, may cause recurrent episodes. Fewer than 1% of people with primary orolabial herpes infections develop herpetic gingivostomatitis. This complication occurs more in children and young adults. The onset is often accompanied by high fever, regional lymphadenopathy, and generalized malaise. Another complication of orolabial herpes is the development of erythema multiforme, an acute inflammation of the skin and mucous membranes with characteristic lesions that have the appearance of targets.

## GENITAL HERPES

Genital herpes, or type 2 herpes simplex, manifests with a broad spectrum of clinical signs. Minor infections may produce no symptoms at all; severe primary infections with type 1 can cause systemic flulike illness. Lesions appear as grouped vesicles on an erythematous base initially involving the vagina, rectum, or penis. New lesions can continue to appear for 7 to 14 days. Lesions are symmetric and usually cause regional lymphadenopathy. Fever and flulike symptoms are common. Typical recurrences begin

with a prodrome of burning, tingling, or itching about 24 hours before the vesicles appear. As the vesicles rupture, erosions and ulcerations begin to appear. Severe infections can cause extensive erosions of the vaginal or anal canal. For further information see Chapter 47.

## Assessment and Diagnostic Findings

Herpes simplex infections are confirmed in several ways. Generally, the appearance of the skin eruption is strongly suggestive. Viral cultures and rapid assays are available, and the type of test used depends on lesion morphology. Acute vesicular lesions are more likely to react positively to the rapid assay, whereas older, crusted patches are better diagnosed with viral culture. In all cases, it is imperative to obtain enough viral cells for testing, and careful collection methods are therefore important. All crusts should be gently removed or vesicles gently unroofed. A sterile cotton swab premoistened in viral culture preservative is used to swab the base of the vesicle to obtain a specimen for analysis.

## Complications

Eczema herpeticum is a condition in which patients with eczema contract herpes that spreads throughout the eczematous areas. The same type of spread of herpes can occur in severe seborrhea, scabies, and other chronic skin conditions.

Herpes Whitlow is an infection of the pulp of a fingertip with herpes type 1 or 2. There is tenderness and erythema of the lateral fold of the cuticle. Deep-seated vesicles appear within 24 hours.

Most cases of neonatal infection with herpes occur during delivery by contact of the infant with the mother's active ulcerations. Rarely, in mothers who have primary infections during pregnancy, intrauterine neonatal infections occur. Fetal anomalies include skin lesions, microcephaly, encephalitis, and intracerebral calcifications.

## Medical Management

In many patients, recurrent orolabial herpes represents more of a nuisance than a disease. Because sun exposure is a common trigger, those with recurrent orolabial herpes should use a sunscreen liberally on the lips and face. Topical treatment with drying agents may accelerate healing. In more severe outbreaks or in patients who have identified a trigger, intermittent treatment with 200 mg of acyclovir administered five times each day for 5 days is often started as soon as the earliest symptoms occur.

Treatment of genital herpes depends on the severity, the frequency, and the psychological impact of recurrences and on the infectious status of the sexual partner. For people who have mild or rare outbreaks, no treatment may be required. For those who have more severe outbreaks, but for whom outbreaks are still infrequent, intermittent treatment as described for oral lesions can be used. Because intermittent treatment reduces the duration of the infection by only 24 to 36 hours, it should be initiated as early as possible.

Patients who have more than six recurrences per year may benefit from suppressive therapy. Use of acyclovir, valacyclovir, or famciclovir suppresses 85% of recurrences, and 20% of patients are free of recurrences during suppressive therapy. Suppressive therapy also reduces viral shedding by almost 95%, making the person less contagious. Treatment with suppressive doses of oral antiviral medications prevents recurrent erythema multiforme.

Eczema herpeticum is managed with oral or intravenous acyclovir.

Management of genital herpes in pregnancy is controversial. Routine prenatal cultures do not predict shedding at the time of delivery. The use of scalp electrodes during delivery should be avoided because they increase the risk for infection in the newborn. Because the risk for neonatal herpes is greater in women with their initial episode during pregnancy, suppression therapy should be started in these women to reduce outbreaks during the third trimester. All women with active lesions at the time of delivery undergo cesarean section.

In immunocompromised patients, suppression therapy should be considered. In severe infections of the hospitalized patient, intravenous acyclovir is prescribed.

## Fungal (Mycotic) Infections

Fungi, tiny members of a subdivision of the plant kingdom that feed on organic matter, are responsible for various common skin infections. In some cases, they affect only the skin and its appendages (ie, hair and nails). In other cases, the internal organs are involved, and this disease may be life-threatening. Superficial infections, however, rarely cause even temporary disability and respond readily to treatment. Secondary infection with bacteria, *Candida*, or both organisms may occur.

The most common fungal skin infection is **tinea**, which is also called ringworm because of its characteristic appearance of ring or rounded tunnel under the skin. Tinea infections affect the head, body, groin, feet, and nails. Table 56-6 summarizes the tinea infections.

To obtain a specimen for diagnosis, the lesion is cleaned, and a scalpel or glass slide is used to remove scales from the margin of the lesion. The scales are dropped onto a slide to which potassium hydroxide has been added. The diagnosis is made by examination

of the infected scales microscopically for spores and hyphae or by isolating the organism in culture. Under Wood's light, a specimen of infected hair appears fluorescent; this may be helpful in diagnosing some cases of tinea capitis.

## TINEA PEDIS: ATHLETE'S FOOT

Tinea pedis (ie, athlete's foot) is the most common fungal infection. It is especially prevalent in those who use communal showers or swimming pools (Odom et al., 2000).

### Clinical Manifestations

Tinea pedis may appear as an acute or chronic infection on the soles of the feet or between the toes. The toenail may also be involved. Lymphangitis and cellulitis occur occasionally when bacterial superinfection occurs. Sometimes, a mixed infection involving fungi, bacteria, and yeast occurs.

### Medical Management

During the acute, vesicular phase, soaks of Burow's solution or potassium permanganate solutions are used to remove the crusts, scales, and debris and to reduce the inflammation. Topical antifungal agents (eg, miconazole, clotrimazole) are applied to the infected areas. Topical therapy is continued for several weeks because of the high rate of recurrence.

### Nursing Management

Footwear provides a favorable environment for fungi, and the causative fungus may be in the shoes or socks. Because moisture encourages the growth of fungi, the patient is instructed to keep the feet as dry as possible, including the areas between the toes.

Table 56-6 • Tinea (Ringworm) Infections

TYPE AND LOCATION	CLINICAL MANIFESTATIONS	TREATMENT
Tinea capitis (head) Contagious fungal infection of the hair shaft	<ul style="list-style-type: none"> <li>• Common in children</li> <li>• Oval, scaling, erythematous patches</li> <li>• Small papules or pustules on the scalp</li> <li>• Brittle hair that breaks easily</li> </ul>	<ul style="list-style-type: none"> <li>• Griseofulvin for 6 weeks</li> <li>• Shampoo hair 2 or 3 times with Nizoral or selenium sulfide shampoo.</li> </ul>
Tinea corporis (body)	<ul style="list-style-type: none"> <li>• Begins with red macule, which spreads to a ring of papules or vesicles with central clearing</li> <li>• Lesions found in clusters.</li> <li>• Many spread to the hair, scalp, or nails</li> <li>• Very pruritic</li> <li>• An infected pet may be the source.</li> </ul>	<ul style="list-style-type: none"> <li>• Mild conditions: topical antifungal creams</li> <li>• Severe conditions: griseofulvin or terbinafine</li> </ul>
Tinea cruris (groin area; "jock itch")	<ul style="list-style-type: none"> <li>• Begins with small, red scaling patches, which spread to form circular elevated plaques</li> <li>• Very pruritic</li> <li>• Clusters of pustules may be seen around borders.</li> </ul>	<ul style="list-style-type: none"> <li>• Mild conditions: topical antifungal creams</li> <li>• Severe conditions: griseofulvin or terbinafine</li> </ul>
Tinea pedis (foot; "athlete's foot")	<ul style="list-style-type: none"> <li>• Soles of one or both feet have scaling and mild redness with maceration in the toe webs.</li> <li>• More acute infections may have clusters of clear vesicles on dusky base.</li> </ul>	<ul style="list-style-type: none"> <li>• Soak feet in vinegar and water solution.</li> <li>• Resistant infections: griseofulvin or terbinafine</li> <li>• Terbinafine (Lamisil) daily for 3 months</li> </ul>
Tinea unguium (toenails; affects about 50% of adults)	<ul style="list-style-type: none"> <li>• Nails thicken, crumble easily, and lack luster</li> <li>• Whole nail may be destroyed.</li> </ul>	<ul style="list-style-type: none"> <li>• Itraconazole (Sporanox) in pulses of 1 week a month for 3 months</li> </ul>

Small pieces of cotton can be placed between the toes at night to absorb moisture. Socks should be made of cotton, and hosiery should have cotton feet, because cotton is an effective absorber of perspiration.

For people whose feet perspire excessively, perforated shoes permit better aeration of the feet. Plastic- or rubber-soled footwear should be avoided. Talcum powder or antifungal powder applied twice daily helps to keep the feet dry. Several pairs of shoes should be alternated so that they can dry completely before being worn again.

## TINEA CORPORIS: RINGWORM OF THE BODY

In tinea corporis (ie, ringworm of the body), the typical ringed lesion appears on the face, neck, trunk, and extremities (Fig. 56-3). Animal (nonhuman) varieties are known to cause an intense inflammatory reaction in humans because they are not adapted to living on human hosts. Humans make contact with animal varieties through contact with pets or objects that have been in contact with an animal.

### Medical Management

Topical antifungal medication may be applied to small areas. Oral antifungal agents are used only in extensive cases. Side effects of oral antifungal agents include photosensitivity, skin rashes, headache, and nausea. Newer antifungal agents, including itraconazole, fluconazole, and terbinafine, have been more effective with fewer systemic side effects than griseofulvin in patients with chronic fungal (dermatophyte) infections.

### Nursing Management

The patient is instructed to use a clean towel and washcloth daily. Because fungal infections thrive in heat and moisture, all skin areas and skin folds that retain moisture must be dried thoroughly. Clean cotton clothing should be worn next to the skin.

## TINEA CAPITIS: RINGWORM OF THE SCALP

Ringworm of the scalp is a contagious fungal infection of the hair shafts and a common cause of hair loss in children. Any child with scaling of the scalp should be considered to have tinea capitis until proven otherwise. Clinical examination reveals one or several round, red scaling patches. Small pustules or papules may

**FIGURE 56-3** Tinea corporis (ringworm) of the face.

be seen at the edges of such patches. As the hairs in the affected areas are invaded by the fungi, they become brittle and break off at or near the surface of the scalp, leaving bald patches or the classic sign of black dots, which are the broken ends of hairs. Because most cases of tinea capitis heal without scarring, the hair loss is only temporary.

### Medical Management

Griseofulvin, an antifungal agent, is prescribed for patients with tinea capitis. Topical agents do not provide an effective cure because the infection occurs within the hair shaft and below the surface of the scalp. However, topical agents can be used to inactivate organisms already on the hair. This minimizes contagion and eliminates the need to clip the hair. Infected hairs break off anyway, and noninfected ones may remain in place. The hair should be shampooed two or three times weekly, and a topical antifungal preparation should be applied to reduce dissemination of the organisms.

### Nursing Management

Because tinea capitis is contagious, the patient and family should be instructed to set up a hygiene regimen for home use. Each person should have a separate comb and brush and should avoid exchanging hats and other headgear. All infected members of the family must be examined because familial infections are relatively common. Household pets should also be examined.

## TINEA CRURIS: RINGWORM OF THE GROIN

Tinea cruris (ie, jock itch) is ringworm infection of the groin, which may extend to the inner thighs and buttock area. It occurs most frequently in young joggers, obese people, and those who wear tight underclothing. The incidence of tinea cruris is increased among people with diabetes.

### Management

Mild infections may be treated with topical medication such as clotrimazole, miconazole, or terbinafine for at least 3 to 4 weeks to ensure eradication of the infection. Oral antifungal agents may be required for more severe infections. Heat, friction, and maceration (from sweating) predispose the patient to the infection. The nurse instructs the patient to avoid excessive heat and humidity as much as possible and to avoid wearing nylon underwear, tight-fitting clothing, and a wet bathing suit. The groin area should be cleaned, dried thoroughly, and dusted with a topical antifungal agent such as tolnaftate (Tinactin) as a preventive measure, because the infection is likely to recur.

## TINEA UNGUIUM: ONYCHOMYCOSIS

Tinea unguium (ie, ringworm of the nails) is a chronic fungal infection of the toenails or, less commonly, the fingernails. It is usually caused by *Trichophyton* species (*T. rubrum*, *T. mentagrophytes*) or *Candida albicans*. It is usually associated with long-standing fungal infection of the feet. The nails become thickened, friable (ie, easily crumbled), and lusterless. In time, debris accumulates under the free edge of the nail. Ultimately, the nail plate separates. Because of the chronicity of this infection, the entire nail may be destroyed.

## Management

An oral antifungal agent is prescribed for 6 weeks when the fingernails are involved and 12 weeks when the toenails are involved. Selection of the antifungal agent depends on the causative fungus. Candidal infections are treated with fluconazole (Diflucan) or itraconazole (Sporanox). Griseofulvin is no longer considered effective therapy because of its long treatment course and poor cure rate. Response to oral antifungal agents in treating infections of the toenails is poor at best. Frequently, when the treatment stops, the infection returns.

## Parasitic Skin Infestation

### PEDICULOSIS: LICE INFESTATION

Lice infestation affects people of all ages. Three varieties of lice infest humans: *Pediculus humanus capitis* (ie, head louse), *Pediculus humanus corporis* (ie, body louse), and *Phthirus pubis* (ie, pubic louse or crab louse). Lice are called ectoparasites because they live on the outside of the host's body. They depend on the host for their nourishment, feeding on human blood approximately five times each day. They inject their digestive juices and excrement into the skin, which causes severe itching.

### PEDICULOSIS CAPITIS

Pediculosis capitis is an infestation of the scalp by the head louse. The female louse lays her eggs (ie, nits) close to the scalp. The nits become firmly attached to the hair shafts with a tenacious substance. The young lice hatch in about 10 days and reach maturity in 2 weeks.

### Clinical Manifestations

Head lice are found most commonly along the back of the head and behind the ears. The eggs are visible to the naked eye as silvery, glistening oval bodies that are difficult to remove from the hair. The bite of the insect causes intense itching, and the resultant scratching often leads to secondary bacterial infection, such as impetigo or furunculosis. The infestation is more common in children and people with long hair. Head lice may be transmitted directly by physical contact or indirectly by infested combs, brushes, wigs, hats, and bedding.

### Medical Management

Treatment involves washing the hair with a shampoo containing lindane (Kwell) or pyrethrin compounds with piperonyl butoxide (RID or R&C Shampoo). The patient is instructed to shampoo the scalp and hair according to the product directions. After the hair is rinsed thoroughly, it is combed with a fine-toothed comb dipped in vinegar to remove any remaining nits or nit shells freed from the hair shafts. They are extremely difficult to remove and may have to be picked off one by one with the fingernails.

All articles, clothing, towels, and bedding that may have lice or nits should be washed in hot water—at least 54°C (130°F)—or dry-cleaned to prevent re-infestation. Upholstered furniture, rugs, and floors should be vacuumed frequently. Combs and brushes are also disinfected with the shampoo. All family members and close contacts are treated. Complications such as severe pruritus, pyoderma, and dermatitis are treated with antipruritics, systemic antibiotics, and topical corticosteroids.

## Nursing Management

The nurse informs the patient that head lice may infest anyone and are not a sign of uncleanliness. Because the condition spreads rapidly, treatment must be started immediately. School epidemics may be managed by having all of the students shampoo their hair on the same night. Students should be warned not to share combs, brushes, and hats. Each family member should be inspected for head lice daily for at least 2 weeks. The patient should be instructed that lindane may be toxic to the central nervous system when used improperly.

### PEDICULOSIS CORPORIS AND PUBIS

Pediculosis corporis is an infestation of the body by the body louse. This is a disease of unwashed people or those who live in close quarters and do not change their clothing. Pediculosis pubis is extremely common. The infestation is generally localized in the genital region and is transmitted chiefly by sexual contact.

### Clinical Manifestations

Chiefly involved are those areas of the skin that come in closest contact with the underclothing (ie, neck, trunk, and thighs). The body louse lives primarily in the seams of underwear and clothing, to which it clings as it pierces the skin with its proboscis. Its bites cause characteristic minute hemorrhagic points. Widespread excoriation may appear as a result of intense itching and scratching, especially on the trunk and neck. Among the secondary lesions produced are parallel linear scratches and a slight degree of eczema. In long-standing cases, the skin may become thick, dry, and scaly, with dark pigmented areas.

Itching is the most common symptom of pediculosis pubis, particularly at night. Reddish brown dust (ie, excretions of the insects) may be found in the patient's underclothing. The pubic area should be examined with a magnifying glass for lice crawling down a hair shaft or nits cemented to the hair or at the junction with the skin. Infestation by pubic lice may coexist with sexually transmitted diseases such as gonorrhea, herpes, or syphilis. There may also be infestation of the hairs of the chest, armpit, beard, and eyelashes. Gray-blue macules may sometimes be seen on the trunk, thighs, and axillae as a result of either the reaction of the insects' saliva with bilirubin (converting it to biliverdin) or an excretion produced by the salivary glands of the louse.

### Medical Management

The patient is instructed to bathe with soap and water, after which lindane (Kwell) or 5% permethrin (Elimite) is applied to affected areas of the skin and to hairy areas, according to the product directions. An alternative topical therapy is an over-the-counter strength of permethrin (1% Nix). If the eyelashes are involved, petrolatum may be thickly applied twice daily for 8 days, followed by mechanical removal of any remaining nits.

Complications, such as severe pruritus, pyoderma, and dermatitis, are treated with antipruritics, systemic antibiotics, and topical corticosteroids. Body lice can transmit epidemic rickettsial disease to humans such as epidemic typhus, relapsing fever, and trench fever. The causative organism may be in the gastrointestinal tract of the insect and may be excreted on the skin surface of the infested person.

## Nursing Management

All family members and sexual contacts must be treated and educated in personal hygiene and methods to prevent or control infestation. The patient and partner must also be scheduled for a diagnostic workup for coexisting sexually transmitted disease. All clothing and bedding should be machine washed in hot water or dry-cleaned.

## SCABIES

Scabies is an infestation of the skin by the itch mite *Sarcoptes scabiei*. The disease may be found in people living in substandard hygienic conditions, but it is also common in very clean individuals and among the sexually active, although infestations do not depend on sexual activity. The mites frequently involve the fingers, and hand contact may produce infection. In children, overnight stays with friends or the exchange of clothes may be a source of infection. Health care personnel who have prolonged hands-on physical contact with an infected patient may likewise become infected.

The adult female burrows into the superficial layer of the skin and remains there for the rest of her life. With her jaws and the sharp edges of the joints of her forelegs, the mite extends the burrow, laying two or three eggs daily for up to 2 months. She then dies. The larvae hatch from the eggs in 3 to 4 days and progress through larval and nymphal states to form adult mites in about 10 days.

## Clinical Manifestations

It takes approximately 4 weeks from the time of contact for the patient's symptoms to appear. The patient complains of severe itching caused by a delayed type of immunologic reaction to the mite or its fecal pellets. During examination, the patient is asked where the itch is most severe. A magnifying glass and a penlight are held at an oblique angle to the skin while a search is made for the small, raised burrows. The burrows may be multiple, straight or wavy, brown or black, threadlike lesions, most commonly observed between the fingers and on the wrists. Other sites are the extensor surfaces of the elbows, the knees, the edges of the feet, the points of the elbows, around the nipples, in the axillary folds, under pendulous breasts, and in or near the groin or gluteal fold, penis, or scrotum. Red, pruritic eruptions usually appear between adjacent skin areas. The burrow, however, is not always visible. Any patient with a rash may have scabies.

One classic sign of scabies is the increased itching that occurs at night, perhaps because the increased warmth of the skin has a stimulating effect on the parasite. Hypersensitivity to the organism and its products of excretion also may contribute to the itching. If the infection has spread, other members of the family and close friends also complain of itching about a month later.

Secondary lesions are quite common and include vesicles, papules, excoriations, and crusts. Bacterial superinfection may result from constant excoriation of the burrows and papules.

## Assessment and Diagnostic Findings

The diagnosis is confirmed by recovering *S. scabiei* or the mites' byproducts from the skin. A sample of superficial epidermis is scraped off the top of the burrows or papules with a small scalpel blade. The scrapings are placed on a microscope slide and examined through a low-powered microscope to demonstrate the mite

at any stage (eg, egg, egg casing, larva, nymph, adult) and fecal pellets.

## Gerontologic Considerations

Elderly patients living in long-term care facilities are more susceptible to outbreaks of scabies because of close living quarters, poor hygiene due to limited physical ability, and the potential for incidental spread of the organisms by nursing staff.

Although the older patient itches severely, the vivid inflammatory reaction seen in younger people seldom occurs. Scabies may not be recognized in the elderly person; the itching may erroneously be attributed to the dry skin of old age or to anxiety.

Health care personnel in extended-care facilities should wear gloves when providing hands-on care for a patient suspected of having scabies until the diagnosis is confirmed and treatment accomplished. It is advisable to treat all residents, staff, and families of patients at the same time to prevent reinfection. Because geriatric patients may be more sensitive to side effects of the scabicides, they should be closely observed for reactions.

## Medical Management

The patient is instructed to take a warm, soapy bath or shower to remove the scaling debris from the crusts and then to dry thoroughly and allow the skin to cool. A prescription scabicide, such as lindane (Kwell), crotamiton (Eurax), or 5% permethrin (Elimite), is applied thinly to the entire skin from the neck down, sparing only the face and scalp (which are not affected in scabies). The medication is left on for 12 to 24 hours, after which the patient is instructed to wash thoroughly. One application may be curative, but it is advisable to repeat the treatment in 1 week.

**NURSING ALERT** The patient must understand medication instructions, because application of a scabicide immediately after bathing and before the skin dries and cools increases percutaneous absorption of the scabicide and the potential for central nervous system abnormalities such as seizures.

## Nursing Management

The patient should wear clean clothing and sleep between freshly laundered bed linens. All bedding and clothing should be washed in hot water and dried on the hot dryer cycle, because the mites can survive up to 36 hours in linens. If bed linens or clothing cannot be washed in hot water, dry-cleaning is advised.

After treatment is completed, the patient should apply an ointment, such as a topical corticosteroid, to skin lesions because the scabicide may irritate the skin. The patient's hypersensitivity does not cease on destruction of the mites. Itching may continue for several weeks as a manifestation of hypersensitivity, particularly in atopic (allergic) people. This is not a sign that the treatment has failed. The patient is instructed not to apply more scabicide because it will cause more irritation and increased itching and advised not to take frequent hot showers because they can dry the skin and produce itching. Oral antihistamines such as diphenhydramine (Benadryl) or hydroxyzine (Atarax) can help control the itching.

All family members and close contacts should be treated simultaneously to eliminate the mites. Some scabicides are approved for use in infants and pregnant women. If scabies is sexually

transmitted, the patient may require treatment for coexisting sexually transmitted disease. Scabies may also coexist with pediculosis.

## Contact Dermatitis

Contact dermatitis is an inflammatory reaction of the skin to physical, chemical, or biologic agents. The epidermis is damaged by repeated physical and chemical irritations. Contact dermatitis may be of the primary irritant type, in which a nonallergic reaction results from exposure to an irritating substance, or it may be allergic (ie, allergic contact dermatitis), resulting from exposure of sensitized people to contact allergens. Allergic dermatoses are discussed in Chapter 53. Common causes of irritant dermatitis are soaps, detergents, scouring compounds, and industrial chemicals. Predisposing factors include extremes of heat and cold, frequent contact with soap and water, and a preexisting skin disease (Chart 56-3).

### Clinical Manifestations

The eruptions begin when the causative agent contacts the skin. The first reactions include itching, burning, and erythema, followed closely by edema, papules, vesicles, and oozing or weeping. In the subacute phase, these vesicular changes are less marked, and they alternate with crusting, drying, fissuring, and peeling. If repeated reactions occur or if the patient continually scratches the skin, lichenification and pigmentation occur. Secondary bacterial invasion may follow.

### Medical Management

The objectives of management are to rest the involved skin and protect it from further damage. The distribution pattern of the reaction is determined to differentiate between allergic and irritant contact dermatitis. A detailed history is obtained. If indicated, the offending irritant is removed. Local irritation should be avoided, and soap is not generally used until healing occurs.

#### Chart 56-3 • PATIENT EDUCATION Strategies for Avoiding Contact Dermatitis

The following precautions may help prevent repeated cases of contact dermatitis. Follow these instructions for at least 4 months after your skin appears to be completely healed.

- Study the pattern and location of your dermatitis and think about which things have touched your skin and which things may have caused the problem.
- Try to avoid contact with these materials.
- Avoid heat, soap, and rubbing, all of which are external irritants.
- Choose bath soaps, laundry detergents, and cosmetics that do not contain fragrance.
- Avoid using a fabric softener dryer sheet (Bounce, Cling). Fabric softeners that are added to the washer may be used.
- Avoid topical medications, lotions, or ointments, except those specifically prescribed for your condition.
- Wash your skin thoroughly immediately after exposure to possible irritants.
- When wearing gloves (for example, for washing dishes or general cleaning), be sure they are cotton-lined. Do not wear them more than 15 or 20 minutes at a time.

Many preparations are advocated for relieving dermatitis. In general, a bland, unmedicated lotion is used for small patches of erythema (ie, red, inflamed skin). Cool, wet dressings also are applied over small areas of vesicular dermatitis. Finely cracked ice added to the water often enhances its antipruritic effect.

Wet dressings usually help clear the oozing eczematous lesions. A thin layer of cream or ointment containing a corticosteroid then may be used. Medicated baths at room temperature are prescribed for larger areas of dermatitis. For severe, widespread conditions, a short course of systemic corticosteroids may be prescribed.

## Noninfectious Inflammatory Dermatoses

### PSORIASIS

Psoriasis is a chronic noninfectious inflammatory disease of the skin in which epidermal cells are produced at a rate that is about six to nine times faster than normal. The cells in the basal layer of the skin divide too quickly, and the newly formed cells move so rapidly to the skin surface that they become evident as profuse scales or plaques of epidermal tissue. The psoriatic epidermal cell may travel from the basal cell layer of the epidermis to the stratum corneum (ie, skin surface) and be cast off in 3 to 4 days, which is in sharp contrast to the normal 26 to 28 days. As a result of the increased number of basal cells and rapid cell passage, the normal events of cell maturation and growth cannot take place. This abnormal process does not allow the normal protective layers of the skin to form.

One of the most common skin diseases, psoriasis affects approximately 2% of the population, appearing more often in people who have a European ancestry. It is thought that the condition stems from a hereditary defect that causes overproduction of keratin. Although the primary cause is unknown, a combination of specific genetic makeup and environmental stimuli may trigger the onset of disease. There is some evidence that the cell proliferation is mediated by the immune system. Periods of emotional stress and anxiety aggravate the condition. Trauma, infections, and seasonal and hormonal changes also are trigger factors. The onset may occur at any age but is most common between the ages of 15 and 50 years. Psoriasis has a tendency to improve and then recur periodically throughout life (Champion et al., 1998).

### Clinical Manifestations

Lesions appear as red, raised patches of skin covered with silvery scales. The scaly patches are formed by the buildup of living and dead skin resulting from the vast increase in the rate of skin-cell growth and turnover (Fig. 56-4). If the scales are scraped away, the dark red base of the lesion is exposed, producing multiple bleeding points. These patches are not moist and may be pruritic. One variation of this condition is called guttate psoriasis because the lesions remain about 1 cm wide and are scattered like raindrops over the body. This variation is believed to be associated with a recent streptococcal throat infection. Psoriasis may range in severity from a cosmetic source of annoyance to a physically disabling and disfiguring disorder.

Particular sites of the body tend to be affected most by this condition; they include the scalp, the extensor surface of the elbows and knees, the lower part of the back, and the genitalia. Bilateral symmetry is a feature of psoriasis. In approximately one fourth to one half of patients, the nails are involved, with pitting, discoloration, crumbling beneath the free edges, and separation of the nail plate. When psoriasis occurs on the palms and soles, it can cause pustular lesions called palmar pustular psoriasis.

of the skin is of little diagnostic value. There are no specific blood tests helpful in diagnosing the condition. When in doubt, the health professional should assess for signs of nail and scalp involvement and for a positive family history.

## Medical Management

The goals of management are to slow the rapid turnover of epidermis, to promote resolution of the psoriatic lesions, and to control the natural cycles of the disease. There is no known cure.

The therapeutic approach should be one that the patient understands; it should be cosmetically acceptable and not too disruptive of lifestyle. Treatment involves the commitment of time and effort by the patient and possibly the family. First, any precipitating or aggravating factors are addressed. An assessment is made of lifestyle, because psoriasis is significantly affected by stress. The patient is informed that treatment of severe psoriasis can be time consuming, expensive, and aesthetically unappealing at times.

The most important principle of psoriasis treatment is gentle removal of scales. This can be accomplished with baths. Oils (eg, olive oil, mineral oil, Aveeno Oiled Oatmeal Bath) or coal tar preparations (eg, Balnetar) can be added to the bath water and a soft brush used to scrub the psoriatic plaques gently. After bathing, the application of emollient creams containing alpha-hydroxy acids (eg, Lac-Hydrin, Penederm) or salicylic acid will continue to soften thick scales. The patient and family should be encouraged to establish a regular skin care routine that can be maintained even when the psoriasis is not in an acute stage.

## PHARMACOLOGIC THERAPY

Three types of therapy are standard: topical, intralesional, and systemic (Table 56-7).

**Topical Agents.** Topically applied agents are used to slow the overactive epidermis without affecting other tissues. Medications include tar preparations, anthralin, salicylic acid, and corticosteroids. Two topical treatments introduced within the last few years are a vitamin D preparation, calcipotriene (Dovonex), and

**FIGURE 56-4** Psoriasis. Courtesy of Roche Laboratories.

## Complications

The disease may be associated with asymmetric rheumatoid factor-negative arthritis of multiple joints. The arthritic development can occur before or after the skin lesions appear. The relation between arthritis and psoriasis is not understood. Another complication is an exfoliative psoriatic state in which the disease progresses to involve the total body surface, called erythrodermic psoriasis. In this case, the patient is more acutely ill, with fever, chills, and an electrolyte imbalance. Erythrodermic psoriasis often appears in people with chronic psoriasis after infections or after exposure to certain medications, including withdrawal of systemic corticosteroids (Champion et al., 1998).

## Assessment and Diagnostic Findings

The presence of the classic plaque-type lesions generally confirms the diagnosis of psoriasis. Because the lesions tend to change histologically as they progress from early to chronic plaques, biopsy

**Table 56-7 • Current Treatments for Psoriasis**

TOPICAL AGENTS	USE	SELECTED AGENTS
Topical corticosteroids	Mild to moderate lesions Moderate to severe lesions Severe lesions Lesions on face and groin	Aristocort, Kenalog, Valisone Lidex, Psorcon, Cutivate Temovate, Diprolene, Ultravate Aclovate, DesOwen, Hytone 2.5%
Topical nonsteroidals	Mild to severe	Retinoids such as tazarotene (Tazorac) Vitamin D <sub>3</sub> derivative calcipotriene (Dovonex)
Coal tar products	Mild to moderate lesions	Coal tar and salicylic acid ointment (Aquatar, Estar gel, Fototar, Zetar); anthralin (AnthraDerm, Dritho-Cream); Neutrogena T-Derm, Psori Gel
Medicated shampoos	Scalp lesions	Neutrogena T-Gel, T-Sal, Zetar, Head & Shoulders, Desenex, Selsun Blue, Bakers P&S (emulsifying agent with phenol, saline solution, and mineral oil)
Intralesional therapy	Thick plaques and nails	Kenalog, Cordran-impregnated tape, Fluoroplex
Systemic therapy	Extensive lesions and nails	Mathotrexate (Folex, Mexate); hydrourea (Hydrea); retinoic acid (Tegison) (not to be used in women of childbearing age)
	Psoriatic arthritis	Oral gold (auranofin), etretinate, methotrexate
Photochemotherapy	Moderate to severe lesions	UVA or UVB light with or without topical medications PUVA (combines UVA light with oral psoralens, or topical tripsoralen)

a retinoid compound, tazarotene (Tazorac). Treatment with these agents tends to suppress **epidermopoiesis** (ie, development of epidermal cells) and cause sloughing of the rapidly growing epidermal cells.

Topical formulations include lotions, ointments, pastes, creams, and shampoos. Older treatments, including tar baths and application of tar preparations on involved skin, are rarely used. Tar and anthralin cause irritation of the skin at the sites of application, are malodorous and difficult to apply, and do not give reliable results. Newer preparations that cause less irritation and have more consistent results are becoming more widely used.

Topical corticosteroids may be applied for their anti-inflammatory effect. Choosing the correct strength of corticosteroid for the involved site and choosing the most effective vehicle base are important aspects of topical treatment. In general, high-potency topical corticosteroids should not be used on the face and intertriginous areas, and their use on other areas should be limited to a 4-week course of twice-daily applications. A 2-week break should be taken before repeating treatment with the high-potency corticosteroids. For long-term therapy, moderate-potency corticosteroids are used. On the face and intertriginous areas, only low-potency corticosteroids are appropriate for long-term use (see Table 56-4).

Occlusive dressings may be applied to increase the effectiveness of the corticosteroid. For the hospitalized patient, large plastic bags may be used—one for the upper body with openings cut for the head and arms and one for the lower body with openings for the legs. This leaves only the extremities to wrap. In some dermatologic units, large rolls of tubular plastic are used, such as those used by dry-cleaners. For patients being treated at home, a vinyl jogging suit may be used. The medication is applied, and the suit is put on over it. The hands can be wrapped in gloves, the feet in plastic bags, and the head in a shower cap. Occlusive dressings should not remain in place longer than 8 hours. The nurse should very carefully inspect the skin for the appearance of atrophy and telangiectasias which are side effects of corticosteroids.

**NURSING ALERT** When plastic substances are used, the nurse needs to check for flammability. Some thin plastic films burn slowly (if touched by a lighted cigarette), whereas others burst rapidly into flame. The patient should be cautioned not to smoke while wrapped in plastic dressing.

When psoriasis involves large areas of the body, topical corticosteroid treatment can become expensive and involve some systemic risk. Some potent corticosteroids, when applied to large areas of the body, have the potential to cause adrenal suppression through percutaneous absorption of the medication. In this event, other treatment modalities (eg, nonsteroidal topical medications, ultraviolet light) may be used instead or in combination to decrease the need for corticosteroids.

Newer nonsteroidal topical preparations are available and effective for many patients. Calcipotriene 0.05% (Dovonex) is a derivative of vitamin D<sub>2</sub>. It works to decrease the mitotic turnover of the psoriatic plaques. Its most common side effect is local irritation, and the intertriginous areas and face should be avoided when using this medication. Patients should be monitored for symptoms of hypercalcemia. It is available as a cream for use on the body and a solution for the scalp. Calcipotriene is not recommended for use by elderly patients because of their more fragile skin or for pregnant or lactating women.

The second advance in topical treatment of psoriasis is tazarotene (Tazorac). Tazarotene, a retinoid, causes sloughing of the scales

covering psoriatic plaques. As with other retinoids, it causes increased sensitivity to sunlight, so patients should be cautioned to use an effective sunscreen and avoid other photosensitizers (eg, tetracycline, antihistamines). Tazarotene is listed as a Category X drug in pregnancy; reports indicate evidence of fetal risk, and the risk of use in pregnant women clearly outweighs any possible benefits. A negative result on a pregnancy test should be obtained before initiating this medication, and an effective contraceptive should be continued during treatment. Side effects of tazarotene include burning, erythema, or irritation at the site of application and worsening of psoriasis.

**Intralesional Agents.** Intralesional injections of triamcinolone acetonide (Aristocort, Kenalog-10, Trymex) can be administered directly into highly visible or isolated patches of psoriasis that are resistant to other forms of therapy. Care must be taken to ensure that normal skin is not injected with the medication.

**Systemic Agents.** Although systemic corticosteroids may cause rapid improvement of psoriasis, their usual risks and the possibility of triggering a severe flare-up on withdrawal limit their use. Systemic cytotoxic preparations, such as methotrexate, have been used in treating extensive psoriasis that fails to respond to other forms of therapy. Other systemic medications in current use include hydroxyurea (Hydrea) and cyclosporine A (CyA).

Methotrexate appears to inhibit DNA synthesis in epidermal cells, thereby reducing the turnover time of the psoriatic epidermis. However, the medication can be toxic, especially to the liver, which can suffer irreversible damage. Laboratory studies must be monitored to ensure that the hepatic, hematopoietic, and renal systems are functioning adequately. Bone marrow suppression is another potential side effect. The patient should avoid drinking alcohol while taking methotrexate, because alcohol ingestion increases the possibility of liver damage. The medication is teratogenic (ie, producing physical defects in the fetus) and should not be administered to pregnant women.

Hydroxyurea also inhibits cell replication by affecting DNA synthesis. The patient is monitored for signs and symptoms of bone marrow depression.

Cyclosporine A, a cyclic peptide used to prevent rejection of transplanted organs, has shown some success in treating severe, therapy-resistant cases of psoriasis. Its use, however, is limited by side effects such as hypertension and nephrotoxicity.

Oral retinoids (ie, synthetic derivatives of vitamin A and its metabolite, vitamin A acid) modulate the growth and differentiation of epithelial tissue. Etretinate is especially useful for severe pustular or erythrodermic psoriasis. Etretinate is a teratogen with a very long half-life; it cannot be used in women with childbearing potential.

## PHOTOCHEMOTHERAPY

One treatment for severely debilitating psoriasis is a psoralen medication combined with ultraviolet-A (PUVA) light therapy. Ultraviolet light is the portion of the electromagnetic spectrum containing wavelengths ranging from 180 to 400 nm. In this treatment, the patient takes a photosensitizing medication (usually 8-methoxypsoralen) in a standard dose and is subsequently exposed to long-wave ultraviolet light as the medication plasma levels peak. Although the mechanism of action is not completely understood, it is thought that when psoralen-treated skin is exposed to ultraviolet-A light, the psoralen binds with DNA and decreases cellular proliferation. PUVA is not without its hazards;

it has been associated with long-term risks of skin cancer, cataracts, and premature aging of the skin.

The PUVA unit consists of a chamber that contains high-output black-light lamps and an external reflectance system. The exposure time is calibrated according to the specific unit in use and the anticipated tolerance of the patient's skin. The patient is usually treated two or three times each week until the psoriasis clears. An interim period of 48 hours between treatments is necessary because it takes this long for any burns resulting from PUVA therapy to become evident.

After the psoriasis clears, the patient begins a maintenance program. Once little or no disease is active, less potent therapies are used to keep minor flare-ups under control.

Ultraviolet-B (UVB) light therapy is also used to treat generalized plaques. UVB light ranges from 270 to 350 nm, although research has shown that a narrow range, 310 to 312 nm, is the action spectrum. It is used alone or combined with topical coal tar. Side effects are similar to those of PUVA therapy. A new development in light therapy is the narrow-band UVB, which ranges from 311 to 312 nm, decreasing exposure to harmful ultraviolet energy while providing more intense, specific therapy (Shelk & Morgan, 2000).

If access to a light treatment unit is not feasible, the patient can expose himself or herself to sunlight. The risks of all light treatments are similar and include acute sunburn reaction; exacerbation of photosensitive disorders such as lupus, rosacea, and polymorphic light eruption; and other skin changes such as increased wrinkles, thickening, and an increased risk for skin cancer.

Excimer lasers have come into use in treating psoriasis. These lasers function at 308 nm. Studies show that medium-sized psoriatic plaques clear in four to six treatments and remain clear for up to 9 months. A laser can be more effective on the scalp or on other hard-to-treat areas, because the laser can be aimed very specifically on the plaque (Lebwohl, 2000). Table 56-7 summarizes the treatment plans.

## NURSING PROCESS: CARE OF THE PATIENT WITH PSORIASIS

### Assessment

The nursing assessment focuses on how the patient is coping with the psoriatic skin condition, appearance of the normal skin, and appearance of the skin lesions, as described previously. The notable manifestations are red, scaling papules that coalesce to form oval, well-defined plaques. Silver-white scales may also be present. Adjacent skin areas show red, smooth plaques with a macerated surface. It is important to examine the areas especially prone to psoriasis: elbows, knees, scalp, gluteal cleft, fingers, and toenails (for small pits).

Psoriasis may cause despair and frustration for the patient; observers may stare, comment, ask embarrassing questions, or even avoid the person. The disease can eventually exhaust the patient's resources, interfere with his or her job, and make life miserable in general. Teenagers are especially vulnerable to the psychological effects of this disorder. The family, too, is affected, because time-consuming treatments, messy salves, and constant shedding of scales may disrupt home life and cause resentment. The patient's frustrations may be expressed through hostility directed at health care personnel and others.

The nurse assesses the impact of the disease on the patient and the coping strategies used for conducting normal activities and interactions with family and friends. Many patients need reassurance that the condition is not infectious, not a reflection of poor personal hygiene, and not skin cancer.

## Diagnosis

### NURSING DIAGNOSES

Based on the nursing assessment data, the patient's major nursing diagnoses may include the following:

- Deficient knowledge about the disease process and treatment
- Impaired skin integrity related to lesions and inflammatory response
- Disturbed body image related to embarrassment over appearance and self-perception of uncleanliness

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications include the following:

- Infection
- Psoriatic arthritis

## Planning and Goals

Major goals for the patient may include increased understanding of psoriasis and the treatment regimen, achievement of smoother skin with control of lesions, development of self-acceptance, and absence of complications.

## Nursing Interventions

### PROMOTING UNDERSTANDING

The nurse explains with sensitivity that, although there is no cure for psoriasis and lifetime management is necessary, the condition can usually be controlled. The pathophysiology of psoriasis is reviewed, as are the factors that provoke it—irritation or injury to the skin (eg, cut, abrasion, sunburn), current illness (eg, pharyngeal streptococcal infection), and emotional stress. It is emphasized that repeated trauma to the skin and an unfavorable environment (eg, cold) or a specific medication (eg, lithium, beta-blockers, indomethacin) may exacerbate psoriasis. The patient is cautioned about taking any nonprescription medications because some may aggravate mild psoriasis.

Reviewing and explaining the treatment regimen are essential to ensure compliance. For example, if the patient has a mild condition confined to localized areas, such as the elbows or knees, application of an emollient to maintain softness and minimize scaling may be all that is required. However, if the patient uses anthralin, the dosage schedule, possible side effects, and problems to report to the nurse or physician should be explained.

Most patients need a comprehensive plan of care that ranges from using topical medications and shampoos to more complex and lengthy treatment with systemic medications and phototherapy, such as PUVA therapy. Patient education materials that include a description of the therapy and specific guidelines are helpful but cannot replace face-to-face discussions of the treatment plan.

### INCREASING SKIN INTEGRITY

To avoid injuring the skin, the patient is advised not to pick at or scratch the affected areas. Measures to prevent dry skin are encouraged because dry skin worsens psoriasis. Too-frequent washing produces more soreness and scaling. Water should be warm, not hot, and the skin should be dried by patting with a towel rather than by rubbing. Emollients have a moisturizing effect,

providing an occlusive film on the skin surface so that normal water loss through the skin is halted and allowing the trapped water to hydrate the stratum corneum. A bath oil or emollient cleansing agent can comfort sore and scaling skin. Softening the skin can prevent fissures (see Plan of Nursing Care 56-1).

### IMPROVING SELF-CONCEPT AND BODY IMAGE

A therapeutic relationship between health care professionals and the patient with psoriasis is one that includes education and support. After the treatment regimen is established, the patient should begin to feel more confident and empowered in carrying it out and in using coping strategies that help deal with the altered self-concept and body image brought about by the disease. Introducing the patient to successful coping strategies used by others with psoriasis and making suggestions for reducing or coping with stressful situations at home, school, and work can facilitate a more positive outlook and acceptance of the chronicity of the disease.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

#### Psoriatic Arthritis

The diagnosis of psoriasis, especially when it is accompanied by the complication of arthritis, is usually difficult to make. Psoriatic arthritis involving the sacroiliac and distal joints of the fingers may be overlooked, especially if the patient has the typical psoriatic lesions. However, patients who complain of mild joint discomfort and some pitting of the fingernails may not be diagnosed with psoriasis until the more obvious cutaneous lesions appear.

The complaint of joint discomfort in the patient with psoriasis should be noted and evaluated. The symptoms of psoriatic arthritis can mimic the symptoms of Reiter's disease and ankylosing spondylitis, and a definitive diagnosis must be made. Treatment of the condition usually involves joint rest, application of heat, and salicylates.

The patient requires education about the care and treatment of the involved joints and the need for compliance with therapy. The incidence of psoriatic arthropathy is unknown because the symptoms are so variable. It is believed, however, that when the psoriasis is extensive and a family history of inflammatory arthritis is elicited, the chance that the patient will develop psoriatic arthritis increases substantially. It is recommended that a rheumatologist be consulted to assist in the diagnosis and treatment of the arthropathy.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

Printed patient education materials may be provided to reinforce face-to-face discussions about treatment guidelines and other con-

siderations. For example, the patient and the family caregiver may need to know that the topical agent anthralin leaves a brownish purple stain on the skin but that the discoloration subsides after anthralin treatment stops. The patient should also be instructed to cover lesions treated with anthralin with gauze, stockinette, or other soft coverings to avoid staining clothing, furniture, and bed linens.

Patients using topical corticosteroid preparations repeatedly on the face and around the eyes should be aware that cataract development is possible. Strict guidelines for applying these medications should be emphasized because overuse can result in skin atrophy, striae, and medication resistance.

Photochemotherapy (PUVA), which is reserved for moderate to severe psoriasis, produces photosensitization, which means that the skin is sensitive to the sun until methoxsalen has been excreted from the body in about 6 to 8 hours. Patients undergoing PUVA treatments should avoid exposure to the sun. If exposure is unavoidable, the skin must be protected with sunscreen and clothing. Gray- or green-tinted, wraparound sunglasses should be worn to protect the eyes during and after treatment, and ophthalmologic examinations should be performed on a regular basis. Nausea, which may be a problem in some patients, is lessened when methoxsalen is taken with food. Lubricants and bath oils may be used to help remove scales and prevent excessive dryness. No other creams or oils are to be used except on areas that have been shielded from ultraviolet light. Contraceptives should be used by sexually active women of reproductive age, because the teratogenic effect of PUVA has not been determined. The patient is kept under constant and careful supervision and is encouraged to recognize unusual changes in the skin.

If indicated, referral may be made to a mental health professional who can help to ease emotional strain and give support. Belonging to a support group may also help patients acknowledge that they are not alone in experiencing life adjustments in response to a visible, chronic disease. The National Psoriasis Foundation publishes periodic bulletins and reports about new and relevant developments in this condition.

Chart 56-4 is a Home Care Checklist for the patient with psoriasis.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Demonstrates knowledge and understanding of disease process and its treatment
  - a. Describes psoriasis and the prescribed therapy
  - b. Verbalizes that trauma, infection, and emotional stress may be trigger factors

Chart 56-4

#### Home Care Checklist • The Patient With Psoriasis

At the completion of the home care instruction, the patient or caregiver will be able to:

- Describe the etiology of psoriasis.
- Describe optimal skin maintenance practices to maintain moisture of skin and prevent infection.
- Demonstrate proper application of prescribed topical medications.
- Describe common side effects of oral medication, if prescribed.
- Demonstrate appropriate therapeutic bath technique, if prescribed.
- Verbalize optimism about condition.
- Identify a support person with whom to discuss feelings and concerns.

	Patient	Caregiver
• Describe the etiology of psoriasis.	✓	✓
• Describe optimal skin maintenance practices to maintain moisture of skin and prevent infection.	✓	✓
• Demonstrate proper application of prescribed topical medications.	✓	✓
• Describe common side effects of oral medication, if prescribed.	✓	✓
• Demonstrate appropriate therapeutic bath technique, if prescribed.	✓	✓
• Verbalize optimism about condition.	✓	
• Identify a support person with whom to discuss feelings and concerns.	✓	

- c. Maintains control with appropriate therapy
  - d. Demonstrates proper application of topical therapy
2. Achieves smoother skin and control of lesions
    - a. Exhibits no new lesions
    - b. Keeps skin lubricated and soft
  3. Develops self-acceptance
    - a. Identifies someone with whom to discuss feelings and concerns
    - b. Expresses optimism about outcomes of treatment
  4. Absence of complications
    - a. Has no joint discomfort
    - b. Reports control of cutaneous lesions with no extension of disease

## EXFOLIATIVE DERMATITIS

Exfoliative dermatitis is a serious condition characterized by progressive inflammation in which erythema and scaling occur in a more or less generalized distribution. It may be associated with chills, fever, prostration, severe toxicity, and an itchy scaling of the skin. There is a profound loss of stratum corneum (ie, outermost layer of the skin), which causes capillary leakage, hypoproteinemia, and negative nitrogen balance. Because of widespread dilation of cutaneous vessels, large amounts of body heat are lost, and exfoliative dermatitis has a marked effect on the entire body.

Exfoliative dermatitis has a variety of causes. It is considered to be a secondary or reactive process to an underlying skin or systemic disease. It may appear as a part of the lymphoma group of diseases and may precede the appearance of lymphoma. Preexisting skin disorders that have been implicated as a cause include psoriasis, atopic dermatitis, and contact dermatitis. It also appears as a severe reaction to many medications, including penicillin and phenylbutazone. The cause is unknown in approximately 25% of cases (Odom et al., 2000).

### Clinical Manifestations

This condition starts acutely as a patchy or a generalized erythematous eruption accompanied by fever, malaise, and occasionally gastrointestinal symptoms. The skin color changes from pink to dark red. After a week, the characteristic exfoliation (ie, scaling) begins, usually in the form of thin flakes that leave the underlying skin smooth and red, with new scales forming as the older ones come off. Hair loss may accompany this disorder. Relapses are common. The systemic effects include high-output heart failure, intestinal disturbances, breast enlargement, elevated levels of uric acid in the blood (ie, hyperuricemia), and temperature disturbances.

### Medical Management

The objectives of management are to maintain fluid and electrolyte balance and to prevent infection. The treatment is individualized and supportive and should be initiated as soon as the condition is diagnosed.

The patient may be hospitalized and placed on bed rest. All medications that may be implicated are discontinued. A comfortable room temperature should be maintained because the patient does not have normal thermoregulatory control as a result of temperature fluctuations caused by vasodilation and evaporative water loss. Fluid and electrolyte balance must be maintained because there is considerable water and protein loss from the skin surface. Plasma volume expanders may be indicated.

## Nursing Management

Continual nursing assessment is carried out to detect infection. The disrupted, erythematous, moist skin is susceptible to infection and becomes colonized with pathogenic organisms, which produce more inflammation. Antibiotics, prescribed if infection is present, are selected on the basis of culture and sensitivity.

**NURSING ALERT** The nurse observes the patient for signs and symptoms of heart failure because hyperemia and increased cutaneous blood flow can produce high-output cardiac failure.

Hypothermia may occur because increased blood flow in the skin, coupled with increased water loss through the skin, leads to heat loss by radiation, conduction, and evaporation. Changes in vital signs are closely monitored and reported.

As in any acute dermatitis, topical therapy is used to provide symptomatic relief. Soothing baths, compresses, and lubrication with emollients are used to treat the extensive dermatitis. The patient is likely to be extremely irritable because of the severe itching. Oral or parenteral corticosteroids may be prescribed when the disease is not controlled by more conservative therapy. When a specific cause is known, more specific therapy may be used. The patient is advised to avoid all irritants in the future, particularly medications.

## Blistering Diseases

Blisters of the skin have many origins, including bacterial, fungal, or viral infections; allergic contact reactions; burns; metabolic disorders; and immunologically mediated reactions. Some of these have been discussed previously (eg, herpes simplex and zoster infections, contact dermatitis). Immunologically mediated diseases are autoimmune reactions and represent a defect of IgM, IgE, IgG, and C3. Some of these conditions are life-threatening; others become chronic problems.

The diagnosis is always made by histologic examination of a biopsy specimen by a dermatopathologist. A specimen from the blister and surrounding skin demonstrates **acantholysis** (ie, separation of epidermal cells from each other because of damage to or an abnormality of the intracellular substance). Circulating antibodies may be detected by immunofluorescent studies of the patient's serum.

## PEMPHIGUS

Pemphigus is a group of serious diseases of the skin characterized by the appearance of bullae (ie, blisters) of various sizes on apparently normal skin (Fig. 56-5) and mucous membranes. Available evidence indicates that pemphigus is an autoimmune disease involving immunoglobulin G. It is thought that the pemphigus antibody is directed against a specific cell-surface antigen in epidermal cells. A blister forms from the antigen-antibody reaction. The level of serum antibody is predictive of disease severity. Genetic factors may also play a role in its development, with the highest incidence among those of Jewish or Mediterranean descent. This disorder usually occurs in men and women in middle and late adulthood. The condition may be associated with penicillins and captopril and with myasthenia gravis.

**FIGURE 56-5** Vesicles on the chin (in pemphigus). Sauer, G. C. (1985). *Manual of Skin Diseases*. Philadelphia: J. B. Lippincott.

## Clinical Manifestations

Most patients present with oral lesions appearing as irregularly shaped erosions that are painful, bleed easily, and heal slowly. The skin bullae enlarge, rupture, and leave large, painful eroded areas that are accompanied by crusting and oozing. A characteristic offensive odor emanates from the bullae and the exuding serum. There is blistering or sloughing of uninvolved skin when minimal pressure is applied (ie, Nikolsky's sign). The eroded skin heals slowly, and huge areas of the body eventually are involved. Bacterial superinfection is common.

## Complications

The most common complications of pemphigus vulgaris arise when the disease process is widespread. Before the advent of corticosteroid and immunosuppressive therapy, patients were very susceptible to secondary bacterial infection. Skin bacteria have relatively easy access to the bullae as they ooze, rupture, and leave denuded areas that are open to the environment. Fluid and electrolyte imbalance results from the loss of both fluid and protein as the bullae rupture. Hypoalbuminemia is common when the disease process includes extensive areas of the body skin surface and mucous membranes.

## Management

The goals of therapy are to bring the disease under control as rapidly as possible, to prevent loss of serum and the development of secondary infection, and to promote re-epithelization (ie, renewal of epithelial tissue).

Corticosteroids are administered in high doses to control the disease and keep the skin free of blisters. The high dosage level is maintained until remission is apparent. In some cases, corticosteroid therapy must be maintained for life.

Corticosteroids are administered with or immediately after a meal and may be accompanied by an antacid as prophylaxis against gastric complications. Essential to therapeutic management are daily evaluations of body weight, blood pressure, blood glucose levels, and fluid balance. High-dose corticosteroid therapy has its own serious toxic effects (see Chap. 42).

Immunosuppressive agents (eg, azathioprine, cyclophosphamide, gold) may be prescribed to help control the disease and reduce the corticosteroid dose. **Plasmapheresis** (ie, plasma exchange) temporarily decreases the serum antibody level and has been used with variable success, although it is generally reserved for life-threatening cases.

## BULLOUS PEMPHIGOID

Bullous pemphigoid is an acquired disease of flaccid blisters appearing on normal or erythematous skin. It appears more often on the flexor surfaces of the arms, legs, axilla, and groin. Oral lesions, if present, are usually transient and minimal. When the blisters break, the skin has shallow erosions that heal fairly quickly. Pruritus can be intense, even before the appearance of the blisters. Bullous pemphigoid is common in the elderly, with a peak incidence at about 60 years of age. There is no gender or racial predilection, and the disease can be found throughout the world.

## Management

Medical treatment includes topical corticosteroids for localized eruptions and systemic corticosteroids for widespread involvement. Systemic prednisone may be continued for months, in alternate-day doses. The patient needs to understand the implications of long-term corticosteroid therapy, including loss of bone mass, osteoporosis, cataracts, peptic ulcers, psychotic reactions, increased risk for infection, weight gain from fluid retention, and the potential for adrenal suppression.

## DERMATITIS HERPETIFORMIS

Dermatitis herpetiformis is an intensely pruritic, chronic disease that manifests with small, tense blisters that are distributed symmetrically over the elbows, knees, buttocks, and nape of the neck. It is most common between the ages of 20 and 40 years but can appear at any age. Most patients with dermatitis herpetiformis have a subclinical defect in gluten metabolism.

## Management

Most patients respond to dapson (combination of tetracycline and nicotinamide) and to a gluten-free diet. All patients should be screened for glucose-6-phosphate dehydrogenase deficiency, because dapson can induce severe hemolysis in those with this deficiency. Patients benefit from dietary counseling because the dietary restrictions are lifelong, and a gluten-free diet is often difficult to follow. They need emotional support as they deal with the process of learning new habits and accepting major changes in their life.

## HERPES GESTATIONIS

Herpes gestationis is a disease that occurs during or shortly after pregnancy. It shares several clinical features with bullous pemphigoid, and despite its name, it has no relation to the herpes virus. This disease is uncommon, with an incidence of approximately 1 case in every 50,000 pregnancies. It appears in the second or third trimester. It begins with urticarial papules on the abdomen and spreads to the trunk and extremities. It usually resolves within a few weeks of delivery but can recur in subsequent pregnancies, with menses, or with the use of oral contraceptives (Odom et al., 2000).

## Management

Herpes gestationis is best managed with systemic corticosteroids. There is debate about whether there is any risk for fetal morbidity or mortality in babies born to mothers with herpes gestationis. As in other blistering diseases, special attention is required to prevent secondary infection.

## NURSING PROCESS: CARE OF THE PATIENT WITH BLISTERING DISEASES

### Assessment

Patients with blistering disorders may experience significant disability. There is constant itching and possible pain in the denuded areas of skin. There may be drainage from the denuded areas, which may be malodorous. Effective assessment and nursing management become a challenge.

Disease activity is monitored clinically by examining the skin for the appearance of new blisters. Areas where healing has occurred may show signs of hyperpigmentation. Particular attention is given to assessing for signs and symptoms of infection.

### Diagnosis

#### NURSING DIAGNOSES

Based on nursing assessment data, the patient's major nursing diagnoses may include the following:

- Acute pain of skin and oral cavity related to blistering and erosions
- Impaired skin integrity related to ruptured bullae and denuded areas of the skin
- Anxiety and ineffective coping related to the appearance of the skin and no hope of a cure
- Deficient knowledge about medications and side effects

#### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications include the following:

- Infection and sepsis related to loss of protective barrier of skin and mucous membranes
- Fluid volume deficit and electrolyte imbalance related to loss of tissue fluids

### Planning and Goals

The major goals for the patient may include relief of discomfort from lesions, skin healing, reduced anxiety and improved coping capacity, and absence of complications.

### Nursing Interventions

#### RELIEVING ORAL DISCOMFORT

The patient's entire oral cavity may be affected with erosions and denuded surfaces. A necrotic slough may develop over these areas, adding to the patient's discomfort and interfering with food intake. Weight loss and hypoproteinemia may result. Meticulous oral hygiene is important to keep the oral mucosa clean and allow the epithelium to regenerate. Frequent rinsing of the mouth is prescribed to rid the mouth of debris and to soothe ulcerated areas. Commercial mouthwashes are avoided. The lips are kept moist with lanolin, petrolatum, or lip balm. Cool mist therapy helps to humidify environmental air.

#### ENHANCING SKIN INTEGRITY AND RELIEVING DISCOMFORT

Cool, wet dressings or baths are protective and soothing. The patient with painful and extensive lesions should be premedicated with analgesics before skin care is initiated. Patients with large

areas of blistering have a characteristic odor that decreases when secondary infection is controlled. After the patient's skin is bathed, it is dried carefully and dusted liberally with nonirritating powder, which enables the patient to move freely in bed. Fairly large amounts are necessary to keep the patient's skin from sticking to the sheets. Tape should never be used on the skin because it may produce more blisters. Hypothermia is common, and measures to keep the patient warm and comfortable are priority nursing activities. The nursing management of patients with bullous skin conditions is similar to that for patients with extensive burns (see Chap. 57).

#### REDUCING ANXIETY

Attention to the psychological needs of the patient requires listening to the patient, being available, giving expert nursing care, and educating the patient and the family. The patient is encouraged to express freely anxieties, discomfort, and feelings of hopelessness. Arranging for a family member or a close friend to spend more time with the patient can be supportive. When patients receive information about the disease and its treatment, uncertainty and anxiety are reduced, and the patient's capacity to act on his or her own behalf is enhanced. Referral for psychological counseling may assist the patient in dealing with fears, anxiety, and depression.

#### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

##### Infection and Sepsis

The patient is susceptible to infection because the barrier function of the skin is compromised. Bullae are also susceptible to infection, and sepsis may follow. The skin is cleaned to remove debris and dead skin and to prevent infection.

Secondary infection may be accompanied by an offensive odor from skin or oral lesions. *C. albicans* of the mouth (ie, thrush) commonly affects patients receiving high-dose corticosteroid therapy. The oral cavity is inspected daily, and any changes are reported. Oral lesions are slow to heal.

Infection is the leading cause of death in patients with blistering diseases. Particular attention is given to assessment for signs and symptoms of local and systemic infection. Seemingly trivial complaints or minimal changes are investigated, because corticosteroids can mask or alter typical signs and symptoms of infection. The patient's vital signs are taken, and temperature fluctuations are monitored. The patient is observed for chills, and all secretions and excretions are monitored for changes suggesting infection. Results of culture and sensitivity tests are monitored. Antimicrobial agents are administered as prescribed, and response to treatment is assessed. Health care personnel must perform effective hand hygiene and wear gloves.

In the hospitalized patient, environmental contamination is reduced as much as possible. Protective isolation measures and standard precautions are warranted.

##### Fluid and Electrolyte Imbalance

Extensive denudation of the skin leads to fluid and electrolyte imbalance because of significant loss of fluids and sodium chloride from the skin. This sodium chloride loss is responsible for many of the systemic symptoms associated with the disease and is treated by intravenous administration of saline solution.

A large amount of protein and blood is lost from the denuded skin areas. Blood component therapy may be prescribed to maintain the blood volume, hemoglobin level, and plasma protein

concentration. Serum albumin, protein, hemoglobin, and hematocrit values are monitored.

The patient is encouraged to maintain adequate oral fluid intake. Cool, nonirritating fluids are encouraged to maintain hydration. Small, frequent meals or snacks of high-protein, high-calorie foods (eg, Ensure, Sustacal, eggnog, milkshakes) help maintain nutritional status. Parenteral nutrition is considered if the patient cannot eat an adequate diet.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Achieves relief from pain of oral lesions
  - a. Identifies therapies that reduce pain
  - b. Uses mouthwashes and anesthetic or antiseptic aerosol mouth spray
  - c. Drinks chilled fluids at 2-hour intervals
2. Achieves skin healing
  - a. States purpose of therapeutic regimen
  - b. Cooperates with soaks and bath regimen
  - c. Reminds caregivers to use liberal amounts of nonirritating powder on bed linens
3. Is less anxious and better able to cope
  - a. Verbalizes concerns about condition, self, and relationships with others
  - b. Participates in self-care
4. Experiences no complications
  - a. Has cultures from bullae, skin, and orifices that are negative for pathogenic organisms
  - b. Has no purulent drainage
  - c. Shows signs that skin is clearing
  - d. Has normal temperature
  - e. Keeps intake record to ensure adequate fluid intake and normal fluid and electrolyte balance
  - f. Verbalizes the rationale for intravenous infusion therapy
  - g. Has urine output within normal limits
  - h. Has serum chemistry and hemoglobin and hematocrit values within normal limits

## TOXIC EPIDERMAL NECROLYSIS AND STEVENS-JOHNSON SYNDROME

Toxic epidermal necrolysis (TEN) and Stevens-Johnson syndrome (SJS) are potentially fatal skin disorders and the most severe form of erythema multiforme. The mortality rate from TEN approaches 30%. Both conditions are triggered by a reaction to medications or result from a viral infection. Antibiotics, antiseizure agents, butazones, and sulfonamides are the most frequent medications implicated in TEN and SJS (Odom et al., 2000).

### Clinical Manifestations

TEN and SJS are characterized initially by conjunctival burning or itching, cutaneous tenderness, fever, cough, sore throat, headache, extreme malaise, and myalgias (ie, aches and pains). These signs are followed by a rapid onset of erythema involving much of the skin surface and mucous membranes, including the oral mucosa, conjunctiva, and genitalia. In severe cases of mucosal involvement, there may be danger of damage to the larynx, bronchi, and esophagus from ulcerations. Large, flaccid bullae develop in

some areas; in other areas, large sheets of epidermis are shed, exposing the underlying dermis. Fingernails, toenails, eyebrows, and eyelashes may be shed along with the surrounding epidermis. The skin is excruciatingly tender, and the loss of skin leaves a weeping surface similar to that of a total-body, partial-thickness burn; hence the condition is also referred to as scalded skin syndrome.

These conditions occur in all ages and both genders. The incidence is increased in older people because of their use of many medications. People with HIV, particularly those with acquired immunodeficiency syndrome (AIDS), and others who are immunocompromised are at higher risk for SJS and TEN. Although the incidence of TEN and SJS in the general population is about 3 cases per 1 million person-years, the risk associated with sulfonamides in HIV-positive individuals may approach 1 case per 1000 (Odom et al., 2000). Most patients with TEN have an abnormal metabolism of the culprit medication, and the mechanism leading to TEN seems to be a cell-mediated cytotoxic reaction (Wolkenstein, 2000).

### Complications

Sepsis and keratoconjunctivitis are complications of TEN and SJS. Unrecognized and untreated sepsis can be life-threatening. Keratoconjunctivitis can impair vision and result in conjunctival retraction, scarring, and corneal lesions.

### Assessment and Diagnostic Findings

Histologic studies of frozen skin cells from a fresh lesion and cytodagnosis of collections of cellular material from a freshly denuded area are performed. A history of ingestion of medications known to precipitate TEN or SJS may confirm medication reaction as the underlying cause.

Immunofluorescent studies may be performed to detect atypical epidermal autoantibodies. A genetic predisposition to erythema multiforme has been suggested but is not confirmed for all cases.

### Medical Management

The goals of treatment include control of fluid and electrolyte balance, prevention of sepsis, and prevention of ophthalmic complications. Supportive care is the mainstay of treatment.

All nonessential medications are discontinued immediately. If possible, the patient is treated in a regional burn center, because aggressive treatment similar to that for severe burns is required. Skin loss may approach 100% of the total body surface area. Surgical débridement or hydrotherapy in a Hubbard tank (ie, large, steel tub) may be performed to remove involved skin.

Tissue samples from the nasopharynx, eyes, ears, blood, urine, skin, and unruptured blisters are obtained for culture to identify pathogenic organisms. Intravenous fluids are prescribed to maintain fluid and electrolyte balance, especially in the patient who has severe mucosal involvement and who cannot easily take oral nourishment. Because an indwelling intravenous catheter may be a site of infection, fluid replacement is carried out by nasogastric tube and then orally as soon as possible.

Initial treatment with systemic corticosteroids is controversial. Some experts argue for early high-dose corticosteroid treatment. However, in most cases, the risk for infection, the complication of fluid and electrolyte imbalance, the delay in the healing process, and the difficulty in initiating oral corticosteroids early in the course of the disease outweigh the perceived benefits. In patients

with TEN thought to result from a medication reaction, corticosteroids may be administered; however, the patients should be closely monitored for the previously stated adverse effects.

One report stated that intravenous administration of immunoglobulin (IVIG) to 10 patients led to improvement within 48 hours and skin healing within 1 week. This response is dramatically better than that obtained with immunosuppressives, and IVIG may soon become the treatment of choice (Rutter & Luger, 2001).

Protecting the skin with topical agents is crucial. Various topical antibacterial and anesthetic agents are used to prevent wound sepsis and to assist with pain management. Systemic antibiotic therapy is used with extreme caution. Temporary biologic dressings (eg, pigskin, amniotic membrane) or plastic semipermeable dressings (eg, Vigilon) may be used to reduce pain, decrease evaporation, and prevent secondary infection until the epithelium regenerates. Meticulous oropharyngeal and eye care is essential when there is severe involvement of the mucous membranes and the eyes.

## NURSING PROCESS: CARE OF THE PATIENT WITH TOXIC EPIDERMAL NECROLYSIS

### Assessment

A careful inspection of the skin is made, including its appearance and the extent of involvement. The normal skin is closely observed to determine if new areas of blisters are developing. Seepage from blisters is monitored for amount, color, and odor. Inspection of the oral cavity for blistering and erosive lesions is performed daily; the patient is assessed daily for itching, burning, and dryness of the eyes. The patient's ability to swallow and drink fluids, as well as speak normally, is determined.

The patient's vital signs are monitored, and special attention is given to the presence and character of fever and the respiratory rate, depth, rhythm, and cough. The characteristics and amount of respiratory secretions are reviewed. Assessment for high fever, tachycardia, and extreme weakness and fatigue is essential, because these factors indicate the process of epidermal necrosis, increased metabolic needs, and possible gastrointestinal and respiratory mucosal sloughing. Urine volume, specific gravity, and color are monitored. The insertion sites of intravenous lines are inspected for signs of local infection. Daily body weights are recorded.

The patient is asked to describe fatigue and pain levels. An attempt is made to evaluate the patient's level of anxiety. The patient's basic coping mechanisms are assessed, and effective coping strategies are identified.

### Diagnosis

#### NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Impaired tissue integrity (ie, oral, eye, and skin) related to epidermal shedding
- Deficient fluid volume and electrolyte losses related to loss of fluids from denuded skin
- Risk for imbalanced body temperature (ie, hypothermia) related to heat loss secondary to skin loss
- Acute pain related to denuded skin, oral lesions, and possible infection

- Anxiety related to the physical appearance of the skin and prognosis

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications include the following:

- Sepsis
- Conjunctival retraction, scars, and corneal lesions

### Planning and Goals

The major goals for the patient may include skin and oral tissue healing, fluid balance, prevention of heat loss, relief of pain, reduced anxiety, and absence of complications.

### Nursing Interventions

#### MAINTAINING SKIN AND MUCOUS MEMBRANE INTEGRITY

The local care of the skin is an important area of nursing management. The skin denudes easily, even when the patient is lifted and turned; it may be necessary to place the patient on a circular turning frame. The nurse applies the prescribed topical agents that reduce the bacterial population of the wound surface. Warm compresses, if prescribed, should be applied gently to denuded areas. The topical antibacterial agent may be used in conjunction with hydrotherapy in a tank, bathtub, or shower. The nurse monitors the patient's condition during the treatment and encourages the patient to exercise the extremities during hydrotherapy.

The painful oral lesions make oral hygiene difficult. Careful oral hygiene is performed to keep the oral mucosa clean. Prescribed mouthwashes, anesthetics, or coating agents are used frequently to rid the mouth of debris, soothe ulcerative areas, and control foul mouth odor. The oral cavity is inspected several times each day, and any changes are documented and reported. Petrolatum or a prescribed ointment is applied to the lips.

#### ATTAINING FLUID BALANCE

The vital signs, urine output, and sensorium are observed for indications of hypovolemia. Mental changes from fluid and electrolyte imbalance, sensory overload, or sensory deprivation may occur. Laboratory test results are evaluated, and abnormal results are reported. The patient is weighed daily (with a bed scale if necessary).

The nurse regulates intravenous fluids at prescribed infusion rates and assesses for systemic (ie, overinfusion or underinfusion) and local (eg, infection) complications. Oral lesions may result in dysphagia, making tube feeding or parenteral nutrition necessary. Prescribed enteral nourishment or enteral supplements can be administered by tube feeding until oral ingestion can be tolerated. A daily calorie count and accurate recording of all intake and output are essential.

#### PREVENTING HYPOTHERMIA

The patient with TEN is prone to chilling. Dehydration may be made worse by exposing the denuded skin to a continuous current of warm air. The patient is usually sensitive to room temperature changes. Measures implemented for a burn patient, such as cotton blankets, ceiling-mounted heat lamps, and heat shields, are useful in maintaining body temperature. To minimize shivering and heat loss, the nurse should work rapidly and efficiently

when large wounds are exposed for wound care. The patient's temperature is monitored frequently.

### RELIEVING PAIN

The nurse assesses the patient's pain, its characteristics, any factors that influence the pain, and the patient's behavioral responses. Prescribed analgesics are administered, and the nurse documents pain relief and any side effects. Analgesics are administered before painful treatments are performed. Providing thorough explanations and speaking calmly to the patient during treatments can allay the anxiety that may intensify pain. Offering emotional support and reassurance and implementing measures that promote rest and sleep are basic in achieving pain control. As the pain diminishes and the patient has more physical and emotional energy, self-management techniques for pain relief, such as progressive muscle relaxation and imagery, may be taught.

### REDUCING ANXIETY

Because the lifestyle of patients with TEN has been abruptly changed to one of complete dependence, an assessment of their emotional state may reveal anxiety, depression, and fear of dying. Patients can be reassured that these reactions are normal. They also need nursing support, honest communication, and hope that their situation can improve. They are encouraged to express their feelings to someone they trust. Listening to their concerns and being readily available with skillful and compassionate care are important anxiety-relieving interventions. Emotional support by a psychiatric nurse, chaplain, psychologist, or psychiatrist may be helpful to promote coping during the long recovery period.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

#### Sepsis

The major cause of death from TEN is infection, and the most common sites of infection are the skin and mucosal surfaces, lungs, and blood. The organisms most often involved are *S. aureus*, *Pseudomonas*, *Klebsiella*, *Escherichia coli*, *Serratia*, and *Candida*. Monitoring vital signs closely and noticing changes in respiratory, renal, and gastrointestinal function may quickly detect the beginning of an infection. Strict asepsis is always maintained during routine skin care measures. Hand hygiene and wearing sterile gloves when carrying out procedures are necessary. When the condition involves a large portion of the body, the patient should be in a private room to prevent possible cross-infection from other patients. Visitors should wear protective garments and wash their hands before and after coming into contact with the patient. People with any infectious disease should not visit the patient until they are no longer a danger to the patient.

#### Conjunctival Retraction, Scars, and Corneal Lesions

The eyes are inspected daily for signs of itching, burning, and dryness, which may indicate progression often to keratoconjunctivitis, the principal eye complication. Applying a cool, damp cloth over the eyes may relieve burning sensations. The eyes are kept clean and observed for signs of discharge or discomfort, and the progression of symptoms is documented and reported. Administering an eye lubricant, when prescribed, may alleviate dryness and prevent corneal abrasion. Using eye patches or reminding the patient to blink periodically may also counteract dryness. The patient is instructed to avoid rubbing the eyes or putting any medication into the eyes that has not been prescribed or approved by the physician.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Achieves increasing skin and oral tissue healing
  - a. Demonstrates areas of healing skin
  - b. Swallows fluids and speaks clearly
2. Attains fluid balance
  - a. Demonstrates laboratory values within normal ranges
  - b. Maintains urine volume and specific gravity within acceptable range
  - c. Shows stable vital signs
  - d. Increases intake of oral fluids without discomfort
  - e. Gains weight, if appropriate
3. Attains thermoregulation
  - a. Registers body temperature within normal range
  - b. Reports no chills
4. Achieves pain relief
  - a. Uses analgesics as prescribed
  - b. Uses self-management techniques for relief of pain
5. Appears less anxious
  - a. Discusses concerns freely
  - b. Sleeps for progressively longer periods
6. Absence of complications, such as sepsis and impaired vision
  - a. Body temperature within normal range
  - b. Laboratory values within normal ranges
  - c. Has no abnormal discharges or signs of infection
  - d. Continues to see objects at baseline acuity level
  - e. Shows no signs of keratoconjunctivitis

## Ulcerations

Superficial loss of surface tissue as a result of death of the cells is called an ulceration. A simple ulcer, such as the kind found in a small, superficial, partial-thickness burn, tends to heal by granulation (ie, new tissue granules) if kept clean and protected from injury. If it is exposed to the air, the serum that escapes will dry and form a scab, under which the epithelial cells will grow and cover the surface completely. Certain diseases cause characteristic ulcers; tuberculous ulcers and syphilitic ulcers are examples.

Ulcers related to problems with arterial circulation are seen in patients with peripheral vascular disease, arteriosclerosis, Raynaud's disease, and frostbite. In these patients, treatment of the ulcers is concurrent with treatment of the arterial disease (see Chap. 31). Nursing management includes the use of the dressings discussed at the beginning of this chapter. If nursing interventions are instituted early in the progression of an ulcer, the condition can often be effectively improved. Surgical amputation of an affected limb is a last resort.

Pressure ulcers involve breakdown of the skin due to prolonged pressure and insufficient blood supply, usually at bony prominences. Information about these ulcers is presented in chapter 11.

## Benign Tumors of the Skin

### CYSTS

Cysts of the skin are epithelium-lined cavities that contain fluid or solid material. Epidermal cysts (ie, epidermoid cysts) occur frequently and may be described as slow-growing, firm, elevated tumors found most frequently on the face, neck, upper chest, and back. Removal of the cysts provides a cure.

Pilar cysts (ie, trichilemmal cysts), formerly called sebaceous cysts, are most frequently found on the scalp. They originate from the middle portion of the hair follicle and from the cells of the outer hair root sheath. The treatment is surgical removal.

## ACTINIC AND SEBORRHEIC KERATOSES

Seborrheic keratoses are benign, wartlike lesions of various sizes and colors, ranging from light tan to black. They are usually located on the face, shoulders, chest, and back and are the most common skin tumors seen in middle-aged and elderly people. They may be cosmetically unacceptable to the patient. A black keratosis may be erroneously diagnosed as malignant melanoma. The treatment is removal of the tumor tissue by excision, electrodesiccation and curettage, or application of carbon dioxide or liquid nitrogen. However, there is no harm in allowing these growths to remain, because there is no medical significance to their presence.

Actinic keratoses are premalignant skin lesions that develop in chronically sun-exposed areas of the body. They appear as rough, scaly patches with underlying erythema. A small percentage of these lesions gradually transform into cutaneous squamous cell carcinoma; they are usually removed by cryotherapy or shave excision.

## VERRUCAE: WARTS

Warts are common, benign skin tumors caused by infection with the human papillomavirus, which belongs to the DNA virus group. All age groups may be affected, but the condition occurs most frequently between ages 12 and 16 years. There are many types of warts.

As a rule, warts are asymptomatic, except when they occur on weight-bearing areas, such as the soles of the feet. They may be treated with locally applied laser therapy, liquid nitrogen, salicylic acid plasters, or electrodesiccation (ie, destruction of skin lesions by monopolar high-frequency electric current).

Warts occurring on the genitalia and perianal areas are known as condylomata acuminata. They may be transmitted sexually and are treated with liquid nitrogen, cryosurgery, electrosurgery, topically applied trichloroacetic acid, and curettage. Condylomata (see Chapter 47) that affect the uterine cervix predispose the patient to cervical cancer.

## ANGIOMAS

Angiomas are benign vascular tumors that involve the skin and the subcutaneous tissues. They are present at birth and may occur as flat, violet-red patches (ie, port-wine angiomas) or as raised, bright-red, nodular lesions (ie, strawberry angiomas). The latter tend to involute spontaneously within the first few years of life, but port-wine angiomas usually persist indefinitely. Most patients use masking cosmetics (ie, Covermark or Dermablend) to camouflage the lesion. The argon laser is being used on various angiomas with some success. Treatment of strawberry angiomas is more successful if undertaken as soon after birth as possible (Odom et al., 2000).

## PIGMENTED NEVI: MOLES

Moles are common skin tumors of various sizes and shades, ranging from yellowish brown to black. They may be flat, macular lesions or elevated papules or nodules that occasionally con-

tain hair. Most pigmented nevi are harmless lesions. However, in rare cases, malignant changes occur, and a melanoma develops at the site of the nevus. Some authorities believe that all congenital moles should be removed, because they may have a higher incidence of malignant change. However, depending on the quantity and location, this may be impractical. Nevi that show a change in color or size or become symptomatic (eg, itch) or develop irregular borders should be removed to determine if malignant changes have occurred. Moles that occur in unusual places should be examined carefully for any irregularity and for notching of the border and variation in color. Early melanomas may display some redness and irritation and areas of bluish pigmentation where the pigment-containing cells have spread deeper into the skin. Late melanomas have areas of paler color, where pigment cells have stopped producing melanin. Nevi larger than 1 cm should be examined carefully. Excised nevi should be examined histologically.

## KELOIDS

Keloids are benign overgrowths of fibrous tissue at the site of a scar or trauma. They appear to be more common among dark-skinned people. Keloids are asymptomatic but may cause disfigurement and cosmetic concern. The treatment, which is not always satisfactory, consists of surgical excision, intralesional corticosteroid therapy, and radiation.

## DERMATOFIBROMA

A dermatofibroma is a common, benign tumor of connective tissue that occurs predominantly on the extremities. It is a firm, dome-shaped papule or nodule that may be skin colored or pinkish brown. Excisional biopsy is the recommended method of treatment.

## NEUROFIBROMATOSIS: VON RECKLINGHAUSEN'S DISEASE

Neurofibromatosis is a hereditary condition manifested by pigmented patches (ie, café-au-lait macules), axillary freckling, and cutaneous neurofibromas that vary in size. Developmental changes may occur in the nervous system, muscles, and bone. Malignant degeneration of the neurofibromas occurs in some patients.

## Malignant Tumors of the Skin: Skin Cancer

Skin cancer is the most common cancer in the United States. If the incidence continues at the present rate, an estimated one of eight fair-skinned Americans will develop skin cancer, especially basal cell carcinoma (Chart 56-5). Because the skin is easily inspected, skin cancer is readily seen and detected and is the most successfully treated type of cancer (Odom et al., 2000).

Exposure to the sun is the leading cause of skin cancer; incidence is related to the total amount of exposure to the sun. Sun damage is cumulative, and harmful effects may be severe by age 20 years. The increase in skin cancer probably reflects changing lifestyles and the emphasis on sunbathing and related activities in light of changes in the environment, such as holes in the Earth's ozone layer. Protective measures should be used throughout life, and nurses need to inform patients about risk factors associated with skin cancer.

## Chart 56-5

## Risk Factors for Skin Cancer

Changes in the ozone layer from the effects of worldwide industrial air pollutants, such as chlorofluorocarbons, have prompted concern that the incidence of skin cancers, especially malignant melanoma, will increase. The ozone layer, a stratospheric blanket of bluish, explosive gas formed by the sun's ultraviolet radiation, varies in depth with the seasons and is thickest at the North and South Poles and thinnest at the equator. Scientists believe that it helps protect the earth from the effects of solar ultraviolet radiation. Proponents of this theory predict an increase in skin cancers as a consequence of changes in the ozone layer. Other skin cancer risk factors follow:

- Fair-skinned, fair-haired, blue-eyed people, particularly those of Celtic origin, with insufficient skin pigmentation to protect underlying tissues

- People who sustain sunburn and who do not tan

- Long-time sun exposure (farmers, fishermen, construction workers)

- Exposure to chemical pollutants (industrial workers in arsenic, nitrates, coal, tar and pitch, oils and paraffins)

- Sun-damaged skin (elderly people)

- History of x-ray therapy for acne or benign lesions

- Scars from severe burns

- Chronic skin irritations

- Immunosuppression

- Genetic factors

## BASAL CELL AND SQUAMOUS CELL CARCINOMA

The most common types of skin cancer are basal cell carcinoma (BCC) and squamous cell (epidermoid) carcinoma (SCC). The third most common type, malignant melanoma, is discussed separately. Skin cancer is diagnosed by biopsy and histologic evaluation.

### Clinical Manifestations

BCC is the most common type of skin cancer. It generally appears on sun-exposed areas of the body and is more prevalent in regions where the population is subjected to intense and extensive exposure to the sun. The incidence is proportional to the age of the patient (average age of 60 years) and the total amount of sun exposure, and it is inversely proportional to the amount of melanin in the skin.

BCC usually begins as a small, waxy nodule with rolled, translucent, pearly borders; telangiectatic vessels may be present. As it grows, it undergoes central ulceration and sometimes crusting (Fig. 56-6). The tumors appear most frequently on the face. BCC is characterized by invasion and erosion of contiguous (adjoining) tissues. It rarely metastasizes, but recurrence is common. However, a neglected lesion can result in the loss of a nose, an ear, or a lip. Other variants of BCC may appear as shiny, flat, gray or yellowish plaques.

SCC is a malignant proliferation arising from the epidermis. Although it usually appears on sun-damaged skin, it may arise from normal skin or from preexisting skin lesions. It is of greater concern than BCC because it is a truly invasive carcinoma, metastasizing by the blood or lymphatic system.

Metastases account for 75% of deaths from SCC. The lesions may be primary, arising on the skin and mucous membranes, or

**FIGURE 56-6** Basal cell carcinoma (*left*) and squamous cell carcinoma (*right*). Reprinted by permission from *New England Journal of Medicine*, 326, 169–170, 1992.

they may develop from a precancerous condition, such as actinic keratosis (ie, lesions occurring in sun-exposed areas), leukoplakia (ie, premalignant lesion of the mucous membrane), or scarred or ulcerated lesions. SCC appears as a rough, thickened, scaly tumor that may be asymptomatic or may involve bleeding (see Fig. 56-6). The border of an SCC lesion may be wider, more infiltrated, and more inflammatory than that of a BCC lesion. Secondary infection can occur. Exposed areas, especially of the upper extremities and of the face, lower lip, ears, nose, and forehead, are common sites (Odom et al., 2000).

### Prognosis

The prognosis for BCC is usually good. Tumors remain localized, and although some require wide excision with resultant disfigurement, the risk for death from BCC is low. The prognosis for SCC depends on the incidence of metastases, which is related to the histologic type and the level or depth of invasion. Usually, tumors arising in sun-damaged areas are less invasive and rarely cause death, whereas SCC that arises without a history of sun or arsenic exposure or scar formation appears to have a greater chance for spread. Regional lymph nodes should be evaluated for metastases (Odom et al., 2000).

### Medical Management

The goal of treatment is to eradicate the tumor. The treatment method depends on the tumor location; the cell type, location, and depth; the cosmetic desires of the patient; the history of previous treatment; whether the tumor is invasive, and whether metastatic nodes are present. The management of BCC and SCC includes surgical excision, Mohs' micrographic surgery, electro-surgery, cryosurgery, and radiation therapy.

### SURGICAL MANAGEMENT

The primary goal is to remove the tumor entirely. The best way to maintain cosmetic appearance is to place the incision properly along natural skin tension lines and natural anatomic body lines. In this way, scars are less noticeable. The size of the incision depends on the tumor size and location but usually involves a length-to-width ratio of 3 : 1.

The adequacy of the surgical excision is verified by microscopic evaluation of sections of the specimen. When the tumor is large, reconstructive surgery with use of a skin flap or skin grafting may be required. The incision is closed in layers to enhance cosmetic effect. A pressure dressing applied over the wound provides support. Infection after a simple excision is uncommon if proper surgical asepsis is maintained.

**Mohs' Micrographic Surgery.** Mohs' micrographic surgery is the technique that is most accurate and that best conserves normal tissue. When the surgical technique was introduced, the excision followed an application of zinc chloride paste to the tumor, but Mohs' surgery is now performed without the initial chemotherapy component. The procedure removes the tumor layer by layer. The first layer excised includes all evident tumor and a small margin of normal-appearing tissue. The specimen is frozen and analyzed by section to determine if all the tumor has been removed. If not, additional layers of tissue are shaved and examined until all tissue margins are tumor free. In this manner, only the tumor and a safe, normal-tissue margin are removed. Mohs' surgery is the recommended tissue-sparing procedure, with cure rates for BCC and SCC approaching 99%. It is the treatment of choice and the most effective for tumors around the eyes, nose, upper lip, and auricular and periauricular areas (Odom et al., 2000).

**Electrosurgery.** Electrosurgery is the destruction or removal of tissue by electrical energy. The current is converted to heat, which then passes to the tissue from a cold electrode. Electrosurgery may be preceded by curettage (ie, excising the skin tumor by scraping its surface with a curette). Electrodesiccation is then implemented to achieve hemostasis and to destroy any viable malignant cells at the base of the wound or along its edges. Electrodesiccation is useful for lesions smaller than 1 to 2 cm (0.4 to 0.8 in) in diameter.

This method takes advantage of the fact that the tumor in each instance is softer than surrounding skin and therefore can be outlined by a curette, which “feels” the extent of the tumor. The tumor is removed and the base cauterized. The process is repeated twice. Usually, healing occurs within a month.

**Cryosurgery.** Cryosurgery destroys the tumor by deep freezing the tissue. A thermocouple needle apparatus is inserted into the skin, and liquid nitrogen is directed to the center of the tumor until the tumor base is  $-40^{\circ}\text{C}$  to  $-60^{\circ}\text{C}$ . Liquid nitrogen has the lowest boiling point of all cryogens tried, is inexpensive, and is easy to obtain. The tumor tissue is frozen, allowed to thaw, and then refrozen. The site thaws naturally and then becomes gelatinous and heals spontaneously. Swelling and edema follow the freezing. The appearance of the lesion varies. Normal healing, which may take 4 to 6 weeks, occurs faster in areas with a good blood supply.

### RADIATION THERAPY

Radiation therapy is frequently performed for cancer of the eyelid, the tip of the nose, and areas in or near vital structures (eg, facial nerve). It is reserved for older patients, because x-ray changes may be seen after 5 to 10 years, and malignant changes in scars may be induced by irradiation 15 to 30 years later.

The patient should be informed that the skin may become red and blistered. A bland skin ointment prescribed by the physician may be applied to relieve discomfort. The patient should also be cautioned to avoid exposure to the sun.

## Nursing Management

Because many skin cancers are removed by excision, patients are usually treated in outpatient surgical units. The role of the nurse is to teach the patient about prevention of skin cancer and about self-care after treatment (Chart 56-6).

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** The wound is usually covered with a dressing to protect the site from physical trauma, external irritants, and contaminants. The patient is advised when to report for a dressing change or is given written and verbal information on how to change dressings, including the type of dressing to purchase, how to remove dressings and apply fresh ones, and the importance of hand washing before and after the procedure.

The patient is advised to watch for excessive bleeding and tight dressings that compromise circulation. If the lesion is in the perioral area, the patient is instructed to drink liquids through a straw and limit talking and facial movement. Dental work should be avoided until the area is completely healed.

After the sutures are removed, an emollient cream may be used to help reduce dryness. Applying a sunscreen over the wound is advised to prevent postoperative hyperpigmentation if the patient spends time outdoors.

Chart 56-6

### Health Promotion: Preventing Skin Cancer

Because skin cancer rates are rising, taking preventive measures such as the ones outlined below may help individuals avoid increasing their skin cancer risk.

- Do not try to tan if your skin burns easily, never tans, or tans poorly.
- Avoid unnecessary exposure to the sun, especially during the time of day when ultraviolet radiation (sunlight) is most intense (10 AM to 3 PM).
- Avoid sunburn.
- Apply sunscreen when in the sun; sunscreens block harmful sun rays.
- Use a sunscreen with an SPF of 15 or higher. Sunscreens are rated in strength from 4 (weakest) to 50 (strongest). The SPF indicates the solar protection factor, or how much longer you can stay in the sun before getting burned. Look for sunscreens that protect against both ultraviolet-A (UVA) and ultraviolet-B (UVB) light.
- Reapply water-resistant sunscreens after swimming, if heavily sweating, and every 2 to 3 hours during prolonged periods of sun exposure.
- Avoid oils. Applied before or during sun exposure, oils do not protect against sunlight or sun damage.
- Use a lip balm that contains a sunscreen with the highest SPF number.
- Wear protective clothing, such as a broad-brimmed hat and long sleeves.
- Remember that up to 50% of ultraviolet rays can penetrate loosely woven clothing.
- Remember that ultraviolet light can penetrate a cloud cover, and a sunburn can still occur.
- Do not use sun lamps for indoor tanning, and avoid commercial tanning booths. These rays are just as harmful.
- Teach children to avoid all but modest sun exposure and to use a sunscreen regularly for lifelong protection.

Follow-up examinations should be at regular intervals, usually every 3 months for a year, and should include palpation of the adjacent lymph nodes. The patient should also be instructed to seek treatment for any moles that are subject to repeated friction and irritation, and to watch for indications of potential malignancy in moles as described previously. The importance of lifelong follow-up evaluations should be emphasized.

**Teaching About Prevention.** Studies show that regular daily use of a sunscreen with a solar protection factor (SPF) of at least 15 can reduce the recurrence of skin cancer by as much as 40%. The sunscreen should be applied to head, neck, arms, and hands every morning at least 30 minutes before leaving the house and reapplied every 4 hours if the skin perspires. Discretionary application (ie, applied only when sun exposure is anticipated) has not shown the same preventive response (Barton, 2001).

## MALIGNANT MELANOMA

A malignant melanoma is a cancerous neoplasm in which atypical melanocytes (ie, pigment cells) are present in the epidermis and the dermis (and sometimes the subcutaneous cells). It is the most lethal of all the skin cancers and is responsible for about 2% of all cancer deaths (Odom et al., 2000).

It can occur in one of several forms: superficial spreading melanoma, lentigo-maligna melanoma, nodular melanoma, and acral-lentiginous melanoma. These types have specific clinical and histologic features as well as different biologic behaviors. Most melanomas arise from cutaneous epidermal melanocytes, but some appear in preexisting nevi (ie, moles) in the skin or develop in the uveal tract of the eye. Melanomas occasionally appear simultaneously with cancer of other organs.

The worldwide incidence of melanoma doubles every 10 years, a rise that is probably related to increased recreational sun exposure and better methods of early detection. Peak incidence occurs between ages 20 and 45. The incidence of melanoma is increasing faster than that of almost any other cancer, and the mortality rate is increasing faster than that of any other cancer except lung cancer. The estimated number of new cases in 2002 is 53,600 and the number of deaths is 7400 (American Cancer Society, 2002).

### Risk Factors

The cause of malignant melanoma is unknown, but ultraviolet rays are strongly suspected, based on indirect evidence such as the increased incidence of melanoma in countries near the equator and in people younger than age 30 who have used a tanning bed more than 10 times per year. In general, 1 in 100 Caucasians will get melanoma every year. Up to 10% of melanoma patients are members of melanoma-prone families who have multiple changing moles (ie, dysplastic nevi) that are susceptible to malignant transformation. Patients with dysplastic nevus syndrome have been found to have unusual moles, larger and more numerous moles, lesions with irregular outlines, and pigmentation located all over the skin. Microscopic examination of dysplastic moles shows disordered, faulty growth. Chart 56-7 lists risk factors for malignant melanoma.

Research has identified a gene that resides on chromosome 9p, the absence of which increases the likelihood that potentially mutagenic DNA damage will escape repair before cell division.

Chart 56-7

### Risk Factors for Malignant Melanoma

- Fair-skinned or freckled, blue-eyed, light-haired people of Celtic or Scandinavian origin
- People who burn and do not tan or who have a significant history of severe sunburn
- Environmental exposure to intense sunlight (older Americans retiring to the southwestern United States appear to have a higher incidence)
- History of melanoma (personal or family)
- Skin with giant congenital nevi

The absence of this gene can be identified in melanoma-prone families (Piepkorn, 2000).

### Clinical Manifestations

Superficial spreading melanoma occurs anywhere on the body and is the most common form of melanoma. It usually affects middle-aged people and occurs most frequently on the trunk and lower extremities. The lesion tends to be circular, with irregular outer portions. The margins of the lesion may be flat or elevated and palpable (Fig. 56-7). This type of melanoma may appear in a combination of colors, with hues of tan, brown, and black mixed with gray, blue-black, or white. Sometimes a dull pink rose color can be seen in a small area within the lesion.

### LENTIGO-MALIGNA MELANOMAS

Lentigo-maligna melanomas are slowly evolving, pigmented lesions that occur on exposed skin areas, especially the dorsum of the hand, the head, and the neck in elderly people. Often, the lesions are present for many years before they are examined by a physician. They first appear as tan, flat lesions, but in time, they undergo changes in size and color.

### NODULAR MELANOMA

Nodular melanoma is a spherical, blueberry-like nodule with a relatively smooth surface and a relatively uniform, blue-black color (see Fig. 56-7). It may be dome shaped with a smooth surface. It may have other shadings of red, gray, or purple. Sometimes, nodular melanomas appear as irregularly shaped plaques.

**FIGURE 56-7** Two forms of malignant melanoma: superficial spreading (left) and nodular (right). From Bickley, L. S., & Szilagyi, P. (2003). *Bates' guide to physical examination and history taking* (8th ed.). Philadelphia: Lippincott Williams & Wilkins.

The patient may describe this as a blood blister that fails to resolve. A nodular melanoma invades directly into adjacent dermis (ie, vertical growth) and therefore has a poorer prognosis.

### ACRAL-LENTIGINOUS MELANOMA

Acral-lentiginous melanoma occurs in areas not excessively exposed to sunlight and where hair follicles are absent. It is found on the palms of the hands, on the soles, in the nail beds, and in the mucous membranes in dark-skinned people. These melanomas appear as irregular, pigmented macules that develop nodules. They may become invasive early.

### Assessment and Diagnostic Findings

Biopsy results confirm the diagnosis of melanoma. An excisional biopsy specimen provides histologic information on the type, level of invasion, and thickness of the lesion. An excisional biopsy specimen that includes a 1-cm margin of normal tissue and a portion of underlying subcutaneous fatty tissue is sufficient for staging a melanoma in situ or an early, noninvasive melanoma. Incisional biopsy should be performed when the suspicious lesion is too large to be removed safely without extensive scarring. Biopsy specimens obtained by shaving, curettage, or needle aspiration are not considered reliable histologic proof of disease.

A thorough history and physical examination should include a meticulous skin examination and palpation of regional lymph nodes that drain the lesional area. Because melanoma occurs in families, a positive family history of melanoma is investigated so that first-degree relatives, who may be at high risk for melanoma, can be evaluated for atypical lesions. After the diagnosis of melanoma has been confirmed, a chest x-ray, complete blood cell count, liver function tests, and radionuclide or computed tomography scans are usually ordered to stage the extent of disease.

### Prognosis

The prognosis for long-term (5-year) survival is considered poor when the lesion is more than 1.5 mm thick or there is regional lymph node involvement. A person with a thin lesion and no lymph node involvement has a 3% chance of developing metastases and a 95% chance of surviving 5 years. If regional lymph nodes are involved, there is a 20% to 50% chance of surviving 5 years. Patients with melanoma on the hand, foot, or scalp have a better prognosis; those with lesions on the torso have an increased chance of metastases to the bone, liver, lungs, spleen, and central nervous system. Men and elderly patients also have poor prognoses (Demis, 1998).

### Medical Management

Treatment depends on the level of invasion and the depth of the lesion. Surgical excision is the treatment of choice for small, superficial lesions. Deeper lesions require wide local excision, after which skin grafting may be needed. Regional lymph node dissection is commonly performed to rule out metastasis, although new surgical approaches call for only sentinel node biopsy. This technique is used to sample the nodes nearest the tumor and spares the patient the long-term sequelae of extensive removal of lymph nodes if the sample node is negative (Wagner, 2000).

Immunotherapy has had varied success. Immunotherapy modifies immune function and other biologic responses to cancer. Several forms of immunotherapy (eg, bacillus Calmette-Guérin

[BCG] vaccine, *Corynebacterium parvum*, levamisole) offer encouraging results. Some investigational therapies include biologic response modifiers (eg, interferon-alpha, interleukin-2), adaptive immunotherapy (ie, lymphokine-activated killer cells), and monoclonal antibodies directed at melanoma antigens. One of these, proleukin, shows promise in preventing recurrence of melanoma (Demis, 1998). Under investigation is the laboratory assay of tyrosinase, an enzyme believed to be produced only by melanoma cells (Demis, 1998). Several other studies are attempting to develop autologous immunization against specific tumor cells. These studies are still in the early experimental stage but show promise of producing a vaccine against melanoma (Piepkorn, 2000).

Current treatments for metastatic melanoma are largely unsuccessful, with cure generally impossible. Further surgical intervention may be performed to debulk the tumor or to remove part of the organ involved (eg, lung, liver, or colon). The rationale for more extensive surgery, however, is for relief of symptoms, not for cure. Chemotherapy for metastatic melanoma may be used; however, only a few agents (eg, dacarbazine, nitrosoureas, cisplatin) have been effective in controlling the disease.

When the melanoma is located in an extremity, regional perfusion may be used; the chemotherapeutic agent is perfused directly into the area that contains the melanoma. This approach delivers a high concentration of cytotoxic agents while avoiding systemic, toxic side effects. The limb is perfused for 1 hour with high concentrations of the medication at temperatures of 39°C to 40°C (102.2°F to 104°F) with a perfusion pump. Inducing hyperthermia enhances the effect of the chemotherapy so that a smaller total dose can be used. It is hoped that regional perfusion can control the metastasis, especially if it is used in combination with surgical excision of the primary lesion and with regional lymph node dissection.

## NURSING PROCESS: CARE OF THE PATIENT WITH MALIGNANT MELANOMA

### Assessment

Assessment of the patient with malignant melanoma is based on the patient's history and symptoms. The patient is asked specifically about pruritus, tenderness, and pain, which are not features of a benign nevus. The patient is also questioned about changes in preexisting moles or the development of new, pigmented lesions. People at risk are assessed carefully.

A magnifying lens and good lighting are needed for inspecting the skin for irregularity and changes in the mole. Signs that suggest malignant changes are referred to as the ABCDs of moles (Chart 56-8).

Common sites of melanomas are the skin of the back, the legs (especially in women), between the toes, and on the feet, face, scalp, fingernails, and backs of hands. In dark-skinned people, melanomas are most likely to occur in less pigmented sites: palms, soles, subungual areas, and mucous membranes. Satellite lesions (ie, those situated near the mole) are inspected.

### Diagnosis

#### NURSING DIAGNOSES

Based on the nursing assessment data, the patient's major nursing diagnoses may include the following:

### Chart 56-8 • ASSESSMENT

#### The ABCDs of Moles

##### A for Asymmetry

- The lesion does not appear balanced on both sides. If an imaginary line were drawn down the middle, the two halves would not look alike.
- The lesion has an irregular surface with uneven elevations (irregular topography) either palpable or visible. A change in the surface may be noted from smooth to scaly.
- Some nodular melanomas have a smooth surface.

##### B for Irregular Border

- Angular indentations or multiple notches appear in the border
- The border is fuzzy or indistinct, as if rubbed with an eraser.

##### C for Variegated Color

- Normal moles are usually a uniform light to medium brown. Darker coloration indicates that the melanocytes have penetrated to a deeper layer of the dermis.
- Colors that may indicate malignancy if found together within a single lesion are shades of red, white, and blue; shades of blue are ominous.
- White areas within a pigmented lesion are suspicious.
- Some malignant melanomas, however, are not variegated but are uniformly colored (bluish-black, bluish-gray, bluish-red).

##### D for Diameter

- A diameter exceeding 6 mm (about the size of a pencil eraser) is considered more suspicious, although this finding without other signs is not significant. Many benign skin growths are larger than 6 mm, whereas some early melanomas may be smaller.

- Acute pain related to surgical excision and grafting
- Anxiety and depression related to possible life-threatening consequences of melanoma and disfigurement
- Deficient knowledge about early signs of melanoma

#### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications include the following:

- Metastasis
- Infection of the surgical site

#### Planning and Goals

The major goals for the patient may include relief of pain and discomfort, reduced anxiety and depression, knowledge of early signs of melanoma, and absence of complications.

#### Nursing Interventions

##### RELIEVING PAIN AND DISCOMFORT

Surgical removal of melanoma in different locations (eg, head, neck, eye, trunk, abdomen, extremities, central nervous system) presents different challenges, taking into consideration the removal of the primary melanoma, the intervening lymphatic vessels, and the lymph nodes to which metastases may spread. Nursing management of the patient having surgery in these regions is discussed in the appropriate chapters.

Nursing intervention after surgery for a malignant melanoma centers on promoting comfort, because wide excision surgery may be necessary. A split-thickness or full-thickness skin graft may be necessary when large defects are created by surgical removal of

a melanoma. Anticipating the need for and administering appropriate analgesic medications are important.

##### REDUCING ANXIETY AND DEPRESSION

Psychological support is essential when disfiguring surgery is performed. Support includes allowing patients to express feelings about the seriousness of this cutaneous neoplasm, understanding their anger and depression, and conveying understanding of these feelings. During the diagnostic workup and staging of the depth, type, and extent of the tumor, the nurse answers questions, clarifies information, and helps clarify misconceptions. Learning that they have a melanoma can cause patients considerable fear and anguish. Pointing out patients' resources, past effective coping mechanisms, and social support systems helps them to cope with the problems associated with diagnosis, treatment, and continuing follow-up. The patient's family should be included in all discussions to clarify the information presented, ask questions that the patient might be reluctant to ask, and provide emotional support.

##### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

##### Metastasis

The prognosis for malignant melanoma is related to metastasis: the deeper and thicker (more than 4 mm) the melanoma, the greater is the likelihood of metastasis. If the melanoma is growing radially (ie, horizontally) and is characterized by peripheral growth with minimal or no dermal invasion, the prognosis is favorable. When the melanoma progresses to the vertical growth phase (ie, dermal invasion), the prognosis is poor. Lesions with ulceration have a poor prognosis. Melanomas of the trunk appear to have a poorer prognosis than those of other sites, perhaps because the network of lymphatics in the trunk permits metastasis to regional lymph nodes.

The role of the nurse in caring for the patient with metastatic disease is holistic. The nurse must be knowledgeable about the most effective current therapies and must deliver supportive care, provide and clarify information about the therapy and the rationale for its use, identify potential side effects of therapy and ways to manage them, and instruct the patient and family about the expected outcomes of treatment. The nurse monitors and documents symptoms that may indicate metastasis: lung (eg, difficulty breathing, shortness of breath, increasing cough), bone (eg, pain, decreased mobility and function, pathologic fractures), and liver (eg, change in liver enzyme levels, pain, jaundice). Nursing care is based on the patient's symptoms.

Although the chance of a cure for malignant melanoma that has metastasized is poor, the nurse encourages the patient to have hope in the therapy employed while maintaining a realistic perspective about the disease and ultimate outcome. Moreover, the nurse provides time for the patient to express fears and concerns regarding future activities and relationships, offers information about support groups and contact people, and arranges palliative and hospice care if appropriate (see Chap. 17).

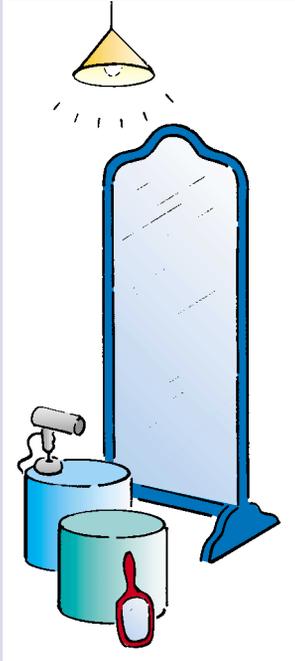

##### PROMOTING HOME AND COMMUNITY-BASED CARE

##### Teaching Patients Self-Care

The best hope of controlling the disease lies in educating patients about the early signs of melanoma. Patients at risk are taught to examine their skin and scalp monthly in a systematic manner (Chart 56-9). The nurse also points out that a key factor in the development of malignant melanoma is exposure to sunlight. Because melanoma is thought to be genetically linked, the family and the patient should be taught sun-avoiding measures.

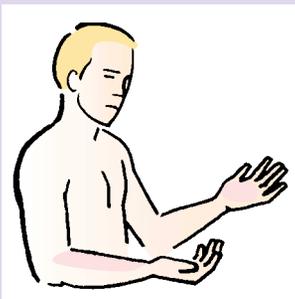

**Chart 56-9 • PATIENT EDUCATION**  
**How to Examine Your Skin**

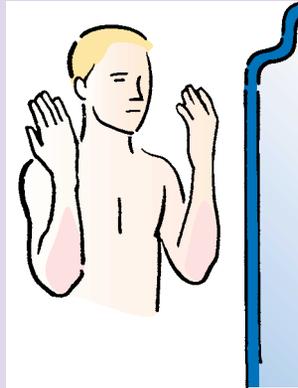

**Step 1**

Make sure the room is well lighted, and that you have nearby a full-length mirror, a hand-held mirror, a hand-held blow dryer, and two chairs or stools. Undress completely.

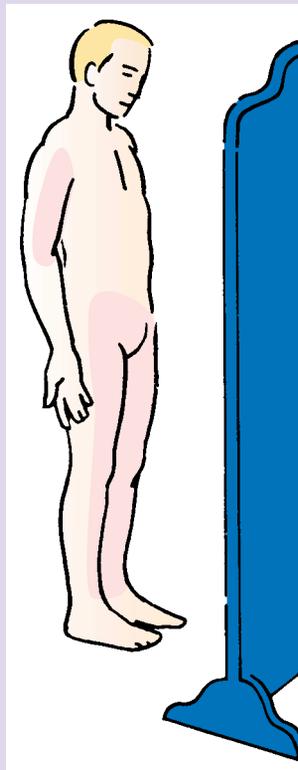

**Step 2**

Hold your hands with the palms face up, as shown in the drawing. Look at your palms, fingers, spaces between the fingers, and forearms. Then turn your hands over and examine the backs of your hands, fingers, spaces between the fingers, fingernails and forearms.

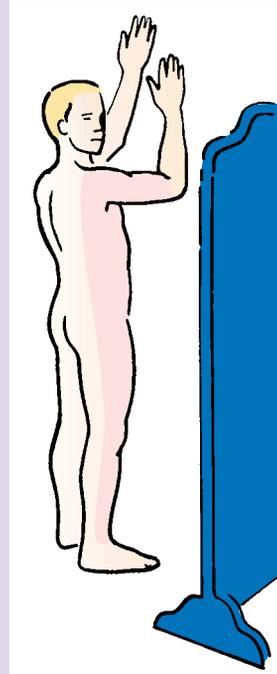

**Step 3**

Now position yourself in front of the full-length mirror. Hold up your arms, bent at the elbows, with your palms facing you in the mirror, look at the backs of your forearms and elbows.

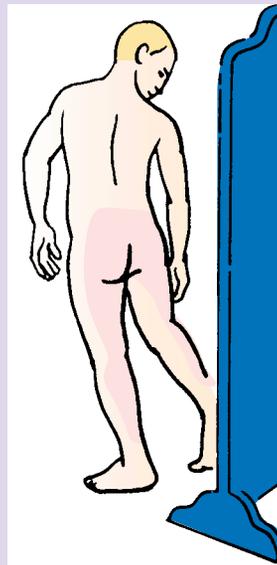

**Step 4**

Again using the full-length mirror, observe the entire front of your body. In turn, look at your face, neck, and arms. Turn your palms to face the mirror and look at your upper arms. Then look at your chest and abdomen; pubic area; thighs and lower legs.

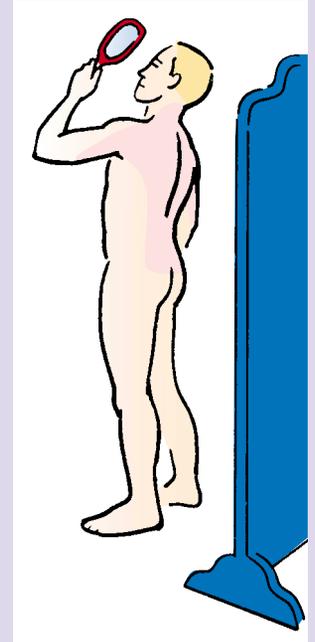

**Step 5**

Still standing in front of the mirror, lift your arms over your head with the palms facing each other. Turn so that your right side is facing the mirror and look at the entire side of your body, your hands and arms, underarms, sides of your trunk, thighs and lower legs. Then turn, and repeat the process with your left side.

**Step 6**

With your back toward the full-length mirror, look at your buttocks and the backs of your thighs and lower legs.

**Step 7**

Now pick up the hand-held mirror. With your back still to the full-length mirror, examine the back of your neck, and your back and buttocks. Also examine the backs of your arms in this way. Some areas are hard to see, and you may find it helpful to ask your spouse or a friend to assist you.

**Step 8**

Use the hand-held mirror and the full-length mirror to look at your scalp. Because the scalp is difficult to examine, we suggest you also use a hand-held blow dryer turned to a cool setting, to lift the hair from the scalp. While some people find it easy to hold the mirror in one hand and the dryer in the other, while looking in the full-length mirror, many do not. For the scalp examination in particular, then, you might ask your spouse or a friend to assist you.

*(continued)*

### Chart 56-9 • PATIENT EDUCATION

#### How to Examine Your Skin (Continued)

#### Step 9

Sit down and prop up one leg on a chair or stool in front of you as shown. Using the hand-held mirror, examine the inside of the propped-up leg, beginning at the groin area and moving the mirror down the leg to your foot. Repeat the procedure for your other leg.

#### Step 10

Still sitting, cross one leg over the other. Use the hand-held mirror to examine the top of your foot, the toes, toenails, and spaces between the toes. Then look at the sole or bottom of your foot. Repeat the procedure for the other foot.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Experiences relief of pain and discomfort
  - a. States pain is diminishing
  - b. Exhibits healing of surgical scar without heat, redness, or swelling
2. Is less anxious
  - a. Expresses fears and fantasies
  - b. Asks questions about medical condition
  - c. Requests repetition of facts about melanoma
  - d. Identifies support and comfort provided by family member or significant other
3. Demonstrates understanding of the means for detecting and preventing melanoma
  - a. Demonstrates how to conduct self-examination of skin on a monthly basis
  - b. Verbalizes the following danger signals of melanoma: change in size, color, shape, or outline of mole, mole surface, or skin around mole
  - c. Identifies measures to protect self from exposure to sunlight
4. Experiences absence of complications
  - a. Recognizes abnormal signs and symptoms that should be reported to physician
  - b. Complies with recommended follow-up procedures and prevention strategies

## METASTATIC SKIN TUMORS

The skin is an important, although not a common, site of metastatic cancer. All types of cancer may metastasize to the skin, but carcinoma of the breast is the primary source of cutaneous metastases in women. Other sources include cancer of the large intestine, ovaries, and lungs. In men, the most common primary sites are the lungs, large intestine, oral cavity, kidneys, or stomach. Skin metastases from melanomas are found in both genders. The clinical appearance of metastatic skin lesions is not distinctive, except perhaps in some cases of breast cancer in which diffuse, brawny hardening of the skin of the involved breast is seen. In most instances, metastatic lesions occur as multiple cutaneous or subcutaneous nodules of various sizes that may be skin colored or different shades of red.

## Other Malignancies of the Skin

### KAPOSI'S SARCOMA

First described by Moritz Kaposi in 1872, Kaposi's sarcoma (KS) has received renewed attention since its association with HIV infection and AIDS. Its occurrence with AIDS involves a more varied and aggressive form of KS than was seen previously. Before the AIDS epidemic, KS was considered a rare malignancy. It was subdivided into three categories: classic KS, African (endemic) KS, and KS associated with immunosuppressant therapy. Classic KS occurs predominantly in men of Mediterranean or Jewish ancestry between the ages of 40 and 70 years. Most patients have nodules or plaques on the lower extremities that rarely metastasize beyond the lower extremities. This KS is chronic, relatively benign, and rarely fatal.

African KS affects people predominantly in the eastern half of Africa near the equator. Men are affected more often than women, and children can be affected as well. The disease may resemble classic KS, or it may infiltrate and progress to lymphadenopathic forms.

KS associated with immunosuppressive therapy, as in transplant recipients, is characterized by local skin lesions and disseminated visceral and mucocutaneous diseases. The greater the degree of immunosuppression, the higher is the incidence of KS.

AIDS-related KS was identified in the early 1980s as distinctly different from previously described types of KS. Typically, it is an aggressive tumor that involves multiple body organs. Its presentation resembles that of KS associated with immunosuppressive therapy. Most patients are between the ages of 20 and 40 years (Odom et al., 2000). More information on this topic can be found in Chapter 52.

### BASAL AND SQUAMOUS CELL CARCINOMAS IN THE IMMUNOCOMPROMISED POPULATION

The incidence of basal cell carcinoma and squamous cell carcinoma is increased in all immunocompromised individuals, including those infected with HIV. Clinically, the tumors have the same appearance as in non-HIV-infected people; however, in HIV patients, the tumors may grow more rapidly and recur more frequently. These tumors are managed the same as for the general population. Frequent follow-up (every 4 to 6 months) is recommended to monitor for recurrence.

## Dermatologic and Plastic Reconstructive Surgery

The word *plastic* comes from a Greek word meaning *to form*. Plastic or reconstructive surgery is performed to reconstruct or alter congenital or acquired defects to restore or improve the body's form and function. Often, the terms plastic and reconstructive are used interchangeably. This type of surgery includes closure of wounds, removal of skin tumors, repair of soft tissue injuries or burns, correction of deformities, and repair of cosmetic defects. Plastic surgery can be used to repair many parts of the body and numerous structures, such as bone, cartilage, fat, fascia, mucous membrane, muscle, nerve, and cutaneous structures. Bone inlays and transplants for deformities and nonunion can be performed, muscle can be transferred, nerves can be reconstructed and spliced, and cartilage can be replaced. As important as any of these measures is the reconstruction of the cutaneous tissues around the neck and the face; this is usually referred to as aesthetic or cosmetic surgery.

### WOUND COVERAGE: GRAFTS AND FLAPS

Various surgical techniques, including skin grafts and flaps, are used to cover skin wounds.

#### Skin Grafts

Skin grafting is a technique in which a section of skin is detached from its own blood supply and transferred as free tissue to a distant (recipient) site. Skin grafting can be used to repair almost any type of wound and is the most common form of reconstructive surgery.

Skin grafts are commonly used to repair defects that result from excision of skin tumors, to cover areas denuded of skin (e.g., burns), and to cover wounds in which insufficient skin is available to permit wound closure. They are also used when primary closure of the wound increases the risk for complications or when primary wound closure would interfere with function.

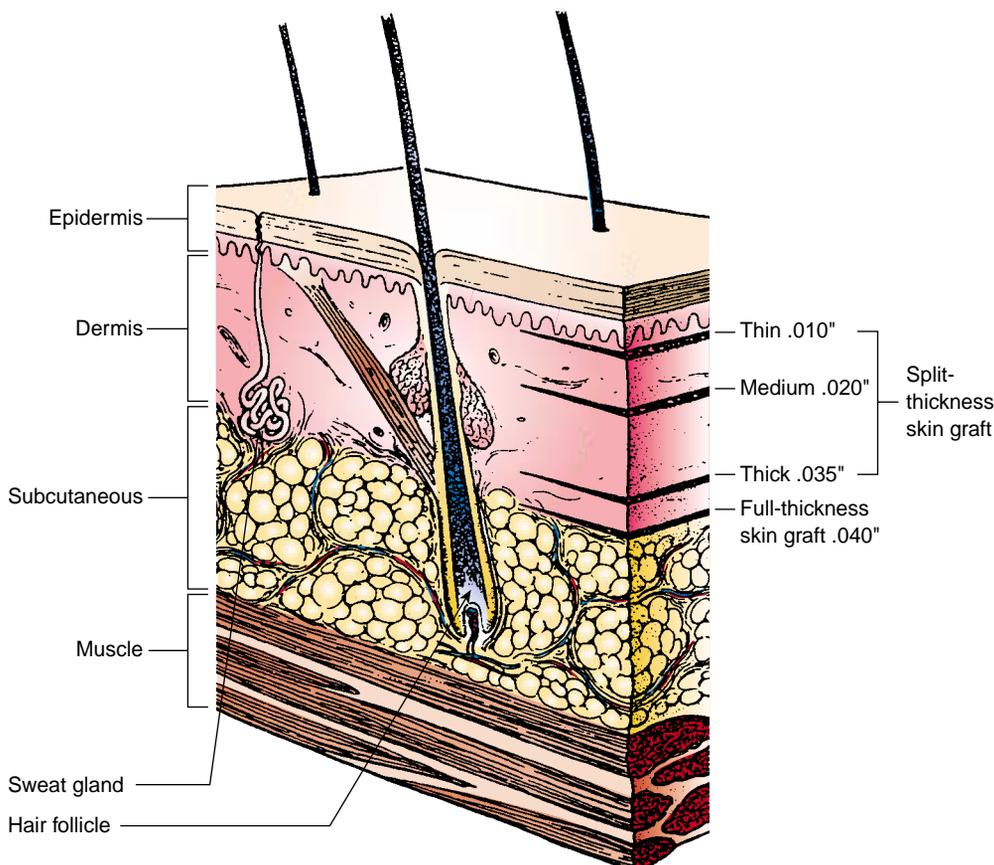

Skin grafts may be classified as autografts, allografts, or xenografts. An autograft is tissue obtained from the patient's own skin. An allograft is tissue obtained from a donor of the same species. These grafts are also called allogeneic or homograft. A xenograft or heterograft is tissue from another species.

Grafts are also referred to by their thickness. A skin graft may be a split-thickness (ie, thin, intermediate, or thick) or full-thickness graft, depending on the amount of dermis included in the specimen. A split-thickness graft can be cut at various thicknesses and is commonly used to cover large wounds or defects for which a full-thickness graft or flap is impractical (Fig. 56-8). A full-thickness graft consists of epidermis and the entire dermis without the underlying fat. It is used to cover wounds that are too large to be closed directly.

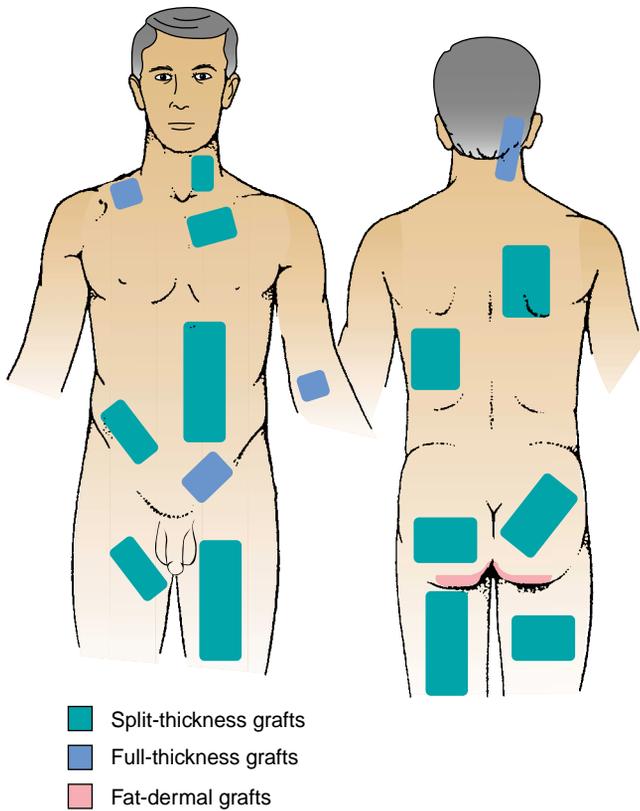

#### DONOR SITE

The donor site is selected with several criteria in mind:

- Achieving the closest possible color match
- Matching the texture and hair-bearing qualities
- Obtaining the thickest possible skin graft without jeopardizing the healing of the donor site (Fig. 56-9)
- Considering the cosmetic effects of the donor site after healing, so that it is in an inconspicuous location

**FIGURE 56-8** Layers of skin appropriate for split-thickness and full-thickness graft.

**FIGURE 56-9** Common donor skin graft sites. Blue skin areas are appropriate for full-thickness grafts; green areas are used for split-thickness grafts; rose sites are used for fat-dermal grafts.

### DONOR SITE CARE

Detailed attention to the donor site is just as important as the care of the recipient area. The donor site heals by re-epithelization of the raw, exposed dermis. Usually, a single layer of nonadherent, fine-mesh gauze is placed directly over the donor site. Absorbent gauze dressings are then placed on top to absorb blood or serum from the wound. A membrane dressing (eg, Op-Site) may be used and provides certain advantages. It is transparent and allows the wound to be observed without disturbing the dressing, and it permits the patient to shower without fear of saturating the dressing with water.

After healing, the patient is instructed to keep the donor site soft and pliable with cream (eg, lanolin, olive oil). Extremes in temperature, external trauma, and sunlight are to be avoided for donor sites and grafted areas because these areas are sensitive, especially to thermal injuries.

### GRAFT APPLICATION

A graft is obtained by a variety of instruments: razor blades, skin-grafting knives, electric- or air-powered dermatomes, or drum dermatomes. The skin graft is taken from the donor or host site and applied to the desired site, called the recipient site or graft bed.

For a graft to survive and be effective, certain conditions must be met:

- The recipient site must have an adequate blood supply so that normal physiologic function can resume.
- The graft must be in close contact with its bed to avoid accumulation of blood or fluid.
- The graft must be fixed firmly (immobilized) so that it remains in place on the recipient site.
- The area must be free of infection.

The graft, when applied to the recipient site, may be sutured in place. It may be slit and spread apart to cover a greater area. The process of revascularization (ie, establishing the blood supply) and reattachment of a skin graft to a recipient bed is referred to as a “take.” After a skin graft is put in place, it may be left exposed (in areas that are impossible to immobilize) or covered with a light dressing or a pressure dressing, depending on the area.

### Nursing Interventions

The nurse instructs the patient to keep the affected part immobilized as much as possible. For a facial graft, strenuous activity must be avoided. A graft on the hand or arm may be immobilized with a splint. When a graft is placed on a lower extremity, the part is kept elevated because the new capillary connections are fragile and excess venous pressure may cause rupture. When ambulation is permitted, the patient wears an elastic stocking to counterbalance venous pressure.

The nurse instructs the patient, family member, or other caregiver to inspect the dressing daily. Unusual drainage or an inflammatory reaction around the wound margin suggests infection and should be reported to the physician. Any fluid, purulent drainage, blood, or serum that has collected is gently evacuated by the surgeon, because accumulation of this material would cause the graft to separate from its bed.

When the graft appears pink, it is vascularized. After 2 to 3 weeks, mineral oil or a lanolin cream is massaged into the wound to moisten the graft. Because there may be loss of feeling or sensation in the grafted area for a prolonged period, the application of heating pads and exposure to sun are avoided to prevent burns and further skin trauma.

### Flaps

Another form of wound coverage is provided by flaps. A flap is a segment of tissue that remains attached at one end (ie, a base or pedicle) while the other end is moved to a recipient area. Its survival depends on functioning arterial and venous blood supplies and lymphatic drainage in its pedicle or base. A flap differs from a graft in that a portion of the tissue is attached to its original site and retains its blood supply. An exception is the free flap, which is described later.

Flaps may consist of skin, mucosa, muscle, adipose tissue, omentum, and bone. They are used for wound coverage and provide bulk, especially when bone, tendon, blood vessels, or nerve tissue is exposed. Flaps are used to repair defects caused by congenital deformity, trauma, or tumor ablation (ie, removal, usually by excision) in an adjacent part of the body.

Flaps offer an aesthetic solution because a flap retains the color and texture of the donor area, is more likely to survive than a graft, and can be used to cover nerves, tendons, and blood vessels. However, several surgical procedures are usually required to advance a flap. The major complication is necrosis of the pedicle or base as a result of failure of the blood supply.

### Free Flaps

A striking advance in reconstructive surgery is the use of free flaps or free-tissue transfer achieved by microvascular techniques. A free flap is completely severed from the body and transferred to another site. A free flap receives early vascular supply from microvascular anastomosis (ie, attachment) with vessels at the recipient site. The procedure usually is completed in one step, eliminating

the need for a series of surgical procedures to move the flap. Microvascular surgery allows surgeons to use a variety of donor sites for tissue reconstruction.

## CHEMICAL FACE PEELING

Chemical face peeling, a technique that involves applying a chemical mixture to the face for superficial destruction of the epidermis and the upper layers of the dermis, treats fine wrinkles, keratoses, and pigment problems. It is especially useful for wrinkles at the upper and lower lip, forehead, and periorbital areas.

Pretreatment may consist of cleansing the face and hair for several days before the procedure with a hexachlorophene detergent. Pretreatment medication (ie, analgesic and tranquilizer for moderate sedation) may be prescribed to alleviate apprehension and control pain. This permits the patient to be sedated but conscious during the procedure, although some patients request general anesthesia.

The type of chemical used depends on the planned depth of the peel. A phenol-based chemical in an oil-water emulsion is commonly used because it produces a controlled, predictable chemical burn. The chemical is applied systematically to the face with cotton-tipped applicators. The conscious patient feels a burning sensation at this time. A mask of waterproof adhesive may then be applied directly to the skin and molded closely to the contours of the face, thereby acting as an occlusive dressing that increases the chemical penetration and action. Some surgeons believe that equally good results can be obtained with occlusive tape. After the tape mask is applied, the burning sensation continues, and the tape mask remains in place for 12 to 24 hours. Frequent small doses of analgesics and tranquilizers are prescribed to keep the patient comfortable.

## Complications

Complications may arise when control of the chemically induced burn cannot be sustained. Complications include pigment changes, infection, milia (ie, small inclusion cysts that disappear after several months), scarring, atrophy, sensitivity changes, and long-term (4 to 5 months) erythema or pruritus.

## Management

Because chemical face peeling is performed in the physician's office or in an outpatient surgical department, most care takes place in the home. After 6 to 8 hours, the face becomes edematous and the eyelids usually swell shut. The patient should be reassured that this reaction is expected and normal. The patient is cautioned to move the mouth as little as possible so that the tape continues to adhere to the skin. The head of the bed is elevated, and liquids are administered through a straw. Most of the burning sensation and discomfort subside after the first 12 to 24 hours.

By the second day, the patient may feel moisture under the dressings as serous exudate seeps from the chemically exfoliated skin. Dressings are usually removed 24 to 48 hours after treatment, exposing skin resembling a second-degree burn. The patient may be alarmed by the appearance of the skin and should be reassured. After the tape mask is removed, some surgeons dust the treated skin surface with thymol-iodine powder for its drying and bacteriostatic effects. Application of triple-antibiotic ointment may be substituted in some cases. The skin surface is left uncovered to dry. The patient may be permitted to wash the face with lukewarm water or advised to shower several times daily to help remove

any remaining facial crusting. An ointment is prescribed to cover the face and soften and loosen the crust between washings.

The nurse reinforces the physician's explanation that the redness of the skin will gradually subside over the next 4 to 12 weeks. Although a line between treated and untreated skin may be seen, makeup is usually permitted after the first few weeks. The patient is cautioned to avoid exposure to direct or reflected sunlight, because the treatment reduces the natural protection of the skin from sun. The skin will probably never tan evenly again. Blotchy pigmentation can occur with exposure to the sun.

## DERMABRASION

Dermabrasion is a form of skin abrasion used to correct acne scarring, aging, and sun-damaged skin. A special instrument (ie, motor-driven wire brush, diamond-impregnated disk, or serrated wheel) is used in the procedure. The epidermis and some superficial dermis are removed, while enough of the dermis is preserved to allow re-epithelization of the treated areas. Results are best in the face because it is rich in intradermal epithelial elements.

## Preparation and Procedure

The primary reason for undergoing dermabrasion is to improve appearance. The surgeon explains to the patient what can be expected from dermabrasion. The patient should also be informed about the nature of the postoperative dressing, what discomfort may be experienced, and how long it will be before the tissues look normal.

Dermabrasion may be performed in the physician's office, the operating room, or an outpatient setting. It is performed under local or general anesthesia. During the procedure, some surgeons use refrigerant anesthetics to turn the skin into a numb, solid mass of rigid tissue and to provide a momentarily bloodless surgical field. During and after planning, the area is irrigated with copious amounts of saline solution to remove debris and allow the surgeon to see the area. A dressing impregnated with ointment is usually applied to the abraded surface.

## Management

The nurse instructs the patient about postoperative effects. Edema occurs during the first 48 hours and may cause the eyelids to close. The head of the bed is elevated to hasten fluid drainage. Erythema occurs and can last for weeks or months. After 24 hours, the dressing may be removed if the physician approves. When the serum oozing from the skin begins to gel, the patient applies the prescribed ointment to the face several times each day to prevent hard crusting and to keep the abraded areas soft and flexible. With the physician's approval, clear-water cleansing or soaking of the face is started to remove crusts from the healing skin.

The patient is advised to avoid extreme cold and heat and excessive straining or lifting, which may bruise delicate new capillaries. Direct or reflected sunlight should be avoided for 3 to 6 months and a sunscreen used.

## FACIAL RECONSTRUCTIVE SURGERY

Reconstructive procedures on the face are individualized to the patient's needs and desired outcomes. They are performed to repair deformities or restore normal function as much as possible. They may vary from closure of small defects to complicated procedures involving implantation of prosthetic devices to conceal a

large defect or reconstruct a lost part of the face (eg, nose, ear, jaw). Each surgical procedure is customized and involves a variety of incisions, flaps, and grafts.

In correcting a primary defect, the surgeon may have to create a secondary defect. Although the procedure may restore some function, such as eating or talking, the cosmetic or aesthetic results may be limited. The original appearance of a patient who has severe damage to soft tissue and bone structure can seldom be restored. Multiple surgical procedures may be required. The process of facial reconstruction is usually slow and tedious.

## NURSING PROCESS: CARE OF THE PATIENT WITH FACIAL RECONSTRUCTION

### Assessment

The face is a part of the body that every person desires to keep at its best or improve, because most human interactions involve the face. When the face loses its appearance and function by injury or disease, significant emotional reactions often occur. Changes in appearance frequently cause anxiety and depression. Patients with facial changes frequently mourn for the lost part, suffer a loss of self-esteem because of reactions or rejection by others, and withdraw and isolate themselves. Health care personnel can acknowledge that anxiety and depression are appropriate for what the patient is experiencing.

The nurse assesses the patient's emotional responses and identifies strengths as well as usual coping mechanisms to determine how the patient will handle the surgical procedure. Any area in which the patient and family need extra support is identified.

The preoperative assessment determines the extent of disfigurement and improvement that can be anticipated, as well as the patient's understanding and acceptance of these limitations. The nurse is in a better position to reinforce facts and clarify misconceptions after the surgeon has fully informed the patient about the procedure, the functional defects that may result, the possible need for a tracheostomy or other prosthesis, and the probability of additional surgery. The nurse instructs the patient about various postoperative measures: intravenous therapy, the use of a nasogastric tube to allow gastric decompression and prevent vomiting, and the frequent and lengthy periods that may be required to care for wounds, flaps, and skin grafts and to change dressings. Extra time is needed when presenting this information to anxious patients because they may not hear, concentrate, or comprehend what is being said.

### Diagnosis

#### NURSING DIAGNOSES

Based on the nursing assessment data, the patient's major postoperative nursing diagnoses may include the following:

- Ineffective airway clearance related to tracheobronchial secretions
- Acute pain related to facial edema and effects of the procedure
- Imbalanced nutrition: less than body requirements related to altered physiology of oral cavity, drooling, impaired chewing and swallowing, or excision affecting the tongue
- Impaired verbal communication related to trauma or surgery producing anatomic and physiologic abnormalities of speech
- Disturbed body image related to disfigurement

- Interrupted family processes related to grief reaction and disruption of family life

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include.

- Infection

### Planning and Goals

The major goals for the patient may include a patent airway and adequate pulmonary function, increased comfort, adequate nutritional status, an effective communication method, positive self-concept, effective family coping, and absence of infection.

### Nursing Interventions

#### MAINTAINING AIRWAY AND PULMONARY FUNCTION

The immediate concern after facial reconstruction is maintenance of an adequate airway. If the patient has regained consciousness, mental confusion with combative, anxious behavior is a sign of hypoxia (ie, reduced oxygen supply to tissues). Sedatives or opioids are not prescribed in this situation because they may impair oxygenation. If the patient shows signs of restlessness, the airway is carefully inspected to detect laryngeal edema or accumulation of tracheobronchial mucus. Secretions are suctioned as necessary until the patient can manage the secretions without help. If the patient has a tracheostomy, suctioning is performed with sterile technique to prevent infection and cross-contamination. Chapter 25 provides information on care of the patient with a tracheostomy.

#### RELIEVING PAIN AND ACHIEVING COMFORT

Facial edema is an uncomfortable but natural consequence of facial reconstructive surgery. The patient's head and upper torso are kept slightly elevated (if the blood pressure is stable) to help reduce facial edema. Catheters attached to closed drainage may be in place to keep the tissue in close apposition and to remove serous discharge. If extensive reconstruction has been performed, the patient's head should be properly aligned and supported so that minimal stress is placed on the suture line.

Analgesics are prescribed to relieve pain. If bone grafts have been used for reconstruction, there is usually considerable pain in the donor area. If the patient has head and neck cancer and increasing levels of pain, comprehensive nursing management is required (see Chap. 13).

#### MAINTAINING ADEQUATE NUTRITION

Fluids may be offered to the patient after oral and pharyngeal edema diminish, the incisional areas and flaps heal, and the patient can swallow saliva. Gradually, soft foods are added as tolerated. If the patient cannot meet nutritional needs by the oral route, parenteral nutrition (ie, infusion of nutrients, water, and vitamins into the stomach or proximal small intestine through a tube) is initiated. The formula strength and feeding rate are gradually increased until the desired daily caloric level is attained. Chapter 36 provides information about nursing management of the patient requiring enteral feedings. Patients who have had radical surgery for large, encroaching neoplasms may have difficulty resuming eating. Positive nutrition is reflected in weight gain, and nutritional status is monitored by measuring body weight daily and assessing serum protein and electrolyte levels periodically.

### ENHANCING COMMUNICATION

Communication problems may range from minimal difficulty to the loss of oral speech. Some tumors and injuries require extensive surgery involving the larynx, tongue, and mandible. Paper, pen or pencil, and a firm writing surface should be provided. If the patient cannot write, a pictograph board may be used. Referral to a speech therapist may be necessary for the patient who has undergone structural changes. The family may become frustrated by the patient's inability to communicate. The patient soon senses this, and both parties may withdraw. Allowing the family to vent their feelings and fears (away from the patient) is important.

### IMPROVING SELF-CONCEPT

Success in rehabilitating the patient undergoing reconstructive surgery depends on the relationships among the patient and the nurse, the physician, and other health care personnel. Mutual trust, respect, and clear lines of communication are essential. Unhurried care provides emotional reassurance and support.

The kinds of dressings worn, the unusual positions to be maintained, and the temporary incapacity experienced can upset the most stable person. Reinforcement of the patient's successful coping strategies improves self-esteem. If prosthetic devices are used, the patient is taught how to use and care for them to gain a sense of greater independence. Once involved in self-care activities, the patient may feel some control over what was previously an overwhelming situation.

Patients with severe disfigurement are encouraged to socialize to experience the reactions of others in a more protected environment. Gradually, they can widen their sphere of contact. Every effort is made to cover or mask defects. Patients may require support by members of the mental health team to accept their changed appearance.

### PROMOTING FAMILY COPING

The family is informed about the patient's appearance after surgery, the supportive equipment, and the ways that the equipment aids recovery. It is helpful to join the family for a few minutes during their first postoperative visit to help them cope with the changes they will see.

A major role of the nurse is to support the family in their decision to participate (or not to participate) in the patient's treatment. Nursing interventions also include helping the family members communicate by suggesting ways to reduce anxiety and stress and to promote problem solving and decision making. These activities encourage family members and promote growth.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

#### Infection

Secondary infection is a primary concern after reconstructive surgery. The source of infection depends on the location and extent of the procedure, the suture line, and the pedicle flap.

The mouth is inspected to determine the location of sutures (when present) so that they are not accidentally disturbed during the cleaning process. The mouth is cleaned according to protocol several times daily. Loose blood clots may be removed with gentle swabbing. The patient is advised not to loosen clots with the tongue because this may cause fresh bleeding. The patient is instructed not to use fingers to clean or remove blood clots because this may introduce organisms that cause infection.

The suture line remains under stress for several days after surgery because of edema, increased drainage, and hematoma formation. The nurse assesses the suture line carefully for signs of

increased tension and infection (ie, elevated temperature, increasing edema, redness, bleeding, and increased pain) with each dressing change. Dressings may need to be changed many times each day until the drainage begins to decrease. Drainage and edema are expected after reconstructive surgery; however, both should decrease, and the process is hastened by using properly placed, functioning suction devices and elevating the head of the bed about 45 degrees. The nurse inspects the suction devices, empties them promptly, and documents the amount and consistency of drainage, as well as any unusual odor. When drainage is not removed or if saturated dressings are left unchanged for long periods, infection is likely to occur. Strict asepsis must be maintained in wound care.

A pedicle flap used in reconstruction may become a source of infection if its circulation becomes compromised. Poor circulation may result from a hematoma forming beneath the flap and causing increased pressure on the underlying vasculature. The nurse inspects the flap for changes in color and temperature indicative of poor circulation. Signs of necrosis, increased drainage, or an odor may be a warning of an infection and should be reported promptly. Reinforcing preoperative teaching about wound healing, the need for strict sterile technique, good personal hygiene, and the need to restrict movement and stress on the operative site is an important part of the nurse's role in postoperative care and in the prevention of secondary infection.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Maintains patent airway
  - a. Demonstrates respiratory rate within normal limits
  - b. Exhibits normal breath sounds
  - c. Demonstrates no signs of choking or aspiration
2. Achieves increasing comfort
  - a. Reports decreasing pain
  - b. Follows instructions on proper positioning
  - c. Avoids movements that stress the operative site
3. Attains adequate nutrition
  - a. Consumes adequate amounts of food and fluids
  - b. Maintains weight within normal range or progressively regains weight lost in the early postoperative period
  - c. Maintains serum protein and electrolyte levels within normal range
4. Communicates effectively
  - a. Uses appropriate aids to enhance communication
  - b. Interacts with health care team members, family, and other support people using new communication strategies
5. Develops positive self-image
  - a. Expresses positive feelings about surgical changes
  - b. Demonstrates increasing independence in self-care activities
  - c. Uses prosthetic devices independently (when appropriate)
  - d. Verbalizes plans for resuming usual activities (eg, work, recreation)
6. Family members cope with situation
  - a. Demonstrate decreasing anxiety and conflict
  - b. Verbalize what to expect
7. Absence of complications
  - a. Demonstrates vital signs within normal limits
  - b. Undergoes normal wound healing without signs of infection or sepsis

- c. Lists signs of infection that should be reported
- d. Understands the need for asepsis (ie, sterile procedures) and good personal hygiene

## FACE LIFT

Rhytidectomy (ie, face lift) is a surgical procedure that removes soft tissue folds and minimizes cutaneous wrinkles on the face. It is performed to create a more youthful appearance.

Psychological preparation requires that the patient recognize the limitations of surgery and the fact that miraculous rejuvenation will not occur. The patient is informed that the face may appear bruised and swollen after the dressings are removed and that several weeks may pass before the edema subsides.

The procedure is performed under local or general anesthesia, often in the outpatient setting. The incisions are concealed in natural skin folds and creases and areas hidden by hair. The loose skin, separated from underlying muscle, is pulled upward and backward. Excess skin that overlaps the incision line is removed. Liposuction-assisted rhytidectomy is being performed more frequently. In this procedure, fat is suctioned from the body through a cannula inserted through a small incision.

## Management

The nurse encourages the patient to rest quietly for the first 2 post-operative days until the dressings are removed. The head of the bed is elevated, and neck flexion is discouraged to avoid compromising the circulation and the suture line. The patient may feel some tightness of the face and neck from pressure created by the newly tightened muscles, fascia, and skin. Analgesics may be prescribed to relieve discomfort. A liquid diet may be given by means of straws, and a soft diet is permitted if chewing is not too uncomfortable.

When the dressings are removed, the skin is gently cleaned of crusting and oozing and coated with the prescribed topical ointment. Any hair matted with drainage may be combed with warm water and a wide-toothed comb.

The patient is advised not to lift or bend for 7 to 10 days because this activity may increase edema and provoke bleeding. Activities are gradually resumed. When all sutures are removed, the hair may be shampooed and blown dry with warm, not hot, air to avoid burning the ears, which may be numb for a while.

The patient needs to know that a face lift will not stop the aging process and that, with time, the tissues will resume the downward drift. Some patients have two or more face lifts.

Sudden pain indicates that blood is accumulating underneath the skin flaps; it should be reported to the surgeon immediately. Complications include sloughing of the skin, deformities of the face and neck, and partial facial paralysis. Cigarette smoking has been implicated as a cause of skin slough in some patients.

## Laser Treatment of Cutaneous Lesions

Lasers are devices that amplify or generate highly specialized light energy. They can mobilize immense heat and power when focused at close range and are valuable tools in surgical procedures. The argon laser, carbon dioxide (CO<sub>2</sub>) laser, and tunable pulse-dye laser are used in dermatologic surgery. Each type of laser emits its own wavelength within the color spectrum.

## ARGON LASER

The argon laser produces a visible blue-green light that is absorbed by vascular tissue and is therefore useful in treating vascular lesions: port-wine stains, telangiectases, vascular tumors, and pigmented lesions. The argon beam can penetrate approximately 1 mm of skin and reach the pigmented layer, causing protein coagulation in this area. An immediate effect is that tiny blood vessels under the skin coagulate, causing the area to turn a much lighter color. A crust forms within a few days.

During the procedure, the patient may require local anesthesia (lidocaine) but only if the lesion, such as a port-wine stain, is wider than 0.5 cm. Laser beams, regardless of type, are reflected and scattered in all directions during the treatment. Laser radiation is hazardous to the eye, and the eyes of the patient and all personnel involved in the surgical procedure and those who are within the immediate surgical environment must be protected with orange, argon light-absorbing safety goggles.

## Management

Cold compresses are usually applied over the treatment area for approximately 6 hours to minimize edema, exudate, and loss of capillary permeability. The nurse advises the patient that swelling will subside in 1 to 2 days and will be followed by a crust that will last 7 to 10 days. The nurse instructs the patient to avoid picking at the crust, to apply an antibacterial ointment sparingly until the crust separates, to avoid applying makeup until the wound heals, and to avoid exposure to the sun. Sunscreen is to be used when exposure is unavoidable.

## CARBON DIOXIDE LASER

The CO<sub>2</sub> laser emits invisible light in the infrared spectrum that is absorbed at the skin surface because of the high water content of the skin and the long wavelength of the CO<sub>2</sub> light. As the laser beam strikes tissue, it is absorbed by the intracellular and extracellular water, which vaporizes, destroying the tissue. The CO<sub>2</sub> laser is a precise surgical instrument that vaporizes and excises tissue with minimal damage. Because the beam can seal blood and lymphatic vessels, it creates a dry surgical field that makes many procedures easier and quicker. It is therefore safe to use on patients with bleeding disorders or those receiving anticoagulant therapy. It is useful for removing epidermal nevi, tattoos, certain warts, skin cancer, ingrown toenails, and keloids. Incisions made with the laser beam heal and scar much like those made by a scalpel.

In addition to wearing safety goggles, the patient and personnel wear laser-grade surgical masks to avoid inhaling the byproduct smoke, referred to as a plume.

## Management

Immediately after undergoing CO<sub>2</sub> laser surgery, the treated area turns a charcoal color. The wound is covered with antibacterial ointment and a nonadhesive dressing. The patient is instructed to keep the wound dry except for gentle cleansing with mild soap several times each day. After the skin is cleaned, a prescribed ointment and light dressing are applied.

Because nerve endings and lymphatic vessels are sealed by the laser, less edema and pain follow the laser procedure than follow conventional surgery. A mild analgesic is sufficient to maintain

patient comfort. Wound healing occurs by secondary intention, with granulation tissue appearing within a week; complete healing occurs in several weeks. Sun exposure to the area should be avoided for approximately 6 months. Application of a sunscreen with an SPF value of at least 15 is recommended. People at high risk for skin cancer from sun exposure are advised to use a sunscreen with an SPF greater than 15 to block ultraviolet-B and ultraviolet-A light.

## PULSE-DYE LASER

The tunable pulse-dye laser with various wavelengths is the latest laser available for dermatologic surgery. It is especially useful in treating cutaneous vascular lesions such as port-wine stains and telangiectasia. Eye protection used for the argon and CO<sub>2</sub> lasers is insufficient when the pulse-dye laser is in use. Special eyeglasses, such as those made of didymium glass, are required for the patient and all personnel. The procedure is generally painless. For procedures requiring anesthesia, lidocaine without epinephrine is sufficient because local vasoconstriction (which epinephrine induces) is unnecessary.

## Management

The patient should be informed that there may be stinging in the treated area for several hours. Applying ice to the area and a light antibacterial ointment followed by a nonstick dressing (eg, Telfa) usually eases discomfort.

**NURSING ALERT** Telfa pads contain latex and should not be used on patients who are latex sensitive. Other dressings such as petrolatum-impregnated gauze should be used to prevent the dressing from adhering to the wound.

If crusting occurs, the patient is advised to wash the area gently with soap and water and reapply the antibacterial cream twice daily until the crust disappears. The nurse also advises the patient to avoid wearing makeup until all crust is removed. Sun exposure should be avoided as well; sunscreens with an SPF value of 15 or greater should be used for 3 to 4 months after the treatment. Complete removal of the lesion at one session, especially a port-wine stain, is rare. The patient should be informed that several treatments may be necessary.

## Critical Thinking Exercises

1. A patient is admitted with generalized psoriasis in an acute flare. About 70% of his skin is involved. What type of treatment will you be expected to administer? What nursing interventions would you anticipate in caring for this man? Explain the physiologic basis for these interventions.
2. You are caring for an elderly man who has had surgery. He is a regular resident of a long-term care facility. When giving him a bath, you find two ulcerations on his buttocks. What are some of the considerations in taking care of this man? What will help prevent further breakdown of the skin?

Which dressings may be appropriate for his wounds? What other hospital resources can you consult in making a care plan for this patient?

3. A middle-aged woman is admitted to same-day surgery for a wide excision of a melanoma on her back. She is very anxious about the cause of this cancer and about her prognosis. What issues would you address in helping her diminish her anxiety? What should she be told about sun exposure? What should she tell her children about their risk for melanoma?

# ● Management of Patients With Burn Injury

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Discuss the classification system used for burn injuries.
2. Describe the local and systemic effects of a major burn injury.
3. Describe the three phases of burn care and the priorities of care for each phase.
4. Compare and contrast the potential fluid and electrolyte alterations of the emergent/resuscitative and acute phases of burn management.
5. Describe the goals of the following aspects of burn wound care and the nurse's role in each: wound cleaning, topical antibacterial therapy, wound dressing, dressing changes, wound débridement, and wound grafting
6. Describe the nurse's role in the following areas of management: pain management, restrictions of activity and joint motion, psychological support of the patient and family, nutritional support, pulmonary care, and patient and family education.
7. Use the nursing process as a framework for care of the patient during the three phases of burn care.

The nurse who cares for a patient with a burn injury requires a high level of knowledge about the physiologic changes that occur after a burn, as well as astute assessment skills to detect subtle changes in the patient's condition. In addition, the nurse must be able to provide sensitive, compassionate care to patients who are critically ill and must initiate rehabilitation early in the course of care. The nurse must also be able to communicate effectively with burn patients, distraught family members, and members of the entire interdisciplinary burn management team. This will ensure quality care, which increases the likelihood of the patient's survival and promotes optimal quality of life.

## Incidence of Burn Injury

The incidence of burn injuries has been declining during the past several decades. Approximately 2 million people require medical attention for burn injury in the United States each year (Kao & Garner, 2000). Of this group, 51,000 require acute hospital admission. About 4,500 people die from burns and related inhalation injuries annually (American Burn Association, 2000). The risk of death increases significantly if the patient has sustained both a cutaneous burn injury and a smoke inhalation injury.

Young children and elderly people are at particularly high risk for burn injury. The skin in people in these two age groups is thin and fragile; therefore, even a limited period of contact with a source of heat can create a full-thickness burn. The National Center for Injury Prevention and Control lists "fire/burn" among the categories of the 1998 Unintentional Injuries and Adverse Effects. Chart 57-1 presents the ranking of "fire/burn" as cause of death by age group.

Most burn injuries occur in the home, usually in the kitchen while cooking and in the bathroom by means of scalds or improper use of electrical appliances around water sources (Gordon & Goodwin, 1997). Careless cooking is one of the leading causes of household fires in the United States. The U.S. Fire Administration reports that nearly one third of all residential fires begin in the kitchen. The major factors contributing to cooking fires include unattended cooking, grease, and combustible materials on the stovetop.

Burns can also occur from work-related injuries. Education to prevent burn injuries in the workplace should include safe handling

Chart  
57-1

### Ranking of "Fire/Burn" as Cause of Death by Age Group

Age	Rank
1-4	3
5-9	3
10-14	3
15-24	7
25-34	6
35-44	5
45-54	5
55-64	6
65-85+	6
All ages, all races, both sexes	7

Unintentional Injuries and Adverse Effects, from National Center for Injury Prevention and Control, 1998.

of chemicals and chemical products and increasing awareness of the potential for injuries caused by hot objects and substances. The National Institute for Burn Medicine, which collects statistical data from burn centers throughout the United States, notes that most patients (75%) are victims of their own actions. Contributing to the statistics are scalds in toddlers, school-age children playing with matches, electrical injury in teenage boys, and smoking in adults combined with the use of drugs and alcohol. One of the major culprits of burn injuries is the inappropriate use of gasoline. The U.S. Home Product Report, 1993-1997 (2000), indicated that there were over 140,000 gasoline-related fires and approximately 500 people died from gasoline-related injuries during this period.

Many burns can be prevented. Nurses can play an active role in preventing fires and burns by teaching prevention concepts and promoting legislation related to fire safety (Chart 57-2). Promoting the use of smoke alarms has had the greatest impact on decreasing fire deaths in the United States.

There are four major goals relating to burns:

1. Prevention
2. Institution of lifesaving measures for the severely burned person

## Glossary

**Alloderm:** processed dermis from human cadaver skin; can be used as dermal layer for skin grafts

**autograft:** a graft derived from one part of a patient's body and used on another part of that same patient's body

**Biobrane:** synthetic dressing composed of a nylon, Silastic membrane combined with a collagen derivative

**carboxyhemoglobin:** a compound of carbon monoxide and hemoglobin, formed in the blood with exposure to carbon monoxide

**collagen:** a protein present in skin, tendon, bone, cartilage, and connective tissue

**contracture:** shrinkage of burn scar through collagen maturation

**cultured epithelial autografts (CEA):** autologous epidermal cells that proliferate in

culture and then are regrafted onto the patient

**dermis:** the second layer of skin containing sweat glands, hair follicles, and nerves

**débridement:** removal of foreign material and devitalized tissue until surrounding healthy tissue is exposed

**donor site:** the area from which skin is taken to provide a skin graft for another part of the body

**epidermis:** the outermost layer of skin

**eschar:** devitalized tissue resulting from a burn

**escharotomy:** a linear excision made through eschar to release constriction of underlying tissue

**excision:** surgical removal of tissue

**fasciotomy:** an incision made through the fascia to release constriction of underlying muscle

**heterograft:** graft obtained from an animal of a species (ie, pigskin) other than that of the recipient; also called a xenograft

**homograft:** a graft transferred from one human (living or cadaveric) to another human; also called allograft

**hydrotherapy:** cleansing of wounds through use of bath, shower, shower cart table, or immersion

**hypertrophic scar:** excessive scar formation that rises above the level of the skin

**Integra:** synthetic dermal substitute

**rule of nines:** method for calculating body surface area burned by dividing the body into multiples of nine

Chart  
57-2**Burn Prevention Tips**

- Keep matches and lighters out of the reach of children.
- Never leave children unattended around fire or in bathroom/bath tub.
- Install and maintain smoke detectors in the home.
- Develop and practice a home exit fire drill with all members of the household.
- Set the water heater temperature no higher than 120°F.
- Do not smoke in bed. Do not fall asleep while smoking.
- Do not throw flammable liquids onto an already burning fire.
- Do not use flammable liquids to start fires.
- Do not remove radiator cap from a hot engine.
- Watch for overhead electrical wires and underground wires when working outside.
- Never store flammable liquids near a fire source, such as a pilot light.
- Use caution when cooking.
- Keep a working fire extinguisher in your home.

3. Prevention of disability and disfigurement through early, specialized, individualized treatment
4. Rehabilitation through reconstructive surgery and rehabilitative programs

## Outlook for Survival and Recovery

Great strides in research have helped to increase the survival rate of burn victims. Mortality has fallen to levels never thought possible. Hunt et al. (2000) reported that survival following large burns based on total body surface area (TBSA) appears to have leveled off. Persons older than 70 years are surviving burns of 30% TBSA; those 60 to 70 years of age, 50% TBSA; those 20 to 30 years of age, 80% TBSA; and those 2 to 5 years of age, 75% TBSA. Research in areas such as fluid resuscitation, emergent burn treatment, inhalation injury treatment, and changes in wound care practice with early **débridement** and **excision** have contributed greatly to the decrease in burn deaths. Additionally, a better understanding of the importance of adequate nutritional support has contributed to increased survival rates. Very young and very old people have a high risk of death after burn injuries due to immature and stressed immunologic systems and pre-existing medical conditions, respectively. Chances of survival are greater in children older than age 5 and in adults younger than age 40. Inhalation injuries in combination with cutaneous burns worsen the prognosis. Outcome depends on the depth and extent of the burn as well as on the pre-injury health status and age of the patient. Acute care of patients with burn injuries has improved to the point at which survival is expected for most patients, and the burn team has shifted its focus to long-term outcomes for these patients.

### Gerontologic Considerations

Reduced mobility, changes in vision, and decreased sensation in the feet and hands place elderly people at higher risk for burn injury; scalds and flames are the leading causes. These changes also place older people at risk for suffering a severe burn because they have difficulty in extinguishing the fire and removing themselves from the burn source.

Morbidity and mortality rates associated with burns are usually greater in elderly patients than in younger patients. Thinning

and loss of elasticity of the skin in the elderly predispose them to a deep injury from a thermal insult that might cause a less severe burn in a younger person. Moreover, chronic illnesses decrease the older person's ability to withstand the multisystem stresses imposed by burn injury.

An important goal of nurses in community and home settings is preventing burn injury, especially among the elderly. Nurses need to assess an elderly patient's ability to perform activities of daily living safely, assist elderly patients and families to modify the environment to ensure safety, and make referrals as needed.

## Pathophysiology of Burns

Burns are caused by a transfer of energy from a heat source to the body. Heat may be transferred through conduction or electromagnetic radiation. Burns are categorized as thermal (which includes electrical burns), radiation, or chemical. Tissue destruction results from coagulation, protein denaturation, or ionization of cellular contents. The skin and the mucosa of the upper airways are the sites of tissue destruction. Deep tissues, including the viscera, can be damaged by electrical burns or through prolonged contact with a heat source. Disruption of the skin can lead to increased fluid loss, infection, hypothermia, scarring, compromised immunity, and changes in function, appearance, and body image.

The depth of the injury depends on the temperature of the burning agent and the duration of contact with the agent. For example, in the case of scald burns in adults, 1 second of contact with hot tap water at 68.9°C (156°F) may result in a burn that destroys both the **epidermis** and the **dermis**, causing a full-thickness (third-degree) injury. Fifteen seconds of exposure to hot water at 56.1°C (133°F) results in a similar full-thickness injury. Temperatures less than 111°F are tolerated for long periods without injury.

## CLASSIFICATION OF BURNS

Burn injuries are described according to the depth of the injury and the extent of body surface area injured.

### Burn Depth

Burns are classified according to the depth of tissue destruction as superficial partial-thickness injuries, deep partial-thickness injuries, or full-thickness injuries. Burn depth determines whether epithelialization will occur. Determining burn depth can be difficult even for the experienced burn care provider. See Chapter 56 for discussion and a diagram of the skin layers; see also Table 57-1. (The categories of superficial partial-thickness, deep partial-thickness, and full-thickness burns are similar to, but not the same as, first-, second-, and third-degree burns.)

In a superficial partial-thickness burn, the epidermis is destroyed or injured and a portion of the dermis may be injured. The damaged skin may be painful and appear red and dry, as in sunburn, or it may blister.

A deep partial-thickness burn involves destruction of the epidermis and upper layers of the dermis and injury to deeper portions of the dermis. The wound is painful, appears red, and exudes fluid. Capillary refill follows tissue blanching. Hair follicles remain intact. Deep partial-thickness burns take longer to heal and are more likely to result in hypertrophic scars.

A full-thickness burn involves total destruction of epidermis and dermis and, in some cases, underlying tissue as well. Wound color ranges widely from white to red, brown, or black. The burned area

Table 57-1 • Characteristics of Burns According to Depth

DEPTH OF BURN AND CAUSES	SKIN INVOLVEMENT	SYMPTOMS	WOUND APPEARANCE	RECUPERATIVE COURSE
<b>Superficial Partial-Thickness (Similar to First Degree)</b>				
Sunburn Low-intensity flash	Epidermis; possibly a portion of dermis	Tingling Hyperesthesia (supersensitivity) Pain that is soothed by cooling	Reddened; blanches with pressure; dry Minimal or no edema Possible blisters	Complete recovery within a week; no scarring Peeling
<b>Deep Partial-Thickness (Similar to Second Degree)</b>				
Scalds Flash flame	Epidermis, upper dermis, portion of deeper dermis	Pain Hyperesthesia Sensitive to cold air	Blistered, mottled red base; broken epidermis; weeping surface Edema	Recovery in 2 to 4 weeks Some scarring and depigmentation contractures Infection may convert it to full thickness
<b>Full-Thickness (Similar to Third Degree)</b>				
Flame Prolonged exposure to hot liquids Electric current Chemical	Epidermis, entire dermis, and sometimes subcutaneous tissue; may involve connective tissue, muscle, and bone	Pain free Shock Hematuria (blood in the urine) and possibly hemolysis (blood cell destruction) Possible entrance and exit wounds (electrical burn)	Dry; pale white, leathery, or charred Broken skin with fat exposed Edema	Eschar sloughs Grafting necessary Scarring and loss of contour and function; contractures Loss of digits or extremity possible

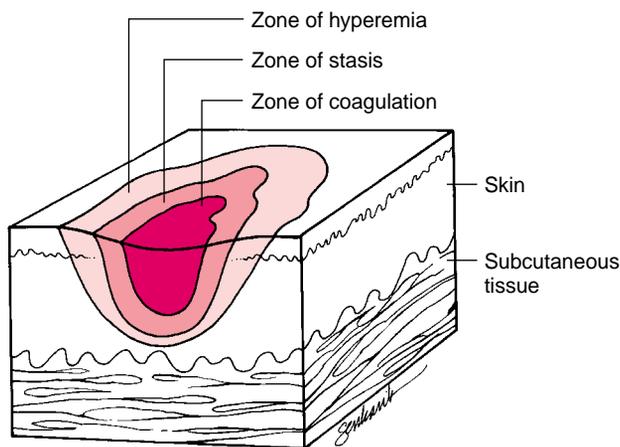

is painless because nerve fibers are destroyed. The wound appears leathery; hair follicles and sweat glands are destroyed (Fig. 57-1).

The following factors are considered in determining the depth of the burn:

- How the injury occurred
- Causative agent, such as flame or scalding liquid
- Temperature of the burning agent
- Duration of contact with the agent
- Thickness of the skin

### Extent of Body Surface Area Injured

Various methods are used to estimate the TBSA affected by burns; among them are the rule of nines, the Lund and Browder method, and the palm method.

**FIGURE 57-1** Zones of burn injury. Each burned area has three zones of injury. The inner zone (known as the area of coagulation, where cellular death occurs) sustains the most damage. The middle area, or zone of stasis, has a compromised blood supply, inflammation, and tissue injury. The outer zone—the zone of hyperemia—sustains the least damage.

### RULE OF NINES

An estimation of the TBSA involved in a burn is simplified by using the **rule of nines** (Fig. 57-2). The rule of nines is a quick way to calculate the extent of burns. The system assigns percentages in multiples of nine to major body surfaces.

### LUND AND BROWDER METHOD

A more precise method of estimating the extent of a burn is the Lund and Browder method, which recognizes that the percentage of TBSA of various anatomic parts, especially the head and legs, and changes with growth. By dividing the body into very small areas and providing an estimate of the proportion of TBSA accounted for by such body parts, one can obtain a reliable estimate of the TBSA burned. The initial evaluation is made on the patient's arrival at the hospital and is revised on the second and third post-burn days because the demarcation usually is not clear until then.

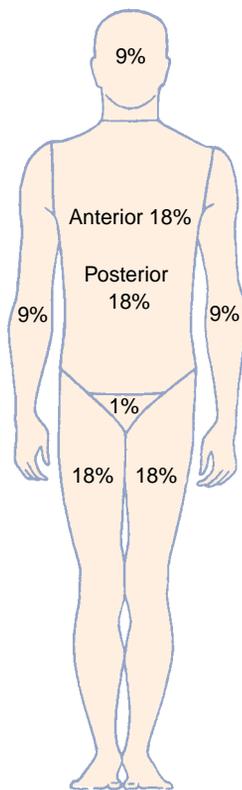

### PALM METHOD

In patients with scattered burns, a method to estimate the percentage of burn is the palm method. The size of the patient's palm is approximately 1% of TBSA.

### LOCAL AND SYSTEMIC RESPONSES TO BURNS

Burns that do not exceed 25% TBSA produce a primarily local response. Burns that exceed 25% TBSA may produce both a local and a systemic response and are considered major burn injuries. This systemic response is due to the release of cytokines and other mediators into the systemic circulation. The release of local mediators and changes in blood flow, tissue edema, and infection can cause progression of the burn injury.

Pathophysiologic changes resulting from major burns during the initial burn-shock period include tissue hypoperfusion and organ hypofunction secondary to decreased cardiac output, followed by a hyperdynamic and hypermetabolic phase. The incidence, magnitude, and duration of pathophysiologic changes in

**FIGURE 57-2** The rule of nines: Estimated percentage of total body surface area (TBSA) in the adult is arrived at by sectioning the body surface into areas with a numerical value related to nine. (Note: The anterior and posterior head total 9% of TBSA.) In burn victims, the total estimated percentage of TBSA injured is used to calculate the patient's fluid replacement needs.

burns are proportional to the extent of burn injury, with a maximal response seen in burns covering 60% or more TBSA.

The initial systemic event after a major burn injury is hemodynamic instability, resulting from loss of capillary integrity and a subsequent shift of fluid, sodium, and protein from the intravascular space into the interstitial spaces. Figure 57-3 illustrates the pathophysiologic processes in acute major burns. Hemodynamic instability involves cardiovascular, fluid and electrolyte, blood volume, pulmonary, and other mechanisms.

### Cardiovascular Response

Hypovolemia is the immediate consequence of fluid loss resulting in decreased perfusion and oxygen delivery. Cardiac output decreases before any significant change in blood volume is evident. As fluid loss continues and vascular volume decreases, cardiac output continues to fall and blood pressure drops. This is the onset of burn shock. In response, the sympathetic nervous system releases catecholamines, resulting in an increase in peripheral resistance (vasoconstriction) and an increase in pulse rate. Peripheral vasoconstriction further decreases cardiac output. Myocardial contractility may be suppressed by the release of inflammatory cytokine necrosis factor (Wolf, Prough & Herndon, 2002).

Prompt fluid resuscitation maintains the blood pressure in the low-normal range and improves cardiac output. Despite adequate fluid resuscitation, cardiac filling pressures (central venous pressure, pulmonary artery pressure, and pulmonary artery wedge pres-

sure) remain low during the burn-shock period. If inadequate fluid resuscitation occurs, distributive shock will occur (see Chap. 15).

Generally, the greatest volume of fluid leak occurs in the first 24 to 36 hours after the burn, peaking by 6 to 8 hours. As the capillaries begin to regain their integrity, burn shock resolves and fluid returns to the vascular compartment. As fluid is reabsorbed from the interstitial tissue into the vascular compartment, blood volume increases. If renal and cardiac function is adequate, urinary output increases. Diuresis continues for several days to 2 weeks.

### Burn Edema

Local swelling due to thermal injury is often extensive. Edema is defined as the presence of excessive fluid in the tissue spaces (Lund, 1999). As previously noted, in burns involving less than 25% TBSA, the loss of capillary integrity and shift of fluid are localized to the burn itself, resulting in blister formation and edema only in the area of injury. Patients with more severe burns develop massive systemic edema. Edema is usually maximal after 24 hours. It begins to resolve 1 to 2 days post-burn and usually is completely resolved in 7 to 10 days post-injury. Edema in burn wounds can be reduced by avoiding excessive fluid during the early post-burn period. Unnecessary over-resuscitation will increase edema formation in both burn tissue and non-burn tissue.

As edema increases in circumferential burns, pressure on small blood vessels and nerves in the distal extremities causes an obstruction of blood flow and consequent ischemia. This complication is known as compartment syndrome. The physician may need to perform an **escharotomy**, a surgical incision into the **eschar** (devitalized tissue resulting from a burn), to relieve the constricting effect of the burned tissue.

### Effects on Fluids, Electrolytes, and Blood Volume

Circulating blood volume decreases dramatically during burn shock. In addition, evaporative fluid loss through the burn wound may reach 3 to 5 L or more over a 24-hour period until the burn surfaces are covered.

During burn shock, serum sodium levels vary in response to fluid resuscitation. Usually hyponatremia (sodium depletion) is present. Hyponatremia is also common during the first week of the acute phase, as water shifts from the interstitial to the vascular space.

Immediately after burn injury, hyperkalemia (excessive potassium) results from massive cell destruction. Hypokalemia (potassium depletion) may occur later with fluid shifts and inadequate potassium replacement.

At the time of burn injury, some red blood cells may be destroyed and others damaged, resulting in anemia. Despite this, the hematocrit may be elevated due to plasma loss. Blood loss during surgical procedures, wound care, and diagnostic studies and ongoing hemolysis further contribute to anemia. Blood transfusions are required periodically to maintain adequate hemoglobin levels for oxygen delivery. Abnormalities in coagulation, including a decrease in platelets (thrombocytopenia) and prolonged clotting and prothrombin times, also occur with burn injury.

### Pulmonary Response

Inhalation injury is the leading cause of death in fire victims. It is estimated that half of these deaths could have been prevented with use of a smoke detector. Often, burn victims make it out of

## Physiology/Pathophysiology

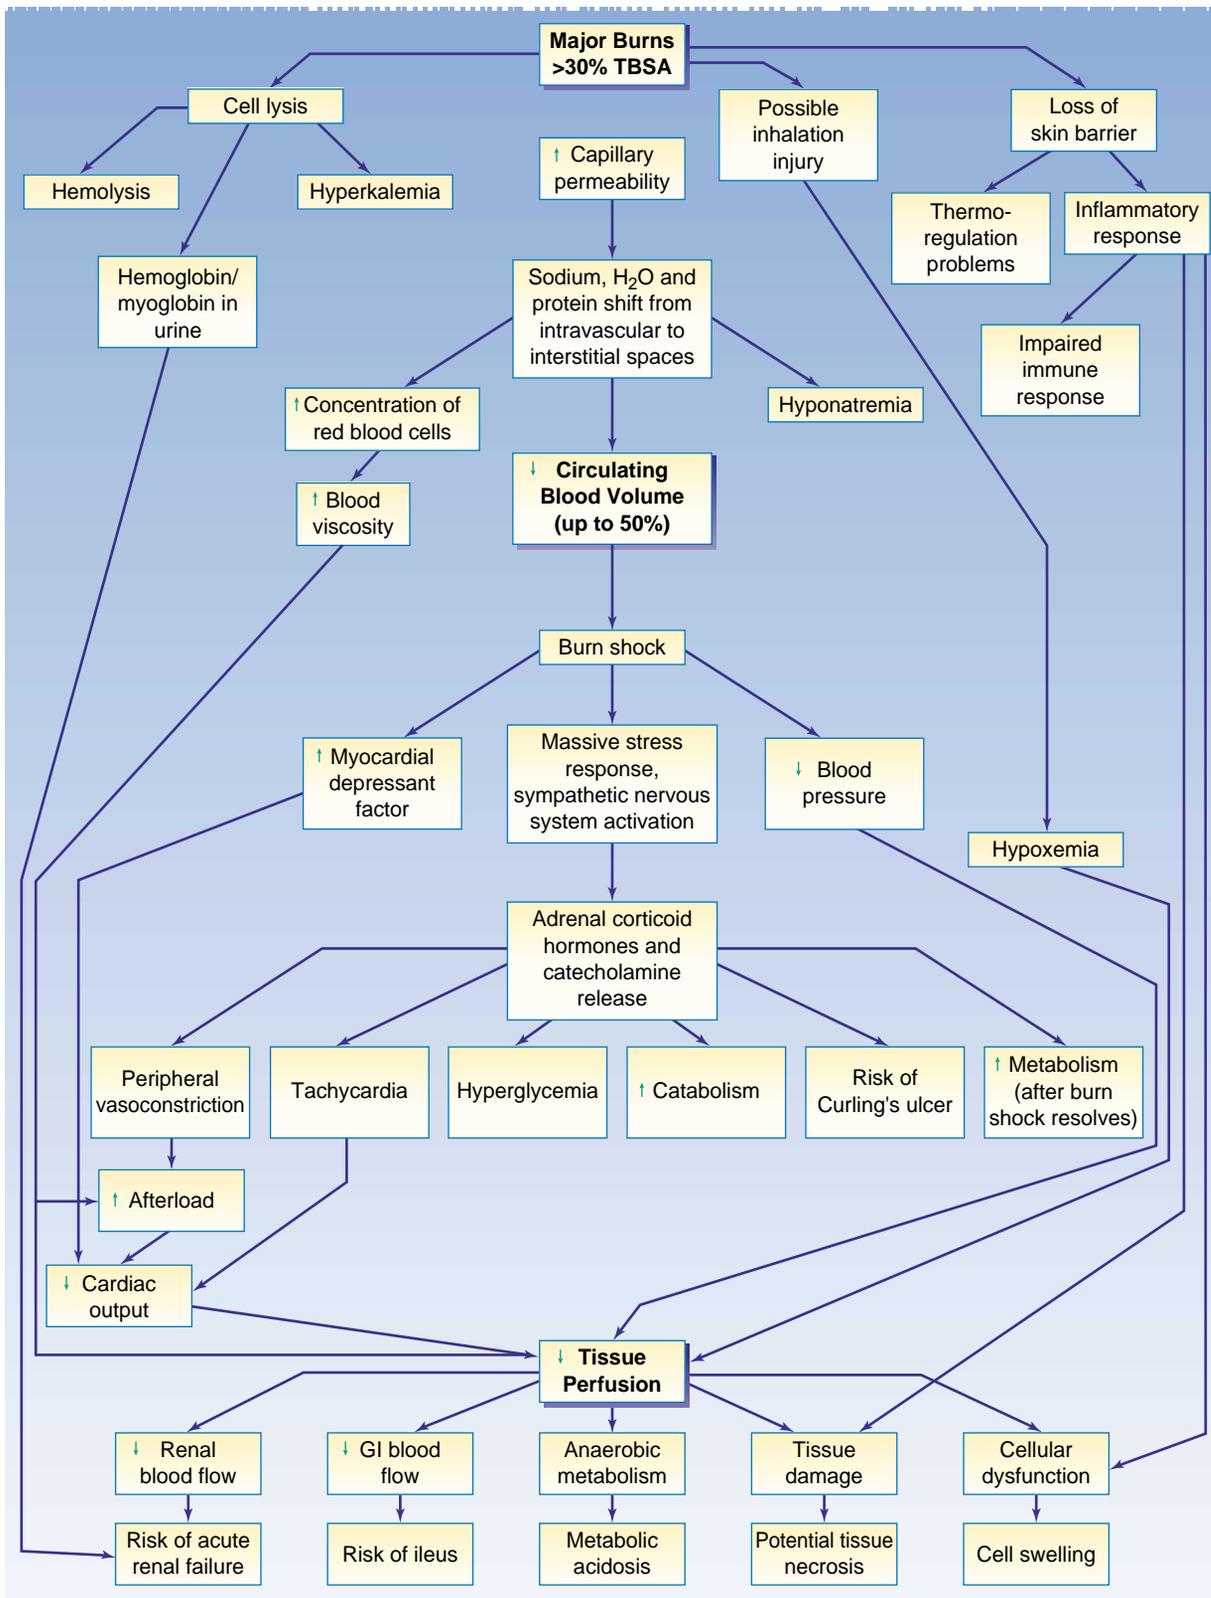

FIGURE 57-3 Overview of physiologic changes that occur after major burn.

a burning home safely. However, once they are outside, they may realize that their loved ones, pets, or valuable items are still inside the burning home. They then re-enter the burning home and are overcome with toxic smoke and fumes and become disoriented or unconscious.

Inhalation injury has a significant impact on survivability of a burn patient. Deterioration in severely burned patients can occur without evidence of a smoke inhalation injury. Bronchoconstriction caused by release of histamine, serotonin, and thromboxane, a powerful vasoconstrictor, as well as chest constriction secondary to circumferential full-thickness chest burns causes this deterioration. One third of all burn patients have a pulmonary problem related to the burn injury (Flynn, 1999). Even without pulmonary injury, hypoxia (oxygen starvation) may be present. Early in the postburn period, catecholamine release in response to the stress of the burn injury alters peripheral blood flow, thereby reducing oxygen delivery to the periphery. Later, hypermetabolism and continued catecholamine release lead to increased tissue oxygen consumption, which can lead to hypoxia. To ensure that adequate oxygen is available to the tissues, supplemental oxygen may be needed.

Pulmonary injuries fall into several categories: upper airway injury; inhalation injury below the glottis, including carbon monoxide poisoning; and restrictive defects. Upper airway injury results from direct heat or edema. It is manifested by mechanical obstruction of the upper airway, including the pharynx and larynx. Because of the cooling effect of rapid vaporization in the pulmonary tract, direct heat injury does not normally occur below the level of the bronchus. Upper airway injury is treated by early nasotracheal or endotracheal intubation.

Inhalation injury below the glottis results from inhaling the products of incomplete combustion or noxious gases. These products include carbon monoxide, sulfur oxides, nitrogen oxides, aldehydes, cyanide, ammonia, chlorine, phosgene, benzene, and halogens. The injury results directly from chemical irritation of the pulmonary tissues at the alveolar level. Inhalation injuries below the glottis cause loss of ciliary action, hypersecretion, severe mucosal edema, and possibly bronchospasm. The pulmonary surfactant is reduced, resulting in atelectasis (collapse of alveoli). Expectoration of carbon particles in the sputum is the cardinal sign of this injury.

Carbon monoxide is probably the most common cause of inhalation injury because it is a byproduct of the combustion of organic materials and is therefore present in smoke. The pathophysiologic effects are due to tissue hypoxia, a result of carbon monoxide combining with hemoglobin to form **carboxyhemoglobin**, which competes with oxygen for available hemoglobin-binding sites. The affinity of hemoglobin for carbon monoxide is 200 times greater than that for oxygen. Treatment usually consists of early intubation and mechanical ventilation with 100% oxygen. However, some patients may require only oxygen therapy, depending on the extent of pulmonary injury and edema. Administering 100% oxygen is essential to accelerate the removal of carbon monoxide from the hemoglobin molecule.

Restrictive defects arise when edema develops under full-thickness burns encircling the neck and thorax. Chest excursion may be greatly restricted, resulting in decreased tidal volume. In such situations, escharotomy is necessary.

Pulmonary abnormalities are not always immediately apparent. More than half of all burn victims with pulmonary involvement do not initially demonstrate pulmonary signs and symptoms. Any patient with possible inhalation injury must be observed for at least 24 hours for respiratory complications. Airway obstruction may

occur very rapidly or develop in hours. Decreased lung compliance, decreased arterial oxygen levels, and respiratory acidosis may occur gradually over the first 5 days after a burn.

Indicators of possible pulmonary damage include the following:

- History indicating that the burn occurred in an enclosed area
- Burns of the face or neck
- Singed nasal hair
- Hoarseness, voice change, dry cough, stridor, sooty sputum
- Bloody sputum
- Labored breathing or tachypnea (rapid breathing) and other signs of reduced oxygen levels (hypoxemia)
- Erythema and blistering of the oral or pharyngeal mucosa

Diagnosis of inhalation injury is an important priority for many burn victims. Serum carboxyhemoglobin levels and arterial blood gas levels are frequently used to assess for inhalation injuries. Bronchoscopy and xenon-133 (<sup>133</sup>Xe) ventilation-perfusion scans can also be used to aid diagnosis in the early postburn period. Pulmonary function studies may also be useful in diagnosing decreased lung compliance or obstructed airflow (Fitzpatrick & Cioffi, 2002; Flynn, 1999).

Pulmonary complications secondary to inhalation injuries include acute respiratory failure and acute respiratory distress syndrome (ARDS). Respiratory failure occurs when impairment of ventilation and gas exchange is life-threatening. The immediate intervention is intubation and mechanical ventilation. If ventilation is impaired by restricted chest excursion, immediate chest escharotomy is needed. ARDS may develop in the first few days after the burn injury secondary to systemic and pulmonary responses to the burn and inhalation injury. Respiratory failure and ARDS are discussed in Chapter 23.

## Other Systemic Responses

Renal function may be altered as a result of decreased blood volume. Destruction of red blood cells at the injury site results in free hemoglobin in the urine. If muscle damage occurs (eg, from electrical burns), myoglobin is released from the muscle cells and excreted by the kidney. Adequate fluid volume replacement restores renal blood flow, increasing the glomerular filtration rate and urine volume. If there is inadequate blood flow through the kidneys, the hemoglobin and myoglobin occlude the renal tubules, resulting in acute tubular necrosis and renal failure (see Chap. 45).

The immunologic defenses of the body are greatly altered by burn injury. Serious burn injury diminishes resistance to infection. As a result, sepsis remains the leading cause of death in thermally injured patients (Cioffi, 2001). The loss of skin integrity is compounded by the release of abnormal inflammatory factors, altered levels of immunoglobulins and serum complement, impaired neutrophil function, and a reduction in lymphocytes (lymphocytopenia). Research suggests that burn injury results in loss of T-helper cell lymphocytes (Munster, 2002). There is a significant impairment of the production and release of granulocytes and macrophages from bone marrow after burn injury. The resulting immunosuppression places the burn patient at high risk for sepsis.

Loss of skin also results in an inability to regulate body temperature. Burn patients may therefore exhibit low body temperatures in the early hours after injury. Then, as hypermetabolism resets core temperatures, burn patients become hyperthermic for much of the postburn period, even in the absence of infection.

Two potential gastrointestinal complications may occur: paralytic ileus (absence of intestinal peristalsis) and Curling's ulcer. Decreased peristalsis and bowel sounds are manifestations of paralytic ileus resulting from burn trauma. Gastric distention and nausea may lead to vomiting unless gastric decompression is initiated. Gastric bleeding secondary to massive physiologic stress may be signaled by occult blood in the stool, regurgitation of "coffee ground" material from the stomach, or bloody vomitus. These signs suggest gastric or duodenal erosion (Curling's ulcer).

## Management of the Patient With a Burn Injury

Burn care must be planned according to the burn depth and local response, the extent of the injury, and the presence of a systemic response. Burn care then proceeds through three phases: emergent/resuscitative phase, acute/intermediate phase, and rehabilitation phase. Although priorities exist for each of the phases, the phases overlap, and assessment and management of specific problems and complications are not limited to these phases but take place throughout burn care. The three phases and the priorities for care are summarized in Table 57-2.

### EMERGENT/RESUSCITATIVE PHASE OF BURN CARE

#### On-the-Scene Care

Anyone who encounters a burn victim for the first time may feel overwhelmed. The burned person's appearance can be frightening at first. It can be difficult not to get caught up with the appearance of the person and instead to concentrate on the burn wounds. However, the burn wound is not the first priority at the scene: the first priority of on-the-scene care for a burn victim is to prevent injury to the rescuer. If needed, fire and emergency medical services should be requested at the first opportunity. Additional emergency procedures are highlighted in Chart 57-3.

#### AIRWAY, BREATHING, CIRCULATION

Although the local effects of a burn are the most evident, the systemic effects pose a greater threat to life. Therefore, it is important to remember the ABCs of all trauma care during the early postburn period:

- Airway
- Breathing
- Circulation; cervical spine immobilization for patients with high-voltage electrical injuries and if indicated for other injuries; cardiac monitoring for patients with all electrical injuries for at least 24 hours after cessation of dysrhythmia

Some practitioners include "DEF" in the trauma assessment: disability, exposure, and fluid resuscitation (Weibelhaus & Hansen, 2001).

**NURSING ALERT** Breathing must be assessed and a patent airway established immediately during the initial minutes of emergency care. Immediate therapy is directed toward establishing an airway and administering humidified 100% oxygen. If such a high concentration of oxygen is not available under emergency conditions, oxygen by mask or nasal cannula is given initially. If qualified personnel and equipment are available and if the victim has severe respiratory distress or airway edema, the rescuers can insert an endotracheal tube and initiate manual ventilation.

The circulatory system must also be assessed quickly. Apical pulse and blood pressure are monitored frequently. Tachycardia (abnormally rapid heart rate) and slight hypotension are expected soon after the burn. The neurologic status is assessed quickly in the patient with extensive burns. Often the burn patient is awake and alert initially, and vital information can be obtained at that time. A secondary head-to-toe survey of the patient is carried out to identify other potentially life-threatening injuries. (The E and F parameters of trauma assessment are discussed in detail later.) Preventing shock in a burn patient is imperative.

**NURSING ALERT** No food or fluid is given by mouth, and the patient is placed in a position that will prevent aspiration of vomitus because nausea and vomiting typically occur due to paralytic ileus resulting from the stress of injury.

Usually, rescue workers will cool the wound, establish an airway, supply oxygen, and insert at least one large-bore intravenous line.

Table 57-2 • Phases of Burn Care

PHASE	DURATION	PRIORITIES
Emergent or immediate resuscitative	From onset of injury to completion of fluid resuscitation	<ul style="list-style-type: none"> <li>• First aid</li> <li>• Prevention of shock</li> <li>• Prevention of respiratory distress</li> <li>• Detection and treatment of concomitant injuries</li> <li>• Wound assessment and initial care</li> </ul>

## Emergency Procedures at the Burn Scene

- **Extinguish the flames.** When clothes catch fire, the flames can be extinguished if the victim falls to the floor or ground and rolls (“drop and roll”); anything available to smother the flames, such as a blanket, rug, or coat, may be used. Standing still forces the victim to breathe flames and smoke, and running fans the flames. If the burn source is electrical, the electrical source must be disconnected.
- **Cool the burn.** After the flames are extinguished, the burned area and adherent clothing are soaked with *cool* water, briefly, to cool the wound and halt the burning process. Once a burn has been sustained, the application of cool water is the best first-aid measure. Soaking the burn area intermittently in cool water or applying cool towels gives immediate and striking relief from pain and limits local tissue edema and damage. However, *never* apply ice directly to the burn, *never* wrap burn victims in ice, and *never* use cold soaks or dressings for longer than several minutes; such procedures may worsen the tissue damage and lead to hypothermia in patients with large burns.
- **Remove restrictive objects.** If possible, remove clothing immediately. Adherent clothing may be left in place once cooled. Other clothing and all jewelry should be removed to allow for assessment and to prevent constriction secondary to rapidly developing edema.
- **Cover the wound.** The burn should be covered as quickly as possible to minimize bacterial contamination and decrease pain by preventing air from coming into contact with the injured surface. Sterile dressings are best, but any clean, dry cloth can be used as an emergency dressing. Ointments and salves should *not* be used. Other than the dressing, no medication or material should be applied to the burn wound.
- **Irrigate chemical burns.** Chemical burns resulting from contact with a corrosive material are irrigated immediately. Most chemical laboratories have a high-pressure shower for such emergencies. If such an injury occurs at home, brush off the chemical agent, remove clothes immediately, and rinse all areas of the body that have come in contact with the chemical. Rinsing can occur in the shower or any other source of continuous running water. If a chemical gets in or near the eyes, the eyes should be flushed with cool, clean water immediately. Outcomes for the patient with chemical burns are significantly improved by rapid, sustained flushing of the injury at the scene.

## Emergency Medical Management

The patient is transported to the nearest emergency department. The hospital and physician are alerted that the patient is en route to the emergency department so that life-saving measures can be initiated immediately by a trained team.

Initial priorities in the emergency department remain airway, breathing, and circulation. For mild pulmonary injury, inspired air is humidified and the patient is encouraged to cough so that secretions can be removed by suctioning. For more severe situations, it is necessary to remove secretions by bronchial suctioning and to administer bronchodilators and mucolytic agents. If edema of the airway develops, endotracheal intubation may be necessary. Continuous positive airway pressure and mechanical ventilation may also be required to achieve adequate oxygenation.

After adequate respiratory status and circulatory status have been established, the patient is assessed for cervical spinal injuries or head injury if the patient was involved in an explosion, a fall, a jump, or an electrical injury. Once the patient’s condition is stable, attention is directed to the burn wound itself. All clothing and jewelry are removed. For chemical burns, flushing of the exposed areas is continued. The patient is checked for contact lenses. These are removed immediately if chemicals have contacted the eyes or if facial burns have occurred.

It is important to validate an account of the burn scenario provided by the patient, witnesses at the scene, and paramedics. Information needs to include time of the burn injury, source of the burn, place where the burn occurred, how the burn was treated at the scene, and any history of falling with the injury. A history of preexisting diseases, allergies, and medications and the use of drugs, alcohol, and tobacco is obtained at this point to plan care. A large-bore (16- or 18-gauge) intravenous catheter should be inserted in a non-burned area (if not inserted earlier). Most patients have a central venous catheter inserted so that large amounts of intravenous fluids can be given quickly and central venous pressures can be monitored. If the burn exceeds 25% TBSA or if the patient is nauseated, a nasogastric tube should be inserted and connected to suction to prevent vomiting due to paralytic ileus (absence of peristalsis).

The physician evaluates the patient’s general condition, assesses the burn, determines the priorities of care, and directs the individualized plan of treatment, which is divided into systemic management and local care of the burned area. Nonsterile gloves, caps, and gowns are worn by personnel while assessing the exposed burned areas. Clean technique is maintained while assessing burn wounds.

Assessment of both the TBSA burned and the depth of the burn is completed after soot and debris have been gently cleansed from the burn wound. Careful attention is paid to keeping the burn patient warm during wound assessment and cleansing. Assessment is repeated frequently throughout burn wound care. Photographs may be taken of the burn areas initially and periodically throughout treatment; in this way, the initial injury and burn wound can be documented. Such documentation is invaluable for insurance and legal claims. Clean sheets are placed under and over the patient to protect the area from contamination, maintain body temperature, and reduce pain caused by air currents passing over exposed nerve endings.

An indwelling urinary catheter is inserted to permit more accurate monitoring of urine output and renal function for patients with moderate to severe burns. Baseline height, weight, arterial blood gases, hematocrit, electrolyte values, blood alcohol level, drug panel, urinalysis, and chest x-rays are obtained. If the patient is elderly or has an electrical burn, a baseline electrocardiogram is obtained. Because burns are contaminated wounds, tetanus prophylaxis is administered if the patient’s immunization status is not current or is unknown.

Although the major focus of care during the emergent phase is physical stabilization, the nurse must also attend to the patient’s and family’s psychological needs. Burn injury is a crisis, causing variable emotional responses. The patient’s and family’s coping abilities and available supports are assessed. Circumstances surrounding the burn injury should be considered when providing care. Individualized psychosocial support must be given to the patient and family. Because the emergent burn patient is usually anxious and in pain, those in attendance should provide reassurance and support, explanations of procedures, and adequate pain relief. Because poor tissue perfusion accompanies burn injuries,

only intravenous pain medication (usually morphine) is given, titrated for the patient. If the patient wishes to see a spiritual advisor, one is notified.

### TRANSFER TO A BURN CENTER

The depth and extent of the burn are considered in determining whether the patient should be transferred to a burn center. Patients with major burns, those who are at the extremes of the age continuum, those with coexisting health problems that may affect recovery, and those with circumstances that increase their risk for acute and long-term complications are transferred to a burn center. Chart 57-4 lists the American Burn Association's criteria for burn center referral after initial assessment and management.

If the patient is to be transported to a burn center, the following measures are instituted before transfer:

- A secure intravenous catheter is inserted with lactated Ringer's solution infusing at the rate required to maintain a urine output of at least 30 mL per hour.
- A patent airway is ensured.
- Adequate pain relief is attained.
- Adequate peripheral circulation is established in any burned extremity.
- Wounds are covered with a clean, dry sheet, and the patient is kept comfortably warm.

All assessments and treatments are documented, and this information is provided to the burn center personnel. The transferring facility must relay accurate intake and output totals to burn center personnel so that adequate fluid resuscitation measures continue.

Chart  
57-4

### Criteria for Classifying the Extent of Burn Injury (American Burn Association)

#### Minor Burn Injury

- Second-degree burn of less than 15% total body surface area (TBSA) in adults or less than 10% TBSA in children
- Third-degree burn of less than 2% TBSA not involving special care areas (eyes, ears, face, hands, feet, perineum, joints)
- Excludes electrical injury, inhalation injury, concurrent trauma, all poor-risk patients (eg, extremes of age, concurrent disease)

#### Moderate, Uncomplicated Burn Injury

- Second-degree burns of 15%–25% TBSA in adults or 10%–20% in children
- Third-degree burns of less than 10% TBSA not involving special care areas
- Excludes electrical injury, inhalation injury, concurrent trauma, all poor-risk patients (eg, extremes of age, concurrent disease)

#### Major Burn Injury

- Second-degree burns exceeding 25% TBSA in adults or 20% in children
- All third-degree burns exceeding 10% TBSA
- All burns involving eyes, ears, face, hands, feet, perineum, joints
- All inhalation injury, electrical injury, concurrent trauma, all poor-risk patients

### MANAGEMENT OF FLUID LOSS AND SHOCK

Next to handling respiratory difficulties, the most urgent need is preventing irreversible shock by replacing lost fluids and electrolytes. As mentioned previously, survival of burn victims depends on adequate fluid resuscitation. Table 57-3 summarizes the fluid and electrolyte changes in the emergent phase of burn care. Intravenous lines and an indwelling catheter must be in place before implementing fluid resuscitation. Baseline weight and laboratory test results are obtained as well. These parameters must be monitored closely in the immediate post-burn (resuscitation) period. Controversy continues regarding the definition of adequate resuscitation and the optimal fluid type for resuscitation. Refinement of resuscitation techniques remains an active area of burn research.

**Fluid Replacement Therapy.** The total volume and rate of intravenous fluid replacement are gauged by the patient's response. The adequacy of fluid resuscitation is determined by following urine output totals, an index of renal perfusion. Output totals of 30 to 50 mL/hour have been used as goals. Other indicators of adequate fluid replacement are a systolic blood pressure exceeding 100 mm Hg and/or a pulse rate less than 110/minute.

**NURSING ALERT** Clinical parameters are far more important in resuscitation than any formula. Indeed, the patient's individual response is the key to assessing the adequacy of fluid resuscitation.

Additional gauges of fluid requirements and response to fluid resuscitation include hematocrit and hemoglobin and serum sodium levels. If the hematocrit and the hemoglobin levels decrease or if the urinary output exceeds 50 mL/hour, the rate of intravenous fluid administration may be decreased. The goal is to maintain serum sodium levels in the normal range during fluid replacement.

Appropriate resuscitation endpoints for burn patients remain controversial. Research in this area has led to the study of hemodynamic and oxygen transport resuscitation endpoints. When these endpoints were used, massive fluid resuscitation volumes were administered that could have deleterious effects. Successful resuscitation is associated with increased delivery of oxygen and consumption of oxygen with declining serum lactate levels (Holm et al., 2000). Attention has been directed recently toward other indicators of adequate resuscitation: base deficit and serum lactate levels. Measurement of serum lactate levels does not appear useful in the treatment of burn patients because of the large amounts of lactate released from burned tissue; however, metabolism of lactate is unaltered. Elevated levels occur despite adequate fluid resuscitation (Yowler & Fratianne, 2000). Factors that are associated with the increased fluid requirements include delayed resuscitation, scald burn injuries, inhalation injuries, high-voltage electrical injuries, hyperglycemia, alcohol intoxication, and chronic diuretic therapy. Second 24-hour post-burn fluid infusion rates incorporate both the maintenance amount of fluid and any additional fluid needs secondary to evaporative water loss through the burn wound.

**Fluid Requirements.** The projected fluid requirements for the first 24 hours are calculated by the clinician based on the extent of the burn injury. Some combination of fluid categories may be used: colloids (whole blood, plasma, and plasma expanders) and crystalloids/electrolytes (physiologic sodium chloride or lactated

**Table 57-3 • Fluid and Electrolyte Changes in the Emergent/Resuscitative Phase**

Fluid accumulation phase (shock phase)  
Plasma → interstitial fluid (edema at burn site)

OBSERVATION	EXPLANATION
Generalized dehydration	Plasma leaks through damaged capillaries.
Reduction of blood volume	Secondary to plasma loss, fall of blood pressure, and diminished cardiac output
Decreased urinary output	Secondary to: Fluid loss Decreased renal blood flow Sodium and water retention caused by increased adrenocortical activity (Hemolysis of red blood cells, causing hemoglobinuria and myonecrosis or myoglobinuria)
Potassium (K <sup>+</sup> ) excess	Massive cellular trauma causes release of K <sup>+</sup> into extracellular fluid (ordinarily, most K <sup>+</sup> is intracellular).
Sodium (Na <sup>+</sup> ) deficit	Large amount of Na <sup>+</sup> is lost in trapped edema fluid and exudate and by shift into cells as K <sup>+</sup> is released from cells (ordinarily most Na <sup>+</sup> is extracellular).
Metabolic acidosis (base-bicarbonate deficit)	Loss of bicarbonate ions accompanies sodium loss.
Hemoconcentration (elevated hematocrit)	Liquid blood component is lost into extravascular space.

Ringer's solution). Adequate fluid resuscitation results in slightly decreased blood volume levels during the first 24 post-burn hours and restores plasma levels to normal by the end of 48 hours. Oral resuscitation can be successful in adults with less than 20% TBSA and children with less than 10% to 15% TBSA.

Formulas have been developed for estimating fluid loss based on the estimated percentage of burned TBSA and the weight of the patient. Length of time since burn injury occurred is also very important in calculating estimated fluid needs. Formulas must be adjusted so that initiation of fluid replacement reflects the time of injury. Resuscitation formulas are approximations only and are individualized to meet the requirements of each patient. The various formulas are discussed below and summarized in Chart 57-5.

As early as 1978, the NIH Consensus Development Conference on Supportive Therapy in Burn Care established that salt and water are required in burn patients, but that colloid may or may not be useful during the first 24 to 48 post-burn hours. The consensus formula provides for the volume of balanced salt solution to be administered in the first 24 hours in a range of 2 to 4 mL/kg per percent burn. In general, 2 mL/kg per percent burn of lactated Ringer's solution may be used initially for adults. This is the most common fluid replacement formula in use today. As with the other formulas, half of the calculated total should be given over the first 8 post-burn hours, and the other half should be given over the next 16 hours. The rate and volume of the infusion must be regulated according to the patient's response by changing the

Chart  
57-5

### Guidelines and Formulas for Fluid Replacement in Burn Patients

#### Consensus Formula

Lactated Ringer's solution (or other balanced saline solution): 2–4 mL × kg body weight × % total body surface area (TBSA) burned. Half to be given in first 8 hours; remaining half to be given over next 16 hours.

#### Evans Formula

- Colloids: 1 mL × kg body weight × % TBSA burned
- Electrolytes (saline): 1 mL × body weight × % TBSA burned
- Glucose (5% in water): 2,000 mL for insensible loss

Day 1: Half to be given in first 8 hours; remaining half over next 16 hours  
Day 2: Half of previous day's colloids and electrolytes; all of insensible fluid replacement  
Maximum of 10,000 mL over 24 hours. Second- and third-degree (partial- and full-thickness) burns exceeding 50% TBSA are calculated on the basis of 50% TBSA.

#### Brooke Army Formula

- Colloids: 0.5 mL × kg body weight × % TBSA burned
- Electrolytes (lactated Ringer's solution): 1.5 mL × kg body weight × % TBSA burned
- Glucose (5% in water): 2,000 mL for insensible loss

Day 1: Half to be given in first 8 hours; remaining half over next 16 hours

Day 2: Half of colloids; half of electrolytes; all of insensible fluid replacement.

Second- and third-degree (partial- and full-thickness) burns exceeding 50% TBSA are calculated on the basis of 50% TBSA.

#### Parkland/Baxter Formula

Lactated Ringer's solution: 4 mL × kg body weight × % TBSA burned  
Day 1: Half to be given in first 8 hours; half to be given over next 16 hours

Day 2: Varies. Colloid is added.

#### Hypertonic Saline Solution

Concentrated solutions of sodium chloride (NaCl) and lactate with concentration of 250–300 mEq of sodium per liter, administered at a rate sufficient to maintain a desired volume of urinary output. Do not increase the infusion rate during the first 8 postburn hours. Serum sodium levels must be monitored closely. Goal: Increase serum sodium level and osmolality to reduce edema and prevent pulmonary complications.

hourly infusion rates. Fluid boluses are recommended only in the presence of marked hypotension, not low urine output. Typical fluid rate changes should involve an increase or decrease in flow rate by no more than 25% to 33% (Yowler & Fratianna, 2000).

Studies demonstrate that with large burns, there is a failure of the sodium-potassium pump (a physiologic mechanism involved in fluid–electrolyte balance) at the cellular level. Thus, patients with very large burns may need proportionately more milliliters of fluid per percent of burn than those with smaller burns. Also, patients with electrical injury, pulmonary injury, and delayed fluid resuscitation and those who were burned while intoxicated may need additional fluids.

The following example illustrates use of the formula in a 70-kg (168-lb) patient with a 50% TBSA burn:

1. Consensus formula: 2 to 4 mL/kg/% TBSA
2.  $2 \times 70 \times 50 = 7,000$  mL/24 hours
3. Plan to administer: First 8 hours = 3,500 mL, or 437 mL/hour; next 16 hours = 3,500 mL, or 219 mL/hour

Most fluid replacement formulas use isotonic electrolyte solutions. Regardless of which standard replacement formula is used, the patient receives approximately the same fluid volume and sodium replacement during the first 48 hours.

Another fluid replacement method requires hypertonic electrolyte solutions. This method uses concentrated solutions of sodium chloride and lactate (a balanced salt solution) so that the resulting fluid has a concentration of 250 to 300 mEq of sodium. The rationale for this replacement method is that by increasing serum osmolality, fluid will be pulled back into the vascular space from the interstitial space. Reduced systemic and pulmonary edema has been reported after administering hypertonic solutions.

**NURSING ALERT** Formulas are only a guide. The patient's response, evidenced by heart rate, blood pressure, and urine output, is the primary determinant of actual fluid therapy and must be assessed at least hourly. Patient outcomes are improved by optimal fluid resuscitation.

### Gerontologic Considerations

Decreased function of the cardiovascular, renal, and pulmonary systems increases the need for close observation of elderly patients with even relatively minor burns during the emergent and acute phases. Acute renal failure is much more common in elderly patients than in those younger than age 40. The margin of difference between hypovolemia and fluid overload is very small. Suppressed immunologic response, a high incidence of malnutrition, and an inability to withstand metabolic stressors (eg, a cold environment) further compromise the elderly person's ability to heal. As a result of these issues in elderly patients who sustain burn injury, close monitoring and prompt treatment of complications are mandatory.

### Nursing Management: Emergent/Resuscitative Phase

Assessment data obtained by prehospital providers (rescuers such as emergency medical technicians) are shared with the physician and nurse in the emergency department. Nursing assessment in the emergent phase of burn injury focuses on the major priorities for any trauma patient; the burn wound is a secondary consider-

ation. Aseptic management of the burn wounds and invasive lines continues.

The nurse monitors vital signs frequently. Respiratory status is monitored closely, and apical, carotid, and femoral pulses are evaluated. Cardiac monitoring is indicated if the patient has a history of cardiac disease, electrical injury, or respiratory problems, or if the pulse is dysrhythmic or the rate is abnormally slow or rapid.

If all extremities are burned, determining blood pressure may be difficult. A sterile dressing applied under the blood pressure cuff will protect the wound from contamination. Because increasing edema makes blood pressure difficult to auscultate, a Doppler (ultrasound) device or a noninvasive electronic blood pressure device may be helpful. In severe burns, an arterial catheter is used for blood pressure measurement and for collecting blood specimens. Peripheral pulses of burned extremities are checked hourly; the Doppler device is useful for this. Elevation of burned extremities is crucial to decrease edema. Elevation of the lower extremities on pillows and of the upper extremities on pillows or by suspension using intravenous poles may be helpful.

Large-bore intravenous catheters and an indwelling urinary catheter are inserted, and the nurse's assessment includes monitoring fluid intake and output. Urine output, an indicator of renal perfusion, is monitored carefully and measured hourly. The amount of urine first obtained when the urinary catheter was inserted is recorded. This may assist in determining the extent of preburn renal function and fluid status. Urine specific gravity, pH, and glucose, acetone, protein, and hemoglobin levels are assessed frequently.

Burgundy-colored urine suggests the presence of hemochromogen and myoglobin resulting from muscle damage. This is associated with deep burns caused by electrical injury or prolonged contact with flames. Glucosuria, a common finding in the early postburn hours, results from the release of stored glucose from the liver in response to stress.

Although not responsible for calculating the patient's fluid requirements, the nurse needs to know the maximum volume of fluid the patient should receive. Infusion pumps and rate controllers are used to deliver a complex regimen of prescribed intravenous fluids. Administering and monitoring intravenous therapy are major nursing responsibilities.

Body temperature, body weight, preburn weight, and history of allergies, tetanus immunization, past medical and surgical problems, current illnesses, and use of medications are assessed. A head-to-toe assessment is performed, focusing on signs and symptoms of concomitant illness, injury, or developing complications. Patients with facial burns should have their eyes examined for potential injury to the corneas. An ophthalmologist is consulted for complete assessment via fluorescent staining.

Assessing the extent of the burn wound continues and is facilitated with anatomic diagrams (described previously). In addition, the nurse works with the physician to assess the depth of the wound and areas of full- and partial-thickness injury. Assessment of the circumstances surrounding the injury is important. Obtaining a history of the burn injury can help to plan the care for the patient. Assessment should include the time of injury, mechanism of burn, whether the burn occurred in a closed space, the possibility of inhalation of noxious chemicals, and any related trauma.

The neurologic assessment focuses on the patient's level of consciousness, psychological status, pain and anxiety levels, and behavior. The patient's and family's understanding of the injury and treatment is assessed as well.

Nursing care of the patient during the emergent/resuscitative phase of burn injury is detailed in the Plan of Nursing Care.

*(text continues on page 1718)*

## Plan of Nursing Care

### Care of the Patient During the Emergent/Resuscitative Phase of Burn Injury

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Impaired gas exchange related to carbon monoxide poisoning, smoke inhalation, and upper airway obstruction

**Goal:** Maintenance of adequate tissue oxygenation

- |   |  |   |
|---|--|---|
| <ol style="list-style-type: none"> <li>1. Provide humidified oxygen.</li> <li>2. Assess breath sounds, and respiratory rate, rhythm, depth, and symmetry. Monitor patient for signs of hypoxia.</li> <li>3. Observe for the following:               <ol style="list-style-type: none"> <li>a. Erythema or blistering of lips or buccal mucosa</li> <li>b. (continued)

## Plan of Nursing Care

### Care of the Patient During the Emergent/Resuscitative Phase of Burn Injury (Continued)

Nursing Interventions	Rationale	Expected Outcomes
3. Maintain IV lines and regulate fluids at appropriate rates, as prescribed.	3. Adequate fluids are necessary to maintain fluid and electrolyte balance and perfusion of vital organs.	
4. Observe for symptoms of deficiency or excess of serum sodium, potassium, calcium, phosphorus, and bicarbonate.	4. Rapid shifts in fluid and electrolyte status are possible in the postburn period.	
5. Elevate head of patient's bed and elevate burned extremities.	5. Elevation promotes venous return.	
6. Notify physician immediately of decreased urine output, blood pressure, central venous, pulmonary artery, or pulmonary artery wedge pressures, or increased pulse rate.	6. Because of the rapid fluid shifts in burn shock, fluid deficit must be detected early so that distributive shock does not occur.	

**Nursing Diagnosis:** Hypothermia related to loss of skin microcirculation and open wounds

**Goal:** Maintenance of adequate body temperature

1. Provide a warm environment through use of heat shield, space blanket, heat lights, or blankets.	1. A stable environment minimizes evaporative heat loss.	<ul style="list-style-type: none"> <li>• Body temperature remains 36.1° to 38.3°C (97° to 101°F)</li> <li>• Absence of chills or shivering</li> </ul>
2. Work quickly when wounds must be exposed.	2. Minimal exposure minimizes heat loss from wound.	
3. Assess core body temperature frequently.	3. Frequent temperature assessments help detect developing hypothermia.	

**Nursing Diagnosis:** Pain related to tissue and nerve injury and emotional impact of injury

**Goal:** Control of pain

1. Use pain intensity scale to assess pain level (ie, 1 to 10). Differentiate from hypoxia.	1. Pain level provides baseline for evaluating effectiveness of pain relief measures. Hypoxia can cause similar signs and must be ruled out before analgesic medication is administered.	<ul style="list-style-type: none"> <li>• States pain level is decreased</li> <li>• Absence of nonverbal cues of pain</li> </ul>
2. Administer intravenous opioid analgesics as prescribed. Observe for respiratory depression in the patient who is not mechanically ventilated. Assess response to analgesic.	2. Intravenous administration is necessary because of altered tissue perfusion from burn injury.	
3. Provide emotional support and reassurance.	3. Emotional support is essential to reduce fear and anxiety resulting from burn injury. Fear and anxiety increase the perception of pain.	

**Nursing Diagnosis:** Anxiety related to fear and the emotional impact of burn injury

**Goal:** Minimization of patient's and family's anxiety

1. Assess patient's and family's understanding of burn injury, coping skills, and family dynamics.	1. Previous successful coping strategies can be fostered for use in the present crisis. Assessment allows planning of individualized interventions.	<ul style="list-style-type: none"> <li>• Patient and family verbalize understanding of emergent burn care</li> <li>• Able to answer simple questions</li> </ul>
2. Individualize responses to the patient's and family's coping level.	2. Reactions to burn injury are extremely variable. Interventions must be appropriate to the patient's and family's present level of coping.	
3. Explain all procedures to the patient and the family in clear, simple terms.	3. Increased understanding alleviates fear of the unknown. High levels of anxiety may interfere with understanding of complex explanations.	

(continued)

## Plan of Nursing Care

### Care of the Patient During the Emergent/Resuscitative Phase of Burn Injury (Continued)

#### Nursing Interventions

- Maintain adequate pain relief.
- Consider administering prescribed anti-anxiety medications if the patient remains extremely anxious despite nonpharmacologic interventions.

#### Rationale

- Pain increases anxiety.
- Anxiety levels during the emergent phase may exceed the patient's coping abilities. Medication decreases physiologic and psychological anxiety responses.

#### Expected Outcomes

**Collaborative Problems:** Acute respiratory failure, distributive shock, acute renal failure, compartment syndrome, paralytic ileus, Curling's ulcer

**Goal:** Absence of complications

#### Acute Respiratory Failure

- Assess for increasing dyspnea, stridor, changes in respiratory patterns.
- Monitor pulse oximetry, arterial blood gas values for decreasing PO<sub>2</sub> and oxygen saturation, and increasing PCO<sub>2</sub>.
- Monitor chest x-ray results.
- Assess for restlessness, confusion, difficulty attending to questions, or decreasing level of consciousness.
- Report deteriorating respiratory status immediately to physician.
- Prepare to assist with intubation or escharotomies as indicated.

- Such signs reflect deteriorating respiratory status.
- Such signs reflect decreased oxygenation status.
- X-ray may disclose pulmonary injury.
- Such manifestations may indicate cerebral hypoxia.
- Acute respiratory failure is life-threatening, and immediate intervention is required.
- Intubation allows mechanical ventilation. Escharotomies allow improved chest excursion with respirations.

- Arterial blood gas values within acceptable limits: PO<sub>2</sub> >80 mm Hg, PCO<sub>2</sub> <50 mm Hg
- Breathes spontaneously with adequate tidal volume
- Chest x-ray findings normal
- Absence of cerebral signs of hypoxia

#### Distributive Shock

- Assess for decreasing urine output, pulmonary artery and pulmonary artery wedge pressures, blood pressure, and cardiac output, or increasing pulse.
- Assess for progressive edema as fluid shifts occur.
- Adjust fluid resuscitation in collaboration with the physician in response to physiologic findings.

- Such signs and symptoms may indicate distributive shock and inadequate intravascular volume.
- As fluid shifts into the interstitial spaces in burn shock, edema occurs and may compromise tissue perfusion.
- Optimal fluid resuscitation prevents distributive shock and improves patient outcomes.

- Urine output between 0.5 and 1.0 mL/kg/hr
- Blood pressure within patient's normal range (usually >90/60 mm Hg)
- Heart rate within patient's normal range (usually <110/min)
- Pressures and cardiac output remain within normal limits

#### Acute Renal Failure

- Monitor urine output and blood urea nitrogen (BUN) and creatinine levels.
- Report decreased urine output or increased BUN and creatinine values to physician.
- Assess urine for hemoglobin or myoglobin.
- Administer increased fluids as prescribed.

- These values reflect renal function.
- These laboratory values indicate possible renal failure.
- Hemoglobin or myoglobin in the urine points to an increased risk of renal failure.
- Fluids help to flush out hemoglobin and myoglobin from renal tubules, decreasing the potential for renal failure.

- Adequate urine output
- BUN and creatinine values remain normal

#### Compartment Syndrome

- Assess peripheral pulses hourly with Doppler ultrasound device.
- Assess warmth, capillary refill, sensation, and movement of extremity hourly. Compare affected with unaffected extremity.

- Assessment with Doppler device substitutes for auscultation and indicates characteristics of arterial blood flow.
- These assessments indicate characteristics of peripheral perfusion.

- Absence of paresthesias or symptoms of ischemia of nerves and muscles
- Peripheral pulses detectable by Doppler

(continued)

## Plan of Nursing Care

### Care of the Patient During the Emergent/Resuscitative Phase of Burn Injury (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> <li>Remove blood pressure cuff after each reading.</li> <li>Elevate burned extremities.</li> <li>Report loss of pulse or sensation or presence of pain to physician immediately.</li> <li>Prepare to assist with escharotomies.</li> </ol>	<ol style="list-style-type: none"> <li>Cuff may act as a tourniquet as extremities swell.</li> <li>Elevation reduces edema formation.</li> <li>These signs and symptoms may indicate inadequate tissue perfusion.</li> <li>Escharotomies relieve the constriction caused by swelling under circumferential burns and improve tissue perfusion.</li> </ol>	
<p><b>Paralytic Ileus</b></p> <ol style="list-style-type: none"> <li>Maintain nasogastric tube on low intermittent suction until bowel sounds resume.</li> <li>Auscultate for bowel sounds, abdominal distention.</li> </ol>	<ol style="list-style-type: none"> <li>This measure relieves gastric and abdominal distention, also prevents vomiting.</li> <li>As bowel sounds resume, feeding may be slowly initiated. Abdominal distention reflects inadequate decompression.</li> </ol>	<ul style="list-style-type: none"> <li>Absence of abdominal distention</li> <li>Normal bowel sounds within 48 hours</li> </ul>
<p><b>Curling's Ulcer</b></p> <ol style="list-style-type: none"> <li>Assess gastric aspirate for pH and blood.</li> <li>Assess stools for occult blood.</li> <li>Administer histamine blockers and antacids as prescribed.</li> </ol>	<ol style="list-style-type: none"> <li>Acidic pH indicates need for antacids or histamine blockers. Blood indicates possible gastric bleeding.</li> <li>Blood in stools may indicate gastric or duodenal ulcer.</li> <li>Such medications reduce gastric acidity and risk of ulceration.</li> </ol>	<ul style="list-style-type: none"> <li>Absence of abdominal distention</li> <li>Normal bowel sounds within 48 hours</li> <li>Gastric aspirate and stools do not contain blood</li> </ul>

## ACUTE OR INTERMEDIATE PHASE OF BURN CARE

The acute or intermediate phase of burn care follows the emergent/resuscitative phase and begins 48 to 72 hours after the burn injury. During this phase, attention is directed toward continued assessment and maintenance of respiratory and circulatory status, fluid and electrolyte balance, and gastrointestinal function. Infection prevention, burn wound care (ie, wound cleaning, topical antibacterial therapy, wound dressing, dressing changes, wound débridement, and wound grafting), pain management, and nutritional support are priorities at this stage and will be discussed in detail.

Airway obstruction caused by upper airway edema can take as long as 48 hours to develop. Changes detected by x-ray and arterial blood gases may occur as the effects of resuscitative fluid and the chemical reaction of smoke ingredients with lung tissues become apparent. The arterial blood gas values and other parameters determine the need for intubation or mechanical ventilation.

As capillaries regain integrity, at 48 or more postburn hours, fluid moves from the interstitial to the intravascular compartment and diuresis begins (Table 57-4). If cardiac or renal function is inadequate, for instance in the elderly patient or in the patient with preexisting cardiac disease, fluid overload occurs and symptoms of congestive heart failure may result (see Chap. 30). Early detection allows for early intervention and carefully calculated fluid intake. Vasoactive medications, diuretics, and fluid restriction may be used to support circulatory function and prevent congestive heart failure and pulmonary edema.

Cautious administration of fluids and electrolytes continues during this phase of burn care because of the shifts in fluid from

the interstitial to intravascular compartments, losses of fluid from large burn wounds, and the patient's physiologic responses to the burn injury. Blood components are administered as needed to treat blood loss and anemia.

Fever is common in burn patients after burn shock resolves. A resetting of the core body temperature in severely burned patients

**Table 57-4 • Fluid and Electrolyte Changes in the Acute Phase**

Fluid remobilization phase (state of diuresis)

Interstitial fluid → plasma

OBSERVATION	EXPLANATION
Hemodilution (decreased hematocrit)	Blood cell concentration is diluted as fluid enters the intravascular compartment; loss of red blood cells destroyed at burn site
Increased urinary output	Fluid shift into intravascular compartment increases renal blood flow and causes increased urine formation.
Sodium (Na <sup>+</sup> ) deficit	With diuresis, sodium is lost with water; existing serum sodium is diluted by water influx.
Potassium (K <sup>+</sup> ) deficit (occurs occasionally in this phase)	Beginning on the fourth or fifth postburn day, K <sup>+</sup> shifts from extracellular fluid into cells.
Metabolic acidosis	Loss of sodium depletes fixed base; relative carbon dioxide content increases.

results in a body temperature a few degrees higher than normal for several weeks after the burn. Bacteremia and septicemia also cause fever in many patients. Acetaminophen (Tylenol) and hypothermia blankets may be required to maintain body temperature in a range of 37.2° to 38.3°C (99° to 101°F) to reduce metabolic stress and tissue oxygen demand.

Central venous, peripheral arterial, or pulmonary artery thermodilution catheters may be required for monitoring venous and arterial pressures, pulmonary artery pressures, pulmonary capillary wedge pressures, or cardiac output. Generally, however, invasive vascular lines are avoided unless essential because they provide an additional port for infection in an already greatly compromised patient.

Infection progressing to septic shock is the major cause of death in patients who have survived the first few days after a major burn. The immunosuppression that accompanies extensive burn injury places the patient at high risk for sepsis. The infection that begins within the burn site may spread to the bloodstream.

### Infection Prevention

Despite aseptic precautions and the use of topical antimicrobial agents, the burn wound is an excellent medium for bacterial growth and proliferation. Bacteria such as *Staphylococcus*, *Proteus*, *Pseudomonas*, *Escherichia coli*, and *Klebsiella* find optimal conditions for growth within the burn wound. The burn eschar is a nonviable crust with no blood supply; therefore, neither polymorphonuclear leukocytes or antibodies nor systemic antibiotics can reach the area. Phenomenal numbers of bacteria—more than 1 billion per gram of tissue—may appear and subsequently spread to the bloodstream or release their toxins, which reach distant sites. Staphylococci and enterococci are the organisms responsible for more than 50% of nosocomial bloodstream infections in patients with burn injuries. Fungi such as *Candida albicans* also grow easily in burn wounds.

When the burn wound is healing through spontaneous re-epithelialization or is being prepared for skin grafting, it must be protected from sepsis. Burn wound sepsis has these characteristics:

- 10<sup>5</sup> bacteria per gram of tissue
- Inflammation
- Sludging and thrombosis of dermal blood vessels

The primary source of bacterial infection appears to be the patient's intestinal tract, the source of most microbes. The intestinal mucosa normally serves as a barrier to keep the internal environment free from a variety of pathogens. After a severe burn injury, the intestinal mucosal barrier becomes markedly permeable. Because of this impaired intestinal mucosal barrier, the disturbed microbial flora and endotoxins found in the intestinal lumen pass freely into the systemic circulation, finally causing infection. If the intestinal mucosa receives some type of protection against permeability change, infection could be avoided. Early enteral feeding is one step to help avoid this increased intestinal permeability and prevent early endotoxin translocation (Cioffi, 2000; Peng, Yuan & Ziao, 2001).

Infection impedes burn wound healing by promoting excessive inflammation and damaging tissue. A major secondary source of pathogenic microbes is the environment. Infection control is a major role of the burn team in providing appropriate burn wound care. Cap, gown, mask, and gloves are worn while caring for the patient with open burn wounds. Clean technique is used when caring directly for burn wounds.

Tissue specimens are obtained for culture regularly to monitor colonization of the wound by microbial organisms. These may be swab, surface, or tissue biopsy cultures. Swab or surface cultures are noninvasive, simple, and painless. However, data obtained from such cultures apply only to the area sampled; therefore, invasive wound biopsy cultures may be required. Antibiotics are seldom prescribed prophylactically because of the risk of promoting resistant strains of bacteria. Systemic antibiotics are administered when there is documentation of burn wound sepsis or other positive cultures such as urine, sputum, or blood. Sensitivity of the organisms to the prescribed antibiotics should be determined before administration. Several parenteral antimicrobial agents may be given together to treat the infection. Careful attention is paid to antibiotic use in the burn unit because inappropriate use of antibiotics significantly affects the microbial flora present in the unit.

### Wound Cleaning

Various measures are used to clean the burn wound. **Hydrotherapy** in the form of shower carts, individual showers, and bed baths can be used to clean the wounds. Total immersion hydrotherapy is performed in some settings. Because of the high risk of infection and sepsis, the use of plastic liners and thorough decontamination of hydrotherapy equipment and wound care areas are necessary to prevent cross-contamination. Tap water alone can be used for burn wound cleansing. The temperature of the water is maintained at 37.8°C (100°F), and the temperature of the room should be maintained between 26.6° and 29.4°C (80° to 85°F). Hydrotherapy, in whatever form, should be limited to a 20- to 30-minute period to prevent chilling of the patient and additional metabolic stress.

During the bath, the patient is encouraged to be as active as possible. Hydrotherapy provides an excellent opportunity for exercising the extremities and cleaning the entire body. When the patient is removed from the tub after the bath, any residue adhering to the body is washed away with a clear water spray or shower. Unburned areas, including the hair, must be washed regularly as well. At the time of wound cleaning, all skin is inspected for any hints of redness, breakdown, or local infection. Hair in and around the burn area, except the eyebrows, should be clipped short. Intact blisters may be left, but the fluid should be aspirated with a needle and syringe and discarded.

Conscientious management of the burn wound is essential. When nonviable loose skin is removed, aseptic conditions must be established. Wound cleaning is usually performed at least daily in wound areas that are not undergoing surgical intervention. When the eschar begins to separate from the viable tissue beneath (approximately 1.5 to 2 weeks after the burn), more frequent cleaning and débridement may be in order.

After the burn wounds are cleaned, they are gently patted with towels and the prescribed method of wound care is performed. Physician preferences, the availability of skilled nursing staff, and resources in terms of number of personnel, supplies, and time must be considered in choosing the best method for a given patient. Whatever the method, the goal is to protect the wound from overwhelming proliferation of pathogenic organisms and invasion of deeper tissues until either spontaneous healing or skin grafting can be achieved.

Patient comfort and ability to participate in the prescribed treatment are also important considerations. Wound care procedures, particularly tub baths, are metabolically stressful. Therefore, the patient is assessed for signs of chilling, fatigue, changes

in hemodynamic status, and pain unrelieved by analgesic medications or relaxation techniques.

## Topical Antibacterial Therapy

There is general agreement that some form of antimicrobial therapy applied to the burn wound is the best method of local care in extensive burn injury. Topical antibacterial therapy does not sterilize the burn wound; it simply reduces the number of bacteria so that the overall microbial population can be controlled by the body's host defense mechanisms. Topical therapy promotes conversion of the open, dirty wound to a closed, clean one.

Criteria for choosing a topical agent include the following:

- It is effective against gram-negative organisms, *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and even fungi.
- It is clinically effective.
- It penetrates the eschar but is not systemically toxic.
- It does not lose its effectiveness, allowing another infection to develop.
- It is cost-effective, available, and acceptable to the patient.
- It is easy to apply, minimizing nursing care time.

The three most commonly used topical agents are silver sulfadiazine (Silvadene), silver nitrate, and mafenide acetate (Sulfamylon). These agents are described in Table 57-5. Many other topical agents are available, including povidone–iodine ointment 10%

(Betadine), gentamicin sulfate, nitrofurazone (Furacin), Dakin's solution, acetic acid, miconazole, and chlortrimazole. Bacitracin may be used for facial burns or on skin grafts initially.

A newer product used in burn wound care is Acticoat Antimicrobial Barrier dressing. Acticoat is a silver-coated dressing approved for treatment of burn wounds and **donor sites**. This dressing is kept moist with water for a controlled, sustained release of silver over the wound to provide an antimicrobial barrier. Acticoat has been shown to have a better antimicrobial performance than the traditional silver-based products commonly used in burn wound treatment. Acticoat is also cost-effective. The dressing can be left in place for up to 5 days, decreasing patient discomfort, the cost of dressing supplies, and nursing time for dressing changes. The dressing has been shown clinically to be very effective for prevention of burn wound infection (Yin, Langford & Burrell, 1999).

No single topical medication is universally effective. Using different agents at different times in the postburn period may be necessary. Bacteriologic cultures are required to monitor the effect of topical medications. Prudent use and alternation of antimicrobial agents result in less resistant strains of bacteria, greater effectiveness of the agents, and a decreased risk of sepsis.

Before a topical agent is reapplied, the previously applied topical agent must be thoroughly removed. The number of times the dressings are changed and soaked is planned to promote optimal therapeutic use of the topical agent.

**Table 57-5 • Overview of Topical Antibacterial Agents Used for Burn Wounds**

AGENT	INDICATION	APPLICATION	NURSING IMPLICATIONS
Silver sulfadiazine 1% (Silvadene) water-soluble cream	<ul style="list-style-type: none"> <li>• Most bactericidal agent</li> <li>• Minimal penetration of eschar</li> </ul>	Apply $\frac{1}{16}$ -inch layer of cream with a sterile glove 1–3 times daily.	<ul style="list-style-type: none"> <li>• Watch for leukopenia 2–3 days after initiation of therapy. (Leukopenia usually resolves within 2–3 days.)</li> <li>• Anticipate formation of pseudoeschar (proteinaceous gel), which is removed easily after 72 hours.</li> </ul>
Mafenide acetate 5% to 10% (Sulfamylon) hydrophilic-based cream	<ul style="list-style-type: none"> <li>• Effective against gram-negative and gram-positive organisms</li> <li>• Diffuses rapidly through eschar</li> <li>• In 10% strength, it is the agent of choice for electrical burns because of its ability to penetrate thick eschar.</li> </ul>	Apply thin layer with sterile glove twice a day and leave open as prescribed. Or if the wound is dressed, change the dressing every 6 hours as prescribed.	<ul style="list-style-type: none"> <li>• Monitor arterial blood gas levels and discontinue as prescribed, if acidosis occurs. Mafenide acetate is a strong carbonic anhydrase inhibitor that may reduce renal buffering and cause metabolic acidosis.</li> <li>• Premedicate the patient with an analgesic before applying mafenide acetate because this agent causes severe burning pain for up to 20 minutes after application.</li> </ul>
Silver nitrate 0.5% aqueous solution	<ul style="list-style-type: none"> <li>• Bacteriostatic and fungicidal</li> <li>• Does <i>not</i> penetrate eschar</li> </ul>	Apply solution to gauze dressing and place over wound. Keep the dressing wet but covered with dry gauze and dry blankets to decrease vaporization. Remoisten every 2 hours, and redress wound twice a day.	<ul style="list-style-type: none"> <li>• Monitor serum sodium (<math>\text{Na}^+</math>) and potassium (<math>\text{K}^+</math>) levels and replace as prescribed. Silver nitrate solution is hypotonic and acts as wick for sodium and potassium.</li> <li>• Protect bed linen and clothing from contact with silver nitrate, which stains everything it touches black.</li> </ul>
Acticoat	<ul style="list-style-type: none"> <li>• Effective against gram-negative and gram-positive organisms and some yeasts and molds</li> <li>• Delivers a uniform, antimicrobial concentration of silver to the burn wound</li> </ul>	Moisten with sterile water only ( <i>never</i> use normal saline). Apply directly to wound. Cover with absorbent secondary dressing. Remoisten every 3–4 hours with sterile water.	<ul style="list-style-type: none"> <li>• Do not use oil-based products or topical antimicrobials with Acticoat burn dressing. Keep Acticoat moist, not saturated. May produce a “pseudoeschar” from silver after application.</li> <li>• Can be left in place for 3–5 days. Now available in Acticoat 7, which can be left in place for up to 7 days without the need to change the dressing.</li> </ul>

## Wound Dressing

When the wound is clean, the burned areas are patted dry and the prescribed topical agent is applied; the wound is then covered with several layers of dressings. A light dressing is used over joint areas to allow for motion (unless the particular area has a graft and motion is contraindicated). A light dressing is also applied over areas for which a splint has been designed to conform to the body contour for proper positioning. Circumferential dressings should be applied distally to proximally. If the hand or foot is burned, the fingers and toes should be wrapped individually to promote adequate healing.

Burns to the face may be left open to air once they have been cleaned and the topical agent has been applied. Careful attention must be given to burns left exposed to ensure that they do not dry out and convert to a deeper burn.

Close communication and cooperation among the patient, surgeon, nurse, and other health care team members are essential for optimal burn wound care. Different wound areas on a given patient may require a variety of wound care techniques. Diagrams posted at the bedside are useful to inform staff of the current prescription for wound care, splints to be applied over dressings, and the exercise regimen to be followed before dressings are reapplied.

### OCCLUSIVE METHOD

There is a role for occlusive dressings in treating specific wounds. An occlusive dressing is a thin gauze that is impregnated with a topical antimicrobial agent or that is applied after topical antimicrobial application. Occlusive dressings are most often used over areas with new skin grafts. Their purpose is to protect the graft, promoting an optimal condition for its adherence to the recipient site. Ideally, these dressings remain in place for 3 to 5 days, at which time they are removed for examination of the graft.

When these dressings are applied, precautions are taken to prevent two body surfaces from touching, such as fingers or toes, ear and scalp, the areas under the breasts, any point of flexion, or between the genital folds. Functional body alignment positions are maintained by using splints or by careful positioning of the patient.

## Dressing Changes

Dressings are changed in the patient's unit, hydrotherapy room, or treatment area approximately 20 minutes after an analgesic agent is administered. They may also be changed in the operating room after the patient is anesthetized. A mask, goggles, hair cover, disposable plastic apron or cover gown, and gloves are worn by health care personnel when removing the dressings. The outer dressings are slit with blunt scissors, and the soiled dressings are removed and disposed of in accordance with established procedures for contaminated materials.

Dressings that adhere to the wound can be removed more comfortably if they are moistened with tap water or if the patient is allowed to soak for a few moments in the tub. The remaining dressings are carefully and gently removed. The patient may participate in removing the dressings, providing some degree of control over this painful procedure. The wounds are then cleaned and débrided to remove debris, any remaining topical agent, exudate, and dead skin. Sterile scissors and forceps may be used to trim loose eschar and encourage separation of devitalized skin. During this procedure, the wound and surrounding skin are carefully inspected. The color, odor, size, exudate, signs of re-epithelialization, and

other characteristics of the wound and the eschar and any changes from the previous dressing change are noted.

## Wound Débridement

As debris accumulates on the wound surface, it can retard keratinocyte migration, thus delaying the epithelialization process. Débridement, another facet of burn wound care, has two goals:

- To remove tissue contaminated by bacteria and foreign bodies, thereby protecting the patient from invasion of bacteria
- To remove devitalized tissue or burn eschar in preparation for grafting and wound healing

There are three types of débridement—natural, mechanical, and surgical.

### NATURAL DÉBRIDEMENT

With natural débridement, the dead tissue separates from the underlying viable tissue spontaneously. After partial- and full-thickness burns, bacteria that are present at the interface of the burned tissue and the viable tissue underneath gradually liquefy the fibrils of **collagen** that hold the eschar in place for the first or second postburn week. Proteolytic and other natural enzymes cause this phenomenon. Using antibacterial topical agents, however, tends to slow this natural process of eschar separation. It is advantageous to the patient to speed this process through other means, such as mechanical or surgical débridement, thereby reducing the time during which bacterial invasion and other iatrogenic problems may arise.

### MECHANICAL DÉBRIDEMENT

Mechanical débridement involves using surgical scissors and forceps to separate and remove the eschar. This technique can be performed by skilled physicians, nurses, or physical therapists and is usually done with daily dressing changes and wound cleaning procedures. Débridement by these means is carried out to the point of pain and bleeding. Hemostatic agents or pressure can be used to stop bleeding from small vessels.

Dressings are also useful débriding agents. Coarse-mesh dressings applied dry or wet-to-dry (applied wet and allowed to dry) will slowly débride the wound of exudate and eschar when they are removed. Topical enzymatic débridement agents are available to promote débridement of the burn wounds. Because such agents do not have antimicrobial properties, they should be used with topical antibacterial therapy to protect the patient from bacterial invasion.

### SURGICAL DÉBRIDEMENT

Early surgical excision to remove devitalized tissue along with early burn wound closure is now being recognized as one of the most important factors contributing to survival in a patient with a major burn injury. Aggressive surgical wound closure has reduced the incidence of burn wound sepsis, thus improving survival rates (Gibran & Heimbach, 2000). Early excision is carried out before the natural separation of eschar is allowed to occur.

Surgical débridement is an operative procedure involving either primary excision (surgical removal of tissue) of the full thickness of the skin down to the fascia (tangential excision) or shaving the burned skin layers gradually down to freely bleeding, viable tissue. Surgical excision is initiated early in burn wound management. This may be performed a few days after the burn or as soon as the patient is hemodynamically stable and edema has decreased.

Ideally, the wound is then covered immediately with a skin graft, if needed, and an occlusive dressing. If the wound bed is not ready for a skin graft at the time of excision, a temporary biologic dressing may be used until a skin graft can be applied during subsequent surgery.

The use of surgical excision carries with it risks and complications, especially with large burns. The procedure creates a high risk of extensive blood loss (as much as 100 to 125 mL of blood per percent body surface excised) and lengthy operating and anesthesia time. However, when conducted in a timely and efficient manner, surgical excision results in shorter hospital stays and possibly a decreased risk of complications from invasive burn wound sepsis.

### Gerontologic Considerations

Eschar separation in full-thickness burns is typically delayed in elderly patients, and older patients are frequently poor risks for surgical excision. Therefore, prolonged hospitalization, immobilization, and associated problems may be common. If the elderly patient can tolerate surgery, early excision with skin grafting is the treatment of choice because it decreases the mortality rate in this population. Prevention of complications of prolonged hospitalization, immobility, and surgery is essential in the care of the elderly burn patient.

## Grafting the Burn Wound

If wounds are deep (full-thickness) or extensive, spontaneous re-epithelialization is not possible. Therefore, coverage of the burn wound is necessary until coverage with a graft of the patient's own skin (**autograft**) is possible. The purposes of wound coverage are to decrease the risk for infection; prevent further loss of protein, fluid, and electrolytes through the wound; and minimize heat loss through evaporation. Several methods of wound coverage are available; some are temporary until grafting with permanent coverage is possible. Wound coverage may consist of biologic, biosynthetic, synthetic, and autologous methods or a combination of these approaches.

The main areas for skin grafting include the face (for cosmetic and psychological reasons); functional areas, such as the hands and feet; and areas that involve joints. Grafting permits earlier functional ability and reduces **contractures** (shrinkage of burn scar through collagen maturation). When burns are very extensive, the chest and abdomen may be grafted first to reduce the burn surface.

Granulation tissue fills the space created by the wound, creates a barrier to bacteria, and serves as a bed for epithelial cell growth. Richly vascular granulation tissue is pink, firm, shiny, and free of exudate and debris. It should have a bacterial count of less than 100,000 per gram of tissue to optimize graft take. If the wound is not ready for skin grafting, the burn wound is excised and allowed to granulate. Once the wound is excised, a wound covering is applied to keep the wound bed moist and promote the granulation process.

### BIOLOGIC DRESSINGS (HOMOGRAFTS AND HETEROGRAFTS)

Biologic dressings have several uses. In extensive burns, they save lives by providing temporary wound closure and protecting the granulation tissue until autografting is possible. Biologic dressings are commonly used in patients with large areas of burn and little remaining normal skin donor sites. Biologic dressings may

also be used to débride wounds after eschar separation. With each biologic dressing change, débridement occurs. Once the biologic dressing appears to be “taking,” or adhering to the granulating surface with minimal underlying exudation, the patient is ready for an autograft.

Biologic dressings also provide temporary immediate coverage for clean, superficial burns and decrease the wound's evaporative water and protein loss. They decrease pain by protecting nerve endings and are an effective barrier against water loss and entry of bacteria. When applied to superficial partial-thickness wounds, they seem to speed healing. Biologic materials can be left open or covered. They stay in place for varying lengths of time but are removed in instances of infection or rejection.

Biologic dressings consist of **homografts** (or allografts) and **heterografts** (or xenografts). Homografts are skin obtained from living or recently deceased humans. The amniotic membrane (amnion) from the human placenta may also be used as a biologic dressing. Heterografts consist of skin taken from animals (usually pigs). Most biologic dressings are used as temporary coverings of burn wounds and are eventually rejected because of the body's immune reaction to them as foreign.

Homografts tend to be the most expensive biologic dressings. They are available from skin banks in fresh and cryopreserved (frozen) forms. Homografts are thought to provide the best infection control of all the biologic or biosynthetic dressings available. Revascularization occurs within 48 hours, and the graft may be left in place for several weeks. Cost, availability, and the possibility of transmission of disease limit the use of homografts.

Amnion is less expensive and is available in hospitals with burn centers and specialized tissue banks, which obtain and process it in cooperation with obstetric services. However, amnion grafts do not become vascularized by the patient's vessels and can be left in place only for short periods.

Pigskin is available from commercial suppliers. It is available fresh, frozen, or lyophilized (freeze-dried) for longer shelf life. Pigskin impregnated with a topical antibacterial agent such as silver nitrate is also available. Pigskin is widely used for temporary covering of clean wounds such as superficial partial-thickness wounds and donor sites. Although pigskin does not vascularize, it will adhere to clean superficial wounds and provides excellent pain control while the underlying wound epithelializes.

### BIOSYNTHETIC AND SYNTHETIC DRESSINGS

Problems with availability, sterility, and cost have prompted the search for biosynthetic and synthetic skin substitutes, which may eventually replace biologic dressings as temporary wound coverings. Currently the most widely used synthetic dressing is **Biobrane**, which is composed of a nylon, Silastic membrane combined with a collagen derivative. The material is semitransparent and sterile. It has an indefinite shelf life and is less costly than homograft or pigskin. Like biologic dressings, Biobrane protects the wound from fluid loss and bacterial invasion.

Biobrane adheres to the wound fibrin, which binds to the nylon–collagen material. Within 5 days, cells migrate into the nylon mesh. Generally, adherence to the wound surface correlates directly with low bacterial counts. When the Biobrane dressing adheres to the wound, the wound remains stable and the Biobrane can remain in place for 3 to 4 weeks. Biobrane dressings (Fig. 57-4) readily adhere to donor sites and meticulously clean débrided partial-thickness wounds; they will remain until spontaneous epithelialization and wound healing occur. Biobrane can be laid on top of a wide-meshed autograft to protect the wound until the autograft epithelium grows out to close the interstices.

**FIGURE 57-4** (A) Use of Biobrane dressing for full-thickness burn wound. Biobrane dressing applied to lower extremity partial-thickness burn. (B) Healed full-thickness burn wound after use of Biobrane. Used with permission. Bertek Pharmaceuticals, Research Triangle Park, North Carolina.

As the Biobrane gradually separates, it is trimmed, leaving a healed wound.

Biobrane is also useful for intermediate or long-term closure of a surgically excised wound until an autograft becomes available. Like biologic dressings, Biobrane should not be used over grossly contaminated or necrotic wounds. Removal of Biobrane after several weeks is similar to but easier than removal of a vascularized allograft and leaves a bleeding granulation bed that readily accepts an autograft.

Another fairly new temporary wound covering is BCG Matrix. This dressing combines beta-glucan, a complex carbohydrate, with collagen in a meshed reinforced wound dressing. Beta-glucan is known to stimulate macrophages, which are vital in the inflammatory process of healing. BCG Matrix is a temporary wound covering intended for use with partial-thickness burns and donor sites. It is applied immediately after cleaning and débridement. If the burn wound surface remains free of infection, BCG Matrix can be left in place until healing is complete.

Several other synthetic dressings are available for burn wound care. Op-Site, a thin, transparent, polyurethane elastic film, can be used to cover clean partial-thickness wounds and donor sites. This dressing is occlusive and waterproof but permeable to water vapor and air; this permeability not only provides protection from microbial contamination but also allows for the exchange of gases, which occurs much more quickly in a moist environment. Other synthetic dressings used for burn wounds include Tegaderm, N-Terface, and DuoDerm.

Burns that are between superficial and deep partial thickness in depth can be treated with a promising new temporary biologic covering, TransCyte, a material composed of human newborn fibroblasts, which are cultured on the nylon mesh of Biobrane. The thin silicone membrane bonded to the mesh provides a moisture vapor barrier for the wound. TransCyte is used to treat burns in which the depth is indeterminate. TransCyte delivers a variety of biologically active proteins, which may benefit the wound healing process. Research has shown that wounds treated with TransCyte healed more quickly and with less hypertrophic scarring than burns treated with the traditional silver sulfadiazine protocols (Noordenbos, Dore & Hansbrough, 1999).

### DERMAL SUBSTITUTES

In an attempt to develop the ideal burn wound covering product, dermal substitutes have been created. Two such products are Integra Artificial Skin and Alloderm.

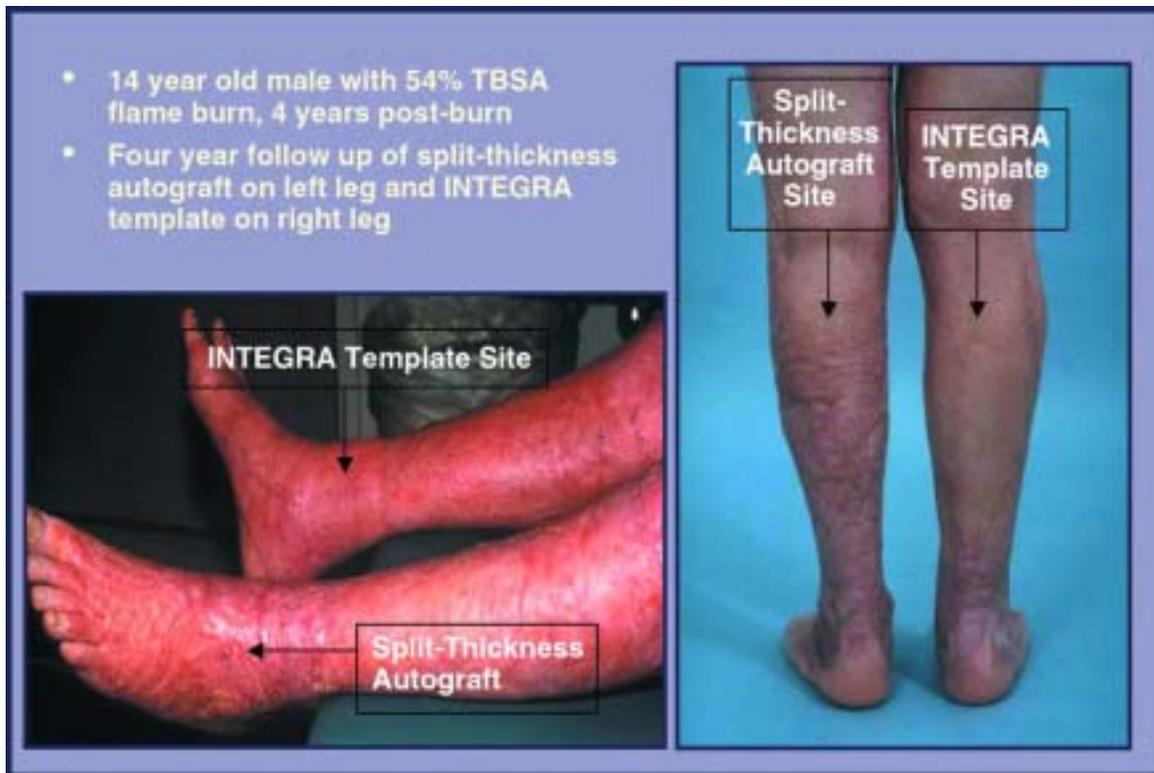

Artificial skin (**Integra**) is the newest type of dermal substitute. A dermal analog, Integra is composed of two main layers. The epidermal layer, consisting of Silastic, acts as a bacterial barrier and prevents water loss from the dermis. The dermal layer is composed of animal collagen. It interfaces with the open wound surface and allows migration of fibroblasts and capillaries into the material. This “neodermis” becomes a permanent structure. The artificial dermis is biodegraded and reabsorbed. The outer silicone membrane is removed 2 to 3 weeks after application and is replaced with the patient’s own skin in the form of a thin epidermal skin graft. Long-term effects of Integra include minimal contracture formation. The graft site is very pliable, almost eliminating the need for repeated cosmetic surgery. Most importantly, Integra has resulted in less hypertrophic scarring (Fig. 57-5), thus eliminating the need for compression devices once the burn wound has healed. The use of Integra is increasing the survivability of burns and improving the functional and cosmetic qualities of the healed burn (Winfrey, Cochran & Hegarty, 1999).

Another promising dermal substitute is **Alloderm**. It is processed dermis from human cadaver skin, which can be used as the dermal layer for skin grafts. When a donor site (the area from which skin is taken to provide a skin graft for another part of the body) is harvested for an autologous skin graft, both the epidermal and dermal layers of skin are removed from the donor site. Alloderm provides a permanent dermal layer replacement. Its use allows the burn surgeon to harvest a thinner skin graft consisting of the epidermal layer only. The patient’s epidermal layer is placed directly over the dermal base (Alloderm). The new graft is then treated according to the burn unit’s protocol. Use of Alloderm has also resulted in less scarring and contractures with healed grafts; donor sites heal much more quickly than conventional donor sites because only the epidermal layer has been harvested. This is important when donor sites are limited because of extensive burns (Luterman, 2000).

### AUTOGRAFTS

Autografts remain the preferred material for definitive burn wound closure following excision. Autografts are the ideal means of covering burn wounds because the grafts are the patient’s own skin and thus are not rejected by the patient’s immune system. They can be split-thickness, full-thickness, pedicle flaps, or epithelial grafts. Full-thickness and pedicle flaps are commonly used for reconstructive surgery, months or years after the initial injury.

Split-thickness autografts can be applied in sheets or in postage stamp–like pieces, or they can be expanded by meshing so that they can cover 1.5 to 9 times more than a given donor site

**FIGURE 57-5** Comparison of Integra template site (right leg) to split thickness autograft site (left leg). Used with permission from Glenn Warden, MD.

area. Skin meshers enable the surgeon to cut tiny slits into a sheet of donor skin, making it possible to cover large areas with smaller amounts of donor skin. These expanded grafts adhere to the recipient site more easily than sheet grafts and prevent the accumulation of blood, serum, air, or purulent material under the graft. However, any kind of graft other than a sheet graft will contribute to scar formation as it heals. Using expanded grafts may be necessary in large wounds but should be viewed as a compromise in terms of cosmesis.

If blood, serum, air, fat, or necrotic tissue lies between the recipient site and the graft, there may be partial or total loss of the graft. Infection and mishandling of the graft, as well as trauma during dressing changes, account for most other instances of graft loss. Using split-thickness grafts allows the remaining donor site to retain sweat glands and hair follicles and minimizes donor site healing time.

Use of **cultured epithelial autograft** (CEA) is common at several burn centers. This involves a biopsy of the patient's skin in an unburned area. Keratinocytes are then isolated and epithelial cells are cultured in a laboratory. The original epithelial cell sample can multiply to 10,000 times its original size over 30 days. These cells are then attached to the burn wound. Varying degrees of success have been reported, and results are encouraging. However, the disadvantages of the CEA are that the grafts are thin and fragile and can shear easily. Research has shown that the outcomes of use of CEA are not as positive as once thought. The quality of burn scars is better, but patients have longer hospital stays and higher hospital costs and require more surgical procedures than those treated by traditional methods. In addition, patients require more reconstructive pro-

cedures in the first 1 to 2 years postinjury. Therefore, CEA use is very limited and reserved for burn patients whose donor sites are limited (Noordenbos et al., 1999).

**Care of the Patient with an Autograft.** Occlusive dressings are commonly used initially after grafting to immobilize the graft. Occupational therapists may be helpful in constructing splints to immobilize newly grafted areas to prevent dislodging the graft. Homografts, heterografts, or synthetic dressings may also be used to protect grafts. The graft may be left open with skin staples to immobilize it, which allows close observation of progress.

The first dressing change is usually performed 3 to 5 days after surgery, or earlier in the case of purulent drainage or a foul odor. If the graft is dislodged, sterile saline compresses will help prevent drying of the graft until the physician reapplies it.

The patient is positioned and turned carefully to avoid disturbing the graft or putting pressure on the graft site. If an extremity has been grafted, it is elevated to minimize edema. The patient begins exercising the grafted area 5 to 7 days after grafting.

**Care of Donor Site.** A moist gauze dressing is applied at the time of surgery to maintain pressure and to stop any oozing. A thrombostatic agent such as thrombin or epinephrine may be applied directly to the site as well. The donor site may be treated in several ways, from single-layer gauze impregnated with petrolatum, scarlet red, or bismuth to new biosynthetic dressings such as Bio-brane or BCG Matrix. Some burn centers are using the Acticoat dressing on donor sites. Despite the type of donor site covering, donor sites must remain clean, dry, and free from pressure. Because a donor site is usually a partial-thickness wound, it will heal

spontaneously within 7 to 14 days with proper care. Donor sites are painful, and additional pain management must be a part of the patient's care.

## Pain Management

Pain is inevitable during recovery from any burn injury. Pain in the burn patient has been described as a tormenting consequence of burn injury and wound healing (Jonsson, Holmsten, Dahlstrom & Jonsson, 1998). Burn pain is thought to have both nociceptive and neuropathic pain components. Management of the often-severe pain is one of the most difficult challenges facing the burn team. Many factors contribute to the burn patient's pain experience. These factors include but are not limited to the severity of the pain, the adequacy of the health care provider's assessment of the pain, the appropriateness and adequacy of pharmacologic treatment of pain, the multiple procedures involved in burn care (ie, wound care, rehabilitative exercises), and appropriate evaluation of the effectiveness of pain relief measures. The outstanding features of burn pain are its intensity and long duration. Further, necessary wound care carries with it the anticipation of pain and anxiety.

In partial-thickness burns, the nerve endings are exposed, resulting in excruciating pain with exposure to air currents. Although nerve endings are destroyed in full-thickness burns, the margins of the burn wound are hypersensitive to pain, and there is pain in adjacent structures. Healing of full-thickness burns creates significant discomfort as regenerating nerve endings become entrapped in scar formation. Most severe burns are a combination of partial-thickness and full-thickness burns.

Burn patients have been described as having three types of pain: background or resting pain, procedural pain, and breakthrough pain. Background pain is pain that exists on a 24-hour basis. Procedural pain is pain caused by procedures such as burn wound care or range of motion exercises. Breakthrough pain occurs when blood levels of analgesic agents fall below the level required to control background pain. The patient's pain level must be assessed throughout the day because each type of pain is different and various pain management strategies may be needed to address different types of pain (McCaffrey & Pasaro, 1999).

The primary pain from the burn itself is intense in the initial acute postburn phase. In the next few weeks thereafter, until the skin heals or skin grafts are applied and heal, the pain intensity remains high because of treatment-induced pain. Wound cleaning, dressing changes, débridement, and physical therapy can all cause intense pain. Donor sites may be intensely painful for several days. Discomfort related to tissue healing, such as itching, tingling, and tightness of contracting skin and joints, adds to the duration, if not the intensity, of pain over weeks or months. Because pain cannot be eliminated short of complete anesthesia, the goal is to minimize the pain with analgesic agents to an acceptable goal set by the patient.

Opioid administration via the intravenous (IV) route, particularly in the emergent and acute phases of burn management, remains the mainstay for pharmacologic management of burn pain. Use of opioids is complicated by the fluctuation in the bioavailability of drugs, protein binding of the drug, and the drug clearance related to the hemodynamic and fluid volume shifts that occur with a burn injury. Absorption of the opioid also may be affected. Titrating analgesic agents to obtain pain relief while minimizing side effects is crucial. The burn patient's requirements for analgesia are often high, but fear of addiction on the part of the patient and health care provider hamper adequate opioid administration.

Morphine sulfate remains the analgesic of choice for treatment of acute burn pain. It is titrated to obtain pain relief based on the patient's self-report of pain using a standardized pain rating scale.

Fentanyl is another useful opioid for burn pain, particularly procedural burn pain. It has been shown to be effective for management of intense pain of short duration. Fentanyl has a rapid onset, high potency, and short duration, all of which make it effective for use with burn wound procedures. Appropriate cardiac and respiratory monitoring must be carried out during its administration.

Patient-controlled analgesia (PCA), in which a pump is used to administer a continuous infusion of an opioid, maintains a steady level of opioid for pain relief. Use of continuous infusion requires close monitoring of the patient's responses.

Sustained-release opioids, such as MS Contin or oxycodone (OxyContin), have also been used successfully in the treatment of burn pain. These medications can effectively treat the resting pain that is often associated with burn injury. Additional medications must be prescribed with these medications to cover breakthrough pain.

Some burn units use self-administered nitrous oxide during burn wound procedures. Proper ventilation and monitoring equipment and availability of qualified personnel to administer nitrous oxide limit its use.

Anxiety and pain go hand in hand for burn patients. The entire burn experience can produce severe anxiety, which can, in turn, exacerbate pain. Therefore, the ideal pain management regimen must incorporate the treatment of pain and anxiety and must be individualized for each patient. Sedation with anxiolytic medications such as lorazepam (Ativan) and midazolam (Versed) may be indicated in addition to the administration of opioids.

The use of nonpharmacologic measures has also proven effective in the management of burn pain. These measures include relaxation techniques, deep breathing exercises, distraction, guided imagery, hypnosis, therapeutic touch, humor, information giving, and music therapy (McCaffrey & Pasaro, 1999).

Music therapy has gained interest recently in the treatment of pain. Researchers have found that music affects both the physiologic and psychological aspects of the pain experience. Music diverts the patient's attention from the painful stimulus; provides reality orientation, distraction, and sensory stimulation; and allows for patient self-expression (Fratianne et al., 2001; Prensner et al., 2001).

## Nutritional Support

Burn injuries produce profound metabolic abnormalities fueled by the exaggerated stress response to the injury. The body's response has been classified as hyperdynamic, hypermetabolic, and hypercatabolic. Hypermetabolism can affect morbidity and mortality by increasing the risk of infection and slowing the healing rate. Patients' metabolic demands vary with the extent of the burn injury. Hypermetabolism is evident immediately after a burn injury. The degree of the response depends on the size of the burn and the patient's age, body composition, size, and genetic response to insult. Persistent hypermetabolism may last up to 1 year after burn injury (Hart et al., 2000).

Major metabolic abnormalities seen after a burn injury include increased catabolic hormones (cortisol and catechols); decreased anabolic hormones (human growth factor and testosterone); a marked increase in the metabolic rate; a sustained increase in body temperature; a marked increase in glucose demands; rapid skeletal

muscle breakdown with amino acids serving as the energy source; lack of ketosis, indicating that fat is not a major source of calories; and catabolism that does not respond to nutrient intake (Demling & Seigne, 2000). Therefore, it is essential to control the stress response by increasing the anabolic process through adequate nutrition and increased muscle activity, decreasing heat loss from wounds, and maintaining a warm environment. Controlling secondary stress, such as pain and anxiety, also helps to control the stress response.

The most important of these interventions is to provide adequate nutrition and calories to decrease catabolism. Nutritional support with optimized protein intake can decrease protein losses by approximately 50% (Cioffi, 2000). Healing of the burn wound consumes large quantities of energy. Effective nutrition management depends on how well the energy expenditure due to the burn injury can be estimated and matched with appropriate amounts of micronutrients, carbohydrates, lipids, and protein. The goal of nutritional support is to promote a state of positive nitrogen balance by optimizing nutrition to match nutrient utilization. The nutritional support required is based on the patient's preburn status and the TBSA burned.

Several formulas exist for estimating the daily metabolic expenditure and caloric requirements of patients with burn injuries. The most commonly used formulas include the Curreiri formula, which uses body weight and percent burn, and a variation of the Harris-Benedict equation, which determines basal energy requirements based on stress and burn size (Demling & Seigne, 2000). Protein requirements may range from 1.5 to 4.0 g of protein per kilogram of body weight every 24 hours. Lipids are included in the nutritional support of every burn patient because of their importance for wound healing, cellular integrity, and absorption of fat-soluble vitamins. Carbohydrates are included to meet caloric requirements as high as 5,000 calories per day and to spare protein, which is essential for wound healing. The patient also needs adequate vitamins and minerals. Existing formulas may underestimate the daily metabolic expenditures associated with burns. The formulas fail to account for added stressors such as pain, anxiety, daily dressing changes, and decreased activity levels. These must be considered when estimating appropriate nutritional support. Research findings have brought about changes in specific guidelines for estimating energy expenditure during the various phases of postburn recovery. The proportions of fat, protein, and carbohydrate must be carefully planned for maximal use (Demling & Seigne, 2000).

The enteral route of feeding is far superior to the parenteral route. Enteral feedings preserve the intestinal barrier function and absorption of peptides and amino acids, which leads to higher nitrogen retention. Feedings are started as soon as possible. If a feeding tube is used, placement into the duodenum is ideal to prevent aspiration and to allow for continuous, uninterrupted feedings during surgical procedures. If the oral route is used, high-protein, high-calorie meals and supplements are given. Dietary consultations are useful in helping patients meet their nutritional needs. Daily calorie counts aid in assessing the adequacy of nutritional intake. Overfeeding must be avoided because it increases metabolism, O<sub>2</sub> consumption, and CO<sub>2</sub> production.

Patients lose a great deal of weight during recovery from severe burns. Reserve fat deposits are catabolized, fluids are lost, and caloric intake may be limited. Because a burn injury lowers the patient's resistance to infection and disease, the nutritional status must be improved and maintained although the patient has a poor appetite and is weak.

Indications for parenteral nutrition include weight loss greater than 10% of normal body weight, inadequate intake of enteral nutrition due to clinical status, prolonged wound exposure, and malnutrition or debilitated condition before injury. The risk of infection at the site of the central venous catheter required for parenteral nutrition must be considered. Moreover, the risk of Curling's ulcer continues in the acute phase.

## DISORDERS OF WOUND HEALING

Disorders of wound healing in the burn patient result from excessive abnormal healing or inadequate new tissue formation. Hypertrophic scarring and keloid formation result from excessive abnormal healing.

### Scars

One of the most devastating sequelae of a burn injury is the formation of **hypertrophic scars**. Clinicians cannot reliably predict or prevent the formation of hypertrophic scars. Hypertrophic scars are more common in children, in people with dark skin, and in areas of stretch or motion. The pathophysiology behind these scars is not completely understood, but they are characterized by an overabundant matrix formation, especially collagen.

Hypertrophic scars and wound contractures are more likely to occur if the initial burn injury extends below the level of the deep dermis. Healing of such deep wounds results in the replacement of normal integument with highly metabolically active tissues that lack the normal architecture of the skin. In the collagen layer beneath the epithelium, many fibroblasts proliferate gradually. Myofibroblasts, cells that have the ability to contract, are also present in immature wounds. As the myofibroblasts contract, the collagen fibers, which normally lie in flat bundles, tend to form a wavy pattern. Eventually the collagen bundles take on a supercoiled appearance and collagen nodules develop. The scar becomes red (because of its hypervascular nature), raised, and hard.

Burn personnel must be proactive in the prevention and management of scar formation. Compression measures are instituted early in burn wound treatment. Ace wraps are used initially to help promote adequate circulation, but they can also be used as the first form of compression. Scar management occurs mainly in the rehabilitative phase, after the wounds are closed. Hypertrophic scarring may cause severe contracture across involved joints. Therefore, prevention and management of this type of scarring is essential (see "Prevention of Hypertrophic Scarring" in the rehabilitation phase discussion). However, these scars are limited to the area of injury and gradually regress over time.

### Keloids

A large, heaped-up mass of scar tissue, a keloid, may develop and extend beyond the wound surface. Keloids tend to be found in people with darkly pigmented skin, tend to grow outside of wound margins, and are likely to recur after surgical excision.

### Failure to Heal

Failure of the wound to heal may result from many factors, including infection and inadequate nutrition. A serum albumin level of less than 2 g/dL is usually a factor in impaired healing in the burn patient.

## Contractures

Contractures are another concern as wounds heal. The burn wound tissue shortens because of the force exerted by the fibroblasts and the flexion of muscles in natural wound healing. An opposing force provided by splints, traction, and purposeful movement and positioning must be used to counteract deformity in burns affecting joints.

## NURSING PROCESS: CARE OF THE PATIENT DURING THE ACUTE PHASE

### Assessment

Continued assessment of the burn patient during the early weeks after the burn injury focuses on hemodynamic alterations, wound healing, pain and psychosocial responses, and early detection of complications. Assessment of respiratory and fluid status remains the highest priority for detection of potential complications.

The nurse assesses vital signs frequently. Continued assessment of peripheral pulses is essential for the first few postburn days while edema continues to increase, potentially damaging peripheral nerves and restricting blood flow. Observation of the electrocardiogram may give clues to cardiac dysrhythmias resulting from potassium imbalance, preexisting cardiac disease, or the effects of electrical injury or burn shock.

Assessment of residual gastric volumes and pH in the patient with a nasogastric tube is also important. Blood in the gastric fluid or the stools must also be noted and reported.

Assessment of the burn wound requires an experienced eye, hand, and sense of smell. Important wound assessment features include size, color, odor, eschar, exudate, abscess formation under the eschar, epithelial buds (small pearl-like clusters of cells on the wound surface), bleeding, granulation tissue appearance, status of grafts and donor sites, and quality of surrounding skin. Any significant changes in the wound are reported to the physician, because they usually indicate burn wound or systemic sepsis and require immediate intervention.

Other significant and ongoing assessments focus on pain and psychosocial responses, daily body weights, caloric intake, general hydration, and serum electrolyte, hemoglobin, and hematocrit levels. Assessment for excessive bleeding from blood vessels adjacent to areas of surgical exploration and débridement is necessary as well. The Plan of Nursing Care provides an outline of nursing activities in the acute phase of burn care.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, priority nursing diagnoses in the acute phase of burn care may include the following:

- Excessive fluid volume related to resumption of capillary integrity and fluid shift from the interstitial to intravascular compartment
- Risk for infection related to loss of skin barrier and impaired immune response
- Imbalanced nutrition, less than body requirements, related to hypermetabolism and wound healing needs
- Impaired skin integrity related to open burn wounds
- Acute pain related to exposed nerves, wound healing, and treatments

- Impaired physical mobility related to burn wound edema, pain, and joint contractures
- Ineffective coping related to fear and anxiety, grieving, and forced dependence on health care providers
- Interrupted family processes related to burn injury
- Deficient knowledge about the course of burn treatment

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop in the acute phase of burn care may include:

- Heart failure and pulmonary edema
- Sepsis
- Acute respiratory failure
- Acute respiratory distress syndrome
- Visceral damage (electrical burns)

## Planning and Goals

The major goals for the patient may include restoration of normal fluid balance, absence of infection, attainment of anabolic state and normal weight, improved skin integrity, reduction of pain and discomfort, optimal physical mobility, adequate patient and family coping, adequate patient and family knowledge of burn treatment, and absence of complications. Achieving these goals requires a collaborative, interdisciplinary approach to patient management.

## Nursing Interventions

### RESTORING NORMAL FLUID BALANCE

To reduce the risk of fluid overload and consequent congestive heart failure, the nurse closely monitors IV and oral fluid intake, using IV infusion pumps to minimize the risk of rapid fluid infusion. To monitor changes in fluid status, careful intake and output and daily weights are obtained. Changes in pulmonary artery, wedge, and central venous pressures, as well as in blood pressure and pulse rate, are reported to the physician. Low-dose dopamine to increase renal perfusion and diuretics may be prescribed to promote increased urine output. The nurse's role is to administer these medications as prescribed and to monitor the patient's response.

### PREVENTING INFECTION

A major part of the nurse's role during the acute phase of burn care is detecting and preventing infection. The nurse is responsible for providing a clean and safe environment and for closely scrutinizing the burn wound to detect early signs of infection. Culture results and white blood cell counts are monitored.

Clean technique is used for wound care procedures. Aseptic technique is used for any invasive procedures, such as insertion of IV lines and urinary catheters or tracheal suctioning. Meticulous hand hygiene before and after each patient contact is also an essential component of preventing infection, even though gloves are worn to provide care.

The nurse protects the patient from sources of contamination, including other patients, staff members, visitors, and equipment. Invasive lines and tubing must be routinely changed according to recommendations of the Centers for Disease Control and Prevention. Tube feeding reservoirs, ventilator circuits, and drainage containers are replaced regularly. Fresh flowers, plants, or fresh

*(text continues on page 1732)*

## Plan of Nursing Care

### Care of the Patient During the Acute Phase of Burn Injury

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Fluid volume excess related to resumption of capillary integrity and fluid shift from interstitial to intravascular compartment

**Goal:** Maintenance of optimal fluid balance

1. Monitor vital signs, intake and output, weight. Assess for edema, jugular vein distention (JVD), crackles, increased arterial pressures.	1. These signs reflect fluid status.	<ul style="list-style-type: none"> <li>• Intake, output, and body weight correlate with expected pattern</li> <li>• Vital signs and arterial pressures remain within designated limits</li> <li>• Urine output increases in response to diuretic and vasoactive medications</li> </ul>
2. Notify physician of urine output <30 mL/hr, weight gain, JVD, crackles, increased arterial pressures.	2. These indicate increased fluid volume.	
3. Maintain intravenous fluids on pumps or rate controllers.	3. Regulation prevents unintentional fluid bolus.	
4. Administer dopamine or diuretics as prescribed. Assess response.	4. Dopamine increases renal perfusion, which increases urine output. Diuretics promote increased urine formation and urine output and decrease intravascular volume.	

**Nursing Diagnosis:** Risk for infection related to loss of skin barrier and impaired immune response

**Goal:** Absence of localized or systemic infection

1. Use asepsis in all aspects of patient care: <ol style="list-style-type: none"> <li>Meticulous hand hygiene before and after patient care.</li> <li>Use clean or sterile gloves for wound care.</li> <li>Wear isolation gown or protective plastic apron for patient care.</li> <li>Wear mask and hair cover when wounds are exposed and during sterile procedures.</li> <li>Change invasive lines and tubings as recommended by CDC.</li> </ol>	1. Aseptic techniques minimize risk of cross-contamination and spread of bacterial contamination.	<ul style="list-style-type: none"> <li>• Wound cultures show minimal bacteria</li> <li>• Negative blood, urine, and sputum cultures</li> <li>• Urine output and vital signs within acceptable range</li> <li>• Absence of signs and symptoms of infection and sepsis</li> </ul>
2. Screen visitors for respiratory, gastrointestinal, or integumentary infections. Provide isolation gowns for visitors without active infection and instruct in hand hygiene.	2. Avoiding known infecting agents prevents introduction of additional microorganisms.	
3. Exclude plants and flowers in water from patient's room.	3. Stagnant water is a potential source of bacterial growth.	
4. Inspect wound for signs of infection, purulent drainage, or discoloration.	4. Such signs indicate localized infection.	
5. Monitor white blood cell (WBC) count, culture and sensitivity results.	5. Increased WBC count indicates infection. Culture and sensitivity indicate microorganisms present and appropriate antibiotics to be used.	
6. Administer antibiotics as prescribed.	6. Antibiotics reduce bacteria.	
7. Provide regular linen changes and assist patient with personal hygiene.	7. These measures reduce potential bacterial colonization of burn wound.	
8. Report to physician decreased bowel sounds, tachycardia, decreased blood pressure, decreased urine output, fever, and flushing.	8. These signs may indicate sepsis.	
9. Administer fluids and vasoactive medications as prescribed. Assess response.	9. These agents are used to maintain tissue perfusion in sepsis.	

(continued)

## Plan of Nursing Care

### Care of the Patient During the Acute Phase of Burn Injury (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Altered nutrition, less than body requirements, related to hypermetabolism and wound healing

**Goal:** Attainment of anabolic nutritional status

- |  |   |  |
|--|---|--|
| <ol style="list-style-type: none"> <li>1. Provide high-calorie, high-protein diet; include patient preferences and home-made food. Provide nutritional supplements as prescribed.</li> <li>2. Monitor patient's daily weight and calorie count.</li> <li>3. Administer supplemental vitamins and minerals as prescribed.</li> <li>4. Administer enteral or parenteral nutrition per protocol if dietary needs are not met through oral intake.</li> <li>5. Report abdominal distention, large gastric residual volumes, or diarrhea to physician.</li> </ol> | <ol style="list-style-type: none"> <li>1. The patient needs sufficient nutrients for wound healing and increased metabolic requirements.</li> <li>2. These measures assist in determining whether dietary needs are being met.</li> <li>3. These help meet additional nutritional needs; adequate vitamins and minerals are necessary for wound healing and cellular function.</li> <li>4. Nutritional techniques ensure that nutritional needs are met.</li> <li>5. These signs may indicate intolerance of route or type of feeding.</li> </ol> | <ul style="list-style-type: none"> <li>• Gains weight daily after initial loss</li> <li>• Exhibits no signs of protein, vitamin, or mineral deficiencies</li> <li>• Meets required nutritional needs entirely by oral intake</li> <li>• Participates in selection of diet with prescribed nutrients</li> <li>• Serum protein levels within acceptable range</li> </ul> |
|--|---|--|

**Nursing Diagnosis:** Impaired skin integrity related to open burn wounds

**Goal:** Demonstration of improved skin integrity

- |   |   |  |
|---|---|--|
| <ol style="list-style-type: none"> <li>1. Clean wounds, body, and hair daily.</li> <li>2. Provide wound care as prescribed.</li> <li>3. Apply topical antibacterial agents and dressing as prescribed.</li> <li>4. Prevent pressure, infection, and mobilization of skin grafts.</li> <li>5. Provide donor site care.</li> <li>6. Provide adequate nutritional support.</li> <li>7. Assess wound and graft sites. Report signs of poor healing, poor graft take, or trauma to physician.</li> </ol> | <ol style="list-style-type: none"> <li>1. Daily cleaning reduces potential bacterial colonization.</li> <li>2. Care promotes wound healing.</li> <li>3. Wound care regimen reduces bacterial colonization and promotes healing.</li> <li>4. These measures promote graft take and healing.</li> <li>5. Care promotes healing of donor site.</li> <li>6. Adequate nutrition is essential for normal granulation and healing.</li> <li>7. Early intervention for poor wound healing or graft take is essential. Grafted or healed burn wounds are susceptible to trauma.</li> </ol> | <ul style="list-style-type: none"> <li>• Skin is generally intact, and free of signs of infection, pressure, and trauma</li> <li>• Open wounds are pink, reepithelializing, and free of infection</li> <li>• Donor sites are clean and reepithelializing</li> <li>• Healed wounds are soft and smooth</li> <li>• Skin is lubricated and elastic</li> </ul> |
|---|---|--|

**Nursing Diagnosis:** Pain related to exposed nerves, wound healing, and treatments

**Goal:** Reduction or control of pain

- |   |   |  |
|---|---|--|
| <ol style="list-style-type: none"> <li>1. Assess pain level using pain intensity scale. Observe for nonverbal indicators of pain: grimacing, tachycardia, clenched fists.</li> <li>2. Educate the patient about the usual pain trajectory in burn recovery and options for pain control. Allow patient as much control as possible regarding pain management.</li> <li>3. Offer analgesics approximately 20 minutes before painful procedures.</li> <li>4. Provide analgesia before pain becomes severe.</li> <li>5. Instruct and assist patient in relaxation, imagery, distraction techniques.</li> </ol> | <ol style="list-style-type: none"> <li>1. Pain assessment data provide baseline for assessing response to interventions.</li> <li>2. Knowledge reduces fear of the unknown and provides some measure of control to the patient.</li> <li>3. Premedication allows time for therapeutic response.</li> <li>4. Pain is more easily controlled before it becomes severe.</li> <li>5. Nonpharmacologic pain measures provide multiple interventions to decrease pain sensation.</li> </ol> | <ul style="list-style-type: none"> <li>• Requests analgesics for specific wound care procedures or physical therapy activities</li> <li>• States pain is minimal</li> <li>• Gives no physiologic or nonverbal cues of moderate or severe pain</li> <li>• Uses pain control measures such as nitrous oxide, relaxation, imagery, and distraction techniques to assist with coping with pain</li> <li>• Can sleep without being disturbed by pain</li> <li>• Reports skin is comfortable with no itching or tightness</li> </ul> |
|---|---|--|

## Plan of Nursing Care

### Care of the Patient During the Acute Phase of Burn Injury (Continued)

Nursing Interventions	Rationale	Expected Outcomes
6. Assess and document the patient's response to interventions.	6. Patient's responses assist in ascertaining best pain control techniques for the patient.	
7. Administer antianxiety and antipruritic agents as indicated.	7. These medications help to increase patient's comfort.	
8. Lubricate healing burn wounds with water- or silica-based lotion.	8. These preparations decrease sensation of skin tightness.	

**Nursing Diagnosis:** Impaired physical mobility related to burn wound edema, pain, and joint contractures

**Goal:** Achievement of optimal physical mobility

1. Position patient carefully to prevent flexed position in burned areas.	1. Proper positioning reduces risk of flexion contractures.	<ul style="list-style-type: none"> <li>• Improves range of motion of joints daily</li> <li>• Demonstrates preinjury range of motion of all joints</li> <li>• Absence of signs of periarticular calcification</li> <li>• Participates in activities of daily living</li> </ul>
2. Implement range-of-motion (ROM) exercises several times daily.	2. ROM exercises minimize muscle atrophy.	
3. Assist with early sitting and ambulation.	3. Early mobility encourages increased use of muscles.	
4. Use splints and exercise devices recommended by occupational and physical therapists.	4. Such devices encourage activity while maintaining proper position of joints.	
5. Encourage self-care to the extent of the patient's ability.	5. Self-care promotes both independence and increased activity.	

**Nursing Diagnosis:** Ineffective individual coping related to fear and anxiety, grieving, and forced dependence on health care providers

**Goal:** Use of appropriate coping strategies to deal with postburn problems

1. Assess patient for coping abilities and previous successful coping strategies.	1. Psychosocial data provide baseline for planning care.	<ul style="list-style-type: none"> <li>• Verbalizes reactions to burns, therapeutic procedures, losses</li> <li>• Identifies effective coping strategies used previously in stressful situations</li> <li>• Accepts dependency on health care providers during acute illness</li> <li>• Resolves grief over losses resulting from burn injury</li> <li>• Participates in decision making regarding care</li> <li>• Has hopeful attitude toward future</li> </ul>
2. Demonstrate acceptance of patient. Provide positive feedback and support.	2. Acceptance encourages self-esteem and continued progress toward independence.	
3. Assist patient to set achievable short-term goals for increased independence in activities of daily living.	3. Short-term goal setting leads to pattern of success for patient. Long-term goals may seem unrealistic or unattainable to patient.	
4. Use multidisciplinary approach to promote mobility and independence.	4. Communication among disciplines provides consistent approach.	
5. Consult with health care team members for assistance with regressive or maladaptive behaviors.	5. Collaboration uses the expertise of others.	

**Nursing Diagnosis:** Altered family processes related to burn injury

**Goal:** Achievement of appropriate patient/family processes

1. Assess patient and family's perception of impact of burn injury on family functioning.	1. Assessment data provide baseline from which to plan care.	<ul style="list-style-type: none"> <li>• Patient verbalizes feelings regarding alteration in family interactions</li> <li>• Family can emotionally support the patient during hospitalization</li> <li>• Family states that needs are met</li> </ul>
2. Demonstrate willingness to listen. Provide realistic support.	2. Empathetic attitude promotes verbalizing of concerns.	
3. Refer family to social services and other resources as needed.	3. Collaboration assists to address concerns comprehensively.	
4. Explain the burn patient's coping patterns to family. Discuss ways that they can support the patient.	4. Explanations help decrease anxiety about the unknown and promote appropriate support of patient by family.

## Plan of Nursing Care

### Care of the Patient During the Acute Phase of Burn Injury (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<b>Acute Respiratory Failure/ARDS</b>		
1. Assess for respiratory distress, changes in respiratory patterns, or onset of adventitious breath sounds. Report to physician.	1. Such problems indicate possible acute respiratory failure. Pulmonary complications may not appear for 24 to 48 hours after the burn injury.	<ul style="list-style-type: none"> <li>• Arterial blood gases within normal limits</li> <li>• Normal lung compliance</li> <li>• Absence of respiratory distress</li> <li>• Improved PO<sub>2</sub> level</li> </ul>
2. Monitor pulse oximetry and arterial blood gas levels for decreasing oxygen saturation and PO <sub>2</sub> . Report to physician.	2. Decreasing oxygenation indicates deteriorating respiratory status. Medical intervention is needed.	
3. Monitor the mechanically ventilated patient for decreased spontaneous tidal volumes and lung compliance.	3. Respiratory problems reflect increased difficulty with ventilation and may indicate the onset of ARDS.	
4. In collaboration with the physician and respiratory therapist, administer positive end-expiratory pressure and pressure support. Assess patient's response.	4. These measures optimize diffusion of oxygen across the alveolar capillary membrane.	
<b>Visceral Damage (Electrical Burns)</b>		
1. Assess patient for signs of deep pain. Focus on areas between entrance and exit wounds of burn.	1. Pain may reflect visceral damage.	<ul style="list-style-type: none"> <li>• Absence of visceral organ damage</li> <li>• Stable cardiac rhythm</li> </ul>
2. Monitor ECG rhythm.	2. The patient with electrical burns is at risk for dysrhythmias.	
3. Report to the physician any complaints of deep pain or dysrhythmias.	3. Visceral damage requires immediate intervention.	

fruit baskets are not permitted in the patient's room because of the risk of microorganism growth. Visitors are screened to avoid exposing the immunocompromised burn patient to pathogens.

Patients can inadvertently promote migration of microorganisms from one burned area to another by touching their wounds or dressings. Bed linens also can spread infection through either colonization with wound microorganisms or fecal contamination. Regularly bathing unburned areas and changing linens can help prevent infection.

#### MAINTAINING ADEQUATE NUTRITION

Oral fluids should be initiated slowly when bowel sounds resume. The patient's tolerance is noted. If vomiting and distention do not occur, fluids may be increased gradually and the patient may advance to a normal diet or to tube feedings.

The nurse collaborates with the dietitian or nutrition support team to plan a protein- and calorie-rich diet that is acceptable to the patient. Family members may be encouraged to bring nutritious and favorite foods to the hospital. Milkshakes and sandwiches made with meat, peanut butter, and cheese may be offered as snacks between meals and late in the evening. Nutritional supplements such as Ensure and Resource may be provided. Caloric intake must be documented. Vitamin and mineral supplements may be prescribed.

If caloric goals cannot be met by oral feeding, a feeding tube is inserted and used for continuous or bolus feedings of specific formulas. The volume of residual gastric secretions should be checked to ensure absorption. Parenteral nutrition may also be required but should be used only if gastrointestinal function is compromised (see Chap. 36).

Patients should be weighed each day and their weights graphed. Patients can use this information to set goals for their own nutritional intake and to monitor weight loss and gain. Ideally, the patient will lose no more than 5% of preburn weight if aggressive nutritional management is implemented.

The patient with anorexia requires encouragement and support from the nurse to increase food intake. The patient's surroundings should be as pleasant as possible at mealtime. Catering to food preferences and offering high-protein, high-vitamin snacks are ways of encouraging the patient to increase intake.

#### PROMOTING SKIN INTEGRITY

Wound care is usually the single most time-consuming element of burn care after the emergent phase. The physician will prescribe the desired topical antibacterial agents and specific biologic, biosynthetic, or synthetic wound coverings and will plan for surgical excision and grafting. The nurse needs to make astute assessments of wound status, to use creative approaches to wound dressing, and to support the patient during the emotionally distressing and very painful experience of wound care.

The nurse serves as the coordinator of the complex aspects of wound care and dressing changes for the patient. The nurse must be aware of the rationale and nursing implications for the various wound management approaches. Nursing functions include assessing and recording any changes or progress in wound healing and keeping all members of the health care team informed of changes in the wound or treatment. A diagram, updated daily by the nurse responsible for the patient's care, helps to inform all those concerned about the latest wound care procedures in use for the patient.

The nurse also assists the patient and family by providing instruction, support, and encouragement to take an active part in dressing changes and wound care when appropriate. Discharge planning needs for wound care are anticipated early in the course of burn management, and the strengths of the patient and family are assessed and used in preparing for eventual discharge and home care.

### RELIEVING PAIN AND DISCOMFORT

Pain measures discussed earlier are continued during the acute phase of burn recovery. Analgesic agents and anxiolytic medications are administered as prescribed. Frequent assessment of pain and discomfort is essential. To increase its effectiveness, analgesic medication is provided before the pain becomes severe. Nursing interventions such as teaching the patient relaxation techniques, giving the patient some control over wound care and analgesia, and providing frequent reassurance are helpful. Guided imagery may be effective in altering the patient's perceptions of and responses to pain. Other pain-relieving approaches include distraction through video programs or video games, hypnosis, biofeedback, and behavioral modification.

The nurse works quickly to complete treatments and dressing changes to reduce pain and discomfort. The patient is encouraged to take analgesic medications before painful procedures. The patient's response to the medication and other interventions is assessed and documented.

Healing burn wounds are typically described by patients as itchy and tight. Oral antipruritic agents, a cool environment, fre-

quent lubrication of the skin with water or a silica-based lotion, exercise and splinting to prevent skin contracture, and diversional activities all help to promote comfort in this phase.

### PROMOTING PHYSICAL MOBILITY

An early priority is to prevent complications resulting from immobility. Deep breathing, turning, and proper repositioning are essential nursing practices that prevent atelectasis and pneumonia, control edema, and prevent pressure ulcers and contractures. These interventions are modified to meet the patient's needs. Low-air-loss and rotation beds may be useful, and early sitting and ambulation are encouraged. Whenever the lower extremities are burned, elastic pressure bandages should be applied before the patient is placed in an upright position. These bandages promote venous return and minimize swelling.

The burn wound is in a dynamic state for a year or more after wound closure. During this time, aggressive efforts must be made to prevent contracture and hypertrophic scarring. Both passive and active range-of-motion exercises are initiated from the day of admission and are continued after grafting, within prescribed limitations. Splints or functional devices may be applied to extremities for contracture control. The nurse monitors the splinted areas for signs of vascular insufficiency and nerve compression.

### STRENGTHENING COPING STRATEGIES

In the acute phase of burn care, the patient is facing the reality of the burn trauma and is grieving over obvious losses. Depression, regression, and manipulative behavior are common responses of

#### NURSING RESEARCH PROFILE 57-1

##### Burn Pain and Anxiety

Beyers, J. F., Bridges, S., Kijek, J., & LaBorde, P. J. (2001). Burn patients' pain and anxiety experiences. *Journal of Burn Care and Rehabilitation*, 22(2), 144–149.

#### Purpose

Pain associated with burns and treatment of burn wounds is common and often excruciating. Its management is important in patient care and is often a nursing challenge. The purpose of this study was to examine burn patients' experiences with pain and anxiety during rest and during painful wound care procedures.

#### Study Sample and Design

A descriptive study was conducted; the sample included 23 acutely burned adults in a southeastern level I trauma center who were undergoing wound care and who had not had previous surgery to treat their burn wounds. Ages ranged from 18 to 75 with a mean age of  $33 \pm 13.2$ . Data on pain and anxiety levels were collected in three phases: at the time of recruitment of subjects, at baseline (defined as at least 8 hours after the last procedure), and during burn wound care procedures (within 5 minutes of scrubbing/débridement/before dressings were reapplied).

Subjects completed the Visual Analogue Scale (VAS-pain) to assess the level of pain they considered acceptable, with possible scores ranging from no pain to worst pain possible. The Short-Form McGill (SF-M) questionnaire was used to measure the sensory and affective dimensions of pain, as well as the patient's present pain on a Likert-type scale (0 = no pain; 5 = excruciating). A Visual Analogue Scale (VAS-anxiety) was used to measure anxiety, with scores ranging along a continuum from no anxiety to worse anxiety possible. Subjects were asked to mark both VAS instruments with an X, indicating the severity of their pain and anxiety. Other data collected included demographic data, analgesic and sedative use, and use of nonpharmacologic

methods as distraction techniques during procedures. Descriptive and nonparametric statistical tests were used to analyze data.

#### Findings

Results showed that burn patients report higher levels of pain during procedures than when at rest. A strong positive relationship between pain and anxiety was found. The most frequently reported pain descriptor on the SF-M was "tender" during baseline measurements. Frequent descriptors during procedures included "throbbing," "hot-burning," and "aching." There were no significant differences in anxiety between resting conditions and procedural dressing changes ( $p > 0.16$ ). There were significant differences between burn patients' acceptable level, resting level, and procedural pain levels ( $p = 0.01$ ). Patients reported their baseline pain as less than their acceptable level of pain. Other findings noted that family presence during procedure was related to decreased procedural pain and decreased use of medications prescribed for relief of anxiety.

#### Nursing Implications

Because burn patients describe burn wound care procedures to be the most painful experience, efforts should be made to identify strategies that are effective in reducing pain intensity. Also, since pain and anxiety were linked, strategies need to be developed to decrease both. The researchers suggested that use of both pharmacologic and nonpharmacologic interventions during wound care procedures may be warranted to help patients cope with anxiety, resting pain, and pain associated with wound care procedures. Future studies of the effect of different pharmacologic interventions with larger and more diverse samples are needed.

patients who have burn injuries. Withdrawal from participation in required treatments and regression must be viewed with an understanding that such behavior helps the patient cope with an enormously stressful event. Much of the patient's energy goes into maintaining vital physical functions and wound healing in the early postburn weeks, leaving little emotional energy for coping in a more effective manner. Nurses can assist patients to develop effective coping strategies by setting specific expectations for behavior, promoting truthful communication to build trust, helping patients practice appropriate strategies, and giving positive reinforcement when appropriate. Most importantly, the nurse and all members of the health care team must demonstrate acceptance of the patient.

The patient frequently vents feelings of anger. At times the anger may be directed inward because of a sense of guilt, perhaps for causing the fire or even for surviving when loved ones perished. The anger may reach outward toward those who escaped unharmed or to those who are now providing care. One way to help the patient handle these emotions is to enlist someone to whom the patient can vent feelings without fear of retaliation. A nurse, social worker, psychiatric liaison nurse, or clergy member who is not involved in direct care activities may fill this role successfully.

Burn patients are very dependent on health care team members during the long period of acute illness. However, even when physically unable to contribute much to self-care, they can be included in decisions regarding care and encouraged to assert their individuality in terms of preferences and recognition of their unique identities. As patients improve in mobility and strength, the nurse works with them to set realistic expectations for self-care, including self-feeding, assistance with wound care procedures, exercise, and planning for the future. Many patients respond positively to the use of contractual agreements and other strategies that recognize their independence and their specific role as part of the health care team moving toward the goal of self-care.

### SUPPORTING PATIENT AND FAMILY PROCESSES

Family functioning is disrupted with burn injury. One of the nurse's responsibilities is to support the patient and family and to address their spoken and unspoken concerns. Family members need to be instructed about ways that they can support the patient as adaptation to burn trauma occurs. The family also needs support by the health care team. The burn injury has tremendous psychological, economic, and practical impact on the patient and family. Referrals for social services or psychological counseling should be made as appropriate. This support continues into the rehabilitation phase.

Burn patients are commonly sent to burn centers far from home. Because burn injuries are not anticipated, family roles are disrupted. Therefore, both the patient and the family need thorough information about the patient's burn care and expected course of treatment. Patient and family education begins at the initiation of burn management. Barriers to learning are assessed and considered in teaching. The preferred learning styles of both the patient and family are assessed. This information is used to tailor teaching activities. The nurse assesses the ability of the patient and family to grasp and cope with the information. Verbal information is supplemented by videos, models, or printed materials if available. Patient and family education is a priority in the rehabilitation phase.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

#### Heart Failure and Pulmonary Edema

The patient is assessed for fluid overload, which may occur as fluid is mobilized from the interstitial compartment back into the intravascular compartment. If the cardiac and renal systems can-

not compensate for the excess vascular volume, congestive heart failure and pulmonary edema may result. The patient is assessed for signs of heart failure, including decreased cardiac output, oliguria, jugular vein distention, edema, and the onset of an  $S_3$  or  $S_4$  heart sound. Increasing central venous, pulmonary artery, and wedge pressures indicate increased fluid volume.

Crackles in the lungs and increased difficulty with respiration may indicate a fluid buildup in the lungs, which is reported promptly to the physician. In the meantime, the patient is positioned comfortably, with the head of the bed raised (if not contraindicated because of other treatments or injuries) to promote lung expansion and gas exchange. Management of this complication includes providing supplemental oxygen, administering IV diuretic agents, carefully assessing the patient's response, and providing vasoactive medications, if indicated.

#### Sepsis

The signs of early systemic sepsis are subtle and require a high index of suspicion and very close monitoring of changes in the patient's status. Early signs of sepsis may include increased temperature, increased pulse rate, widened pulse pressure, and flushed dry skin in unburned areas. As with many observations of the burn patient, one needs to look for patterns or trends in the data. (See Chap. 15 for a more detailed discussion of septic shock.)

Wound and blood cultures are performed as prescribed, and results are reported to the physician immediately. The nurse also observes for and reports early signs of sepsis and promptly intervenes, administering prescribed IV fluids and antibiotics to prevent septic shock, a complication with a high mortality rate. Antibiotics must be given as scheduled to maintain proper blood concentrations. Serum antibiotic levels are monitored for evidence of maximal effectiveness, and the patient is monitored for toxic side effects.

#### Acute Respiratory Failure and Acute Respiratory Distress Syndrome

The patient's respiratory status is monitored closely for increased difficulty breathing, change in respiratory pattern, and onset of adventitious (abnormal) sounds. Typically at this stage, signs and symptoms of injury to the respiratory tract become apparent. Respiratory failure may follow. As described previously, signs of hypoxia (decreased  $O_2$  to the tissues), decreased breath sounds, wheezing, tachypnea, stridor, and sputum tinged with soot (or in some cases containing sloughed tracheal tissue) are among the many possible findings. Patients receiving mechanical ventilation must be assessed for a decrease in tidal volume and lung compliance. The key sign of the onset of ARDS is hypoxemia while receiving 100% oxygen, decreased lung compliance, and significant shunting. The physician should be notified immediately of deteriorating respiratory status.

Medical management of the patient with acute respiratory failure requires intubation and mechanical ventilation (if not already in use). If ARDS has developed, higher oxygen levels, positive end-expiratory pressure, and pressure support are used with mechanical ventilation to promote gas exchange across the alveolar-capillary membrane.

#### Visceral Damage

The nurse must be alert to signs of necrosis of visceral organs due to electrical injury. Tissues affected are usually between the entrance and exit wounds of the electrical burn. All patients with electrical burns should undergo electrocardiographic monitoring, with dysrhythmias being reported to the physician. Careful attention must also be paid to signs or reports of pain related to

deep muscle ischemia. To minimize the severity of complications, visceral ischemia must be detected as early as possible. The physician can perform **fasciotomies** to relieve the swelling and ischemia in the muscles and fascia and to promote oxygenation of the injured tissues. Because of the deep incisions involved with fasciotomies, the patient must be monitored carefully for signs of excessive blood loss and hypovolemia.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Achieves optimal fluid balance
  - a. Maintains intake and output and body weight that correlate with expected pattern
  - b. Exhibits vital signs and central venous, pulmonary artery, and pulmonary artery wedge pressures within designated limits
  - c. Demonstrates increased urine output in response to diuretic and vasoactive medications
  - d. Has heart rate less than 110 beats/min in normal sinus rhythm
2. Has no localized or systemic infection
  - a. Has wound culture results showing minimal bacteria
  - b. Has normal urine and sputum culture results
3. Demonstrates anabolic nutritional status
  - a. Gains weight daily after initial loss secondary to fluid diuresis and no oral intake of food or fluid
  - b. Shows no signs of protein, vitamin, or mineral deficiencies
  - c. Meets required nutritional needs entirely by oral intake
  - d. Participates in selecting diet containing prescribed nutrients
  - e. Exhibits normal serum protein levels
4. Demonstrates improved skin integrity
  - a. Sustains generally intact skin that remains free of infection, pressure, and injury
  - b. Demonstrates remaining open wound areas that are pink, re-epithelializing, and free of infection
  - c. Demonstrates donor graft sites that are clean and healing
  - d. Has healed wounds that are soft and smooth
  - e. Demonstrates skin that is lubricated and elastic
5. Has minimal pain
  - a. Requests analgesic agents for specific wound care procedures or physical therapy activities
  - b. Reports minimal pain
  - c. Gives no physiologic, verbal, or nonverbal cues that pain is moderate or severe
  - d. Uses pain control measures such as nitrous oxide, relaxation, imagery, and distraction techniques to cope with and alleviate pain and discomfort
  - e. Can sleep without being disturbed by pain
  - f. Reports skin is comfortable, with no itching or tightness
6. Demonstrates optimal physical mobility
  - a. Improves range of motion of joints daily
  - b. Demonstrates preinjury range of motion of all joints
  - c. Has no signs of calcification around the joints
  - d. Participates in activities of daily living
7. Uses appropriate coping strategies to deal with postburn problems
  - a. Verbalizes reactions to burns, therapeutic procedures, losses
  - b. Identifies coping strategies used effectively in previous stressful situations
  - c. Accepts dependency on health care providers during acute phase
  - d. Verbalizes realistic view of problems resulting from burn injury and plans for future
  - e. Cooperates with health care providers in required therapy
  - f. Participates in decision making regarding care
  - g. Resolves grief over losses resulting from burn injury and circumstances surrounding injury (eg, death of others, damage to home or other property)
  - h. States realistic objectives for plastic surgery, further medical intervention, and results
    - i. Verbalizes realistic abilities and goals
    - j. Displays hopeful attitude toward future
8. Relates appropriately in patient/family processes
  - a. Patient and family verbalize feelings regarding change in family interactions
  - b. Family emotionally supports the patient during the hospitalization
  - c. Family states that own needs are met
9. Patient and family verbalize understanding of the treatment course
  - a. States rationale for different aspects of treatment
  - b. States realistic time period for recovery
10. Absence of complications
  - a. Lungs clear on auscultation
  - b. Exhibits no dyspnea or orthopnea and can breathe easily when standing, sitting, and lying down
  - c. Exhibits no S<sub>3</sub> or S<sub>4</sub> heart sounds or jugular venous distention
  - d. Exhibits urine output; central venous, pulmonary artery, and pulmonary artery wedge pressures; and cardiac output within normal or acceptable limits
  - e. Exhibits normal blood, sputum, and urine culture results
  - f. Maintains arterial blood gas values within normal or acceptable limits
  - g. Has normal lung compliance
  - h. Has no visceral organ damage
  - i. Has stable cardiac rhythm

## REHABILITATION PHASE OF BURN CARE

Although long-term aspects of burn care are discussed last in this chapter, rehabilitation begins immediately after the burn has occurred—as early as the emergent period—and often extends for years after injury. In the aftermath of the acute stages of injury, the burn patient increasingly focuses on the alterations in self-image and lifestyle that may occur. Wound healing, psychosocial support, and restoring maximal functional activity remain priorities. The focus on maintaining fluid and electrolyte balance and improving nutritional status continues. Reconstructive surgery to improve body appearance and function may be needed.

Burn injuries can have a major impact on quality of life. Changes in physical activity and social, psychological, and employment status may occur. Therefore, psychological and vocational counseling and referral to support groups may be helpful to promote recovery and quality of life. Family members also need support and guidance in assisting the patient to return to optimal health.

## Prevention of Hypertrophic Scarring

The wound is in a dynamic state for 1.5 to 2 years after the burn occurs. If appropriate measures are instituted during this active period, the scar tissue loses its redness and softens. Healed areas that are prone to hypertrophic scarring require the patient to wear a pressure garment (Fig. 57-6). These devices are especially useful for partial-thickness wounds that required more than 2 weeks to heal and for the edges of grafted skin. Applying elastic pressure garments loosens collagen bundles and encourages parallel orientation of the collagen to the skin surface, with the disappearance of the dermal nodules. As pressure continues over time, there is a restructuring of the collagen and a decrease in vascularity and cellularity (Serghiou, Young, Ott et al., 2002).

The physical therapist, occupational therapist, or a representative of the manufacturer of elastic pressure garments measures the patient for correct fit. While awaiting the arrival of the garment, soft, tubular, knitted elastic pressure bandages can be used to help desensitize the patient's skin, protect healing areas, apply pressure, and promote venous return. Patients must be instructed about the need for lubrication and protection of the healing skin and the need for pressure garments for at least a year after the injury. A program including elastic pressure garments, splints, and exercise under the supervision of an experienced physical and occupational therapy team is recommended for optimal functional and cosmetic results.

## NURSING PROCESS: CARE OF THE PATIENT DURING THE REHABILITATION PHASE

### Assessment

Information about the patient's educational level, occupation, leisure activities, cultural background, religion, and family interactions is obtained early. The patient's self-concept, mental status, emotional response to the injury and hospitalization, level of intellectual functioning, previous hospitalizations, response to pain and pain relief measures, and sleep pattern are also essential components of a comprehensive assessment. Information about the patient's general self-concept, self-esteem, and coping strategies in the past will be valuable in addressing emotional needs.

**FIGURE 57-6** Elastic pressure garments. Application of pressure garments helps prevent hypertrophic burn scarring. Used with permission of Jobst Institute, Inc., Toledo, Ohio.

Ongoing physical assessments related to rehabilitation goals include range of motion of affected joints, functional abilities in activities of daily living, early signs of skin breakdown from splints or positioning devices, evidence of neuropathies (neurologic damage), activity tolerance, and quality or condition of healing skin. The patient's participation in care and ability to demonstrate self-care in such areas as ambulation, eating, wound cleaning, and applying pressure wraps are documented on a regular basis. In addition to these assessment parameters, specific complications and treatments require additional specific assessments; for example, the patient undergoing primary excision requires postoperative assessment.

Recovery from burn injury involves every system of the body. Therefore, assessment of the burn patient must be comprehensive and continuous. Priorities will vary at different points during the rehabilitation phase. Understanding the pathophysiologic responses to burn injury forms the framework for detecting early progress or signs and symptoms of complications. Early detection leads to early intervention and enhances the potential for successful rehabilitation.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, priority nursing diagnoses in the long-term rehabilitation phase of burn care may include the following:

- Activity intolerance related to pain on exercise, limited joint mobility, muscle wasting, and limited endurance
- Disturbed body image related to altered physical appearance and self-concept
- Deficient knowledge about postdischarge home care and follow-up needs

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop in the rehabilitation phase include:

- Contractures
- Inadequate psychological adaptation to burn injury

## Planning and Goals

The major goals for the patient include increased participation in activities of daily living; increased understanding of the injury, treatment, and planned follow-up care; adaptation and adjustment to alterations in body image, self-concept, and lifestyle; and absence of complications.

## Nursing Interventions

### PROMOTING ACTIVITY TOLERANCE

Nursing interventions that must be carried out according to a strict regimen and the pain that accompanies movement take their toll on a burn patient. The patient may become confused and disoriented and lack the energy to participate optimally in care. The nurse must schedule care in such a way that the patient has periods of uninterrupted sleep. A good time for planned patient rest is after the stress of dressing changes and exercise, while pain interventions and sedatives may still be effective. This plan must be communicated to family members and other care providers.

Burn patients may have insomnia related to frequent nightmares about the burn injury or to other fears and anxieties about the outcome of the injury. The nurse listens to and reassures the

patient and administers hypnotic agents, as prescribed, to promote sleep.

Reducing metabolic stress by relieving pain, preventing chilling or fever, and promoting the physical integrity of all body systems will help the patient conserve energy for therapeutic activities and wound healing.

The nurse incorporates physical therapy exercises in the patient's care to prevent muscle atrophy and to maintain the mobility required for daily activities. The patient's activity tolerance, strength, and endurance will gradually increase if activity occurs over increasingly longer periods. Fatigue, fever, and pain tolerance are monitored and used to determine the amount of activity to be encouraged on a daily basis. Activities such as family visits and recreational or play therapy (eg, video games, radio, TV) can provide diversion, improve the patient's outlook, and increase tolerance for physical activity.

### IMPROVING BODY IMAGE AND SELF-CONCEPT

Burn patients frequently suffer profound losses. These include not only a loss of body image due to disfigurement but also losses of personal property, homes, loved ones, and ability to work. They lack the benefit of anticipatory grief often seen in a patient approaching surgery or a person dealing with the terminal illness of a loved one.

As care progresses, the patient who is recovering from burns becomes aware of daily improvement and begins to exhibit basic concerns: Will I be disfigured? How long will I be in the hospital? What about my job and family? Will I ever be independent again? How can I pay for my care? Was my burn the result of my carelessness? As the patient expresses such concerns, the nurse must take time to listen and to provide realistic support. The nurse can refer patients to a support group, such as those usually available at regional burn centers or through organizations such as the Phoenix Society. Through participation in such groups, patients will meet others with similar experiences and learn coping strategies to help them deal with their losses. Interaction with other burn survivors allows the patient to see that adaptation to the burn injury is possible. If a support group is not available, visits from burn survivors can be helpful to the patient coping with such a traumatic injury.

A major responsibility of the nurse is to assess constantly the patient's psychosocial reactions. What are the patient's fears and concerns? Does the patient fear loss of control of care, independence, or sanity itself? Is the patient afraid of rejection by family and loved ones? Does he or she fear being unable to cope with pain or physical appearance? Does the patient have concerns about sexuality, including sexual function? Being aware of these anxieties and understanding the basis of the patient's fears enable the nurse to provide support and to cooperate with other members of the health care team in developing a plan to help the patient deal with these feelings.

When caring for burn patients, the nurse needs to be aware that there are prejudices and misunderstandings in society about those who are viewed as different. Opportunities and accommodations available to others are often denied those who are disfigured. Such amenities include social participation, employment, prestige, various roles, and status. The health care team must actively promote a healthy body image and self-concept in burn survivors so that they can accept or challenge others' perceptions of those who are disfigured. Survivors themselves must show others who they are, how they function, and how they want to be treated.

The nurse can help patients practice their responses to people who may stare or inquire about their injury once they are discharged from the hospital. The nurse can help patients build self-

esteem by recognizing their uniqueness—for example, with small gestures such as providing a birthday cake, combing the patient's hair before visiting hours, giving information about the availability of a cosmetician to enhance appearance, and teaching the patient ways to direct attention away from a disfigured body to the self within. Consultants such as psychologists, social workers, vocational counselors, and teachers are valuable participants in assisting burn patients to regain their self-esteem.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

#### Contractures

With early and aggressive physical and occupational therapy, contractures are rarely a long-term complication. However, surgical intervention is indicated if a full range of motion in the burn patient is not achieved. (See Chap. 11 for a discussion of prevention of contractures.)

#### Impaired Psychological Adaptation to the Burn Injury

Some patients, particularly those with limited coping skills or psychological function or a history of psychiatric problems before the burn injury, may not achieve adequate psychological adaptation to the burn injury. Psychological counseling or psychiatric referral may be made to assess the patient's emotional status, to help the patient develop coping skills, and to intervene if major psychological issues or ineffective coping is identified.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

As the inpatient phase of recovery becomes shorter, the focus of rehabilitative interventions is directed toward outpatient care or care in a rehabilitation center. In the long term, much of the care of healing burns will be performed by the patient and others at home. Throughout the phases of burn care, efforts are made to prepare the patient and family for the care that will continue at home. Thus, they are instructed about the measures and procedures that they will need to perform. For example, patients commonly have small areas of clean, open wounds that are healing slowly. They are instructed to wash these areas daily with mild soap and water and to apply the prescribed topical agent or dressing.

In addition to instructions about wound care, patients and families require careful written and verbal instructions about prevention of complications, pain management, and nutrition. Information about specific exercises and use of pressure garments and splints is reviewed with both the patient and family; written instructions are provided for reference. They are taught to recognize abnormal signs and instructed to report them to the physician. All of this information will enable patients to progress successfully through the rehabilitative phase of burn management. The patient and family are assisted in planning for the patient's continued care by identifying and acquiring supplies and equipment that are needed at home (Chart 57-6).

#### Continuing Care

Follow-up care by an interdisciplinary burn care team will be necessary. Preparations should begin during the early stages of care. Patients who receive care in a burn center usually return to the burn clinic or center periodically for evaluation by the burn team, modification of home care instructions, and planning for reconstructive surgery. Other patients receive ongoing care from the general or plastic surgeon who cared for them during the acute phase of their management. Still other patients require the services

## Chart 57-6

## Home Care Checklist • The Patient with a Burn Injury

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
<b>Mental Health</b>		
Identify strategies to promote own mental health; for example:		
• Remember that changes in lifestyle take time.	✓	✓
• Resume previous interests and activities gradually.	✓	
• Take one day at a time to regain physical and mental strength.	✓	
• Be aware of own feelings and fears and discuss them with selected others.	✓	✓
• Expect concerns, frustrations, and depression about changes in appearance.	✓	✓
• Be honest with self, family, and friends about needs, hopes, and fears.	✓	✓
• Realize that emotional adjustment to the burn injury will occur with time.	✓	✓
<b>Burn Skin Precautions and Wound Care</b>		
Identify the following skin precautions and wound care:		
• Wear sun block with the highest SPF possible to protect burned skin from the sun.	✓	
• Avoid further trauma to burned skin; leave unbroken blisters that may form.	✓	✓
• Lubricate healed burned skin with mild lotion (as prescribed); avoid scratching.	✓	
• Wear wide-brimmed hats if face has been burned to protect the area from the sun.	✓	
• Use only mild soap and lotion (ie, products without perfume) on burned areas.	✓	✓
<b>Exercise</b>		
Describe the following guidelines for exercise:		
• Do as much for self as possible.	✓	
• Adhere to the exercise regimen given by the therapist.	✓	
• Participate in exercise every day, several times a day, even when “not feeling like it.”	✓	
<b>Nutrition</b>		
Identify the following guidelines for nutrition:		
• Eat a diet high in calories and protein.	✓	
• Drink adequate volume of fluids to prevent constipation associated with use of analgesic medications.	✓	
<b>Pain Management</b>		
Describe the following steps for managing pain:		
• Take analgesic medication as prescribed.	✓	
• Avoid situations that require alertness (analgesic agents may produce drowsiness).	✓	
• Use analgesic medication as prescribed (30 minutes before painful procedures such as dressing changes).	✓	✓
• Use relaxation and distraction to relieve pain and discomfort.	✓	
<b>Thermoregulation</b>		
Identify strategies to compensate for inability to regulate body temperature:		
• Dress to accommodate cold and hot weather or environment.	✓	
• Avoid extremes of temperature.	✓	
<b>Clothing Considerations</b>		
State the following strategies in selection of clothing to wear:		
• Avoid tight clothing over burned areas.	✓	
• Select white cotton, loose-fitting clothing so that dyes in colored clothes do not irritate healing skin.	✓	
• Wear clothing and gloves to protect healing skin from unnecessary bruises, bumps, and scratches.	✓	
<b>Management of Burn Scar</b>		
Describe the following strategies to manage burn scar:		
• Massage and stretch skin to maintain/increase its elasticity.	✓	✓
• Use lotion for massage as recommended by therapist.	✓	✓
• Wear compression garments 23 hours a day.	✓	
<b>Resumption of Sexual Relations</b>		
Identify the following guidelines regarding resumption of sexual relationships:		
• Realize that resumption of sexual relationships is the rule rather than the exception.	✓	✓
• Expect sensitivity of and around the genital area for several months if these areas were burned.	✓	
• Resume sexual activity slowly; endurance will increase with time.	✓

of a rehabilitation center and may be transferred to such a center for aggressive rehabilitation before going home. Many patients require outpatient physical or occupational therapy, often several times weekly. It is often the nurse who is responsible for coordinating all aspects of care and ensuring that the patient's needs are met. Such coordination is an important aspect in assisting a burn victim to achieve independence.

Patients who return home after a severe burn injury, those who cannot manage their own burn care, and those with inadequate support systems will need referral for home care. During visits to the patient at home, the home care nurse assesses the patient's physical and psychological status as well as the adequacy of the home setting for safe and adequate care. The nurse monitors the patient's progress and adherence to the plan of care and notes any problems that interfere with the patient's ability to carry out the care. During the visit, the nurse assists the patient and family with wound care and exercises. Patients with severe or persistent depression or difficulty adjusting to changes in their social and/or occupational roles are identified and referred to the burn team for possible referral to a psychologist, psychiatrist, or vocational counselor.

The burn team or home care nurse identifies community resources that may be helpful for the patient and family. Several burn patient support groups and other organizations throughout the United States offer services for burn victims. They provide caring people (often recovered burn victims) who can visit a burn patient in the hospital or home or telephone the patient and family periodically to provide support and counseling about skin care, cosmetics, and problems related to psychosocial adjustment. Such organizations, and many regional burn centers, sponsor group meetings and social functions at which outpatients are welcome. Some also provide school-reentry programs and are active in burn prevention activities. If more information is needed regarding burn prevention, the American Burn Association can help locate the nearest burn center and offer current burn prevention tips (see Chart 57-2).

Because so much attention is given to the burn wound and the treatments that are necessary to treat the burn wound and to prevent complications, the patient, family, and health care providers may inadvertently ignore the patient's ongoing needs for health promotion and screening. Thus, the patient and family are reminded of the importance of periodic health screening and preventive care (eg, gynecologic examinations, dental care).

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Demonstrates activity tolerance required for desired daily activities
  - a. Obtains sufficient sleep daily
  - b. Reports absence of nightmares or sleep disturbances
  - c. Shows gradually increasing tolerance and endurance in physical activities
  - d. Can concentrate during conversations
  - e. Has energy available to sustain desired daily activities
2. Adapts to altered body image
  - a. Verbalizes accurate description of alterations in body image and accepts physical appearance
  - b. Demonstrates interest in resources that may improve body appearance and function
  - c. Uses cosmetics, wigs, and prostheses as desired to achieve acceptable appearance

- d. Socializes with significant others, peers, and usual social group
- e. Seeks and achieves return to role in family, school, and community as a contributing member
3. Demonstrates knowledge of required self-care and follow-up care
  - a. Describes surgical procedures and treatments accurately
  - b. Verbalizes detailed plan for follow-up care
  - c. Demonstrates ability to perform wound care and prescribed exercises
  - d. Returns for follow-up appointments as scheduled
  - e. Identifies resource people and agencies to contact for specific problems
4. Exhibits no complications
  - a. Demonstrates full range of motion
  - b. Shows no signs of withdrawal or depression
  - c. Displays no psychotic behaviors

## Burn Care in the Home

More and more burns are being treated exclusively in outpatient settings, including wound clinics, physicians' offices, and emergency department clinics. The outpatient setting is appropriate for the care of minor burns and most moderate burns. However, a number of factors must be considered in determining the appropriate site of care. These factors include the age of the patient, the extent and depth of the burn, the availability of family support systems and community resources to assist the patient, the patient's adherence to the prescribed plan of care, and the distance from home to the outpatient setting.

Initially, looking at and touching the burn wound may be difficult and even frightening to some family members and patients. However, with encouragement and support, most can handle burn wound care with little need for daily professional care. Instructions, both verbal and written, are given to the patient about burn wound care, pain management strategies, the need for adequate nutrition, and the importance of exercise and rest. Instruction is also given about signs and symptoms of infection that should be reported to the physician. The importance of notifying the physician about complications early and of keeping follow-up appointments is emphasized to the patient and family.

### Gerontologic Considerations

Nursing assessment of the elderly burn patient should include particular attention to pulmonary function, response to fluid resuscitation, and signs of mental confusion or disorientation. A careful history of preburn medications and preexisting illnesses is essential.

Nursing care promotes early mobilization, aggressive pulmonary care, and attention to preventing complications. Because of lowered resistance, burn wound sepsis and lethal systemic septicemia are more likely in elderly patients. Moreover, fever may not be present in the elderly to signal such events. Therefore, surveillance for other signs of infection becomes even more important.

Rehabilitation must take into account preexisting functional abilities and limitations, such as arthritis and low activity tolerance. Elderly patients commonly lack family members who can provide home care, so social services and community nursing services must be contacted to provide optimal care and supervision after hospital discharge.

## Critical Thinking Exercises

1. A 60-year-old man weighing 50 kg is transferred to the emergency department after his tractor caught on fire, burning both of his legs circumferentially, his anterior chest, and his entire right upper extremity. Using the rule of nines chart, estimate the percent of TBSA burned. What are the emergent priorities for this patient? What are the fluid resuscitation requirements for this patient based on his percent burn and his weight? What assessment parameters would you be monitoring closely?
2. Your 25-year-old patient received burns over 60% of her body, including her upper extremities and face, as a result of a kitchen fire 2 weeks ago. She is depressed and distraught about the pain associated with wound care and the changes in her appearance. What assessments are important in her care, and what nursing interventions would be appropriate for her at this time?
3. Your 26-year-old burn patient is scheduled for surgery. The burn physician plans on using Integra on his upper extremity burns after débridement and to apply Acticoat to the superficial burns. What patient education would you give this patient about Integra and Acticoat? Explain what these two products are, their purpose, and the benefits of their use. Explain how the implications for nursing care differ for the two products.
4. Your 41-year-old patient, an attorney, is expected to be discharged from the hospital in a week following 6 weeks of treatment for severe burns to the lower part of her body. She has used a wheelchair for the last 20 years as a result of a spinal cord injury. The burns occurred when she was lighting a candle at home and it fell onto her clothing. What preparation would be important in making arrangements for referral and home care if she lives alone? What specific safety precautions should be included in discharge teaching for her?

# ● Assessment and Management of Patients With Eye and Vision Disorders

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

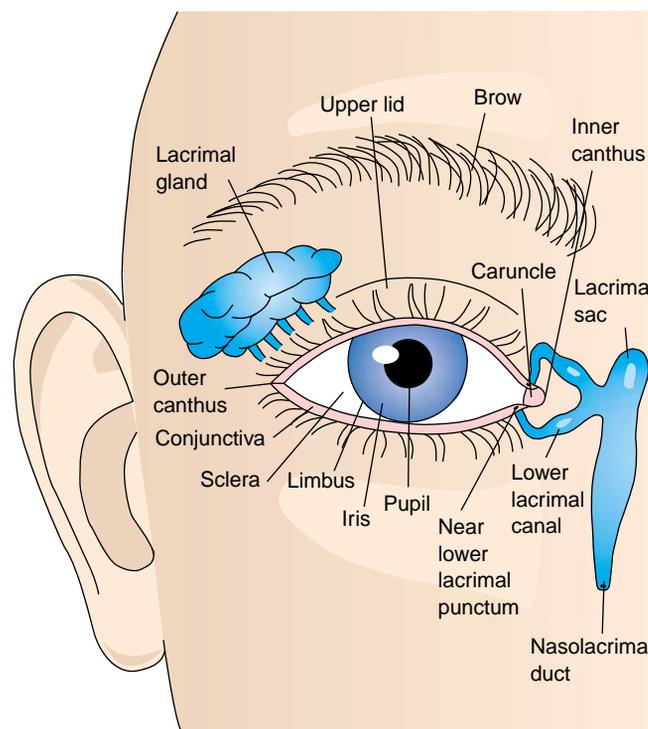

1. Identify significant eye structures and describe their functions.
2. Identify diagnostic tests for assessment of vision and evaluation of visual disabilities.
3. Discuss clinical features of ocular disorders, diagnostic assessment and examinations, medical or surgical management, and patient care.
4. Describe therapeutic effects of ophthalmic medications.
5. Define low vision and blindness and differentiate between functional and visual impairment.
6. List and describe assessment and management strategies for low vision.
7. Demonstrate orientation and mobility techniques for low-vision patients in a hospital setting.
8. Demonstrate instillation of eye drops and ointment.
9. Discuss general discharge instructions for patients after ocular surgery.

The ability to see the world clearly can easily be taken for granted. The eye is a sensitive, highly specialized sense organ subject to various disorders, many of which lead to impaired vision. Impaired vision affects an individual's independence in self-care, work and lifestyle choices, sense of self-esteem, safety, ability to interact with society and the environment, and overall quality of life. Many of the leading causes of visual impairment are associated with aging (eg, cataracts, glaucoma, macular degeneration), and two thirds of the visually impaired population is older than 65 years of age. Younger people are also at risk for eye disorders, particularly traumatic injuries.

Although most people with eye disorders are treated in an ambulatory care setting, many patients receiving health care have an eye disease as a comorbid condition. In addition to understanding the prevention, treatment, and consequences of eye disorders, nurses in all settings should assess visual acuity in those at risk (eg, patients who are elderly, those with diabetes or acquired immunodeficiency syndrome [AIDS]), refer patients to eye care specialists as appropriate, implement measures to prevent further visual loss, and help patients adapt to impaired vision.

## Anatomic and Physiologic Overview

Unlike most organs of the body, the eye is available for external examination, and its anatomy is more easily assessed than many other body parts (Fig. 58-1). The eyeball, or globe, sits in a protective bony structure known as the orbit. Lined with muscle and

**FIGURE 58-1** External structures of the eye and position of the lacrimal structures.

## Glossary

**accommodation:** process by which the eye adjusts for near distance (eg, reading) by changing the curvature of the lens to focus a clear image on the retina

**anterior chamber:** space in the eye bordered anteriorly by the cornea and posteriorly by the iris and pupil

**aphakia:** absence of the natural lens

**astigmatism:** refractive error in which light rays are spread over a diffuse area rather than sharply focused on the retina, a condition caused by differences in the curvature of the cornea and lens

**binocular vision:** normal ability of both eyes to focus on one object and fuse the two images into one

**blindness:** inability to see, usually defined as corrected visual acuity of 20/400 or less, or a visual field of no more than 20 degrees in the better eye

**chemosis:** edema of the conjunctiva

**cones:** retinal photoreceptor cells essential for visual acuity and color discrimination

**diplopia:** seeing one object as two; double vision

**emmetropia:** absence of refractive error

**enucleation:** complete removal of the eyeball and part of the optic nerve

**exenteration:** surgical removal of the entire contents of the orbit, including the eyeball and lids

**visceration:** removal of the intraocular contents through a corneal or scleral in-

cision; the optic nerve, sclera, extraocular muscles, and sometimes, the cornea are left intact

**hyperemia:** "red eye" resulting from dilation of the vasculature of the conjunctiva

**hyperopia:** farsightedness; a refractive error in which the focus of light rays from a distant object is behind the retina

**hyphema:** blood in the anterior chamber

**hypopyon:** collection of inflammatory cells that has the appearance of a pale layer in the inferior anterior chamber of the eye

**injection:** congestion of blood vessels

**keratoconus:** cone-shaped deformity of the cornea

**keratopathy, bullous:** corneal edema with painful blisters in the epithelium due to excessive corneal hydration

**limbus:** junction of the cornea and sclera

**miotics:** medications that cause pupillary constriction

**mydriatics:** medications that cause pupillary dilation

**myopia:** nearsightedness; a refractive error in which the focus of light rays from a distant object is anterior to the retina

**neovascularization:** growth of abnormal new blood vessels

**nystagmus:** involuntary oscillation of the eyeball

**papilledema:** swelling of the optic disc due to increased intracranial pressure

**photophobia:** ocular pain on exposure to light

**posterior chamber:** space between the iris and vitreous

**proptosis:** downward displacement of the eyeball resulting from an inflammatory condition of the orbit or a mass within the orbital cavity

**ptosis:** drooping eyelid

**refraction:** determination of the refractive errors of the eye and correction by lenses

**rods:** retinal photoreceptor cells essential for bright and dim light

**scotomas:** blind or partially blind areas in the visual field

**strabismus:** a condition in which there is deviation from perfect ocular alignment

**sympathetic ophthalmia:** an inflammatory condition created in the fellow eye by the affected eye (without useful vision); the condition may become chronic and result in blindness (of the fellow eye)

**trachoma:** a bilateral chronic follicular conjunctivitis of childhood that leads to blindness during adulthood, if left untreated

**vitreous humor:** gelatinous material (transparent and colorless) that fills the eyeball behind the lens

**Note:** Common abbreviations related to vision and eye health are OD (ocular dexter, right eye), OS (ocular sinister, left eye), and OU (ocular uterque, both eyes).

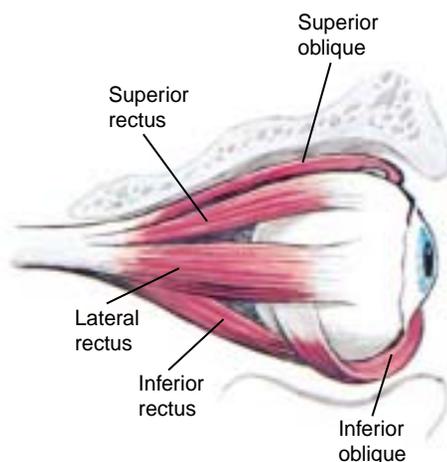

connective and adipose tissues, the orbit is about 4 cm high, wide, and deep, and it is shaped roughly like a four-sided pyramid, surrounded on three sides by the sinuses: ethmoid (medially), frontal (superiorly), and maxillary (inferiorly). The optic nerve and the ophthalmic artery enter the orbit at its apex through the optic foramen. The eyeball is moved through all fields of gaze by the extraocular muscles. The four rectus muscles and two oblique muscles (Fig. 58-2) are innervated by cranial nerves (CN) III, IV, and VI. Normally, the movements of the two eyes are coordinated, and the brain perceives a single image.

The eyelids, composed of thin elastic skin that covers striated and smooth muscles, protect the anterior portion of the eye. The eyelids contain multiple glands, including sebaceous, sweat, and accessory lacrimal glands, and they are lined with conjunctival material. The upper lid normally covers the uppermost portion of the iris and is innervated by the oculomotor nerve (CN III). The lid margins contain meibomian glands, the inferior and superior puncta, and the eyelashes. The triangular spaces formed by the junction of the eyelids are known as the inner or medial canthus and the outer or lateral canthus. With every blink of the eyes, the lids wash the cornea and conjunctiva with tears.

Tears are vitally important to eye health. They are formed by the lacrimal gland and the accessory lacrimal glands. A healthy tear is composed of three layers: lipoid, aqueous, and mucoid. If there is a defect in the composition of any of these layers, the integrity of the cornea may be compromised. Tears are secreted in response to reflex or emotional stimuli.

The conjunctiva, a mucous membrane, provides a barrier to the external environment and nourishes the eye. The goblet cells of the conjunctiva secrete lubricating mucus. The bulbar conjunctiva covers the sclera, whereas the palpebral conjunctiva lines the inner surface of the upper and lower eyelids. The junction of the two portions is known as the fornix.

The sclera, commonly known as the white of the eye, is a dense, fibrous structure that comprises the posterior five sixths of the eye (Fig. 58-3). The sclera helps to maintain the shape of the eyeball and protects the intraocular contents from trauma. The sclera may have a slightly bluish tinge in young children, a dull white color in adults, and a slightly yellowish color in the elderly. Externally, it is overlaid with conjunctiva, which is a thin, transparent, mucous membrane that contains fine blood vessels. The conjunctiva meets the cornea at the **limbus** on the outermost edge of the iris.

**FIGURE 58-2** The extraocular muscles responsible for eye movement. The medial rectus muscle (not shown) is responsible for opposing the movement of the lateral rectus muscle.

The cornea (Fig. 58-4), a transparent, avascular, domelike structure, forms the most anterior portion of the eyeball and is the main refracting surface of the eye. It is composed of five layers: epithelium, Bowman's membrane, stroma, Descemet's membrane, and endothelium. The epithelial cells are capable of rapid replication and are completely replaced every 7 days.

Behind the cornea lies the **anterior chamber**, filled with a continually replenished supply of clear aqueous humor, which nourishes the cornea. The aqueous humor is produced by the ciliary body, and its production is related to the intraocular pressure (IOP). Normal pressure is 10 to 21 mm Hg.

The uvea consists of the iris, the ciliary body, and the choroid. The iris, or colored part of the eye, is a highly vascularized, pigmented collection of fibers surrounding the pupil. The pupil is a space that dilates and constricts in response to light. Normal pupils are round and constrict symmetrically when a bright light shines on them. About 20% of the population has pupils that are slightly unequal in size but that respond equally to light. Dilation and constriction are controlled by the sphincter and dilator pupillae muscles. The dilator muscles are controlled by the sympathetic nervous system, whereas the sphincter muscles are controlled by the parasympathetic nervous system.

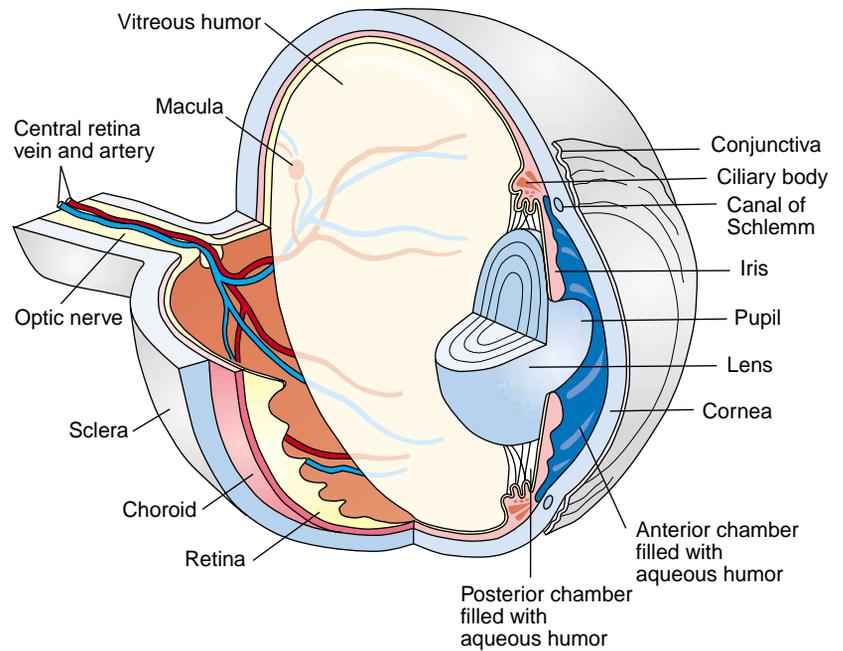

Directly behind the pupil and iris lies the lens, a colorless and almost completely transparent, biconvex structure held in position by zonular fibers. It is avascular and has no nerve or pain fibers. The lens enables focusing for near vision and refocusing for distance vision. The ability to focus and refocus is called **accommodation**. The lens is suspended behind the iris by the zonules and is connected to the ciliary body. The ciliary body controls accommodation through the zonular fibers and the ciliary muscles. The aqueous humor is anterior to the lens; posterior to the lens is the **vitreous humor**. All cells formed throughout life are retained by the lens, which makes the cell structure of the lens susceptible to the degenerative effects of aging. The lens continues to grow throughout life, laying down fibers in concentric rings. This gradual thickening becomes evident in the fifth decade of life and eventually results in an increasingly dense core or nucleus, which can limit accommodative powers.

The **posterior chamber** is a small space between the vitreous and the iris. Aqueous fluid is manufactured in the posterior chamber by the ciliary body. This aqueous fluid flows from the posterior chamber into the anterior chamber, from which it drains through the trabecular meshwork into the canal of Schlemm.

The choroid lies between the retina and the sclera. It is a vascular tissue, supplying blood to the portion of the sensory retina closest to it.

The ocular fundus is the largest chamber of the eye and contains the **vitreous humor**, a clear, gelatinous substance, composed mostly of water and encapsulated by a hyaloid membrane. The vitreous humor occupies about two thirds of the eye's volume and helps maintain the shape of the eye. As the body ages, the gel-like characteristics are gradually lost, and various cells and fibers cast shadows that the patient perceives as "floaters." The vitreous is in continuous contact with the retina and is attached to the retina by scattered collagenous filaments. The vitreous shrinks and shifts with age.

The innermost surface of the fundus is the retina. The retina is composed of 10 microscopic layers and has the consistency of wet tissue paper. It is neural tissue, an extension of the optic nerve. Viewed through the pupil, the landmarks of the retina are the optic disc, the retinal vessels, and the macula. The point of entrance of the optic nerve into the retina is the optic disc. The optic disc is oval or circular, is pink, and has sharp margins. In

**FIGURE 58-3** Three-dimensional cross-section of the eye.

the disc, a physiologic depression or cup is present centrally, with the retinal blood vessels emanating from it. The retinal tissues arise from the optic disc and line the inner surface of the vitreous chamber. The retinal vessels also enter the eye through the optic nerve, branching out through the retina and forming superior and inferior arcades. The area of the retina responsible for central vision is the macula. The rest of the retina is responsible for peripheral vision. In the center of the macula is the most sensitive

area, the fovea, which is avascular and surrounded by the superior and inferior vascular arcades. Two important layers of the retina are the retinal pigment epithelium (RPE) and the sensory retina. A single layer of cells constitutes the RPE, and these cells have numerous functions, including the absorption of light. The sensory retina contains the photoreceptor cells: **rods** and **cones**. Rods and cones are long, narrow cells shaped like rods or cones. The rods are mainly responsible for night vision or vision in low

**FIGURE 58-4** Internal structures of the eye. From Goldblum, K. (Ed.) (1997). *Core curriculum for ophthalmic nursing*. American Society of Ophthalmic Registered Nurses. Dubuque, IA: Kendall/Hall Publishing.

light, whereas the cones provide the best vision for bright light, color vision, and fine detail. Cones are distributed throughout the retina with their greatest concentration in the fovea. Rods are absent in the fovea.

Good visual acuity depends on a healthy, functioning eyeball and an intact visual pathway (Fig. 58-5). This pathway is made up of the retina, optic nerve, optic chiasm, optic tracks, lateral geniculate bodies, optic radiations, and the visual cortex area of the brain. The pathway is an extension of the central nervous system.

The optic nerve is also known as the second cranial nerve (CN II). Its purpose is to transmit impulses from the retina to the occipital lobe of the brain. The optic nerve head, or optic disc, is the physiologic blind spot in each eye. The optic nerve leaves the eye and then meets the optic nerve from the other eye at the optic chiasm. The chiasm is the anatomic point at which the nasal

fibers from the nasal retina of each eye cross to the opposite side of the brain. The nerve fibers from the temporal retina of each eye remain uncrossed. Fibers from the right half of each eye, which would be the left visual field, therefore carry impulses to the right occipital lobe. Fibers from the left half of each eye, or the right visual field, carry impulses to the left occipital lobe. Beyond the chiasm, these fibers are known as the optic tract. The optic tract continues on to the lateral geniculate body. The lateral geniculate body leads to the optic radiations and then to the cortex of the occipital lobe of the brain.

## Assessment

The health care provider, through careful questioning, elicits the necessary information that can lead to the diagnosis of an ophthalmic condition. Pertinent questions to ask during the interview can be found in Chart 58-1.

## OCULAR EXAMINATION

After the patient's chief complaint or concern has been identified and the history has been obtained, visual acuity should be assessed. This is an essential part of the eye examination and a measure against which all therapeutic outcomes are based.

### Visual Acuity

Most health care providers are familiar with the standard Snellen chart. This chart is composed of a series of progressively smaller rows of letters and is used to test distance vision. The fraction 20/20 is considered the standard of normal vision. Most people can see the letters on the line designated as 20/20 from a distance of 20 feet. A person whose vision is 20/200 can see an object from 20 feet away that a person whose vision is 20/20 can see from 200 feet away.

The patient is positioned at the proscribed distance, usually 20 feet, from the chart and is asked to read the smallest line that he or she can see. The patient should wear distance correction

**FIGURE 58-5** The visual pathway. From Goldblum, K. (Ed.) (1997). *Core curriculum for ophthalmic nursing*, American Society of Ophthalmic Registered Nurses. Dubuque, IA: Kendall/Hall Publishing.

**Chart 58-1 • ASSESSMENT**

**Taking an Ocular History**

- What does the patient perceive to be the problem?
- Is visual acuity diminished?
- Does the patient experience blurred, double, or distorted vision?
- Is there pain; is it sharp or dull; is it worse when blinking?
- Is the discomfort an itching sensation or more of a foreign body sensation?
- Are both eyes affected?
- Is there a history of discharge? If so, question color, consistency, odor.
- What is the duration of the problem?
- Is this a recurrence of a previous condition?
- How has the patient self-treated?
- What makes the symptoms improve or worsen?
- Are there any systemic diseases? What medications are used in their treatment?
- What concurrent ophthalmic conditions does the patient have?
- Is there an ophthalmic surgery history?
- Have other family members had the same symptoms or condition?

(eyeglasses or contact lenses) if required, and each eye should be tested separately. The right eye is commonly tested first and then the left. If the patient is unable to read the 20/20 line, he or she is given a pinhole occluder and asked to read again using the eye in question. A makeshift occluder may be created by making a pinhole in an index card and asking the patient to look through the pinhole. Squinting produces the same effect. Patients should be encouraged to read more letters and to guess, if necessary. Often, patients avoid guessing and prefer not to try at all rather than to make a mistake. The patient should be encouraged to read every letter possible.

The visual acuity (VA) is recorded in the following way. If the patient reads all five letters from the 20/20 line with the right eye (OD) and three of the five letters on the 20/15 line with the left eye (OS), the examiner writes OD 20/20, OS 20/15-2, or VA 20/20, 20/15-2.

If the patient is unable to read the largest letter on the chart (the 20/200 line), the patient should be moved toward the chart or the chart moved toward the patient, until the patient is able to identify the largest letter on the chart. If the patient can recognize only the letter E on the top line at a distance of 10 feet, the visual acuity would be recorded as 10'/200. If the patient is unable to see the letter E at any distance, the examiner should determine if the patient can count fingers (CF). The examiner holds up a random number of fingers and asks the patient to count the number he or she sees. If the patient correctly identifies the number of fingers at 3 feet, the examiner would record CF/3'.

If the patient is unable to count fingers, the examiner raises one hand up and down or moves it side to side and asks in which direction the hand is moving. This level of vision is known as hand motions (HM). A patient who can perceive only light is described as having light perception (LP). The vision of a patient who is unable to perceive light is described as no light perception (NLP).

## The External Eye Examination

After the visual acuity has been recorded, an external eye examination is performed. The position of the eyelids is noted. Commonly, the upper 2 mm of the iris is covered by the upper lid. The patient is examined for **ptosis** (ie, drooping eyelid) and for lid retraction (ie, too much of the eye exposed). Sometimes, the upper or lower lid turns out, affecting closure. The lid margins and lashes should have no edema, erythema, or lesions. The examiner looks for scaling or crusting, and the sclera is inspected. A normal sclera is opaque and white. Lesions on the conjunctiva, discharge, and tearing or blinking are noted.

The room should be darkened so that the pupils can be examined. The pupillary response should be checked with a penlight to be certain that the pupils are equally reactive and regular. A normal pupil is black. An irregular pupil may result from trauma, previous surgery, or a disease process.

The patient's eyes are observed in primary or direct gaze, and any head tilt is noted. A tilt may indicate cranial nerve palsy. The patient is asked to stare at a target; each eye is covered and uncovered quickly while the examiner looks for any shift in gaze. The examiner observes for **nystagmus** (ie, oscillating movement of the eyeball). The extraocular movements of the eyes are simply tested by having the patient follow the examiner's finger or hand light through the six cardinal directions of gaze (ie, up, down, right, left, and both diagonals). This is especially important when screening patients for ocular trauma or for neurologic disorders.

## Diagnostic Evaluation

### DIRECT OPHTHALMOSCOPY

A direct ophthalmoscope is a hand-held instrument with various plus and minus lenses. The lenses can be rotated into place, enabling the examiner to bring the cornea, lens, and retina into focus sequentially. The examiner holds the ophthalmoscope in the right hand and uses the right eye to examine the patient's right eye. The examiner switches to the left hand and left eye when examining the patient's left eye. During this examination, the room should be darkened, and the patient's eye should be on the same level as the examiner's eye. The patient and the examiner should be comfortable, and both should breathe normally. The patient is given a target to gaze on and is encouraged to keep both eyes open and steady.

When the fundus is examined, the vasculature comes into focus first. The veins are larger in diameter than the arteries. The examiner should focus on a large vessel and then follow it toward the midline of the body, which leads to the optic nerve. The central depression in the disc is known as the cup. The normal cup is about one third of the disc. The size of the physiologic optic cup should be estimated. Are the disc margins sharp, or are they blurred? Do the veins have a silvery or coppery appearance? The periphery of the retina can be examined by having the patient shift his or her gaze. The last area of the fundus to be examined should be the macula, because this area is the most light sensitive. The retina of a young person often has a glistening effect, which is sometimes referred to as a cellophane reflex.

The healthy fundus should be free of any lesions. The examiner should look for intraretinal hemorrhages, which may appear as red smudges or, if the patient has hypertension, may look somewhat flame shaped. Lipid may be present in the retina of patients with hypercholesterolemia or diabetes. This lipid has a yellowish appearance. Soft exudates that have a fuzzy, white appearance (ie, cotton-wool spots) should be noted. The examiner looks for microaneurysms, which look like little red dots, and nevi. Drusen (ie, small, hyaline, globular growths), commonly found in macular degeneration, appear to be yellowish areas with indistinct edges. Small drusen have a more distinct edge. The examiner should sketch the fundus and document any abnormalities.

### INDIRECT OPHTHALMOSCOPY

The indirect ophthalmoscope is an instrument commonly used by the ophthalmologist. It produces a bright and intense light. The light source is affixed with a pair of binocular lenses, which are mounted on the examiner's head. The ophthalmoscope is used with a hand-held, 20-diopter lens. This instrument enables the examiner to see larger areas of the retina, although in an unmagnified state.

### SLIT-LAMP EXAMINATION

The slit lamp is a binocular microscope mounted on a table. This instrument enables the user to examine the eye with magnification of 10 to 40 times the real image. The illumination can be varied from a broad to a narrow beam of light for different parts of the eye. For example, by varying the width and intensity of the light, the anterior chamber can be examined for signs of inflammation. Cataracts may be evaluated by changing the angle of the light. When a hand-held contact lens, such as a three-mirror lens, is used with the slit lamp, the angle of the anterior chamber may be examined, as may the ocular fundus.

## COLOR VISION TESTING

The ability to differentiate colors has a dramatic effect on the activities of daily living. For example, the inability to differentiate between red and green can compromise traffic safety. Some careers (eg, commercial art, color photography, airline pilot, electrician) may be closed to people with significant color deficiencies. The photoreceptor cells responsible for color vision are the cones, and the greatest area of color sensitivity is in the macula, the area of densest cone concentration.

A screening test, such as the polychromatic plates discussed in the next paragraph, can be used to establish whether a person's color vision is within normal range. Color vision deficits can be inherited. For example, red/green color deficiencies are inherited in an X-linked manner, affecting approximately 8% of men and 0.4% of women. Acquired color vision losses may be caused by medications (eg, digitalis toxicity) or pathology such as cataracts. A simple test, such as asking a patient if the red top on a bottle of eye drops appears redder to one eye than the other, can be an effective tool. Changes in the appreciation of the gradations of the color red can indicate macular or optic nerve disease.

Because alteration in color vision is sometimes indicative of conditions of the optic nerve, color vision testing is often performed in a neuro-ophthalmologic workup. The most common color vision test is performed using Ishihara polychromatic plates. These plates are bound together in a booklet. On each plate of this booklet are dots of primary colors that are integrated into a background of secondary colors. The dots are arranged in simple patterns, such as numbers or geometric shapes. Patients with diminished color vision may be unable to identify the hidden shapes. Patients with central vision conditions (eg, macular degeneration) have more difficulty identifying colors than those with peripheral vision conditions (eg, glaucoma) because central vision identifies color.

## AMSLER GRID

The Amsler grid is a test often used for patients with macular problems, such as macular degeneration. It consists of a geometric grid of identical squares with a central fixation point. The grid should be viewed by the patient wearing normal reading glasses. Each eye is tested separately. The patient is instructed to stare at the central fixation spot on the grid and report any distortion in the squares of the grid itself. For patients with macular problems, some of the squares may look faded, or the lines may be wavy. Patients with age-related macular degeneration are commonly given these Amsler grids to take home. The patient is encouraged to check them frequently, as often as daily, to detect any early signs of distortion that may indicate the development of a neovascular choroidal membrane, an advanced stage of macular degeneration characterized by the growth of abnormal choroidal vessels.

## ULTRASONOGRAPHY

Lesions in the globe or the orbit may not be directly visible and are evaluated by ultrasonography. A probe placed against the eye aims the beam of sound. High-frequency sound waves emitted from a special transmitter are bounced back from the lesion and collected by a receiver that amplifies and displays the sound waves on a special screen. Ultrasonography can be used to identify orbital tumors, retinal detachment, and changes in tissue composition.

## COLOR FUNDUS PHOTOGRAPHY

Fundus photography is a technique used to detect and document retinal lesions. The patient's pupils are widely dilated during the procedure, and visual acuity is diminished for about 30 minutes due to retinal "bleaching" by the intense flashing lights.

## FLUORESCEIN ANGIOGRAPHY

Fluorescein angiography evaluates clinically significant macular edema, documents macular capillary nonperfusion, and identifies retinal and choroidal **neovascularization** (ie, growth of abnormal new blood vessels) in age-related macular degeneration. It is an invasive procedure in which fluorescein dye is injected, usually into an antecubital area vein. Within 10 to 15 seconds, this dye can be seen coursing through the retinal vessels. Over a 10-minute period, serial black-and-white photographs are taken of the retinal vasculature. The dye may impart a gold tone to the skin of some patients, and urine may turn deep yellow or orange. This discoloration usually disappears in 24 hours.

## TONOMETRY

Tonometry measures IOP by determining the amount of force necessary to indent or flatten (applanate) a small anterior area of the globe of the eye. The principle involved is that a soft eye is dented more easily than a hard eye. Pressure is measured in millimeters of mercury (mm Hg). High readings indicate high pressure; low readings, low pressure. The three most common types of tonometers are indentation, applanation, and noncontact. The procedure is noninvasive and is usually painless. A topical anesthetic eye drop is instilled in the lower conjunctival sac, and the tonometer is then used to measure the IOP.

## GONIOSCOPY

Gonioscopy visualizes the angle of the anterior chamber to identify abnormalities in appearance and measurements. The gonioscope uses a refracting lens that can be a direct or indirect lens. The indirect lens views the mirror image of the opposite anterior chamber angle and can be used only with a slit lamp. The direct gonioscopic lens gives a direct view of the angle and its structures.

## PERIMETRY TESTING

Perimetry testing evaluates the field of vision. A visual field is the area or extent of physical space visible to an eye in a given position. Its average extent is 65 degrees upward, 75 degrees downward, 60 degrees inward, and 95 degrees outward when the eye is in the primary gaze (ie, looking directly forward). It is a three-dimensional contour representing areas of relative retinal sensitivity. Visual acuity is sharpest at the very top of the field and declines progressively toward the periphery. Visual field testing (ie, perimetry) helps to identify which parts of the patient's central and peripheral visual fields have useful vision. It is most helpful in detecting central **scotomas** (ie, blind areas in the visual field) in macular degeneration and the peripheral field defects in glaucoma and retinitis pigmentosa.

The two methods of perimetric testing are manual and automated perimetry. Manual perimetry involves the use of moving (kinetic) or stationary (static) stimuli or targets. An example of kinetic manual perimetry is the tangent screen. A tangent screen is a black felt material mounted on a wall that has a series of con-

centric circles dissected by straight lines emanating from the center. It tests the central 30 degrees of the visual field. Automated perimetry uses stationary targets, which are harder to detect than moving targets. In this test, a computer projects light randomly in different areas of a hollow dome while the patient looks through a telescopic opening and depresses a button whenever he or she detects the light stimulus. Automated perimetry is more accurate than manual perimetry.

## Impaired Vision

### REFRACTIVE ERRORS

In refractive errors, vision is impaired because a shortened or elongated eyeball prevents light rays from focusing sharply on the retina. Blurred vision from refractive error can be corrected with eyeglasses or contact lenses. The appropriate eyeglass or contact lens is determined by **refraction**. Refraction ophthalmology consists of placing various types of lenses in front of the patient's eyes to determine which lens best improves the patient's vision.

The depth of the eyeball is important in determining refractive error (Fig. 58-6). Patients for whom the visual image focuses precisely on the macula and who do not need eyeglasses or contact lenses are said to have **emmetropia** (normal vision). People who have **myopia** are said to be nearsighted. They have deeper eyeballs; the distant visual image focuses in front of, or short of, the retina. Myopic people experience blurred distance vision. When people have a shorter depth to their eyes, the visual image focuses beyond the retina; the eyes are shallower and are called hyperopic. People with **hyperopia** are farsighted. These patients experience near vision blurriness, whereas their distance vision is excellent.

Another important cause of refractive error is **astigmatism**, an irregularity in the curve of the cornea. Because astigmatism causes

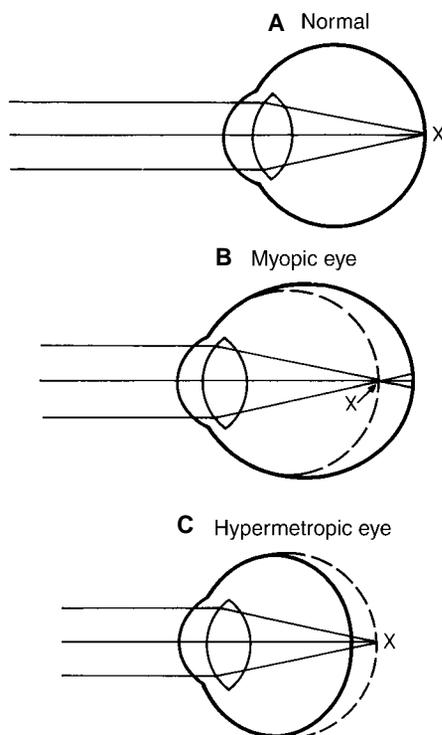

a distortion of the visual image, acuity of distance and near vision can be decreased. Eyeglasses with a cylinder correction or rigid or soft toric contact lenses are appropriate for these patients.

## LOW VISION AND BLINDNESS

*Low vision* is a general term describing visual impairment that requires patients to use devices and strategies in addition to corrective lenses to perform visual tasks. Low vision is defined as a best corrected visual acuity (BCVA) of 20/70 to 20/200 (Table 58-1).

**Blindness** is defined as a BCVA of 20/400 to no light perception. The clinical definition of absolute blindness is the absence of light perception. Legal blindness is a condition of impaired vision in which an individual has a BCVA that does not exceed 20/200 in the better eye or whose widest visual field diameter is 20 degrees or less. This definition does not equate with functional ability, nor does it classify the degrees of visual impairment. Legal blindness ranges from an inability to perceive light to having some vision remaining. An individual who meets the criteria for legal blindness may obtain government financial assistance. There are more than 1,046,000 legally blind Americans who are 40 years of age or older. African Americans have a higher rate of blindness than do Caucasians (Preshel & Prevent Blindness America, 2002).

Impaired vision is accompanied by difficulty in performing functional activities. Individuals with visual acuity of 20/80 to 20/100 with a visual field restriction of 60 degrees to greater than 20 degrees can read at a nearly normal level with optical aids. Their visual orientation is near normal but requires increased scanning of the environment (ie, systematic use of head and eye movements). In a visual acuity range of 20/200 to 20/400 with a 20-degree to greater than 10-degree visual field restriction, the individual can read slowly with optical aids. His or her visual

**FIGURE 58-6** Eyeball shape determines visual acuity in refractive errors. (A) Normal eye. (B) Myopic eye. (C) Hypermetropic eye.

**Table 58-1 • Categories of Visual Impairment**

CATEGORY OF VISUAL IMPAIRMENT	VISUAL ACUITY (BEST CORRECTED)
Low vision	
1	6/18 3/10 (0.3) 20/70
2	6/60 1/10 (0.1) 20/200
Blindness	
3	3/60 (finger counting at 3m) 1/20 (0.05) 20/400
4	1/60 (finger counting at 1m) 1/50 (0.02) 5/300
5	No light perception

#### Visual Field

Patients with a visual field radius no greater than 10 degrees but greater than 5 degrees around central fixation should be placed in category 3, and patients with a field no greater than 5 degrees around central fixation in category 4—even if the central acuity is not impaired.

Adapted from the *International Classification of Diseases*, World Health Organization, 1977; and from Vaughn, D. G., Asbury, T., & Riorda-Eva, P. (Eds.). (1999). *General ophthalmology*. Stamford, CT: Appleton & Lange.

orientation is slow, with constant scanning of the environment; individuals in this category have travel vision. Individuals with hand motion vision or no vision may benefit from the use of mobility devices (eg, cane, guide dog) and should be encouraged to learn Braille and to use computer aids.

The most common causes of blindness and visual impairment among adults 40 years of age or older are diabetic retinopathy, macular degeneration, glaucoma, and cataracts, (Preshel & Prevent Blindness America, 2002). Macular degeneration is more prevalent among Caucasians, whereas glaucoma is more prevalent among African Americans. Age-related changes in the eye are described in Table 58-2.

## Low-Vision Assessment

The assessment of low vision includes a thorough history and the examination of distance and near visual acuity, visual field, contrast sensitivity, glare, color perception, and refraction. Specially designed, low-vision visual acuity charts are used to evaluate patients.

### PATIENT INTERVIEW

During history taking, the cause and duration of the patient's visual impairment are identified. Patients with retinitis pigmentosa, for example, have a genetic abnormality. Patients with diabetic macular edema typically have fluctuating visual acuity. Patients with macular degeneration have central acuity problems. Central acuity problems cause difficulty in performing activities that require finer vision, such as reading. People with peripheral field defects have more difficulties with mobility. The patient's customary activities of daily living, medication regimen, habits (eg, smoking), acceptance of the physical limitations brought about by the visual impairment, and realistic expectations of low-vision aids must also be identified. These aspects of the patient's activities are important indicators for planning care that will include guidelines for safety and referrals to social services.

### ASSESSMENT

Contrast-sensitivity testing measures visual acuity in different degrees of contrast. The initial test may take the form of simply turning on the lights while testing the distance acuity. If the patient can read better with the lights on, the patient can benefit from magnification. Glare testing enables the examiner to obtain a more realistic evaluation of the patient's ability to function in his or her environment. Glare can reduce a person's ability to see, especially in patients with cataracts. Devices that test glare, such as the Brightness Acuity Tester, produce three degrees of bright light to create a dazzle effect while the patient is viewing a target, such as Snellen letters on the wall. The lights have been calibrated to imitate certain objects that create glare, such as the brightness of a car's headlights at night.

### Medical Management

Managing low vision involves magnification and image enhancement through the use of low-vision aids and strategies and through referrals to social services and community agencies serving the visually impaired. The goals are to enhance visual function and assist patients with low vision to perform customary activities. Low-vision aids include optical and nonoptical devices (Table 58-3). The optical devices include convex lens aids, such as magnifiers and spectacles; telescopic devices; anti-reflective lenses that diminish glare; and electronic reading systems, such as closed-circuit television and computers with large print. Continuing advances in computer software provide very useful products for patients with low vision. Scanners teamed with the appropriate software enable the user to scan printed data into the computer and have it read by computer voice or to increase the magnification for reading. Magnifiers can be hand-held or attached to a stand with or without illumination. Telescopic devices can be spectacle telescopes or clip-on or hand-held loupes.

Nonoptical aids include large-print publications and a variety of writing aids. The Internet continues to expand, and a tele-

Table 58-2 • Age-Related Changes in the Eye

THE EXTERNAL EYE	STRUCTURAL CHANGE	FUNCTIONAL CHANGE	HISTORY & PHYSICAL FINDINGS
Eyelids and lacrimal structures	Loss of skin elasticity and orbital fat, decreased muscle tone; wrinkles develop	Lid margins turn in causing lashes to irritate cornea and conjunctiva (entropion); or lid margins may turn out, resulting in increased corneal exposure (ectropion)	Reports of burning, foreign body sensation, increased tearing (epiphoria); injection, inflammation, and ulceration may occur
Refractive changes; presbyopia	Loss of accommodative power in the lens with age	Reading materials must be held at increasing distance in order to focus	Patient reports, "Arms are too short!"; need for increased light; reading glasses or bifocals needed
Cataract	Opacities in the normally crystalline lens	Interference with the focus of a sharp image on the retina	Patients report increased glare, decreased vision, changes in color values (blue and yellow especially affected)
Posterior vitreous detachment	Liquefaction and shrinkage of vitreous body	May lead to retinal tears and detachment	Reports light flashes, cobwebs, floaters
Age-related macular degeneration (AMD)	Drusen (yellowish aging spots in the retina) appear and coalesce in the macula. Abnormal choroidal blood vessels may lead to formation of fibrotic disciform scars in the macula	Central vision is affected; onset is more gradual in dry AMD, more rapid in wet AMD; distortion and loss of central vision may occur	Reading vision is affected; words may be missing letters, faded areas appear on the page, straight lines may appear wavy; drusen, pigmentary changes in retina; abnormal submacular choroidal vessels

## GENETICS IN NURSING PRACTICE—Eye and Vision Disorders

### SELECTED EYE AND VISION DISORDERS INFLUENCED BY GENETIC FACTORS

- Albinism
- Aniridia
- Color blindness
- Glaucoma
- Homocystinuria
- Isolated familial congenital cataracts
- Leber hereditary optic neuropathy
- Marfan syndrome
- Retinitis pigmentosa

### NURSING ASSESSMENTS

#### FAMILY HISTORY ASSESSMENT

- Assess history of family members with glaucoma, cataracts, night blindness (retinitis pigmentosa), color blindness, or other vision impairment.
- Inquire about family members with other disorders that may include visual impairment, such as cutaneous, metabolic, connective tissue disorders, and hearing loss.

#### PHYSICAL ASSESSMENT

- Assess for other systemic and/or clinical features such as cutaneous or skeletal conditions, or hearing loss.

### MANAGEMENT ISSUES SPECIFIC TO GENETICS

- Inquire whether DNA gene mutation or other genetic testing has been performed on any affected family members.

- If indicated, refer for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, availability of genetic testing, and gene-based interventions.
- Offer appropriate genetics information and resources.
- Assess patient's understanding of genetics information.
- Provide support to families with newly diagnosed genetic-related sensorineural disorders.
- Participate in management and coordination of care of patients with genetic conditions and individuals predisposed to develop or pass on a genetic condition

### GENETICS RESOURCES

Genetic Alliance—a directory of support groups for patients and families with genetic conditions; <http://www.geneticalliance.org>

Gene Clinics—a listing of common genetic disorders with up-to-date clinical summaries, genetic counseling and testing information; <http://www.geneclinics.org>

National Organization of Rare Disorders—a directory of support groups and information for patients and families with rare genetic disorders; <http://www.rarediseases.org>

OMIM: Online Mendelian Inheritance in Man—a complete listing of inherited genetic conditions; <http://www.ncbi.nlm.nih.gov/omim/stats/html>

phone system has been developed that allows access to the Internet and e-mail using voice commands (see Chart 58-2).

Strategies that enhance the performance of visual tasks include modification of body movements and illumination and training for independent living skills. Head movements and po-

sitions can be modified to place images in functional areas of the visual field. Illumination is an added feature in magnifiers. Adjusting the lighting helps with reading and other activities. Simple optical and nonoptical aids are available in low-vision clinics.

**Table 58-3 • Activities Affected by Visual Impairment and Visual Aids**

ACTIVITY	OPTICAL AIDS	NONOPTICAL AIDS
Shopping	Hand magnifier	Lighting, color cues
Fixing a snack	Bifocals	Color cues, consistent storage plan
Eating out	Hand magnifier	Flashlight, portable lamp
Identifying money	Bifocals, hand magnifier	Arrange paper money in wallet compartments
Reading print	High-power spectacle, bifocals, hand magnifier, stand magnifier, closed-circuit television	Lighting, high-contrast print, large print, reading slit
Writing	Hand magnifier, focusable telescope, closed-circuit television	Lighting, bold-tip pen, black ink
Using a telephone	Hand magnifier	Large print dial or touch tone buttons, hand-printed directory
Crossing streets	Telescope	Cane, ask directions
Finding taxis and bus signs	Telescope	
Reading medication labels	Hand magnifier	Color codes, large print
Reading stove dials	Hand magnifier	Color codes, raised dots
Adjusting the thermostat	Hand magnifier	Enlarged print model
Using a computer	Spectacles	High-contrast color, large-print program
Reading signs	Spectacles	Move closer
Watching sporting event	Telescope	Sit in front rows

Chart  
58-2**Web Access for the Visually Impaired**

People with impaired vision need not be left behind in the computer age. Various technologies are available. A list of general equipment needs follows:

- Computer: typically with IBM compatible software and a Windows operating system
- Internet service provider (eg, AOL, Netscape, Earthlink, Hotmail)
- Screen-reader program: converts text on the computer screen to synthesized speech (eg, JAWS for Windows, Window-Eyes, Slimware Window Bridge, outspoken); cost varies between \$500 and \$800
- Browser program to navigate the World Wide Web (eg, Microsoft Internet Explorer, IBM Home Page Reader)

Referrals to community agencies may be necessary for low-vision patients living alone who are unable to self-administer their medications. Community agencies, such as The Lighthouse National Center for Vision and Aging, offer services to low-vision patients that include training in independent living skills and the provision of occupational and recreational activities and a wide variety of assistive devices for vision enhancement and orientation and mobility.

**VISION RESTORATION FOR THE BLIND**

Ophthalmologists have worked toward visual restoration for blind individuals for years, and computer technology now provides opportunities for restoring sight. For example, a multiple-unit artificial retina chipset (MARC) has been devised for implanting within the eye. The MARC can be enabled to receive signals from an external camera mounted in a glasses frame. The acquired image is wirelessly transmitted to the chip, which provides a type of artificial vision and which, with training, allows the patient to achieve some useful vision. Although the device is still experimental, some work has been done with patients who have lost vision from retinitis pigmentosa and age-related macular degeneration (Humayan et al., 1999).

**Nursing Management**

Coping with blindness involves three types of adaptation: emotional, physical, and social. The emotional adjustment to blindness or severe visual impairment determines the success of the physical and social adjustments of the patient. Successful emotional adjustment means acceptance of blindness or severe visual impairment.

**PROMOTING COPING EFFORTS**

Effective coping may not occur until the patient recognizes the permanence of the blindness. Clinging to false hopes of regaining vision hampers effective adaptation to blindness. A newly blind patient and his or her family members (especially those who live with the patient) undergo the various steps of grieving: denial and shock, anger and protest, restitution, loss resolution, and acceptance. The ability to accept the changes that must come with visual loss and willingness to adapt to those changes influence the successful rehabilitation of the patient who is blind. Additional aspects to consider are value changes, independence–dependence conflicts, coping with stigma, and learning to function in social settings without visual cues and landmarks.

**PROMOTING SPATIAL ORIENTATION AND MOBILITY**

People who are blind detect and incorporate less information about their environment than do sighted people. The blind person relies on egocentric, sequential, and positional information, which centers on the person and his or her relationship to the objects in the environment. For example, the topographic concepts of front, back, left, right, above, and below and measures of distances are most useful in determining the exact position, sequence, and location of objects in relation to the person who is blind. Although their basis of information may be different from that of sighted people, people who are blind can comprehend spatial concepts.

The goal of orientation and mobility training is to foster independence in the environment. Training may be accomplished by using auditory and tactile cues and by providing anticipatory information. Having a concept of the spatial composition of the environment (ie, cognitive map) enhances independence of those who are blind. Orientation and mobility training programs are offered by community agencies serving the blind or visually impaired. Training includes using mobility devices for travel, the long cane, electronic travel aids, dog guides, and orientation aids. The basic orientation and mobility techniques used by a sighted person to assist a person who is blind or visually impaired to ambulate safely and efficiently are called sighted-guide techniques.

**Spatial Orientation and Mobility in Institutional Settings.** A blind or severely visually impaired patient requires strategies for adapting to the environment. The monocular postoperative patient whose functioning eye is restricted by a surgical patch or by postoperative inflammation requires early ambulation just like any postoperative patient. The activities of daily living, such as walking to a chair from a bed, require spatial concepts. The patient needs to know where he or she is in relation to the rest of the room, to understand the changes that may occur, and how to approach the desired location safely. This requires a collaborative effort between the patient and the nurse, who serves as the sighted guide.

Patients whose visual impairment results from a chronic progressive eye disorder, such as glaucoma, have better cognitive mapping skills than the suddenly blinded patient. They have developed the use of spatial and topographic concepts early and gradually; hence, remembering a room layout is easier for them. Suddenly blinded patients have more difficulty in adjusting; and emotional and behavioral issues of coping with blindness may hinder their learning. These patients require intensive emotional support. The nurse must assess the degree of physical assistance the patient with a visual deficit requires and communicate this to other health care personnel.

The food tray's composition is likened to the face of a clock. For example, the main plate may be described as being at 12 o'clock or the coffee cup at 3 o'clock. In the hospital, the bedside table and the call button must always be within reach. The parts of the call button are explained, and the patient is encouraged to touch and press the buttons or dials until the activity is mastered. The patient must be familiarized with the location of the telephone, water pitcher, and other objects on the bedside table. All articles and furniture must be replaced in the same positions. Introducing oneself on entering a patient's room is always a polite gesture and helps in the orientation of a blind patient.

The nurse should be aware of the importance of technique in providing physical assistance, developing independence, and ensuring safety. The readiness of the patient and his or her family to learn must be assessed before initiating orientation and mobility training.

## PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** The nurse, social workers, family, and others collaborate to assess the patient's home condition and support system. If available, a low-vision specialist should be consulted before discharge, particularly for patients for whom identifying and administering medications pose problems. The level of visual acuity and patient preference help to determine appropriate interventions. For example, a plastic pill container with dividers that has been prefilled with a week's supply of medication can make medication administration easier for some patients, whereas others may prefer to have medication bottles marked with textured paints. Many patients require referral to social services. Patients with habits that may jeopardize safety, such as smoking, need to be cautioned and assisted to make their environment safe.

**Community Programs and Services.** In the United States, laws such as the Rehabilitation Act, the Civil Rights Act, and the Americans With Disabilities Act support assistance of the blind. Governmental services include income assistance through Social Security Disability Income and Supplemental Security Income; health insurance through Medicaid and Medicare programs; support services, such as vocational rehabilitation programs offered by the Division of Blind Services; tax exemptions and tax deductions; Department of Veterans Affairs programs for visually impaired veterans; and U.S. Postal Service reduced postage for Braille materials and talking books. Some private and nonprofit services are identified in "Resources and Websites" at the end of this chapter.

## Glaucoma

Glaucoma is a group of ocular conditions characterized by optic nerve damage. The optic nerve damage is related to the IOP caused by congestion of aqueous humor in the eye. There is a range of pressures that have been considered "normal" but that may be associated with vision loss in some patients. Glaucoma is one of the leading causes of irreversible blindness in the world and is the leading cause of blindness among adults in the United States. It is estimated that at least 2 million Americans have glaucoma and that 5 to 10 million more are at risk (Margolis et al., 2002). Glaucoma is more prevalent among people older than 40 years of age, and the incidence increases with age. It is also more prevalent among men than women and in the African American and Asian populations (Chart 58-3). There is no cure for glaucoma, but research continues.

### Chart 58-3 Risk Factors for Glaucoma

- Family history of glaucoma
- African American race
- Older age
- Diabetes
- Cardiovascular disease
- Migraine syndromes
- Nearsightedness (myopia)
- Eye trauma
- Prolonged use of topical or systemic corticosteroids

## Aqueous Humor and Intraocular Pressure

Aqueous humor flows between the iris and the lens, nourishing the cornea and lens. Most (90%) of the fluid then flows out of the anterior chamber, draining through the spongy trabecular meshwork into the canal of Schlemm and the episcleral veins (Fig. 58-7). About 10% of the aqueous fluid exits through the ciliary body into the suprachoroidal space and then drains into the venous circulation of the ciliary body, choroid, and sclera. Unimpeded outflow of aqueous fluid depends on an intact drainage system and an open angle (about 45 degrees) between the iris and the cornea. A narrower angle places the iris closer to the trabecular meshwork, diminishing the angle. The amount of aqueous humor produced tends to decrease with age, in systemic diseases such as diabetes, and in ocular inflammatory conditions.

IOP is determined by the rate of aqueous production, the resistance encountered by the aqueous humor as it flows out of the passages, and the venous pressure of the episcleral veins that drain into the anterior ciliary vein. When aqueous fluid production and drainage are in balance, the IOP is between 10 and 21 mm Hg. When aqueous fluid is inhibited from flowing out, pressure builds up within the eye. Fluctuations in IOP occur with time of day, exertion, diet, and medications. It tends to increase with blinking, tight lid squeezing, and upward gazing. Systemic conditions such as hypertension and intraocular conditions such as uveitis and retinal detachment have been associated with elevated IOP. Exposure to cold weather, alcohol, a fat-free diet, heroin, and marijuana have been found to lower IOP.

## Pathophysiology

There are two accepted theories regarding how increased IOP damages the optic nerve in glaucoma. The direct mechanical theory suggests that high IOP damages the retinal layer as it passes through the optic nerve head. The indirect ischemic theory suggests that high IOP compresses the microcirculation in the optic nerve head, resulting in cell injury and death. Some glaucomas appear as exclusively mechanical, and some are exclusively ischemic types. Typically, most cases are a combination of both.

Regardless of the cause of damage, glaucomatous changes typically evolve through clearly discernible stages:

1. *Initiating events:* precipitating factors include illness, emotional stress, congenital narrow angles, long-term use of

**FIGURE 58-7** Normal outflow of aqueous humor. (A) Trabecular meshwork. (B) Uveoscleral route. From Kanski, J. J. (1999). *Clinical ophthalmology*. Oxford: Butterworth-Heinemann Ltd.

corticosteroids, and **mydriatics** (ie, medications causing pupillary dilation). These events lead to the second stage.

2. **Structural alterations in the aqueous outflow system:** tissue and cellular changes caused by factors that affect aqueous humor dynamics lead to structural alterations and to the third stage.
3. **Functional alterations:** conditions such as increased IOP or impaired blood flow create functional changes that lead to the fourth stage.
4. **Optic nerve damage:** atrophy of the optic nerve is characterized by loss of nerve fibers and blood supply, and this fourth stage inevitably progresses to the fifth stage.
5. **Visual loss:** progressive loss of vision is characterized by visual field defects.

## Classification of Glaucoma

There are several types of glaucoma. Whether glaucoma is known as *open-angle* or *angle-closure* glaucoma depends on which mechanisms cause impaired aqueous outflow. Glaucoma can be pri-

mary or secondary, depending on whether associated factors contribute to the rise in IOP.

Although glaucoma classification is changing as knowledge increases, current clinical forms of glaucoma are open-angle glaucomas, angle-closure glaucomas (also called pupillary block), congenital glaucomas, and glaucomas associated with other conditions, such as developmental anomalies, corticosteroid use, and other ocular conditions. The two common clinical forms of glaucoma encountered in adults are open-angle and angle-closure glaucoma. Table 58-4 explains the general characteristics of the different types of open-angle and angle-closure glaucomas.

## Clinical Manifestations

Glaucoma is often called the silent thief of sight because most patients are unaware that they have the disease until they have experienced visual changes and vision loss. The patient may not seek health care until he or she experiences blurred vision or “halos” around lights, difficulty focusing, difficulty adjusting eyes in low lighting, loss of peripheral vision, aching or discomfort around the eyes, and headache.

**Table 58-4 • Glaucoma Types, Clinical Manifestation, and Treatment**

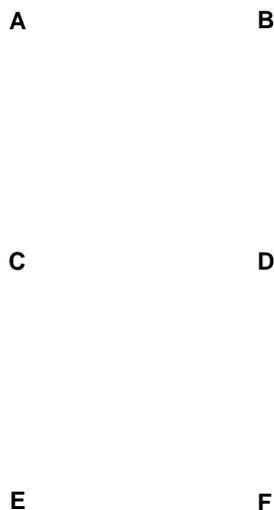

TYPES OF GLAUCOMA	CLINICAL MANIFESTATIONS	TREATMENT
<b>Open-Angle Glaucomas</b>		
Usually bilateral, but one eye may be more severely affected than the other. In all three types of open-angle glaucoma, the anterior chamber angle is open and appears normal.		
Chronic open-angle glaucoma (COAG)	Optic nerve damage, visual field defects, IOP >21 mm Hg. May have fluctuating IOPs. Usually no symptoms but possible ocular pain, headache, and halos.	Decrease IOP 20% to 50%. Additional topical and oral agents added as necessary. If medical treatment is unsuccessful, laser trabeculoplasty (LT) can provide a 20% drop in intraocular pressure. Glaucoma filtering surgery if continued optic nerve damage despite medication therapy and LT.
Normal tension glaucoma	IOP ≤ 21 mm Hg. Optic nerve damage, visual field defects.	Treatment similar to COAG, however, the best management for normal tension glaucoma management is yet to be established. Goal is to lower the IOP by at least 30%.
Ocular hypertension	Elevated IOP. Possible ocular pain or headache.	Lower IOP by at least 20%.
<b>Angle-Closure (Pupillary Block) Glaucomas</b>		
Obstruction in aqueous humor outflow due to the complete or partial closure of the angle from the forward shift of the peripheral iris to the trabecula. The obstruction results in an increased IOP.		
Acute angle-closure glaucoma (AACG)	Rapidly progressive visual impairment, periocular pain, conjunctival hyperemia, and congestion. Pain may be associated with nausea, vomiting, bradycardia, and profuse sweating. Reduced central visual acuity, severely elevated IOP, corneal edema. Pupil is vertically oval, fixed in a semi-dilated position, and unreactive to light and accommodation.	Ocular emergency; administration of hyperosmotics, acetazolamide, and topical ocular hypotensive agents, such as pilocarpine and beta-blockers (betaxolol). Possible laser incision in the iris (iridotomy) to release blocked aqueous and reduce IOP. Other eye is also treated with pilocarpine eye drops and/or surgical management to avoid a similar spontaneous attack.
Subacute angle-closure glaucoma	Transient blurring of vision, halos around lights; temporal headaches and/or ocular pain; pupil may be semi-dilated.	Prophylactic peripheral laser iridotomy. Can lead to acute or chronic angle-closure glaucoma if untreated.
Chronic angle-closure glaucoma	Progression of glaucomatous cupping and significant visual field loss; IOP may be normal or elevated; ocular pain and headache.	Management similar to that for COAG: includes laser iridotomy and medications.

## Assessment and Diagnostic Findings

The purpose of a glaucoma workup is to establish the diagnostic category, assess the optic nerve damage, and formulate a treatment plan. The patient's ocular and medical history must be detailed to investigate the history of predisposing factors. There are four major types of examinations used in glaucoma evaluation, diagnosis, and management: tonometry to measure the IOP, ophthalmoscopy to inspect the optic nerve, gonioscopy to examine the filtration angle of the anterior chamber, and perimetry to assess the visual fields.

The changes in the optic nerve significant for the diagnosis of glaucoma are pallor and cupping of the optic nerve disc. The pallor of the optic nerve is caused by a lack of blood supply that results from cellular destruction. Cupping is characterized by exaggerated bending of the blood vessels as they cross the optic disc, resulting in an enlarged optic cup that appears more basin-like compared with a normal cup. The progression of cupping in glaucoma is caused by the gradual loss of retinal nerve fibers accompanied by the loss of blood supply, resulting in increased pallor of the optic disc.

As the optic nerve damage increases, visual perception in the area is lost. The localized areas of visual loss (ie, scotomas) represent loss of retinal sensitivity and are measured and mapped by perimetry. The results are mapped on a graph. In patients with glaucoma, the graph has a distinct pattern that is different from other ocular diseases and is useful in establishing the diagnosis. Figure 58-8 shows the progression of visual field defects caused by glaucoma.

**FIGURE 58-8** Progression of glaucomatous visual field defects. A central scotoma at 10 to 20 degrees of fixation near the blind spot is the initial significant finding (A, B). As the glaucoma progresses, the scotomas enlarge and deepen, resulting in peripheral vision loss. (C) Defect within 5 degrees of fixation point nasally. (D) Peripheral involvement enlarges. (E) Ringlike scotoma. (F) Eventually, vision is lost. The resulting “island of vision” becomes the characteristic visual field appearance of glaucoma and correlates with the “tunnel vision,” in which peripheral vision is lost. From Kanski, J. J. (1999). *Clinical ophthalmology*. Oxford: Butterworth-Heinemann Ltd.

## Medical Management

The aim of all glaucoma treatment is prevention of optic nerve damage through medical therapy, laser or nonlaser surgery, or a combination of these approaches. Lifelong therapy is almost always necessary because glaucoma cannot be cured. Although treatment cannot reverse optic nerve damage, further damage can be controlled. The treatment goal is to maintain an IOP within a range unlikely to cause further damage.

The initial target for IOP among patients with elevated IOP and those with low-tension glaucoma with progressive visual field loss is typically set at 30% lower than the current pressure. The patient is monitored for the stability of the optic nerve. If there is evidence of progressive damage, the target IOP is again lowered until the optic nerve shows stability.

Treatment focuses on achieving the greatest benefit at the least risk, cost, and inconvenience to the patient. All treatment options have potential complications, especially surgery, which yields the best success rates. In the United States, medical management is the common approach, and surgical management is the last resort. In Great Britain, the initial treatment of choice is surgery (Fechtner & Singh, 2001).

### PHARMACOLOGIC THERAPY

Medical management of glaucoma relies on systemic and topical ocular medications that lower IOP. Periodic follow-up examinations are essential to monitor IOP, appearance of the optic nerve, visual fields, and side effects of medications. In considering a therapeutic regimen, the ophthalmologist aims for the greatest effectiveness with the least side effects, inconvenience, and cost. Therapy takes into account the patient's health and stage of glaucoma. Comfort, affordability, convenience, lifestyle, and personality are factors to consider in the patient's compliance with the medical regimen.

The patient is usually started on the lowest dose of topical medication and then advanced to increased concentrations until the desired IOP level is reached and maintained. Because of their efficacy, minimal dosing (can be used once each day), and low cost, beta-blockers are the preferred initial topical medications. One eye is treated first, with the other eye used as a control in determining the efficacy of the medication; once efficacy has been established, treatment of the fellow eye is started. If the IOP is elevated in both eyes, both are treated. When results are not satisfactory, a new medication is substituted. The main markers of the efficacy of the medication in glaucoma control are lowering of the IOP to the target pressure, appearance of the optic nerve head, and the visual field.

Several types of ocular medications are used to treat glaucoma (Table 58-5), including **miotics** (ie, cause pupillary constriction), adrenergic agonists (ie, sympathomimetic agents), beta-blockers, alpha<sub>2</sub>-agonists (ie, adrenergic agents), carbonic anhydrase inhibitors, and prostaglandins. Cholinergics (ie, miotics) increase the outflow of the aqueous humor by affecting ciliary muscle contraction and pupil constriction, allowing flow through a larger opening between the iris and the trabecular meshwork. Adrenergic agonists increase aqueous outflow but primarily decrease aqueous production with an action similar to beta-blockers and carbonic anhydrase inhibitors.

### SURGICAL MANAGEMENT

In *laser trabeculoplasty* for glaucoma, laser burns are applied to the inner surface of the trabecular meshwork to open the intratrabecular spaces and widen the canal of Schlemm, thereby pro-

Table 58-5 • Medications Used in the Management of Glaucoma

MEDICATION	ACTION	SIDE EFFECTS	NURSING IMPLICATIONS
Cholinergics (miotics) (pilocarpine, carbachol)	Increases aqueous fluid outflow by contracting the ciliary muscle and causing miosis (constriction of the pupil) and opening of trabecular meshwork	Periorbital pain, blurry vision, difficulty seeing in the dark	Caution patients about diminished vision in dimly lit areas
Adrenergic agonists (dipivefrin, epinephrine)	Reduces production of aqueous humor and increases outflow	Eye redness and burning; can have systemic effects, including palpitations, elevated blood pressure, tremor, headaches, and anxiety	Teach patients punctal occlusion to limit systemic effects (described in Chart 58–10.)
Beta-blockers (betaxolol, timolol)	Decreases aqueous humor production	Can have systemic effects, including bradycardia, exacerbation of pulmonary disease, and hypotension	Contraindicated in patients with asthma, chronic obstructive pulmonary disease, second- or third-degree heart block, bradycardia, or cardiac failure; teach patients punctal occlusion to limit systemic effects
Alpha-adrenergic agonists (apraclonidine, brimonidine)	Decreases aqueous humor production	Eye redness, dry mouth and nasal passages	Teach patients punctal occlusion to limit systemic effects
Carbonic anhydrase inhibitors (acetazolamide, methazolamide, dorzolamide)	Decreases aqueous humor production	Oral medications (acetazolamide and methazolamide) associated with serious side effects, including anaphylactic reactions, electrolyte loss, depression, lethargy, gastrointestinal upset, impotence, and weight loss; topical form (dorzolamide) side effects include topical allergy	Do not administer to patients with sulfa allergies; monitor electrolyte levels
Prostaglandin analogs (latanoprost)	Increases uveoscleral outflow	Darkening of the iris, conjunctival redness, possible rash	Instruct patients to report any side effects

moting outflow of aqueous humor and decreasing IOP. The procedure is indicated when IOP is inadequately controlled by medications; it is contraindicated when the trabecular meshwork cannot be fully visualized because of narrow angles. A serious complication of this procedure is a transient rise in IOP (usually 2 hours after surgery) that may become persistent. IOP assessment in the immediate postoperative period is essential.

In *laser iridotomy* for pupillary block glaucoma, an opening is made in the iris to eliminate the pupillary block. Laser iridotomy is contraindicated in patients with corneal edema, which interferes with laser targeting and strength. Potential complications are burns to the cornea, lens, or retina; transient elevated IOP; closure of the iridotomy; uveitis; and blurring. Pilocarpine is usually prescribed to prevent closure of the iridotomy.

*Filtering procedures* for chronic glaucoma are used to create an opening or fistula in the trabecular meshwork to drain aqueous humor from the anterior chamber to the subconjunctival space into a bleb, thereby bypassing the usual drainage structures. This allows the aqueous humor to flow and exit by different routes (ie, absorption by the conjunctival vessels or mixing with tears). *Trabeculectomy* is the standard filtering technique used to remove part of the trabecular meshwork. Complications include hemorrhage, an extremely low (hypotony) or elevated IOP, uveitis, cataracts, bleb failure, bleb leak, and endophthalmitis. Unlike other surgical procedures, the filtering procedure's goal in glau-

coma treatment is to achieve incomplete healing of the surgical wound. The outflow of aqueous humor in a newly created drainage fistula is circumvented by the granulation of fibrovascular tissue or scar tissue formation on the surgical site. Scarring is inhibited by using antifibrosis agents such as the antimetabolites fluorouracil (Efudex) and mitomycin (Mutamycin). Like all antineoplastic agents, they require special handling procedures before, during, and after the procedure. Fluorouracil can be administered intraoperatively and by subconjunctival injection during follow-up; mitomycin is much more potent and is administered only intraoperatively.

*Drainage implants or shunts* are open tubes implanted in the anterior chamber to shunt aqueous humor to an attached plate in the conjunctival space. A fibrous capsule develops around the episcleral plate and filters the aqueous humor, thereby regulating the outflow and controlling IOP.

## Nursing Management

### TEACHING PATIENTS ABOUT GLAUCOMA CARE

The medical and surgical management of glaucoma slows the progression of glaucoma but does not cure it. The lifelong therapeutic regimen mandates patient education. The nature of the disease and the importance of strict adherence to the medication regimen must be explained to help ensure compliance. A thor-

ough patient interview is essential to determine systemic conditions, current systemic and ocular medications, family history, and problems with compliance to glaucoma medications. Then the medication program can be discussed, particularly the interactions of glaucoma-control medications with other medications. For example, the diuretic effect of acetazolamide has an additive effect on the diuretic effects of other antihypertensive medications and can result in hypokalemia. The effects of glaucoma-control medications on vision must also be explained. Miotics and sympathomimetics result in altered focus; therefore, patients need to be cautious in navigating their surroundings. Information about instilling ocular medication and preventing systemic absorption with punctal occlusion is described in the section on ophthalmic medications.

Nurses in all settings encounter patients with glaucoma. Even patients with long-standing disease and those with glaucoma as a secondary diagnosis should be assessed for knowledge level and compliance with the therapeutic regimen. Chart 58-4 contains points to review with glaucoma patients.

### CONTINUING GLAUCOMA CARE AT HOME

For patients with severe glaucoma and impaired function, referral to services that assist the patient in performing customary activities may be needed. The loss of peripheral vision impairs mobility the most. These patients need to be referred to low-vision and rehabilitation services. Patients who meet the criteria for legal blindness should be offered referrals to agencies that assist in obtaining federal assistance.

Reassurance and emotional support are important aspects of care. A lifelong disease involving a possible loss of sight has psychological, physical, social, and vocational ramifications. The

family must be integrated into the plan of care, and because the disease has a familial tendency, family members should be encouraged to undergo examinations at least once every 2 years to detect glaucoma early.

## Cataracts

A cataract is a lens opacity or cloudiness (Fig. 58-9). Cataracts rank only behind arthritis and heart disease as a leading cause of disability in older adults. Cataracts affect nearly 20.5 million Americans who are 40 years of age or older, or about one in every six people in this age range. By age 80, more than half of all Americans have cataracts. According to the World Health Organization, cataract is the leading cause of blindness in the world (Preshel & Prevent Blindness America, 2002).

### Pathophysiology

Cataracts can develop in one or both eyes at any age for a variety of causes (Chart 58-5). Visual impairment normally progresses at the same rate in both eyes over many years or in a matter of months. The three most common types of senile (age-related) cataracts are defined by their location in the lens: nuclear, cortical, and posterior subcapsular. The extent of visual impairment depends on the size, density, and location in the lens. More than one type can be present in one eye.

A nuclear cataract is associated with myopia (ie, nearsightedness), which worsens when the cataract progresses. If dense, the cataract severely blurs vision. Periodic changes in prescription eyeglasses help manage this problem.

A cortical cataract involves the anterior, posterior, or equatorial cortex of the lens. A cataract in the equator or periphery of the cortex does not interfere with the passage of light through the center of the lens and has little effect on vision. Cortical cataracts progress at a highly variable rate. Vision is worse in very bright light. Studies show that people with the highest levels of sunlight exposure have twice the risk of developing cortical cataracts than those with low-level sunlight exposure (West et al., 1998).

Posterior subcapsular cataracts occur in front of the posterior capsule. This type typically develops in younger people and, in some cases, is associated with prolonged corticosteroid use, inflammation, or trauma. Near vision is diminished, and the eye is increasingly sensitive to glare from bright light (eg, sunlight, headlights).

### Chart 58-4 • PATIENT EDUCATION Managing Glaucoma

- Know your intraocular pressure (IOP) measurement and the desired range.
- Be informed about the extent of your vision loss and optic nerve damage.
- Keep a record of your eye pressure measurements and visual field test results to monitor your own progress.
- Review all your medications (including over-the-counter and herbal medications) with your ophthalmologist, and mention any side effects each time you visit.
- Ask about potential side effects and drug interactions of your eye medications.
- Ask whether generic or less costly forms of your eye medications are available.
- Review the dosing schedule with your ophthalmologist and inform him or her if you have trouble complying with the schedule.
- Participate in the decision-making process. Let your doctor know what dosing schedule works for you and other preferences regarding your eye care.
- Have the nurse observe you instilling eye medication to determine whether you are administering it properly.
- Be aware that glaucoma medications can cause adverse effects if used inappropriately. Eyedrops are to be administered as prescribed, not when eyes feel irritated.
- Ask your ophthalmologist to send a report to your primary care physician after each appointment.
- Keep all follow-up appointments.

**FIGURE 58-9** A cataract is a cloudy or opaque lens. On visual inspection, the lens appears grey or milky. From Rubin, E., & Farber, J. L. (1999). *Pathology* (3rd ed.). Philadelphia: Lippincott Williams & Wilkins.

Chart 58-5

### Risk Factors for Cataract Formation

#### Aging

- Loss of lens transparency
- Clumping or aggregation of lens protein (which leads to light scattering)
- Accumulation of a yellow-brown pigment due to the breakdown of lens protein
- Decreased oxygen uptake
- Increase in sodium and calcium
- Decrease in levels of vitamin C, protein, and glutathione (an antioxidant)

#### Associated Ocular Conditions

- Retinitis pigmentosa
- Myopia
- Retinal detachment and retinal surgery
- Infection (eg, herpes zoster, uveitis)

#### Toxic Factors

- Corticosteroids, especially at high doses and in long-term use
- Alkaline chemical eye burns, poisoning
- Cigarette smoking
- Calcium, copper, iron, gold, silver, and mercury, which tend to deposit in the pupillary area of the lens

#### Nutritional Factors

- Reduced levels of antioxidants
- Poor nutrition
- Obesity

#### Physical Factors

- Dehydration associated with chronic diarrhea, use of purgatives in anorexia nervosa, and use of hyperbaric oxygenation
- Blunt trauma, perforation of the lens with a sharp object or foreign body, electric shock
- Ultraviolet radiation in sunlight and x-ray

#### Systemic Diseases and Syndromes

- Diabetes mellitus
- Down syndrome
- Disorders related to lipid metabolism
- Renal disorders
- Musculoskeletal disorders

## Clinical Manifestations

Painless, blurry vision is characteristic of cataracts. The patient perceives that surroundings are dimmer, as if glasses need cleaning. Light scattering is common, and the individual experiences reduced contrast sensitivity, sensitivity to glare, and reduced visual acuity. Other effects include myopic shift, astigmatism, monocular **diplopia** (ie, double vision), color shift (ie, the aging lens becomes progressively more absorbent at the blue end of the spectrum), brunescens (ie, color values shift to yellow-brown), and reduced light transmission.

## Assessment and Diagnostic Findings

Decreased visual acuity is directly proportionate to cataract density. The Snellen visual acuity test, ophthalmoscopy, and slit-lamp biomicroscopic examination are used to establish the degree of cataract formation. The degree of lens opacity does not always correlate with the patient's functional status. Some patients can perform normal activities despite clinically significant cataracts. Others with less lens opacification have a disproportionate de-

crease in visual acuity; hence, visual acuity is an imperfect measure of visual impairment.

## Medical Management

No nonsurgical treatment cures cataracts. Ongoing studies are investigating ways to slow cataract progression, such as intake of antioxidants (eg, vitamin C, beta-carotene, vitamin E) (Age-Related Eye Disease Research Study Group, 2001). In the early stages of cataract development, glasses, contact lenses, strong bifocals, or magnifying lenses may improve vision. Reducing glare with proper light and appropriate lighting can facilitate reading. Mydriatics can be used as short-term treatment to dilate the pupil and allow more light to reach the retina, although this increases glare.

## SURGICAL MANAGEMENT

Fewer than 15% of people with cataracts suffer vision problems severe enough to require surgery. In general, if reduced vision from cataract does not interfere with normal activities, surgery may not be needed. However, in deciding when cataract surgery is to be performed, the patient's functional and visual status should be a primary consideration. Surgery is performed on an outpatient basis and usually takes less than 1 hour, with the patient being discharged in 30 minutes or less afterward. Although complications from cataract surgery are uncommon, they can have significant effects on vision (Table 58-6). Restoration of visual function through a safe and minimally invasive procedure is the surgical goal, which is achieved with advances in topical anesthesia, smaller wound incision (ie, clear cornea incision), and lens design (ie, foldable and more accurate intraocular lens measurements).

Topical anesthesia, such as lidocaine gel applied to the surface of the eye, eliminates the hazards of regional anesthesia, such as ocular perforation, retrobulbar hemorrhage, optic injuries, diplopia, and ptosis, and is ideal for patients receiving anticoagulants. Moreover, patients can communicate and cooperate during surgery.

When both eyes have cataracts, one eye is treated first, with at least several weeks, preferably months, separating the two operations. Because cataract surgery is performed to improve visual functioning, the delay for the other eye gives time for the patient and the surgeon to evaluate whether the results from the first surgery are adequate enough to preclude the need for a second operation. The delay also provides time for the first eye to recover; if there are any complications, the surgeon may decide to perform the second procedure differently.

**Intracapsular Cataract Extraction.** From the late 1800s until the 1970s, the technique of choice for cataract extraction was intracapsular cataract extraction (ICCE). The entire lens (ie, nucleus, cortex, and capsule) is removed, and fine sutures close the incision. ICCE is infrequently performed today; however, it is indicated when there is a need to remove the entire lens, such as with a subluxated cataract (ie, partially or completely dislocated lens).

**Extracapsular Surgery.** Extracapsular cataract extraction (ECCE) achieves the intactness of smaller incisional wounds (less trauma to the eye) and maintenance of the posterior capsule of the lens, reducing postoperative complications, particularly aphakic retinal detachment and cystoid macular edema. In ECCE, a portion of the anterior capsule is removed, allowing extraction of the lens nucleus and cortex. The posterior capsule and zonular support are left intact. An intact zonular-capsular diaphragm provides the needed safe anchor for the posterior chamber intraocular lens (IOL). After the pupil has been dilated and the surgeon has made

Table 58-6 • Potential Complications of Cataract Surgery

COMPLICATION	EFFECTS	MANAGEMENT AND OUTCOME
<p><b>Immediate Preoperative</b></p> <p>Retrobulbar hemorrhage: can result from retrobulbar infiltration of anesthetic agents if the short ciliary artery is located by the injectia</p>	Increased IOP, proptosis, lid tightness, and subconjunctival hemorrhage with or without edema	Emergent lateral canthotomy (slitting of the canthus) is performed to stop central retinal perfusion when the IOP is dangerously elevated. If this procedure fails to reduce IOP, a puncture of the anterior chamber with removal of fluid is considered. The patient must be closely monitored for at least a few hours. Postponement of cataract surgery for 2 to 4 weeks is advised. Complications such as iris prolapse, vitreous loss, and choroidal hemorrhage could result in a catastrophic visual outcome.
<p><b>Intraoperative Complications</b></p> <p>Rupture of the posterior capsule</p> <p>Suprachoroidal (expulsive) hemorrhage: profuse bleeding into the suprachoroidal space</p>	May result in loss of vitreous	Anterior vitrectomy is required if vitreous loss occurs. Closure of the incision and administration of a hyperosmotic agent to reduce IOP or corticosteroids to reduce intraocular inflammation. Vitrectomy is performed 1 to 2 weeks later. Visual prognosis is poor; some useful vision may be salvaged on rare occasions.
<p><b>Early Postoperative Complications</b></p> <p>Acute bacterial endophthalmitis: devastating complication that occurs in about 1 in 1000 cases; the most common causative organisms are <i>Staphylococcus epidermitis</i>, <i>S. aureus</i>, <i>Pseudomonas</i> and <i>Proteus</i> species</p>	Characterized by marked visual loss, pain, lid edema, hypopyon, corneal haze, and chemosis	Managed by aggressive antibiotic therapy. Broad-spectrum antibiotics are administered while awaiting culture and sensitivity results. Once results are obtained, the appropriate antibiotics are administered via intravitreal injection. Corticosteroid therapy is also administered.
<p><b>Late Postoperative Complications</b></p> <p>Suture-related problems</p>	Toxic reactions or mechanical injury from broken or loose sutures	Suture removal relieves the symptoms. Topical corticosteroids are used when the incision is not healed and sutures cannot be removed.
Malposition of the IOL	Results in astigmatism, sensitivity to glare, or appearance of halos	Miotics are used for mild cases, whereas IOL removal and replacement is necessary for severe cases.
Chronic endophthalmitis	Persistent, low-grade inflammation and granuloma	Corticosteroids and antibiotics are administered systemically. If the condition persists, removal of the IOL and capsular bag, vitrectomy, and intravitreal injection of antibiotics are required.
Opacification of the posterior capsule (most common late complication of extracapsular cataract extraction)	Visual acuity is diminished.	YAG laser is used to create a hole in the posterior capsule. Blurred vision is cleared immediately.

IOP, intraocular pressure.

a small incision on the upper edge of the cornea, a viscoelastic substance (clear gel) is injected into the space between the cornea and the lens. This prevents the space from collapsing and facilitates insertion of the IOL.

**Phacoemulsification.** This method of extracapsular surgery uses an ultrasonic device that liquefies the nucleus and cortex, which are then suctioned out through a tube. The posterior capsule is left intact. Because the incision is even smaller than the standard ECCE, the wound heals more rapidly, and there is early stabilization of refractive error and less astigmatism. Hardware and software advances in ultrasonic technology—including new phaco needles that are used to cut and aspirate the cataract—permit safe and efficient removal of nearly all cataracts through a clear cornea incision that is as small or smaller than required for available foldable lenses. Ultimately, advances in technology will achieve an injectable IOL.

**Lens Replacement.** After removal of the crystalline lens, the patient is referred to as *aphakic* (ie, without lens). The lens, which focuses light on the retina, must be replaced for the patient to see clearly. There are three lens replacement options: aphakic eyeglasses, contact lenses, and IOL implants.

Aphakic glasses are effective but heavy. Objects are magnified by 25%, making them appear closer than they actually are. Objects are magnified unequally, creating distortion. Peripheral vision is also limited, and **binocular vision** (ie, ability of both eyes to focus on one object and fuse the two images into one) is impossible if the other eye is phakic (normal).

Contact lenses provide patients with almost normal vision, but because contact lenses need to be removed occasionally, the patient also needs a pair of aphakic glasses. Contact lenses are not advised for patients who have difficulty inserting, removing, and cleaning them. Frequent handling and improper disinfection increase the risk for infection.

Insertion of IOLs during cataract surgery is the usual approach to lens replacement. After ICCE, the surgeon implants an anterior chamber IOL in front of the iris. Posterior chamber lenses, generally used in ECCE, are implanted behind the iris. ECCE and posterior chamber IOLs are associated with a relatively low incidence of complications (eg, hyphema, macular edema, secondary glaucoma, damage to the corneal endothelium). IOL implantation is contraindicated in patients with recurrent uveitis, proliferative diabetic retinopathy, neovascular glaucoma, or rubeosis iridis. Like any device, IOLs can malfunction and cause complications.

## Nursing Management

The patient with cataracts should receive the usual preoperative care for ambulatory surgical patients undergoing eye surgery. According to the study on Medical Testing for Cataract Surgery, routine preoperative testing before cataract surgery does not improve health or clinical outcomes. Hence, the standard battery of preoperative tests should be prescribed only when they would have been indicated by the patient's medical history (Schein et al., 2000).

### PROVIDING PREOPERATIVE CARE

To reduce the risk for retrobulbar hemorrhage (after retrobulbar injection), any anticoagulation therapy that the patient is receiving is withheld, if medically appropriate. Aspirin should be withheld for 5 to 7 days, nonsteroidal anti-inflammatory medications (NSAIDs) for 3 to 5 days, and warfarin (Coumadin) until the prothrombin time of 1.5 is almost reached.

Dilating drops are administered every 10 minutes for four doses at least 1 hour before surgery. Additional dilating drops may be administered in the operating room (immediately before surgery) if the affected eye is not fully dilated. Antibiotic, corticosteroid, and NSAID drops may be administered prophylactically to prevent postoperative infection and inflammation.

### PROVIDING POSTOPERATIVE CARE

After recovery from anesthesia, the patient receives verbal and written instruction regarding how to protect the eye, administer medications, recognize signs of complications, and obtain emergency care. Activities to be avoided are identified in Chart 58-6. The nurse also explains that there is minimal discomfort after surgery and in-

structs the patient to take a mild analgesic agent, such as acetaminophen, as needed. Antibiotic, anti-inflammatory, and corticosteroid eye drops or ointments are prescribed postoperatively. A clinical pathway for the care of patients undergoing ambulatory cataract surgery is presented in Appendix A at the end of the book.

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** To prevent accidental rubbing or poking of the eye, the patient wears a protective eye patch for 24 hours after surgery, followed by eyeglasses worn during the day and a metal shield worn at night for 1 to 4 weeks. The nurse instructs the patient and family in applying and caring for the eye shield. Sunglasses should be worn while outdoors during the day because the eye is sensitive to light.

Slight morning discharge, some redness, and a scratchy feeling may be expected for a few days. A clean, damp washcloth may be used to remove slight morning eye discharge. Because cataract surgery increases the risk for retinal detachment, the patient must know to notify the surgeon if new floaters (ie, dots) in vision, flashing lights, decrease in vision, pain, or increase in redness occurs.

**Continuing Care.** The eye patch is removed after the first follow-up appointment. Patients may experience blurring of vision for several days to weeks. Sutures left in the eye alter the curvature of the cornea, resulting in temporary blurring and some astigmatism. Vision gradually improves as the eye heals. Patients with IOL implants have visual improvement faster than those waiting for aphakic glasses or contact lenses. Vision is stabilized when the eye is completely healed, usually within 6 to 12 weeks, when final corrective prescription is completed. Visual correction is needed for any remaining nearsightedness or farsightedness (even in patients with IOL implants).

## Corneal Disorders

### CORNEAL DYSTROPHIES

Corneal dystrophies are inherited as autosomal dominant traits and manifest when the person is about 20 years of age. They are characterized by deposits in the corneal layers. Decreased vision

Chart 58-6

#### Home Care Checklist • Intraocular Lens Implant

At the completion of the home care instruction, the patient or caregiver will be able to:

- |   | Patient | Caregiver |
|---|---------|-----------|
| • Wear glasses or metal eye shield at all times following surgery as instructed by the physician.   | ✓       |           |
| • Always wash hands before touching or cleaning the postoperative eye.  | ✓       | ✓         |
| • Clean postoperative eye with a clean tissue; wipe the closed eye with a single gesture from the inner canthus outward.  | ✓       | ✓         |
| • Bathe or shower; shampoo hair cautiously or seek assistance.  | ✓       |           |
| • Avoid lying on the side of the affected eye the night after surgery.  | ✓       |           |
| • Keep activity light (eg, walking, reading, watching television). Resume the following activities only as directed by the physician: driving, sexual activity, unusually strenuous activity. | ✓       |           |
| • Remember not to lift, push, or pull objects heavier than 15 lb.   | ✓       |           |
| • Avoid bending or stooping for an extended period.   | ✓       |           |
| • Be careful when climbing or descending stairs.  | ✓       |           |
| • Know when to call the physician.*   | ✓       | ✓         |

\*Call the physician immediately if any of the following problems occur before the next physician's appointment: (1) vision changes; (2) continuous flashing lights appear to the affected eye; (3) redness, swelling, or pain increase in the eye; (4) the amount or type of eye drainage changes; (5) the eye is injured in any way; (6) significant pain is not relieved by acetaminophen.

is caused by the irregular corneal surface and corneal deposits. Corneal endothelial decompensation leads to corneal edema and blurring of vision. Persistent edema leads to **bullous keratopathy**, which is formation of blisters that cause pain and discomfort on rupturing. This condition is usually associated with primary open-angle glaucoma.

A bandage contact lens is used to flatten the bullae, protect the exposed corneal nerve endings, and relieve discomfort. Symptomatic treatments, such as hypertonic drops or ointment (5% sodium chloride), may reduce epithelial edema; lowering the IOP also reduces stromal edema. Penetrating keratoplasty has a high success rate in advanced cases (see “Corneal Surgeries”). For diffuse bullous keratopathy, amniotic membrane transplantation may become the procedure of choice for patients with limited visual potential (Rapuano, 2000).

## KERATOCONUS

**Keratoconus** is a condition characterized by a conical protuberance of the cornea with progressive thinning on protrusion and irregular astigmatism. The hereditary condition has a higher incidence among women. Onset occurs at puberty; the condition may progress for more than 20 years and is bilateral. Corneal scarring occurs in severe cases. Blurred vision is a prominent symptom. Rigid, gas-permeable contact lenses correct irregular astigmatism and improve vision. Advances in contact lens design have reduced the need for surgery. Penetrating keratoplasty is indicated when contact lens correction is no longer effective.

## CORNEAL SURGERIES

Among the surgical procedures used to treat diseased corneal tissue are phototherapeutic keratectomy (PTK) and keratoplasty.

### Phototherapeutic Keratectomy

PTK is a laser procedure that is used to treat diseased corneal tissue by removing or reducing corneal opacities and smoothing the anterior corneal surface to improve functional vision. PTK is a safer, more effective (when indicated) alternative than penetrating or lamellar keratoplasty. PTK is contraindicated in patients with active herpetic keratitis because the ultraviolet rays may reactivate latent virus. Common side effects are induced hyperopia and stromal haze. Complications are delayed re-epithelialization (particularly in patients with diabetes) and bacterial keratitis. Postoperative management consists of oral analgesics for eye pain. Re-epithelialization is promoted with a pressure patch or therapeutic soft contact lens. Antibiotic and corticosteroid ointment and NSAIDs are prescribed postoperatively. Follow-up examinations are required for up to 2 years.

### Keratoplasty

Keratoplasty (ie, corneal transplantation or corneal grafting) involves replacing abnormal host tissue with a healthy donor corneal tissue. Common indications are keratoconus, corneal dystrophy, corneal scarring from herpes simplex keratitis, and chemical burns.

Several factors affect the success of the graft: ocular structures (eg, lids, conjunctiva), tear film function, adequacy of blinking, and viability of the donor endothelium. Tissue that is the possible source of disease transmission from donor to recipient or

cornea with functionally compromised endothelium is typically not used for grafting (Chart 58-7), nor is corneal tissue used from donors who have undergone laser-assisted in situ keratomileusis (LASIK) because the cornea is no longer intact. Conditions such as glaucoma, retinal disease, and **strabismus** (ie, deviation in ocular alignment) can negatively influence the outcome. Promising experimental therapies include stem cell transplants (Rongé, 2001) and autologous limbal epithelial cell transplants (Tsai et al., 2000).

The surgeon determines the graft size before the procedure, and the appropriate size is marked on the surface of the cornea. The surgeon prepares the donor cornea and the recipient bed, removes the diseased cornea, places the donor cornea on the recipient bed, and sutures it in place. Sutures remain in place for 12 to 18 months. Potential complications include early graft failure due to poor quality of donor tissue, surgical trauma, acute infection, and persistently increased IOP and late graft failure due to rejection.

Postoperatively, the patient receives mydriatic medications (2 weeks) and topical corticosteroids (12 months; daily doses for 6 months and tapered doses thereafter). Patients typically describe a sensation of postoperative eye discomfort rather than acute pain.

## Nursing Management

The nurse reinforces the surgeon’s recommendations and instructions regarding visual rehabilitation and visual improvement by explaining why a technically successful graft may initially produce disappointing results because the procedure has produced a new optical surface and only after several months do patients start seeing the natural and true colors of their environment. Correction of a resultant refractive error with eyeglasses or contact lenses determines the final visual outcome. The nurse assesses the patient’s support system and his or her ability to comply with long-term follow-up, which includes frequent clinic visits for several months for tapering of topical corticosteroid therapy, selective suture removal, and ongoing evaluation of the graft site and visual

Chart  
58-7

### Contraindications to the Use of Donor Tissue for Corneal Transplantation: Donor Characteristics

#### Systemic Disorders

- Death from unknown cause
- Creutzfeldt-Jacob disease
- AIDS or high risk for HIV infection
- Hepatitis
- Eye infection, systemic infection

#### Intrinsic Eye Disease

- Retinoblastoma
- Ocular inflammation
- Malignant tumors of anterior segment
- Disorders of the conjunctiva or corneal surface involving the optical zone of the cornea

#### Other

- History of eye trauma
- Corneal scars
- Previous surgical procedure
- Corneal graft
- LASIK eye surgery

acuity. The nurse also initiates appropriate referral to community services when indicated.

Because graft failure is an ophthalmic emergency that can occur at any time, the primary goal of nursing care is to teach the patient to identify signs and symptoms of graft failure. The early symptoms are blurred vision, discomfort, tearing, or redness of the eye. Decreased vision results after graft destruction. Patients must contact the ophthalmologist as soon as symptoms occur. Treatment of graft rejection is prompt administration of hourly topical corticosteroids and periocular corticosteroid injections. Systemic immunosuppressive agents may be necessary for severe, resistant cases.

## REFRACTIVE SURGERIES

Refractive surgeries are cosmetic, elective procedures performed to reshape corneal tissue and correct refractive errors so that eyeglasses or contact lenses are no longer needed. Current procedures include radial keratotomy, photorefractive keratectomy (PRK), and LASIK.

Refractive surgery alters the major optical function of the eye and thereby carries certain surgical risks. The patient must fully understand benefits, potential risks and complications, common side effects, and limitations of the procedure. Refractive surgery does not alter the normal aging process of the eye. If the reason for the procedure is occupational vision requirements, the results must satisfy both the patient and the employer. Precise visual outcome cannot be guaranteed with certainty. Typically, patients must be at least 18 years of age.

The corneal structure must be normal and refractive error stable. Patients are required to discontinue using contact lenses for a period before the procedure (ie, 2 to 3 weeks for soft lenses and 4 weeks for hard lenses). Patients with conditions that are likely to adversely affect corneal wound healing (eg, corticosteroid use, immunosuppression, elevated IOP) are not good candidates for the procedure. Any superficial eye disease must be diagnosed and fully treated before a refractive procedure.

### Radial Keratotomy

Radial keratotomy (RK) is indicated for low myopia (less than 8D). The procedure involves making four to eight, deep, radial incisions in the paracentral and peripheral cornea with a metal or diamond blade. The corneal contour then becomes flatter. Glare, photosensitivity, fluctuations of vision during the day, and occasional diplopia are common side effects. As the popularity of laser refractive surgery grows, RK procedures decrease.

### Laser Vision Correction Photorefractive Keratectomy

Laser vision correction photorefractive keratectomy (PRK) is a procedure used to treat myopia and hyperopia with or without astigmatism. The 193-mm argon fluoride excimer laser is applied directly to the cornea according to carefully calculated measurements. For myopia, the relative curvature is decreased; for hyperopia, the relative curvature is increased. A bandage contact lens is placed over the cornea to promote epithelial healing and reduce pain similar to that of severe corneal abrasion. PRK requires a longer visual recovery period than RK, but PRK provides more predictable and stable results. Except for the side effect of corneal haze and night vision problems, PRK has not

been associated with the two major disadvantages of RK: hyperopic drift and weakening of the structural integrity of the cornea.

### Laser-Assisted In Situ Keratomileusis (LASIK)

An improvement over PRK, particularly for correcting high (severe) myopia, LASIK involves flattening the anterior curvature of the cornea by removing a stromal lamella or layer. The surgeon creates a corneal flap with a microkeratome, which is an automatic corneal shaper similar to a carpenter's plane. The surgeon retracts a flap of corneal tissue less than one third of the thickness of a human hair to access the corneal stroma and then uses the excimer laser on the stromal bed to reshape the cornea according to calculated measurements (Fig. 58-10). The corneal flap, a naturally adhering bandage, is rolled back and repositioned. LASIK also appears to be an effective, predictable, stable, and safe procedure for correcting residual myopia after cataract surgery (Ayala et al., 2001).

LASIK causes less postoperative discomfort, has fewer side effects, and is safer than PRK. The patient has no corneal haze and requires less postoperative care. With LASIK, however, the cornea has been invaded at a deeper level, and any complications are more significant than those that can occur with PRK.

### PERIOPERATIVE COMPLICATIONS

**Ablation-Related Complications.** Ablation complications of LASIK include an elevated area within the corneal treatment ablation zone (ie, central island). Signs and symptoms of this complication include ghosting, blurred vision, halo formation around lights, decreased visual activity, and contrast sensitivity in low light. Most of the island formations resolve over time; reablation is considered only after the island appears stable after repeated examinations for at least 3 months.

**Diffuse Lamellar Keratitis.** As LASIK increases in popularity and is performed more often, the vision-threatening complication known as diffuse lamellar keratitis (DLK) is reported more often. DLK is a peculiar, noninfectious, inflammatory reaction in the lamellar interface after LASIK. DLK is characterized by a white, granular, diffuse, culture-negative lamellar keratitis occurring in

**FIGURE 58-10** LASIK combines delicate surgical procedures and laser treatment. A flap is surgically created and lifted to one side. A laser is then applied to the cornea to reshape it. With permission from The Wilmer Laser Vision Center, Lutherville, MD.

the first week after surgery. Studies suggest that, because no single agent appears to be solely the cause of DLK, the cause is multifactorial (Holland et. al., 2000).

DLK is diagnosed by identifying cells in the lamellar interface by slit-lamp examination from postoperative day 1. Depending on the severity of the condition, treatment methods range from administering corticosteroid drops to intervening surgically.

**Central Islands and Decentered Ablations.** Decentered or eccentric ablation involves a shift of the center of the ablation pattern from the pupil or visual axis to a more eccentric location. Symptoms include decreased visual acuity, halos, glare, and ghosting, especially in low-light settings.

### LASIK Enhancements

LASIK enhancements are surgical options from improved technology and software used to treat a wider range of myopia, hyperopia, and astigmatism in eyes with a history of LASIK surgery. Astigmatic keratotomy continues to work well for patients with significant regular astigmatism. A newer procedure, Intacs implantation, is performed for patients left with significant myopia but who have thin corneas. Hyperopic excimer laser enhancements are indicated for patients who have undergone myopic LASIK and have consecutive hyperopia.

### IMPLANTABLE DEVICES

Because the results of refractive surgery on high (severe) myopia, hyperopia, and astigmatism are less predictable, there has been increasing interest in the use of phakic IOLs. Anterior and posterior chamber IOLs are now in use, and design improvements continue to be made. Phakic IOL implantation does not compromise the central optical zone and retains the normal aspheric contour of the cornea. Most importantly, it is reversible. Early research results on vision quality favor phakic IOL over LASIK. Potential complications include cataract, iritis or uveitis, endothelial cell loss, and increased IOP.

Intacs is an implantable intrastromal corneal ring used to correct mild to moderate myopia. The intrastromal corneal ring segments are placed in the corneal stroma outside of the central optical zone and reshape the anterior surface of the cornea.

### Management

Patient satisfaction is the ultimate goal; therefore, patient education and counseling about potential risks, complications, and postoperative follow-up are critical. Minimal postoperative care includes topical corticosteroid drops. The length of postoperative follow-up depends on the refractive procedure, with PRK requiring a longer course, followed by RK and then LASIK.

## Retinal Disorders

Although the retina is composed of multiple microscopic layers, the two innermost layers, the sensory retina and the retinal pigment epithelium (RPE), are the most relevant to common retinal disorders. Just as the film in a camera captures an image, so does the retina, the neural tissue of the eye. The rods and cones, the photoreceptor cells, are found in the sensory layer of the retina. Beneath the sensory layer lies the RPE, the pigmented layer. When the rods and cones are stimulated by light, an electrical impulse is generated, and the image is transmitted to the brain.

## RETINAL DETACHMENT

Retinal detachment refers to the separation of the RPE from the sensory layer. The four types of retinal detachment are rhegmatogenous, traction, a combination of rhegmatogenous and traction, and exudative. *Rhegmatogenous detachment* is the most common form. In this condition, a hole or tear develops in the sensory retina, allowing some of the liquid vitreous to seep through the sensory retina and detach it from the RPE (Fig. 58-11). People at risk for this type of detachment include those with high myopia or **aphakia** after cataract surgery. Trauma may also play a role in rhegmatogenous retinal detachment. Between 5% and 10% of all rhegmatogenous retinal detachments are associated with proliferative retinopathy, a retinopathy associated with diabetic neovascularization (see Chap. 41).

Tension, or a pulling force, is responsible for *traction retinal detachment*. An ophthalmologist must ascertain all of the areas of retinal break and identify and release the scars or bands of fibrous material providing traction on the retina. Generally, patients with this condition have developed fibrous scar tissue from conditions such as diabetic retinopathy, vitreous hemorrhage, or the retinopathy of prematurity. The hemorrhages and fibrous proliferation associated with these conditions exert a pulling force on the delicate retina.

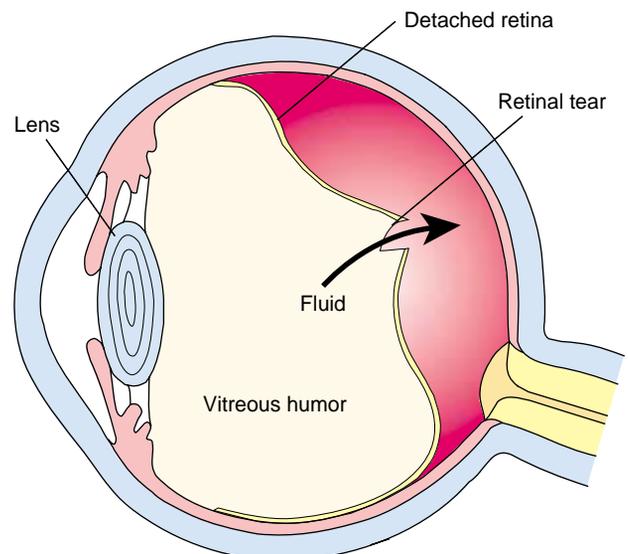

Patients can have both rhegmatogenous and traction retinal detachment. *Exudative retinal detachments* are the result of the production of a serous fluid under the retina from the choroid. Conditions such as uveitis and macular degeneration may cause the production of this serous fluid.

### Clinical Manifestations

Patients may report the sensation of a shade or curtain coming across the vision of one eye, cobwebs, bright flashing lights, or the sudden onset of a great number of floaters. Patients do not complain of pain.

### Assessment and Diagnostic Findings

After visual acuity is determined, the patient must have a dilated fundus examination using an indirect ophthalmoscope and a Goldmann three-mirror examination. This examination is detailed

**FIGURE 58-11** Retinal detachment.

and prolonged, and it can be very uncomfortable for the patient. Many patients describe this as looking directly into the sun. All retinal breaks, all fibrous bands that may be causing traction on the retina, and all degenerative changes must be identified. A detailed retinal drawing is made by the ophthalmologist.

## Surgical Management

In rhegmatogenous detachment, an attempt is made to reattach the sensory retina to the RPE surgically. The retinal surgeon compresses the sclera (often with a scleral buckle or a silicone band; Fig. 58-12) to indent the scleral wall from the outside of the eye and bring the two retinal layers in contact with each other. Gas bubbles, silicone oil, or perfluorocarbon and liquids may also be injected into the vitreous cavity to help push the sensory retina up against the RPE. Argon laser photocoagulation or cryotherapy is also used to “spot-weld” small holes.

In traction retinal detachment, a vitrectomy is performed. A vitrectomy is an intraocular procedure in which 1- to 4-mm incisions are made at the pars plana. One incision allows the introduction of a light source (ie, endoilluminator), and another incision serves as the portal for the vitrectomy instrument. The surgeon dissects preretinal membranes under direct visualization while the retina is stabilized by an intraoperative vitreous substitute. Technologic advances, including the use of operating microscopes, micro-instrumentation, irrigating contact lenses, and instruments that combine vitreous cutting, aspiration, and illumination capabilities into one device, have allowed tremendous progress in vitreoretinal surgery. The techniques of vitreoretinal surgery can be used in various procedures, including the removal of foreign bodies, vitreous opacities such as blood, and dislocated lenses. Traction on the retina may be relieved through vitrectomy and may be combined with scleral buckling to repair retinal breaks. Treatment of macular holes includes vitrectomy, laser photocoagulation, air-fluid-gas exchanges, and the use of growth factor.

## Nursing Management

For the most part, nursing interventions consist of educating the patient and providing supportive care.

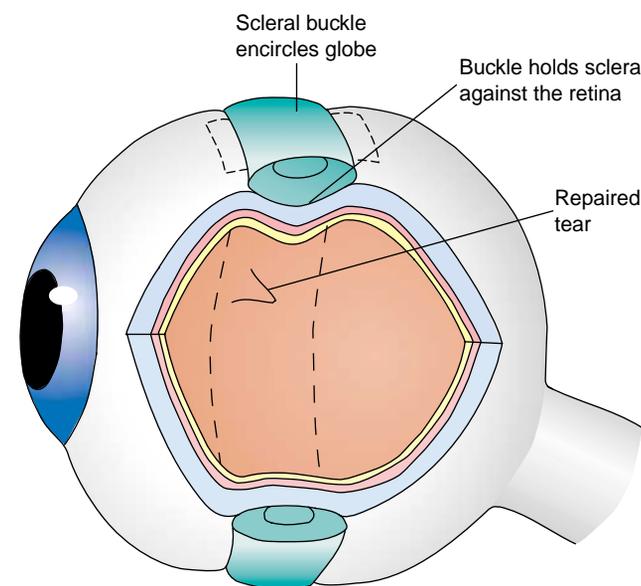

FIGURE 58-12 Scleral buckle.

## PROMOTING COMFORT

If gas tamponade is used to flatten the retina, the patient may have to be specially positioned to make the gas bubble float into the best position. Some patients must lie face down or on their side for days. Patients and family members should be made aware of these special needs beforehand, so that the patient can be made as comfortable as possible.

## TEACHING ABOUT COMPLICATIONS

In many cases, vitreoretinal procedures are performed on an out-patient basis, and the patient is seen the next day for a follow-up examination and closely monitored thereafter as required. Postoperative complications in these patients may include increased IOP, endophthalmitis, development of other retinal detachments, development of cataracts, and loss of turgor of the eye. Patients must be taught the signs and symptoms of complications, particularly of increasing IOP and postoperative infection.

## RETINAL VASCULAR DISORDERS

Loss of vision can occur from occlusion of a retinal artery or vein. Such occlusions may result from atherosclerosis, cardiac valvular disease, venous stasis, hypertension, or increased blood viscosity.

### Central Retinal Vein Occlusion

Blood supply to and from the ocular fundus is provided by the central retinal artery and vein. Patients who have suffered a central retinal vein occlusion report decreased visual acuity, which may range from mild blurring to vision that is limited to only hand-motion vision.

Direct ophthalmoscopy of the retina shows optic disc swelling, venous dilation and tortuosity, retinal hemorrhages, cotton-wool spots, and a “blood and thunder” (extremely bloody) appearance of the retina. The better the initial visual acuity, the better the general prognosis.

Fluorescein angiography may show extensive areas of capillary closure. The patient should be monitored carefully over the ensuing several months for signs of neovascularization and neovascular glaucoma. Laser panretinal photocoagulation may be necessary to treat the abnormal neovascularization. Neovascularization of the iris may cause neovascular glaucoma, which may be difficult to control.

### Branch Retinal Vein Occlusion

Some patients with branch retinal vein occlusions are symptom free, whereas others complain of a sudden loss of vision if the macular area is involved. A more gradual loss of vision may occur if macular edema associated with the branch retinal vein occlusion develops.

On examination, the ocular fundus appears similar to that found with central retinal vein occlusion; however, only those portions of the retina affected by the obstructive veins have what is known as a “blood and thunder” appearance. The diagnostic evaluation and follow-up assessments are the same as for central retinal vein occlusion. Potential complications are similar. Potential associated conditions include glaucoma, systemic hypertension, diabetes mellitus, hyperlipidemia, and hyperviscosity syndrome.

## Central Retinal Artery Occlusion

The patient with central retinal artery occlusion presents with a sudden loss of vision. Visual acuity is reduced to counting the examiner's fingers, or the field of vision is tremendously restricted. A relative afferent pupillary defect is present. Examination of the ocular fundus reveals a pale retina with a cherry-red spot at the fovea. The retinal arteries are thin, and emboli are occasionally seen in the central retinal artery or its branches. Central retinal artery occlusion is a true ocular emergency. Various treatments are used, including ocular massage, anterior chamber paracentesis, intravenous administration of hyperosmotic agents such as acetazolamide, and high concentrations of oxygen.

## MACULAR DEGENERATION

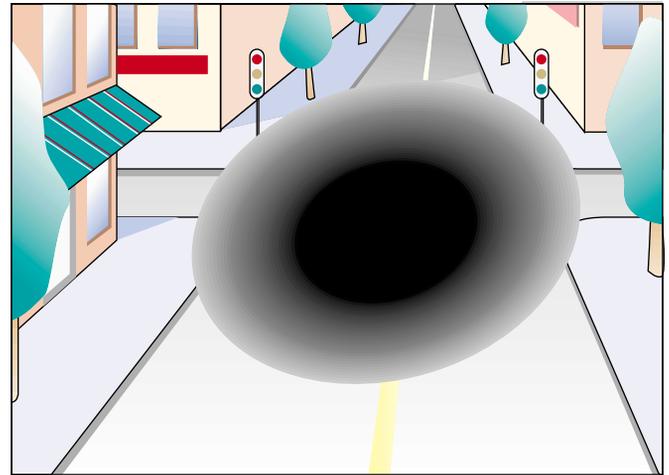

Macular degeneration is the most common cause of visual loss in people older than age 60 (Margolis et al., 2002). Commonly called age-related macular degeneration (AMD), it is characterized by tiny, yellowish spots called drusen (Fig. 58-13) beneath the retina. Most people older than 60 years of age have at least a few small drusen. There is a wide range of visual loss in patients with macular degeneration, but most patients do not experience total blindness. Central vision is generally the most affected, with most patients retaining peripheral vision (Fig. 58-14). There are two types of AMD, commonly known as the dry type and wet type.

Between 85% and 90% of people with AMD have the dry or nonexudative type in which the outer layers of the retina slowly break down (Fig. 58-15). With this breakdown comes the appearance of drusen. When the drusen occur outside of the macular area, patients generally have no symptoms. When the drusen occur within the macula, there is a gradual blurring of vision that patients may notice when they try to read. There is no known treatment that can slow or cure this type of AMD.

The second type of AMD, the wet or exudative type, may have an abrupt onset. Patients complain that straight lines appear crooked and distorted or that letters in words appear broken up. This effect results from proliferation of abnormal blood vessels growing under the retina, within the choroid layer of the eye, a condition known as choroidal neovascularization (CNV). The affected vessels can leak fluid and blood, elevating the retina. Some patients can be treated with the laser to stop the leakage from these vessels. This treatment is not ideal because vision may

**FIGURE 58-13** Retina showing drusen and AMD.

**FIGURE 58-14** Visual loss associated with macular degeneration.

be affected by the laser treatment and abnormal vessels often grow back after treatment.

## Medical Management

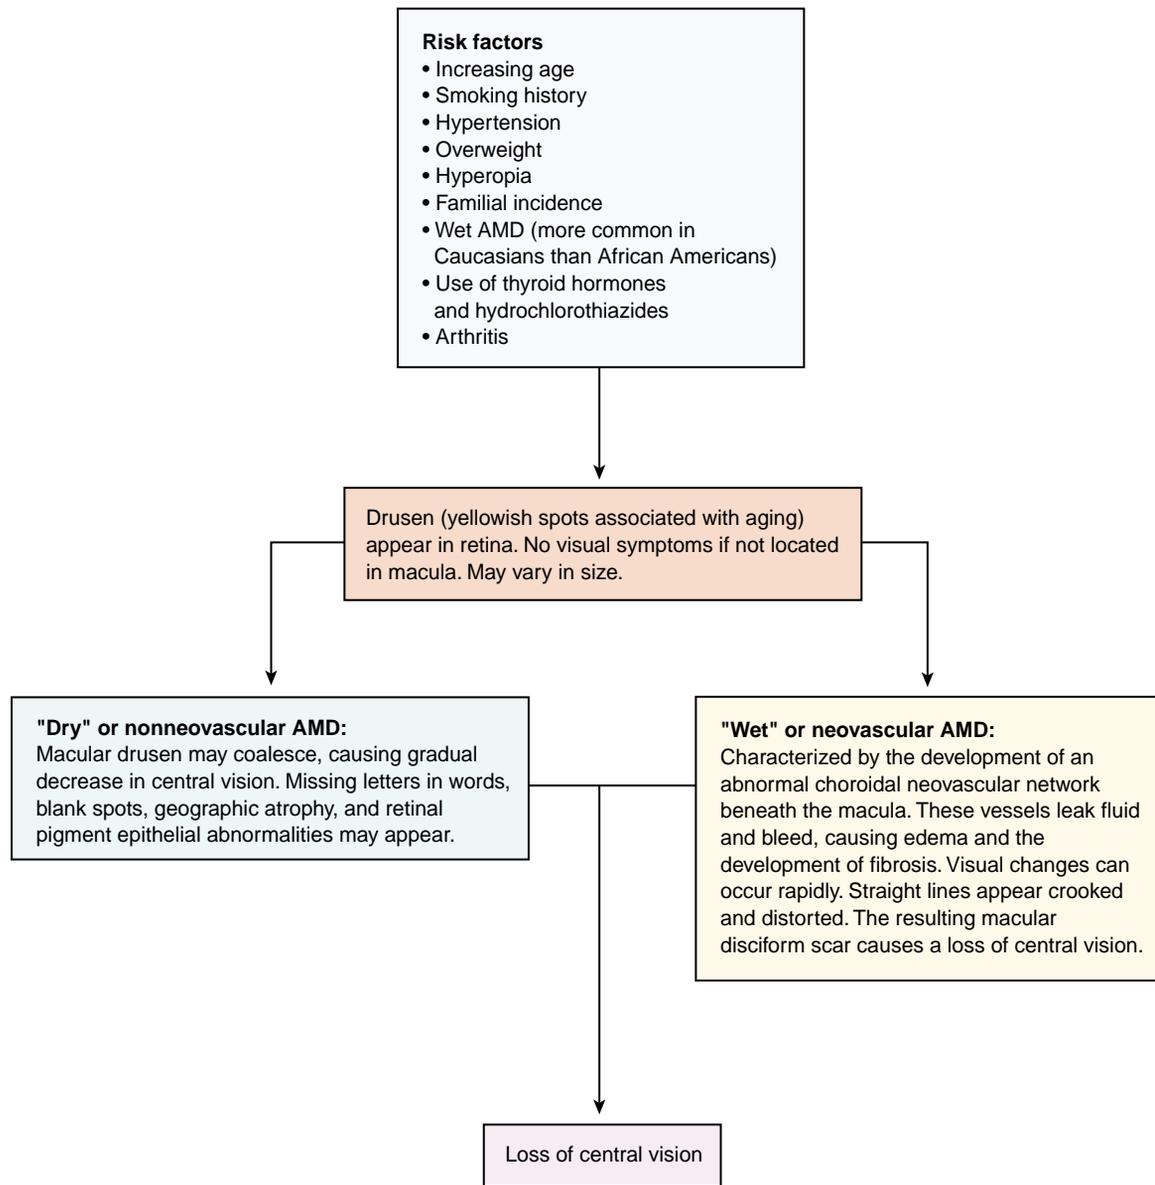

### PHOTODYNAMIC THERAPY

Visual loss from CNV lesions in AMD is a growing problem. With the growth of these new vessels from the choriocapillary layer, fibrous tissue develops that can, over months, destroy central vision. Laser treatment has been used to close these abnormal vessels, but the very process of photocoagulation carries with it some level of retinal destruction, albeit less than the natural scarring that would occur in the untreated eye. Photodynamic therapy (PDT) has been developed in an attempt to ameliorate the CNV while causing minimal damage to the retina. The Treatment of Age-Related Macular Degeneration With Photodynamic Therapy (TAP) study group (1999) has shown that PDT can reduce the risk of visual loss for certain groups of patients who have classic subfoveal choroidal neovascularization due to macular degeneration.

PDT is a two-step process (Fig. 58-16). Verteporfin, a photosensitive dye, is infused intravenously over 10 minutes. Fifteen minutes after the start of the infusion, a diode laser is used to treat the abnormal network of vessels. The dye within the vessels takes up the energy of the diode laser, but the surrounding retina does not, avoiding damage to adjacent areas. Retreatment may be necessary over time.

## Nursing Management

Nursing management is primarily educational. Verteporfin is a light-activated dye, and patient education is important preoperatively. The patient should be instructed to bring dark sunglasses, gloves, a wide-brimmed hat, long-sleeved shirt, and slacks to the PDT setting. The patient must be cautioned to avoid exposure to direct sunlight or bright light for 5 days after treatment. The dye within the blood vessels near the surface of the skin could become activated with exposure to strong light. This would include bright sunlight, tanning booths, halogen lights, and the bright lights used in dental offices and operating rooms. Ordinary indoor light is not a problem. If a patient must go outdoors within the first 5 days after treatment, he or she should be counseled to wear

**FIGURE 58-15** Progression of age-related macular degeneration (AMD): pathways to vision loss.

long-sleeved shirts and slacks made of tightly woven fabrics. Gloves, shoes, socks, sunglasses, and a wide-brimmed hat should also be worn if the patient has to go outdoors during daylight hours during this period. Inadvertent sunlight exposure can lead to severe blistering of the skin and sunburn that may require plastic surgery.

### Macular Translocation

Wet macular degeneration is characterized by the development of an abnormal CNV membrane to the detriment of central vision. One approach to this problem is the surgical procedure known as macular translocation, in which a 360-degree retinal detachment is surgically created and the retina is gently lifted and resettled, placing the macular area a slight distance away from the

area of CNV. Laser treatment can then be applied to the abnormal neovascular network with minimal damage occurring to the macula. Pilot studies are evaluating whether this surgical approach is an effective alternative to laser treatments of CNV due to AMD.

### Angiogenesis

An important component of the effort against neovascular AMD is the investigation into the causes of the development and progression of angiogenesis (ie, abnormal blood vessel formation). Investigations continue in the laboratory to search for agents that can inhibit angiogenesis. This has implications for ocular neovascularization and treatment of other disorders such as solid tumors.

to determine whether large doses of macronutrients are effective in preventing or slowing the course of AMD. The study revealed that use of antioxidants (ie, vitamin C, vitamin E, and beta-carotene) and minerals (ie, zinc oxide) can slow the progression of AMD and vision loss for people at high risk for developing advanced AMD.

## Orbital and Ocular Trauma

Whether affecting the eye or the orbit, trauma to the eye and surrounding structures may have devastating consequences for vision. It is preferable to prevent injury rather than treat it. Chart 58-8 details safety measures to prevent orbital and ocular trauma.

### ORBITAL TRAUMA

Injury to the orbit is usually associated with a head injury; hence, the patient's general medical condition must first be stabilized before conducting an ocular examination. Only then is the globe assessed for soft tissue injury. During inspection, the face is meticulously assessed for underlying fractures, which should always be suspected in cases of blunt trauma. To establish the extent of ocular injury, visual acuity is assessed as soon as possible, even if it is only a rough estimate. Soft tissue orbital injuries often result in damage to the optic nerve. Major ocular injuries indicated by a soft globe, prolapsing tissue, ruptured globe, hemorrhage, and loss of red reflex require immediate surgical attention.

### Soft Tissue Injury and Hemorrhage

The signs and symptoms of soft tissue injury from blunt or penetrating trauma include tenderness, ecchymosis, lid swelling, **proptosis** (ie, downward displacement of the eyeball), and hemorrhage. Closed injuries lead to contusions with subconjunctival hemorrhage, commonly known as a *black eye*. Blood accumulates in the tissues of the conjunctiva. Hemorrhage may be caused by a soft tissue injury to the eyelid or by an underlying fracture.

Management of soft tissue hemorrhage that does not threaten vision is usually conservative and consists of thorough inspection, cleansing, and repair of wounds. Cold compresses are used in the early phase, followed by warm compresses. Hematomas that appear as swollen, fluctuating areas may be surgically drained or aspirated; if they are causing significant orbital pressure, they may be surgically evacuated.

Penetrating injuries or severe blow to the head can result in severe optic nerve damage. Visual loss can be sudden or delayed and progressive. Immediate loss of vision after an ocular injury is usually irreversible. Delayed visual loss has a better prognosis. Corticosteroid therapy is indicated to reduce optic nerve swelling. Surgery, such as optic nerve decompression, may be performed.

### Orbital Fractures

Orbital fractures are detected by facial x-rays. Depending on the orbital structures involved, orbital fractures can be classified as blow-out, zygomatic or tripod, maxillary, midfacial, orbital apex, and orbital roof fractures. Blow-out fractures result from compression of soft tissue and sudden increase in orbital pressure when the force is transmitted to the orbital floor, the area of least resistance.

**FIGURE 58-16** Photodynamic therapy (PDT) for slowing progression of age-related macular degeneration. Light-sensitive verteporfin dye is injected into defective vessels. A special laser activates the dye, which releases singlet oxygen that is toxic to endothelial cells, shutting down the vessels without damaging the retina. With permission from Valenz, K. D. (2001). Laser surgery shines as ray of hope. *Helix* 18(3):12–13.

### Management

Most patients benefit from the use of bright lighting and magnification devices and from referral to a low-vision center. Some low-vision centers send representatives into the patient's home or place of employment to evaluate the living and working conditions and make recommendations to improve lighting, thereby improving vision and promoting safety. The home care nurse can make the same assessment and recommendations.

Amsler grids are given to patients to use in their home to monitor for a sudden onset or distortion of vision. These may provide the earliest sign that macular degeneration is getting worse. Patients should be encouraged to use these grids and to look at them, one eye at a time, several times each week with glasses on. If there is a change in the grid (eg, if the lines or squares appear distorted or faded), the patient should be instructed to notify the ophthalmologist immediately and to arrange to be seen promptly.

The Age-Related Eye Disease Study Group (2001), a multicenter clinical trial, has provided promising information about the prevention and treatment of AMD. The study was designed

## Chart 58-8

## Health Promotion • Preventing Eye Injuries

**In and Around the House**

- Make sure that all spray nozzles are directed away from you before you press down on the handle.
- Read instructions carefully before using cleaning fluids, detergents, ammonia, or harsh chemicals. Wash hands thoroughly after use.
- Use grease shields on frying pans to decrease spattering.
- Wear special goggles to shield your eyes from fumes and splashes when using powerful chemicals.
- Use opaque goggles to avoid burns from sunlamps.

**In the Workshop**

- Protect your eyes from flying fragments, fumes, dust particles, sparks, and splashed chemicals by wearing safety glasses.
- Read instructions thoroughly before using tools and chemicals, and follow precautions for their use.

**Around Children**

- Pay attention to age and maturity level of a child when selecting toys and games. Avoid projectile toys, such as darts and pellet guns.
- Supervise children when they are playing with toys or games that can be dangerous.
- Teach children the correct way to handle potentially dangerous items, such as scissors and pencils.

**In the Garden**

- Do not let anyone stand at the side of or in front of a moving lawn mower.
- Pick up rocks and stones before going over them with the lawn mower. These stones can be hurled out of the rotary

blades and rebound off curbs or walls, causing severe injury to the eye.

- Make sure that pesticide spray can nozzles are directed away from your face.
- Avoid low-hanging branches.

**Around the Car**

- Before opening the hood of the car, put out all smoking materials and matches. Use a flashlight, not a match or lighter, to look at the battery at night.
- Wear goggles when grinding metal or striking metal against metal while performing auto body repair.
- When using jumper cables to start the car, wear goggles; make sure the cars are not touching one another; make sure the jumper cable clamps never touch each other; never lean over the battery when attaching cables. Never attach a cable to the negative terminal of the dead battery.

**In Sports**

- Wear protective safety glasses, especially for sports such as racquetball, squash, tennis, baseball, and basketball.
- Wear protective caps, helmets, or face protectors when appropriate, especially for sports such as ice hockey.

**Around Fireworks**

- Wear eye glasses or safety goggles.
- Do not use explosive fireworks.
- Never allow children to ignite fireworks.
- Do not stand near others when lighting fireworks.
- Do not try to relight duds. Douse them in water.

The inferior rectus and inferior oblique muscles, with their fat and fascial attachments, or the nerve that courses along the inferior oblique muscle may become entrapped, and the globe may be displaced inward (ie, enophthalmos). Computed tomography (CT) can firmly identify the muscle and its auxiliary structures that are entrapped. These fractures are usually caused by blunt small objects, such as a fist, knee, elbow, or tennis or golf balls.

Orbital roof fractures are dangerous because of potential complications to the brain. Surgical management of these fractures requires a neurosurgeon and an ophthalmologist. The most common indications for surgical intervention are displacement of bone fragments disfiguring the normal facial contours, interference with normal binocular vision caused by extraocular muscle entrapment, interference with mastication in zygomatic fracture, and obstruction of the nasolacrimal duct. Surgery is usually non-emergent, and a period of 10 to 14 days gives the ophthalmologist time to assess ocular function, especially the extraocular muscles and the nasolacrimal duct. Emergency surgical repair is usually not performed unless the globe is displaced to the maxillary sinus. Operative repair is primarily directed at freeing the entrapped ocular structures and restoring the integrity of the orbital floor. Cosmetic surgery for deformities of the globe and enophthalmos may follow after 4 to 6 months, but successful repair is usually difficult.

**Foreign Bodies**

Foreign bodies that enter the orbit are usually tolerated, except for copper, iron, and vegetable materials such as those from plants or trees, which may cause purulent infection. X-rays and

CT scans are used to identify the foreign body. Careful history taking is important, especially if the foreign body has been in the orbit for a period of time and the incident forgotten. It is important to identify metallic foreign bodies because they prohibit the use of magnetic resonance imaging (MRI) as a diagnostic tool.

After the extent of the orbital damage is assessed, the decision is made between conservative treatment and surgical removal. In general, orbital foreign bodies are usually removed if they are superficial and anterior in location, have sharp edges that may affect adjacent orbital structures, or are composed of copper, iron, or vegetable material. The surgical intervention is directed at prevention of further ocular injury and maintaining the integrity of the affected areas. Cultures are usually obtained, and the patient is placed on prophylactic intravenous antibiotics that are later changed to oral antibiotics.

**OCULAR TRAUMA**

Ocular trauma is the leading cause of blindness among children and young adults, especially male trauma victims. The most common circumstances of ocular trauma are occupational injuries (eg, construction industry), sports (eg, baseball, basketball, racket sports, boxing), weapons (eg, air guns, BB guns), assault, motor vehicle crashes (eg, broken windshields), and war (eg, blast fragments).

For the nonophthalmic practitioner, initial intervention is performed in only two conditions: chemical burns, for which irrigation of the eye with normal saline solution or even plain tap water must occur immediately, and a foreign body, for which

absolutely no attempt is made to remove the foreign material, small or big, or apply pressure or patch to the injured eye. The eye must be protected using a metal shield, if available, or a stiff paper cup (Fig. 58-17). All traumatic eye injuries should be properly shielded.

### Assessment and Diagnostic Findings

A thorough history is obtained, particularly assessing the patient's ocular history, such as preinjury vision in the affected eye or past ocular surgery. Details related to the injury that help in the diagnosis and assessment of need for further tests include the nature of the ocular injury (ie, blunt or penetrating trauma), the type of activity causing the injury to determine the nature of the force striking the eye, and whether onset of vision loss was sudden, slow, or progressive. For chemical eye burns, the chemical agent must be identified and tested for pH if a sample is available. The corneal surface is examined for foreign bodies, wounds, and abrasions, after which the other external structures of the eye are examined. Pupillary size, shape, and light reaction of the pupil of the affected eye are compared with the other eye. Ocular motility, which is the ability of the eyes to move synchronously up, down, right, and left, is also assessed.

### Medical Management

#### SPLASH INJURIES

Splash injuries are irrigated with normal saline solution before further evaluation. In cases of ruptured globe, cycloplegic agents (ie, agents that paralyze the ciliary muscle) or topical antibiotics must be deferred because of potential toxicity to exposed intraocular tissues. Further manipulation of the eye must be avoided until the patient is under general anesthesia. Parenteral, broad-spectrum antibiotics are initiated. Tetanus antitoxin is administered, if indicated, as well as analgesics. (Tetanus prophylaxis is recommended for full-thickness ocular and skin wounds.) Any topical medication (eg, anesthetic, dyes) must be sterile.

#### FOREIGN BODIES AND CORNEAL ABRASIONS

After removal of a foreign body from the surface of the eye, an antibiotic ointment is applied, and the eye is patched. The eye is examined daily for evidence of infection until the wound is completely healed.

Contact lens wear is a common cause of corneal abrasion. The patient experiences severe pain and **photophobia** (ie, ocular pain on exposure to light). Corneal epithelial defects are treated with antibiotic ointment and a pressure patch to immobilize the eyelids. It is of utmost importance that topical anesthetic eye drops are not given to a patient for repeated use after corneal injury because their effects mask further damage, delay healing, and can

lead to permanent corneal scarring. Corticosteroids are avoided while the epithelial defect exists.

### Penetrating Injuries and Contusions of the Eyeball

Sharp penetrating injury or blunt contusion force can rupture the eyeball. When the eye wall, cornea, and sclera rupture, rapid decompression or herniation of the orbital contents into adjacent sinuses can occur. In general, blunt traumatic injuries (with an increased incidence of retinal detachment, intraocular tissue avulsion, and herniation) have a worse prognosis than penetrating injuries. Most penetrating injuries result in marked loss of vision with the following signs: hemorrhagic **chemosis** (ie, edema of the conjunctiva), conjunctival laceration, shallow anterior chamber with or without an eccentrically placed pupil, **hyphema** (ie, hemorrhage within the chamber), or vitreous hemorrhage.

Hyphema is caused by contusion forces that tear the vessels of the iris and damage the anterior chamber angle. Preventing rebleeding and prolonged increased IOP are the goals of treatment for hyphema. In severe cases in which patient compliance is questionable, the patient is hospitalized with moderate activity restriction. An eye shield is applied. Topical corticosteroids are prescribed to reduce inflammation. An antifibrinolytic agent, aminocaproic acid (Amicar), stabilizes clot formation at the site of hemorrhage. Aspirin is contraindicated.

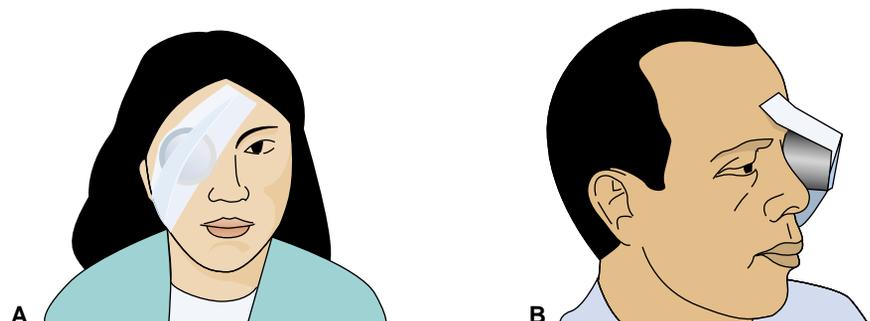

A ruptured globe and severe injuries with intraocular hemorrhage require surgical intervention. Vitrectomy is performed for traumatic retinal detachments. Primary **enucleation** (ie, complete removal of the eyeball and part of the optic nerve) is considered only if the globe is irreparable and has no light perception. It is a general rule that enucleation is performed within 2 weeks of the initial injury (in an eye that has no useful vision after sustaining penetrating injury) to prevent the risk of **sympathetic ophthalmia**, an inflammation created in the fellow eye by the affected eye that can result in blindness of the fellow eye.

#### Intraocular Foreign Bodies

A patient who complains of blurred vision and discomfort should be questioned carefully about recent injuries and exposures. Patients may be injured in a number of different situations and suffer an intraocular foreign body (IOFB). Precipitating circumstances can include working in construction, striking metal against metal, being involved in motor vehicle crashes with facial injury, gunshot wounds, and grinding-wheel work.

IOFB is diagnosed and localized by slit-lamp biomicroscopy and indirect ophthalmoscopy, as well as CT or ultrasonography. MRI is contraindicated because most foreign bodies are metallic

**FIGURE 58-17** Two kinds of eye patches. (A) Metal shield. (B) Stiff paper cup shield (innovative substitute when metal shield is unavailable). Adapted from MacCumber, M. W. (Ed.). (1997). *Management of ocular injuries and emergencies*. Philadelphia: Lippincott-Raven.

and magnetic. It is important to determine the composition, size, and location of the IOFB and affected eye structures. Every effort should be made to identify the type of IOFB and whether it is magnetic. Iron, steel, copper, and vegetable matter cause intense inflammatory reactions. The incidence of endophthalmitis is also high. If the cornea is perforated, tetanus prophylaxis and intravenous antibiotics are administered. The extraction route (ie, surgical incision) of the foreign body depends on its location and composition and associated ocular injuries. Specially designed IOFB forceps and magnets are used to grasp and remove the foreign body. Any damaged area of the retina is treated to prevent retinal detachment.

## OCULAR BURNS

Alkali, acid, and other chemically active organic substances, such as mace and tear gas, cause chemical burns. Alkali burns (eg, lye, ammonia) result in the most injury because they penetrate the ocular tissues rapidly and continue to cause damage long after the initial injury is sustained. They also cause an immediate rise in IOP. Acids (eg, bleach, car batteries, refrigerant) generally cause less damage because the precipitated necrotic tissue proteins form a barrier to further penetration and damage. Chemical burns may appear as superficial punctate keratopathy (ie, spotty damage to the cornea), subconjunctival hemorrhage, or complete marbling of the cornea.

In treating chemical burns, every minute counts. Immediate tap-water irrigation should be started on site before transport of the patient to an emergency department. Only a brief history and examination are performed. The corneal surfaces and conjunctival fornices are immediately and copiously irrigated with normal saline or any neutral solution. A local anesthetic is instilled, and a lid speculum is applied to overcome blepharospasm (ie, spasms of the eyelid muscles that result in closure of the lids). Particulate matter must be removed from the fornices using moistened, cotton-tip applicators and minimal pressure on the globe. Irrigation continues until the conjunctival pH normalizes (between 7.3 and 7.6). The pH of the corneal surface is checked by placing a pH paper strip in the fornix. Antibiotics are instilled, and the eye is patched.

The goal of intermediate treatment is to prevent tissue ulceration and promote re-epithelialization. Intense lubrication using nonpreserved (ie, without preservatives to avoid allergic reactions) tears is essential. Re-epithelialization is promoted with patching or therapeutic soft lenses. The patient is usually monitored daily for several days. Prognosis depends on the type of injury and adequacy of the irrigation immediately after exposure. Long-term treatment consists of two phases: restoration of the ocular surface through grafting procedures and surgical restoration of corneal integrity and optical clarity.

Thermal injury is caused by exposure to a hot object (eg, curling iron, tobacco, ash), whereas photochemical injury results from ultraviolet irradiation or infrared exposure (eg, exposure to the reflections from snow, sun gazing, viewing an eclipse of the sun without an adequate filter). These injuries can cause corneal epithelial defect, corneal opacity, conjunctival chemosis and **injection** (ie, congestion of blood vessels), and burns of the eyelids and periocular region. Antibiotics and a pressure patch for 24 hours constitute the treatment of mild injuries. Scarring of the eyelids may require oculoplastic surgery, whereas corneal scarring may require corneal surgery.

## Infectious and Inflammatory Conditions

Inflammation and infection of eye structures are common. Eye infection is a leading cause of blindness worldwide. Table 58-7 describes selected common infections and their treatment.

### DRY EYE SYNDROME

Dry eye syndrome, or keratoconjunctivitis sicca, is a deficiency in the production of any of the aqueous, mucin, or lipid tear film components; lid surface abnormalities; or epithelial abnormalities related to systemic diseases (eg, thyroid disorders, Parkinson's disease), infection, injury, or complications of medications (eg, antihistamines, oral contraceptives, phenothiazines).

### Clinical Manifestations

The most common complaint in dry eye syndrome is a scratchy or foreign body sensation. Other symptoms include itching, excessive mucus secretion, inability to produce tears, a burning sensation, redness, pain, and difficulty moving the lids.

### Assessment and Diagnostic Findings

Slit-lamp examination shows an absent or interrupted tear meniscus at the lower lid margin, and the conjunctiva is thickened, edematous, hyperemic, and has lost its luster. A tear meniscus is the crescent-shaped edge of the tear film in the lower lid margin. Chronic dry eyes may result in chronic conjunctival and corneal irritation that can lead to corneal erosion, scarring, ulceration, thinning, or perforation that can seriously threaten vision. Secondary bacterial infection can occur.

### Management

Management of dry eye syndrome requires the complete cooperation of the patient with a regimen that needs to be followed at home for a long period, or complete relief of symptoms is unlikely. Instillation of artificial tears during the day and an ointment at night is the usual regimen to hydrate and lubricate the eye through stimulating tears and preserving a moist ocular surface. Anti-inflammatory medications are also used, and moisture chambers (eg, moisture chamber spectacles, swim goggles) may provide additional relief.

Patients may become hypersensitive to chemical preservatives such as benzalkonium chloride and thimerosal. For these patients, preservative-free ophthalmic solutions are used. Management of the dry eye syndrome also includes the concurrent treatment of infections, such as chronic blepharitis and acne rosacea, and treating the underlying systemic disease, such as Sjögren's syndrome (an autoimmune disease).

In advanced cases of dry eye syndrome, surgical treatment that includes punctal occlusion, grafting procedures, and lateral tarsorrhaphy (ie, uniting the edges of the lids) are options. Punctal plugs are made of silicone material for the temporary or permanent occlusion of the puncta. This helps preserve the natural tears and prolongs the effects of artificial tears. Short-term occlusion is performed by inserting punctal or silicone rods in all four puncta. If tearing is induced, the upper plugs are removed, and the remaining lower plugs are removed in another week. Permanent occlusion is performed only in severe cases among adults who do not develop tearing after partial occlusion and who have results

Table 58-7 • Common Infections and Inflammatory Disorders of Eye Structures

DISORDER	DESCRIPTION	MANAGEMENT
<b>Hordeolum (sty)</b>	Acute suppurative infection of the glands of the eyelids caused by <i>Staphylococcus aureus</i> . The lid is red and edematous with a small collection of pus in the form of an abscess. There is considerable discomfort.	Warm compresses are applied directly to the affected lid area three to four times a day for 10 to 15 minutes. If the condition is not improved after 48 hours, incision and drainage may be indicated. Application of topical antibiotics may be prescribed thereafter.
<b>Chalazion</b>	Sterile inflammatory process involving chronic granulomatous inflammation of the meibomian glands; can appear as a single granuloma or multiple granulomas in the upper or lower eyelids.	Warm compresses applied three to four times a day for 10 to 15 minutes may resolve the inflammation in the early stages. Most often, however, surgical excision is indicated. Corticosteroid injection to the chalazion lesion may be used for smaller lesions.
<b>Blepharitis</b>	Chronic bilateral inflammation of the eyelid margins. There are two types: staphylococcal and seborrheic. Staphylococcal blepharitis is usually ulcerative and is more serious due to the involvement of the base of hair follicles. Permanent scarring can result.	The seborrheic type is chronic and is usually resistant to treatment, but the milder cases may respond to lid hygiene. Staphylococcal blepharitis requires topical antibiotic treatment. Instructions on lid hygiene (to keep the lid margins clean and free of exudates) are given to the patient.
<b>Bacterial keratitis</b>	Infection of the cornea by <i>S. aureus</i> , <i>Streptococcus pneumoniae</i> , and <i>Pseudomonas aeruginosa</i>	Fortified (high-concentration) antibiotic eyedrops are administered every 30 minutes around the clock for the first few days, then every 1–2 hours. Systemic antibiotics may be administered. Cycloplegics are administered to reduce pain caused by ciliary spasm. Corticosteroid therapy and subconjunctival injections of antibiotics are controversial.
<b>Herpes simplex keratitis</b>	Leading cause of corneal blindness in the United States. Symptoms are severe pain, tearing, and photophobia. The dendritic ulcer has a branching, linear pattern with feathery edges and terminal bulbs at its ends. Herpes simplex keratitis can lead to recurrent stromal keratitis and persist to 12 months with residual corneal scarring.	Many lesions heal without treatment and residual effects. The treatment goal is to minimize the damaging effect of the inflammatory response and eliminate viral replication within the cornea. Penetrating keratoplasty is indicated for corneal scarring and must be performed when the herpetic disease has been inactive for many months.

on a repeated Schirmer's test of 2 mm or less (filter paper is used to measure tear production).

## CONJUNCTIVITIS

Conjunctivitis (ie, inflammation of the conjunctiva) is the most common ocular disease worldwide. It is characterized by a pink appearance (hence the common term *pink eye*) because of subconjunctival blood vessel hemorrhages.

### Clinical Manifestations

General symptoms include foreign body sensation, scratching or burning sensation, itching, and photophobia. Conjunctivitis may be unilateral or bilateral, but the infection usually starts in one eye and then spreads to the other eye by hand contact.

### Assessment and Diagnostic Findings

The four main clinical features important to evaluate are the type of discharge (ie, watery, mucoid, purulent, or mucopurulent), type of conjunctival reaction (ie, follicular or papillary), presence of pseudomembranes or true membranes, and presence or ab-

sence of lymphadenopathy (ie, enlargement of the preauricular and submandibular lymph nodes where the eyelids drain). Pseudomembranes consist of coagulated exudate that adheres to the surface of the inflamed conjunctiva. True membranes form when the exudate adheres to the superficial layer of the conjunctiva, and removal results in bleeding. Follicles are multiple, slightly elevated lesions encircled by tiny blood vessels; they look like grains of rice. Papillae are hyperplastic conjunctival epithelium in numerous projections that are usually seen as a fine mosaic pattern under slit-lamp examination. Diagnosis is based on the distinctive characteristics of ocular signs, acute or chronic presentation, and identification of any precipitating events. Positive results of swab smear preparations and cultures confirm the diagnosis.

### Types of Conjunctivitis

Conjunctivitis is classified according to its cause. The major causes are microbial infection, allergy, and irritating toxic stimuli. A wide spectrum of exogenous microbes can cause conjunctivitis, including bacteria (eg, *Chlamydia*), viruses, fungus, and parasites. Conjunctivitis can also result from infection of an existing ocular infection or can be a manifestation of a systemic disease.

## MICROBIAL CONJUNCTIVITIS

Bacterial conjunctivitis can be acute or chronic. The acute type can develop into a chronic condition. Signs and symptoms can vary from mild to severe. Chronic bacterial conjunctivitis is usually seen in patients with lacrimal duct obstruction, chronic dacryocystitis, and chronic blepharitis. The most common causative microorganisms are *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Staphylococcus aureus*.

Bacterial conjunctivitis manifests with an acute onset of redness, burning, and discharge. There is papillary formation, conjunctival irritation, and injection in the fornices. The exudates are variable but are usually present on waking in the morning. The eyes may be difficult to open because of adhesions caused by the exudate. Purulent discharge occurs in severe acute bacterial infections, whereas mucopurulent discharge appears in mild cases. In gonococcal conjunctivitis, the symptoms are more acute. The exudate is profuse and purulent, and there is lymphadenopathy. Pseudomembranes may be present.

Viral conjunctivitis (Fig. 58-18) can also be acute and chronic. The discharge is watery, and follicles are prominent. Severe cases include pseudomembranes. The common causative organisms are adenovirus and herpes simplex virus. Conjunctivitis caused by adenovirus is highly contagious. The symptoms include extreme tearing, redness, and foreign body sensation that can involve one or both eyes. The condition is usually preceded by symptoms of upper respiratory infection. Corneal involvement causes extreme photophobia. There is lid edema, ptosis, conjunctival **hyperemia** (ie, dilation of the conjunctival blood vessels), watery discharge, follicles, and papillae. These signs and symptoms vary from mild to severe and may last for 2 weeks. Viral conjunctivitis, although self-limited, tends to last longer than bacterial conjunctivitis.

Epidemic keratoconjunctivitis (EKC) is most often accompanied by preauricular lymphadenopathy and occasionally periorbital pain. There are marked follicular and papillary formations. EKC can lead to keratopathy. EKC is a highly contagious viral conjunctivitis that is easily transmitted from one person to another among household members, school children, and health care workers. The outbreak of epidemics is seasonal, especially during the summer when people frequent swimming pools.

Chlamydial conjunctivitis includes trachoma and inclusion conjunctivitis. Trachoma is an ancient disease and is the leading cause of preventable blindness in the world. It is prevalent in areas with hot, dry, and dusty climates and in areas with poor living conditions. It is spread by direct contact or fomites, and the vectors can be insects such as flies and gnats.

**FIGURE 58-18** Conjunctival hyperemia in viral conjunctivitis.

**Trachoma** is a bilateral chronic follicular conjunctivitis of childhood that leads to blindness during adulthood, if left untreated. The onset in children is usually insidious, but it can be acute or subacute in adults. The initial symptoms include red inflamed eyes, tearing, photophobia, ocular pain, purulent exudates, preauricular lymphadenopathy, and lid edema. Initial ocular signs include follicular and papillary formations. At the middle stage of the disease, there is an acute inflammation with papillary hypertrophy and follicular necrosis, after which trichiasis (turning inward of hair follicles) and entropion begin to develop. The lashes that are turned in rub against the cornea and, after prolonged irritation, cause corneal erosion and ulceration. The late stage of the disease is characterized by scarred conjunctiva, subepithelial keratitis, abnormal vascularization of the cornea (pannus), and residual scars from the follicles that look like depressions in the conjunctiva (ie, Herbert's pits). Severe corneal ulceration can lead to perforation and blindness.

Inclusion conjunctivitis affects sexually active young people who have genital chlamydial infection. Transmission is by oral-genital sex or hand-to-eye transmission. It has been reported that indirect transmission has been acquired from inadequately chlorinated swimming pools. The eye lesions usually appear a week after exposure and may be associated with a nonspecific urethritis or cervicitis. The discharge is mucopurulent, follicles are present, and there is lymphadenopathy.

## ALLERGIC CONJUNCTIVITIS

Immunologic or allergic conjunctivitis is a hypersensitivity reaction as a part of allergic rhinitis (hay fever), or it can be an independent allergic reaction. The patient usually has a history of an allergy to pollens and other environmental allergens. There is extreme itching, epiphora (ie, excessive secretion of tears), injection, and usually severe photophobia. The stringlike mucoid discharge is usually associated with rubbing the eyes because of severe itching. Vernal conjunctivitis is also known as seasonal conjunctivitis because it appears mostly during warm weather. There may be large formations of papillae that have a cobblestone appearance. It is more common in children and young adults. Most affected individuals have a history of asthma or eczema.

## TOXIC CONJUNCTIVITIS

Chemical conjunctivitis can be the result of medications, chlorine from swimming pools (more common during the summer), exposure to toxic fumes among industrial workers, or exposure to other irritants such as smoke, hair sprays, acids, and alkalis.

## Management

The management of conjunctivitis depends on the type. Most types of mild and viral conjunctivitis are self-limiting, benign conditions that may not require treatment and laboratory procedures. For more severe cases, topical antibiotics, eye drops, or ointment are prescribed.

Patients with gonococcal conjunctivitis require urgent antibiotic therapy. If left untreated, this ocular disease can lead to corneal perforation and blindness. The systemic complications can include meningitis and generalized septicemia.

Acute bacterial conjunctivitis is almost always self-limiting. If left untreated, the disease follows a 2-week course with resolution of symptoms. If treated with appropriate antibiotics, it may last for a few days, with the exception of gonococcal and staphylococcal conjunctivitis. Viral conjunctivitis is not responsive to any treatment. Cold compresses may alleviate some symptoms. It is

extremely important to remember that viral conjunctivitis, especially EKC, is highly transmissible. Patients must be made aware of the contagious nature of the disease, and adequate instructions must be given. These instructions should include an emphasis on handwashing and avoiding sharing hand towels, face cloths, and eye drops. Tissues should be directly discarded into a trashcan.

Proper steps must be taken to avoid nosocomial infections. Frequent hand hygiene, procedures for environmental cleaning, and disinfection of equipment used for eye examination must be strictly followed at all times (Chart 58-9). During outbreaks of conjunctivitis caused by adenovirus, it is necessary that health care facilities assign specified areas for treating patients with or suspected of having conjunctivitis caused by adenovirus to prevent spread. All forms of tonometry must be avoided unless medically indicated. All multidose medications must be discarded at the end of each day or when contaminated. Infected employees and others must not be allowed to work or attend school until symptoms have resolved, which can take 3 to 7 days.

Patients with allergic conjunctivitis, especially recurrent vernal or seasonal conjunctivitis, are usually given corticosteroids in ophthalmic preparations. Depending on the severity of the disease, they may be given oral preparations. Use of vasoconstrictors, such as topical epinephrine solution, cold compresses, ice packs, and cool ventilation usually provide comfort by decreasing swelling.

### Chart 58-9 • PATIENT EDUCATION Instructions for Patients With Viral Conjunctivitis

Viral conjunctivitis is a highly contagious eye infection. It can easily spread from one person to another. The symptoms can be alarming, but they are not serious. The following information will help you understand this eye condition and how to take care of yourself and/or your family member at home.

- Your eyes will look red and will have watery discharge, and your lids will be swollen for about a week.
- You will experience eye pain, a sandy sensation in your eye, and sensitivity to light.
- Symptoms will resolve after about 1 week.
- You may use light cold compresses over your eyes for about 10 minutes four to five times a day to soothe the pain.
- You may use artificial tears for the sandy sensation in your eye and mild pain medications such as acetaminophen (Tylenol).
- You need to stay at home. Children must not play outside. You may return to work or school after 7 days when the redness and discharge have cleared. You may obtain a doctor's note to return to work or school.
- Do not share towels, linens, makeup, or toys.
- Wash your hands thoroughly with soap and water frequently, including and before and after you apply artificial tears or cold compresses.
- Use a new tissue every time you wipe the discharge from your eye. You may dampen the tissue with clean water to clean the outside of the eye.
- You may wash your face and take a shower as you normally do.
- Discard all of your makeup articles. You must not apply makeup until the disease is over.
- You may wear dark glasses if bright lights bother you.
- If the discharge from your eye turns yellowish and puslike or you experience changes in your vision, you need to return to the health care provider for an examination.

For trachoma, treatment is usually broad-spectrum antibiotics administered topically and systemically. Surgical management includes the correction of trichiasis to prevent conjunctival scarring. Adult inclusion conjunctivitis requires a 1-week course of antibiotics. Prevention of reinfection is important, and affected individuals and their sexual partners must be advised to seek assessment and treatment for sexually transmitted disease, if indicated.

For conjunctivitis caused by chemical irritants, the eye must be irrigated immediately and profusely with saline or sterile water.

## UVEITIS

Inflammation of the uveal tract is called uveitis and can affect the iris, the ciliary body, or the choroid. There are two types of uveitis: nongranulomatous and granulomatous.

The most common type of uveitis is the nongranulomatous type, which manifests as an acute condition with pain, photophobia, and a pattern of conjunctival injection, especially around the cornea. The pupil is small or irregular, and vision is blurred. There may be small, fine precipitates on the posterior corneal surface and cells in the aqueous humor (ie, cell and flare). If severe, a **hypopyon** (ie, accumulation of pus in the anterior chamber) may occur. The condition may be unilateral or bilateral and may be recurrent. Repeated attacks of nongranulomatous anterior uveitis can cause anterior synechia (ie, peripheral iris adheres to the cornea and impedes outflow of aqueous humor). The development of posterior synechia (ie, adherence of the iris and lens) blocks aqueous outflow from the posterior chamber. Secondary glaucoma can result from either anterior or posterior synechia. Cataracts may also occur as a sequela to uveitis.

Granulomatous uveitis can have a more insidious onset and can involve any portion of the uveal tract. It tends to be chronic. Symptoms such as photophobia and pain may be minimal. The keratic precipitate may be large and grayish. Vision is markedly and adversely affected. Conjunctival injection is diffuse, and there may be vitreous clouding. In a severe posterior uveitis, such as chorioretinitis, there may be retinal and choroidal hemorrhages.

## Management

Because photophobia is a common complaint, patients should wear dark glasses outdoors. Ciliary spasm and synechia are best avoided through mydriasis; cyclopentolate (Cyclogyl) and atropine are commonly used. Local corticosteroid drops, such as Pred Forte 1% and Flarex 0.1%, instilled four to six times a day are also used to decrease inflammation. In very severe cases, systemic corticosteroids, as well as intravitreal corticosteroids, may be used.

If the uveitis is recurrent, a medical workup should be initiated to discover any underlying causes. This evaluation should include a physical examination, complete systems review, and diagnostic tests, including a complete blood cell count, erythrocyte sedimentation rate, antinuclear antibodies (ANA), VDRL, and Lyme disease titer. Underlying causes include toxoplasmosis, herpes zoster virus, ocular candidiasis, histoplasmosis, herpes simplex virus, tuberculosis, and syphilis.

## ORBITAL CELLULITIS

Orbital cellulitis is inflammation of the tissues surrounding the eye and may result from bacterial, fungal, or viral inflammatory conditions of contiguous structures, such as the face, oropharynx, dental structures, or intracranial structures. It can also result from

foreign bodies and from a preexisting ocular infection, such as dacryocystitis and panophthalmitis, or from generalized septicemia. Infection of the sinuses is the most frequent cause. Infection originating in the sinuses can spread easily to the orbit through the thin bony walls and foramina or by means of the interconnecting venous system of the orbit and sinuses. The most common causative organisms are staphylococci and streptococci in adults and *H. influenzae* in children.

The severe intraorbital tension caused by abscess formation and the impairment of optic nerve function in orbital cellulitis can result in permanent visual loss. Because of the orbit's proximity to the brain, orbital cellulitis can lead to life-threatening complications, such as intracranial abscess and cavernous sinus thrombosis.

## Management

Immediate administration of high-dose, broad-spectrum, systemic antibiotics is indicated. Cultures and Gram-stained smears are obtained. Monitoring changes in visual acuity, degree of proptosis, central nervous system function (eg, nausea, vomiting, fever, level of consciousness), displacement of the globe, extraocular movements, pupillary signs, and the fundus is extremely important. Consultation with an otolaryngologist is necessary, especially when sinusitis is suspected. In the event of abscess formation or progressive loss of vision, surgical drainage of the abscess or sinus is performed. Sinusotomy and antibiotic irrigation are also performed.

## Orbital and Ocular Tumors

### BENIGN TUMORS OF THE ORBIT

Benign tumors can develop from infancy and grow rapidly or slowly and present themselves in later life. Some benign tumors are superficial and are easily identifiable by external presentation, palpation, and x-rays, but some are deep and may require a CT scan for a more thorough and precise diagnosis. There can be a significant proptosis, and visual function may be jeopardized. Benign tumors are masses characterized by the lack of infiltration in the surrounding tissues. Examples are cystic dermoid cysts and mucocele, hemangiomas, lymphangiomas, lacrimal tumors, and neurofibromas.

## Management

To prevent recurrence, benign masses are excised completely when possible. Sometimes, excision is difficult because of the involvement of some portions of the orbital bones, such as deep dermoid cysts, in which dissection of the bone is required. Subtotal resection may be indicated in deep benign tumors that intertwine with other orbital structures, such as optic nerve meningiomas. Complete removal of the tumor may endanger visual function.

### BENIGN TUMORS OF THE EYELIDS

Benign tumors include a wide variety of neoplasms and increase in frequency with age. Nevi may be unpigmented at birth and may enlarge and darken in adolescence or may never acquire any pigment at all. Hemangiomas are vascular capillary tumors that may be bright, superficial, strawberry-red lesions (ie, strawberry nevus) or bluish and purplish deeper lesions. Milia are small,

white, slightly elevated cysts of the eyelid that, when in multiples, create a blemish. Xanthelasma are yellowish, lipid deposits on both lids near the inner angle of the eye that commonly appear as a result of the aging of the skin or a lipid disorder. Molluscum contagiosum lesions are flat, symmetric growths along the lid margin caused by a virus that can result in conjunctivitis and keratitis after debris gets into the conjunctival sac.

## Management

Treatment of benign congenital lid lesions is rarely indicated, except when visual function is affected. Corticosteroid injection to the hemangioma lesion is usually effective, but surgical excision may be performed. Benign lid lesions usually present aesthetic problems rather than visual function problems. Surgical excision, or electrocautery, is primarily performed for cosmetic reasons, except for cases of molluscum contagiosum, for which surgical intervention is performed to prevent an infectious process that may ensue.

### BENIGN TUMORS OF THE CONJUNCTIVA

Conjunctival nevus, a congenital, benign neoplasm, is a flat, slightly elevated, brown spot that becomes pigmented during late childhood or adolescence. This should be differentiated from the pigmented lesion melanosis acquired at middle age, which tends to wax and wane and become malignant melanoma. Keratin- and sebum-containing dermoid cysts are congenital and can be found in the conjunctiva. Dermolipoma is a congenital tumor that manifests as a smooth, rounded growth in the conjunctiva near the lateral canthus. Papillomas are usually soft with irregular surfaces and appear on the lid margins. Treatment consists of surgical excision.

### MALIGNANT TUMORS OF THE ORBIT

Rhabdomyosarcoma is the most common malignant primary orbital tumor in childhood, but it can also develop in elderly persons. The symptoms of rhabdomyosarcoma include sudden painless proptosis of one eye followed by lid swelling, conjunctival chemosis, and impairment of ocular motility. Imaging of these tumors establishes the size, configuration, location, and stage of the disease; delineates the degree of bone destruction; and is useful in estimating the field for radiation therapy, if needed. The most common site of metastasis is the lung.

## Management

Management of these primary malignant orbital tumors involves three major therapeutic modalities: surgery, radiation therapy, and adjuvant chemotherapy. The degree of orbital destruction is important in planning the surgical approach. In the orbit, resection often involves removal of the globe. The psychological needs of the patient and family, especially the parents of a pediatric patient, are paramount in planning the management approach.

### MALIGNANT TUMORS OF THE EYELID

Basal cell carcinoma is the most common malignant tumor of the eyelid. Squamous cell carcinoma occurs less frequently but is considered the second most common malignant tumor. Malignant melanoma is rare. Malignant eyelid tumors occur more fre-

quently among people with fair complexion who have a history of chronic exposure to the sun.

Basal cell carcinoma appears as a painless nodule that may ulcerate. The lesion is invasive, spreads to the surrounding tissues, and grows slowly but does not metastasize. It usually appears on the lower lid margin near the inner canthus with a pearly white margin. Squamous cell carcinoma of the eyelids may resemble basal cell carcinoma initially because it also grows slowly and painlessly. It tends to ulcerate and invade the surrounding tissues, but it can metastasize to the regional lymph nodes. Malignant melanoma may not be pigmented and can arise from nevi. It spreads to the surrounding tissues and metastasizes to other organs.

### Management

Complete excision of these carcinomas is followed by reconstruction with skin grafting if the surgical excision is extensive. The ocular postoperative site and the graft donor site are monitored for bleeding. Donor graft sites may include the buccal mucosa, the thigh, or the abdomen. The patient is referred to an oncologist for evaluation for the need for radiation therapy treatment and monitoring for metastasis. Early diagnosis and surgical management are the basis of a good prognosis. These conditions have life-threatening consequences, and surgical excisions may result in facial disfigurement. Emotional support and reassurance are important aspects of nursing management.

## MALIGNANT TUMORS OF THE CONJUNCTIVA

Conjunctival carcinoma most often grows in the exposed areas of the conjunctiva. The typical lesions are usually gelatinous and whitish due to keratin formation. They grow gradually, and deep invasion and metastasis are rare. Malignant melanoma is rare but may arise from a preexisting nevus or acquired melanosis during middle age. Squamous cell carcinoma is also rare but invasive.

### Management

The management is surgical incision. Some benign tumors and most malignant tumors recur. To avoid recurrences, patients usually undergo radiation therapy and cryotherapy after the excision of malignant tumors. Cosmetic disfigurement may result from extensive excision when deep invasion by the malignant tumor is involved.

## MALIGNANT TUMOR OF THE GLOBE: OCULAR MELANOMA

A malignant tumor of the retina, retinoblastoma, occurs in childhood, is hereditary, and requires complete enucleation if there is to be a chance for successful outcome. Another cancer that primarily occurs in adults is ocular melanoma. This rare, malignant choroidal tumor is often discovered on a retinal examination. In its early stages, it could be mistaken for a nevus. Many ophthalmologists may practice for decades and never encounter this lesion. For this reason, any patient who is suspected of having ocular melanoma should be immediately referred to an ocular oncologist with experience in this disease.

Although many patients do not have symptoms in the early stages, some patients complain of blurred vision or a change in eye color. A number of such tumors have been found in people with blindness who have painful eyes. In addition to a complete physical examination to discover any evidence of metastasis (to the liver, lung, and breast), retinal fundus photography, fluorescein angiography, and ultrasonography are performed. The diagnosis is confirmed at biopsy after enucleation.

### Management

Tumors are classified according to size (ie, small, medium, and large). Very small tumors are generally monitored, whereas medium and large tumors require treatment. Treatment consists of radiation, enucleation, or both. Radiation therapy is achieved by external beam performed in repeated doses over several days or

### GENETICS IN NURSING PRACTICE—Genes and the Eye

The mapping of the human genome enhances the opportunity to understand the genetic component of ophthalmic disorders and to develop new methods of prevention and treatment. Apparently more than one gene is involved in any particular condition, making genetic counseling an important part of the care and prevention of inherited diseases. Ocular effects of some genetic conditions follow.

#### MARFAN'S SYNDROME

Ophthalmic consequences may include amblyopia and dislocation of the lens. Patients are often myopic and may be at increased risk for retinal detachment.

#### LEBER'S CONGENITAL AMAUROSIS

To date, four genes are implicated in this disorder, which is characterized by decreased vision and onset in childhood, generally before 7 years of age. It accounts for 10% to 18% of congenital

blindness (some infants may be blind from birth). Other signs and symptoms include strabismus, nystagmus, photophobia, cataracts, and keratoconus.

#### RETINOBLASTOMA

A malignant retinal tumor occurring in 1 of every 15,000 live births, it is hereditary in 30% to 40% of cases. All bilateral cases are hereditary. The retinoblastoma gene is found on chromosome 13, region q14. If this gene is inhibited, the growth in retinal cells is unchecked and the retinoblastoma results. Signs and symptoms include an initial leukocoria or "white" pupil with a peculiar light reflection and possibly strabismus as well. Less frequent signs are uveitis, glaucoma, hyphema, nystagmus, and periorbital cellulitis. Treatment for this life-threatening tumor is enucleation, if the tumor is large and unilateral. If the eye is removed before cancer spreads to the optic nerve, the cure rate is greater than 90%.

through the surgical implantation of a radioactive plaque, which is removed after several days.

## Surgical Procedures and Enucleation

### ORBITAL SURGERIES

Orbital surgeries may be performed to repair fractures, remove a foreign body, or remove benign or malignant growths. Surgical procedures involving the orbit and lids affect facial appearance (ie, cosmesis). The goals are to recover and preserve visual function and to maintain the anatomic relationship of the ocular structures to achieve cosmesis. During the repair of orbital fractures, the orbital bones are realigned to follow the anatomic positions of facial structures.

Orbital surgical procedures involve working around delicate structures of the eye, such as the optic nerve, retinal blood vessels, and ocular muscles. Complications of orbital surgical procedures may include blindness as a result of damage to the optic nerve and its blood supply. Sudden pain and loss of vision may indicate intraorbital hemorrhage or compression of the optic nerve. Ptosis and diplopia may result from trauma to the extraocular muscles during the surgical procedure, but these conditions typically resolve after a few weeks.

### Postoperative Management

Prophylaxis with intravenous antibiotics is the usual postoperative regimen after orbital surgery, especially with repair of orbital fractures and intraorbital foreign body removal. Intravenous corticosteroids are used if there is a concern about optic nerve swelling. Topical ocular antibiotics are typically instilled, and antibiotic ointments are applied externally to the skin suture sites.

For the first 24 to 48 hours postoperatively, ice compresses are applied over the periocular area to decrease periorbital swelling, facial swelling, and hematoma. The head of the patient's bed should be elevated to a comfortable position (30 to 45 degrees).

Discharge teaching should include medication instructions for oral antibiotics, instillation of ophthalmic medications, and application of ocular compresses.

### ENUCLEATION

Enucleation is the removal of the entire eye and part of the optic nerve. It may be performed for the following conditions:

- Severe injury resulting in prolapse of uveal tissue or loss of light projection or perception
- An irritated, blind, painful, deformed, or disfigured eye, usually caused by glaucoma, retinal detachment, or chronic inflammation
- An eye without useful vision that is producing or has produced sympathetic ophthalmia in the other eye
- Intraocular tumors that are untreatable by other means

The procedure for enucleation involves the separation and cutting of each of the ocular muscles, dissection of the Tenon's capsule (ie, fibrous membrane covering the sclera), and the cutting of the optic nerve from the eyeball. The insertion of an orbital implant typically follows, and the conjunctiva is closed. A large pressure dressing is applied over the area.

**Evisceration** involves the surgical removal of the intraocular contents through an incision or opening in the cornea or sclera. The optic nerve, sclera, extraocular muscles, and sometimes, the

cornea are left intact. The main advantage of evisceration over enucleation is that the final cosmetic result and motility after fitting the ocular prosthesis are enhanced. This procedure would be more acceptable to a patient whose concept of the alteration of body image is severely threatened. The main disadvantage is the high risk of sympathetic ophthalmia.

**Exenteration** is the removal of the eyelids, the eye, and various amounts of orbital contents. It is indicated in malignancies in the orbit that are life threatening or when more conservative modalities of treatment have failed or are inappropriate. An example is squamous cell carcinoma of the paranasal sinuses, skin, and conjunctiva with deep orbital involvement. In its most extensive form, exenteration may include the removal of all orbital tissues and resection of the orbital bones.

### Ocular Prostheses

Orbital implants and conformers (ie, ocular prostheses usually made of silicone rubber) maintain the shape of the eye after enucleation or evisceration to prevent a contracted sunken appearance. The temporary conformer is placed over the conjunctival closure after the implantation of an orbital implant. A conformer is placed after the enucleation or evisceration procedure to protect the suture line, maintain the fornices, prevent contracture of the socket in preparation for the ocular prosthesis, and promote the integrity of the eyelids.

All ocular prosthetics have limitations in their motility. There are two designs of eye prostheses. The anophthalmic ocular prostheses are used in the absence of the globe. Scleral shells look just like the anophthalmic prosthesis (Fig. 58-19) but are thinner and fit over a globe with intact corneal sensation. An eye prosthesis usually lasts about 6 years, depending on the quality of fit, comfort, and cosmetic appearance. When the anophthalmic socket is completely healed, conformers are replaced with prosthetic eyes.

An ocularist is a specially trained and skilled professional who makes prosthetic eyes. After the ophthalmologist is satisfied that the anophthalmic socket is completely healed and is ready for prosthetic fitting, the patient is referred to an ocularist. The healing period is usually 6 to 8 weeks. It is advisable for the patient to have a consultation with the ocularist before the fitting. Obtaining accurate information and verbalizing concerns can lessen anxiety about wearing an ocular prosthesis.

### Medical Management

Removal of an eye has physical, social, and psychological ramifications for any person. The significance of loss of the eye and vision must be addressed in the plan of care. The patient's preparation should include information about the surgical procedure and placement of orbital implants and conformers and the availability of ocular prosthetics to enhance cosmetic appearance. In some cases, patients may choose to see an ocularist before the surgery to discuss ocular prosthetics.

### Nursing Management

#### TEACHING ABOUT POSTSURGICAL AND PROSTHETIC CARE

Patients who undergo eye removal need to know that they will usually have a large ocular pressure dressing, which is typically removed after a week, and that an ophthalmic topical antibiotic ointment is applied in the socket three times daily.

**FIGURE 58-19** Eye prostheses. (Left) Anophthalmic ocular prosthesis. (Right) Scleral shell.

After the removal of an eye, there is a loss of depth perception. Patients must be advised to take extra caution in their ambulation and movement to avoid miscalculations that may result in injury. It may take some time to adjust to monocular vision.

The patient must be advised that conformers may accidentally fall out of the socket. If this happens, the conformer must be washed, wiped dry, and placed back in the socket. When surgical eye removal is unexpected, such as in severe ocular trauma, leaving no time for the patient and family to prepare for the loss, the nurse's role in providing reassurance and emotional support is crucial.

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** Patients need to be taught how to insert, remove, and care for the prosthetic eye. Proper hand washing must be observed before inserting and removing an ocular prosthesis. A suction cup may be used if there are problems with manual dexterity. Precautions, such as draping a towel over the sink and closing the sink drain, must be taken to avoid loss of the prosthesis. When instructing patients or family members, a return demonstration is important to assess the level of understanding and ability to perform the procedure.

Before insertion, the inner punctal or outer lateral aspects and the superior and inferior aspects of the prosthesis must be identified by locating the identifying marks, such as a reddish color in the inner punctal area. For people with low vision, other forms of identifying markers, such as dots or notches, are used. The upper lid is raised high enough to create a space; then the patient learns to slide the prosthesis up, underneath, and behind the upper eyelid. Meanwhile, the patient pulls the lower eyelid down to help put the prosthesis in place and to have its inferior edge fall back gradually to the lower eyelid. The lower eyelid is checked for correct positioning.

To remove the prosthesis, the patient cups one hand on the cheek to catch the prosthesis, places the forefinger of the free hand against the midportion of the lower eyelid, and gazes upward. Gazing upward brings the inferior edge of the prosthesis nearer the inferior eyelid margin. With the finger pushing inward, downward, and laterally against the lower eyelid, the prosthesis slides out, and the cupped hand acts as the receptacle.

**Continuing Care.** An eye prosthesis can be worn and left in place for several months. Hygiene and comfort are usually maintained with daily irrigation of the prosthesis in place with the use of a

balanced salt solution, hard contact lens solution, or artificial tears. In the case of dry eye symptoms, the use of ophthalmic ointment lubricants or oil-based drops, such as vitamin E and mineral oil, can be helpful. Removing crusting and mucous discharge that accumulates overnight is performed with the prosthesis in place. Malpositions may occur when wiping or rubbing the prosthesis in the socket. The prosthesis can be turned back in place with the use of clean fingers. Proper wiping of the prosthesis should be a gentle temporal-to-nasal motion to avoid malpositions.

The prosthesis needs to be removed and cleaned when it becomes uncomfortable and when there is increased mucous discharge. The socket should also be rendered free of mucus and inspected for any signs of infection. Any unusual discomfort, irritation, or redness of the globe or eyelids may indicate excessive wear, debris under the shell, or lack of proper hygiene. Any infection or irritation that does not subside needs medical attention.

## Ocular Consequences of Systemic Disease

### DIABETIC RETINOPATHY

Of all of the medical disorders that the nurse encounters, diabetes mellitus is one of the most common and one that can have devastating effects on the patient. Diabetes affects every system of the body in a deleterious way and consequently affects the patient's family and society in general. Diabetes is the leading cause of new cases of blindness in people between 20 and 74 years of age in the United States today. Before the discovery of insulin in the 1920s, diabetic retinopathy was relatively rare. Most people with diabetes did not survive for more than 1 or 2 years; however, with the use of insulin, more and more patients are able to survive and enjoy relatively normal life spans. They are also confronted with the complications of long-term diabetes. One of the most serious complications is retinopathy. Chapter 41 provides a detailed discussion of diabetic retinopathy (Aiello et al., 2001).

### CYTOMEGALOVIRUS RETINITIS

Many ophthalmic complications are associated with AIDS. On autopsy, up to 90% of patients have ocular lesions directly related to AIDS. Cytomegalovirus (CMV) is the most common cause of retinal inflammation in patients with AIDS. About 40% of patients who have CMV retinitis lose their central vision in both eyes by the time of death.

Early symptoms of CMV retinitis vary from patient to patient. Some patients complain of floaters or a decrease in peripheral vision. Some patients have a paracentral or central scotoma, whereas others have a fluctuation in vision from macular edema. The retina often becomes thin and atrophic and susceptible to retinal tears and breaks.

CMV retinitis generally takes one of three forms: hemorrhagic, brushfire, or granular. In the hemorrhagic type, large areas of white, necrotic retina may be associated retinal hemorrhage. The brushfire form appears to have a yellow-white margin, which begins at the edge of burned-out atrophic retina. This retinitis expands and, if untreated, involves the entire retina. The granular form of CMV retinitis consists of white, granular lesions in the periphery of the retina that gradually expand. The white, feathery infiltration of the retina destroys sensory retina and leads to necrosis, optic atrophy, and retinal detachment.

## Medical Management

### PHARMACOLOGIC THERAPY

Pharmacologic agents available for treatment of CMV retinitis include ganciclovir (Cytovene), foscarnet (Foscavir), and cidofovir (Vistide).

Ganciclovir is administered intravenously, orally, or intravitreously in the acute stage of CMV retinitis. A surgically implanted intraocular device has provided a new mode of effective ganciclovir administration. This enables a higher, more effective dose of medication to be administered and is well tolerated by patients. This constant intraocular concentration of ganciclovir lasts for about 6 to 10 months before the inserts must be replaced. Once begun, ganciclovir must be given continuously. A study that combined the use of the intravitreal implant with oral ganciclovir demonstrated a reduction in the risk of new CMV disease as well as a delay in the progression of the retinitis (Martin et al., 1999). This very potent medication, when administered systemically, can cause neutropenia, thrombocytopenia, anemia, and elevated serum creatinine levels. Although the surgically implanted sustained release device enables higher concentrations of ganciclovir to reach the CMV retinitis, there are risks and complications associated with the devices, including endophthalmitis, retinal detachment, and hypotony.

Foscarnet inhibits viral DNA replication. It may be the medication of choice when ganciclovir is ineffective. It may be administered intravenously or locally by intravitreal injections. The combination of foscarnet and ganciclovir has been more effective than either medication alone. Nephrotoxicity may occur with systemic foscarnet, and renal function must be monitored carefully.

Cidofovir impedes CMV replication. This medication is administered intravenously. Cidofovir has been shown to delay the progression of CMV retinitis significantly. Nephrotoxicity, proteinuria, and increased serum creatinine levels are significant side effects of its administration.

### HYPERTENSION-RELATED EYE CHANGES

Hypertension, known as the silent killer, can shorten the life span by as many as 20 years. End-organ damage affects the heart, brain, kidney, and eye. Hypertension may be manifested in one of two forms: chronic or acute. This differentiation is determined by the rapidity in rise of the blood pressure as well as the degree of elevation. The retinal changes observed with each form are different and have different consequences for the eye.

Chronic hypertension and atherosclerosis go hand in hand, and the associated retinal changes are evidenced by the development of retinal arteriolar changes, such as tortuosity, narrowing, and a change in light reflex. Funduscopic examination reveals a copper or silver coloration of the arterioles and venous compression (arteriovenous nicking) at the arteriolar and venous crossings. Intraretinal hemorrhages from hypertension appear flame shaped because they occur in the nerve fiber layer of the retina.

Acute hypertension can result from pheochromocytoma, acute renal failure, pregnancy-induced hypertension, and malignant essential hypertension. The retinopathy associated with these crisis states is extensive, and the manifestations include cotton-wool spots, retinal hemorrhages, retinal edema, and retinal exudates, often clustered around the macula.

The choroid is also affected by the profound and abrupt rise in blood pressure and resulting vasoconstriction, and ischemia may result in serous retinal detachments and infarction of the

retinal pigment epithelium (RPE). Ischemic optic neuropathy and **papilledema** (ie, swelling of the optic disc due to increased IOP) may also result.

## Concepts in Ocular Medication Administration

The main objective of ocular medication delivery is to maximize the amount of medication that reaches the ocular site of action in sufficient concentration to produce a beneficial therapeutic effect. This is determined by the dynamics of ocular pharmacokinetics: absorption, distribution, metabolism, and excretion.

Topical administration of ocular medications results in only a 1% to 7% absorption rate by the ocular tissues. Ocular absorption involves the entry of a medication into the aqueous humor through the different routes of ocular drug administration. The rate and extent of aqueous humor absorption are determined by the characteristics of the medication and the barriers imposed by the anatomy and physiology of the eye. The natural barriers of absorption that diminish the efficacy of ocular medications include the following:

- *Limited size of the conjunctival sac.* The conjunctival sac can hold only 50  $\mu\text{L}$ , and any excess is wasted. The volume of one eye drop from commercial topical ocular solutions typically ranges from 20 to 35  $\mu\text{L}$ .
- *Corneal membrane barriers.* The epithelial, stromal, and endothelial layers are barriers to absorption.
- *Blood–ocular barriers.* Blood–ocular barriers prevent high ocular tissue concentration of most ophthalmic medications because they separate the bloodstream from the ocular tissues and keep foreign substances from entering the eye, thereby limiting a medication's efficacy.
- *Tearing, blinking, and drainage.* Increased tear production and drainage due to ocular irritation or an ocular condition may dilute or wash out an instilled eye drop; blinking expels an instilled eye drop from the conjunctival sac.

Distribution of an ocular medication into the ocular tissues involves partitioning and compartmentalizing of the medication between the tissues of the conjunctiva, cornea, lens, iris, ciliary body, choroid, and vitreous. Medications penetrate the corneal epithelium by diffusion by passing through the cells (intracellular) or by passing between the cells (intercellular). Water-soluble (hydrophilic) medications diffuse through the intracellular route, and fat-soluble (lipophilic) medications diffuse through the intercellular route. Topical administration usually does not reach the retina in significant concentrations. Because the space between the ciliary process and the lens is small, medication diffusion in the vitreous is slow. When high therapeutic medication concentration in the vitreous is required, intraocular injection is often chosen to bypass the natural ocular anatomic and physiologic barriers.

Aqueous solutions are most commonly used for the eye. They are the least expensive medications and interfere least with vision. However, corneal contact time is brief because tears dilute the medication. Ophthalmic ointments have extended retention time in the conjunctival sac and a higher concentration than eye drops. The major disadvantage of ointments is the blurred vision that results after application. In general, eyelids and eyelid margins are best treated with ointments. The conjunctiva, limbus, cornea, and anterior chamber are treated most effectively with instilled solutions or suspensions. Subconjunctival injection may be necessary for better absorption in the anterior chamber. If high med-

ication concentrations are required in the posterior chamber, intravitreal injections or systemically absorbed medications are considered. Contact lenses and collagen shields soaked in antibiotics are alternative delivery methods for treating corneal infections. Of all these delivery methods, the topical route of administration—instilled eye drops and applied ointments—remain the most common. Topical instillation, which is the least invasive method, permits self-administration of medication. It also produces fewer side effects.

Preservatives are commonly used in ocular medications. Benzalkonium chloride, for example, prevents the growth of organisms and enhances the corneal permeability of most medications. Some patients are allergic to this preservative. This may be suspected even if the patient had never before experienced an allergic reaction to systemic use of the medication in question. Eye drops without preservatives can be prepared by pharmacists.

## COMMONLY USED OCULAR MEDICATIONS

Common ocular medications include topical anesthetic, mydriatic, and cycloplegic agents that reduce IOP; anti-infective medications, corticosteroids, NSAIDs, antiallergy medications, eye irrigants, and lubricants.

### Topical Anesthetics

One to two drops of proparacaine hydrochloride (Ophthaine 0.5%) and tetracaine hydrochloride (Pontocaine 0.5%) are instilled before diagnostic procedures such as tonometry and gonioscopy and in minor ocular procedures such as removal of sutures or conjunctival or corneal scrapings. The nurse must instruct patients not to rub their eyes while anesthetized because this may result in corneal damage. Patients must never be allowed to take topical anesthetics home. Prolonged use can delay wound healing and

can lead to permanent corneal opacification and scarring, resulting in visual loss. Topical anesthetic is also used for severe eye pain to allow the patient to open his or her eyes for examination or treatment (eg, eye irrigation for chemical burns). Anesthesia occurs within 20 seconds to 1 minute and lasts 10 to 20 minutes.

### Mydriatics and Cycloplegics

Mydriasis, or pupil dilation, is the main objective of the administration of mydriatic and cycloplegic agents (Table 58-8). These two medications function differently and are used in combination to achieve the maximal dilation that is needed during surgery and fundus examinations to give the ophthalmologist a better view of the internal eye structures. Mydriatics potentiate alpha-adrenergic sympathetic effects that result in the relaxation of the ciliary muscle. This causes the pupil to dilate. This sympathetic action alone, however, is not enough to sustain mydriasis because of its short duration of action. The strong light used during an eye examination also stimulates miosis (ie, pupillary contraction). Cycloplegic medications are administered to paralyze the iris sphincter.

Patients are instructed about the temporary effects of mydriasis on vision, such as glare and the inability to focus properly. Patients may not be able to read and should not drive. The effects of the various mydriatics and cycloplegics can last 3 hours to several days. Patients are advised to wear sunglasses (most eye clinics provide protective sunglasses) and to have a responsible adult drive them home.

Mydriatic and cycloplegic agents affect the central nervous system. Their effects are most prominent in children and elderly patients; these patients must be assessed closely for symptoms, such as rise in blood pressure, tachycardia, dizziness, ataxia, confusion, disorientation, incoherent speech, and hallucination. These medications are contraindicated in patients with narrow

Table 58-8 • Mydriatics and Cycloplegics

DRUG	AVAILABLE PREPARATION/ CONCENTRATION	INDICATION/DOSAGE	PEAK		RECOVERY TIME	
			Mydriasis	Cycloplegia	Mydriasis	Cycloplegia
Phenylephrine	Solutions (2.5%, 10%)	Administered with cycloplegics in pupillary dilation for ophthalmoscopy and surgical procedures every 5–10 min $\times$ 3 or until the pupils are fully dilated	10–60 min	—	3–6 h	—
Atropine	Ointment (0.5%–2%) Solutions (0.5%–3%)	In glaucoma, uveitis, or after surgery, 2 $\times$ to 4 $\times$ daily	30–40 min	60–180 min	7–10 d	6–12 d
Scopolamine	Solution (0.25%)	The same as atropine	20–30 min	30–60 min	3–7 d	3–7 d
Homatropine	Solution (5%–2.5%)	The same as atropine and scopolamine	40–60 min	30–60 min	1–3 d	1–3 d
Cyclopentolate	Solution (0.5%–2%)	Administered with mydriatics q 5–10 min $\times$ 3 or until the pupils are fully dilated for ophthalmoscopy and surgical procedures	30–60 min	25–75 min	1 d	6–24 h
Tropicamide	Solution (0.25%–1%)		20–40 min	20–35 min	6 h	<6 h

Data on peak and recovery time from *Ophthalmic Drug Facts by Facts and Comparisons* (1998), pp. 45 and 49. Copyright 1998 by Facts and Comparisons, a Wolters Kluwer Company. Adapted with permission.

angles or shallow anterior chambers and in patients taking monoamine oxidase inhibitors or tricyclic antidepressants.

## Medications Used to Treat Glaucoma

Therapeutic medications for glaucoma are used to lower IOP by decreasing aqueous production or increasing aqueous outflow. Because glaucoma calls for lifetime therapy, patients must be instructed regarding both the ocular and systemic side effects of the medications.

Most antiglaucoma medications affect the accommodation of the lens and limit light entry through a constricted pupil. Visual acuity and the ability to focus may be affected. Factors to consider in selecting glaucoma medications are efficacy, systemic and ocular side effects, convenience, and cost.

## Anti-Infective Medications

Anti-infective medications include antibiotic, antifungal, and antiviral agents. Most are available as drops, ointments, or subconjunctival or intravitreal injections. Antibiotics include penicillin, cephalosporins, aminoglycosides, and fluoroquinolones. The main antifungal agent is amphotericin B. Side effects of amphotericin are serious and include severe pain, conjunctival necrosis, iritis, and retinal toxicity. Antiviral medications include acyclovir and ganciclovir. They are used to treat ocular infections associated with herpesvirus and CMV. Patients receiving ocular anti-infective agents are subject to the same side effects and adverse reactions as those receiving oral or parenteral medications.

## Corticosteroids and Nonsteroidal Anti-Inflammatory Drugs

The topical preparations of corticosteroids are commonly used in inflammatory conditions of the eyelids, conjunctiva, cornea, anterior chamber, lens, and uvea. In posterior segment diseases that involve the posterior sclera, retina, and optic nerve, the topical agents are less effective, and parenteral and oral routes are preferred. The topical eye drop preparation is prepared in suspension; the patient is instructed to shake the bottle several times to obtain the maximum therapeutic effect of the medication.

The most common ocular side effects of long-term topical corticosteroid administration are glaucoma, cataracts, susceptibility to infection, impaired wound healing, mydriasis, and ptosis. High IOP may develop, which is reversible after corticosteroid use is discontinued. To avoid the side effects of corticosteroids, NSAIDs are used as an alternative in controlling inflammatory eye conditions and postoperatively to reduce inflammation. NSAID therapy in combination with topical and oral preparations is an important adjunct therapy in managing uveitis.

## Antiallergy Medications

Ocular hypersensitivity reactions, such as allergic conjunctivitis, are extremely common. These conditions result primarily from responses to environmental allergens. Most allergens are airborne or carried to the eye by the hand or by other means, although allergic reactions may also be drug induced. Corticosteroids are also commonly used as anti-inflammatory and immunosuppressive agents to control ocular hypersensitivity reaction.

## Ocular Irrigants

Most irrigating solutions are used to cleanse the external lids to maintain lid hygiene, to irrigate the external corneal surface to regain normal pH (such as in chemical burns), to irrigate the corneal surface to eliminate debris, or to inflate the globe intraoperatively. These solutions have various compositions that include sodium, potassium, magnesium, calcium, bicarbonate, glucose, and glutathione (ie, substance found in the aqueous humor). Sterile irrigating solutions, such as Dacriose, for lid hygiene are available. Irrigating solutions are safe to use with an intact corneal surface; however, the corneal surface should not be irrigated in cases of threatened corneal perforation. For patients with severe corneal ulcer, specific orders must be obtained regarding whether it is safe to irrigate the corneal surface or just to cleanse the external lids. Although it is good practice to promote hygiene, prevention of complications must be the primary concern. Normal saline solutions are commonly used to irrigate the corneal surface when chemical burns occur.

## Ocular Lubricants

Lubricants, such as artificial tears, help to alleviate corneal irritation, such as dry eye syndrome. Artificial tears are topical preparations of methyl or hydroxypropyl cellulose that are prepared as eye drop solutions, ointments, or ocular inserts (inserted at the lower conjunctival cul-de-sac once each day). The eye drops can be instilled as often as every hour, depending on the severity of symptoms.

## NURSING MANAGEMENT

The objectives in administering ocular medications are to ensure proper administration to maximize the therapeutic effects and to ensure the safety of the patient by monitoring manifestations of possible systemic and local side effects. Absorption of eye drops by the nasolacrimal duct is undesirable because of the potential systemic side effects of ocular medications. To diminish systemic absorption and minimize the side effects, it is important to occlude the puncta (Chart 58-10). This is especially important for patients most vulnerable to medication overdose, including elderly people, children, infants, women who are lactating or are pregnant, and patients with cardiac, pulmonary, hepatic, or renal disease.

A 30-second interval between eye drop instillations has a 45% rate of washout loss. A 1-minute interval between instillation of differing types of ocular drops is recommended (Margolis et al., 2002).

Before the administration of ocular medications, the nurse should warn the patient that blurred vision, stinging, and a burning sensation are symptoms that ordinarily occur after instillation and are temporary. Risk for interactions of the ocular medication with other ocular and systemic medications must be emphasized; therefore, a careful patient interview regarding medications being taken must be obtained.

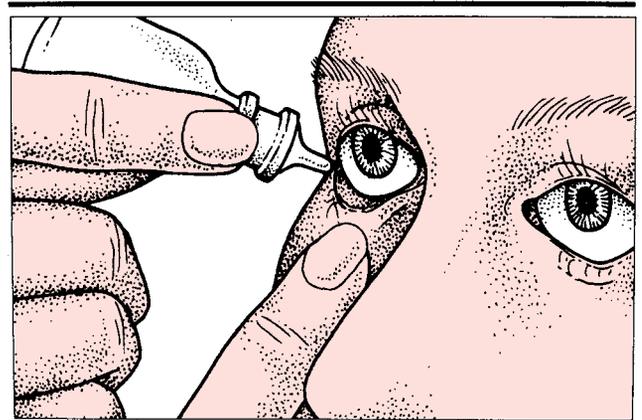

Emphasis must be placed on hand-washing techniques before and after medication instillation. The tip of the eye drop bottle or the ointment tube must never touch any part of the eye. The medication must be recapped immediately after each use. If patients who instill their own medications cannot feel the eye drops when they are instilled, the eye medication may be refrigerated, because a cold drop is easier to detect. A 5-minute interval between successive eye drop administration allows adequate drug retention and absorption. The patient or the caregiver at home should be asked to demonstrate actual eye drop or ointment instillation and punctal occlusion.

Chart  
58-10

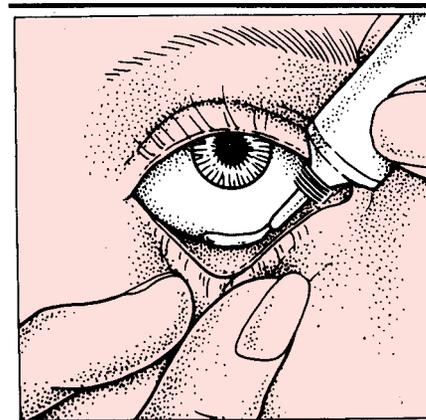

## Guidelines for Instilling Eye Medications

Follow these general guidelines when instilling eye medications:

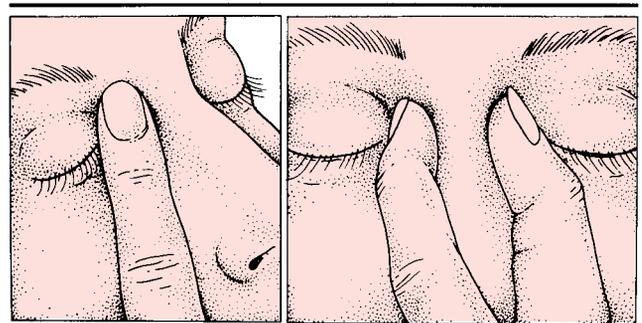

- Shake suspensions or “milky” solutions to obtain the desired medication level.
- Wash hands thoroughly before and after the procedure.
- Ensure adequate lighting.
- Read the label of the eye medication to make sure it is the correct medication.
- Assume a comfortable position.
- Do not touch the tip of the medication container to any part of the eye or face.
- Hold the lower lid down; do not press on the eyeball. Apply gentle pressure to the cheek bone to anchor the finger holding the lid.

- Instill eye drops before applying ointments.
- Apply a ½-inch ribbon of ointment to the lower conjunctival sac.

- Keep the eyelids closed, and apply gentle pressure on the inner canthus (punctal occlusion) near the bridge of the nose for 1 or 2 minutes immediately after instilling eyedrops.
- Using a clean tissue, gently pat skin to absorb excess eyedrops that run onto the cheeks.
- Wait 5 to 10 minutes before instilling another eye medication.

## Issues in Ophthalmology

Issues that arise in any area of health care usually pose more questions than answers. In ophthalmology, the well-being of the patient physically, emotionally, financially, socially, and spiritually can be at risk when vision is threatened. Patients with a deteriorating eye condition often worry about the impact that visual loss will have on their lives. As they experience visual distortions, scotomas, or gradual visual loss, what was a vague worry can become a consuming preoccupation. The patient may equate a decrease in visual acuity with a loss of independence. The loss of a driver's license may force a patient to relocate his or her home or give up or change careers.

These vulnerable patients may be easy targets for unscrupulous practitioners, who may offer unproven treatments, often at great expense to the patient who is desperate for any treatment that may prove beneficial. Patients travel from one physician to another in search of any treatment that may forestall visual loss. For example, a patient with 20/200 vision may wrongly believe that there is nothing to lose and will submit to invasive surgeries, only to end with a visual acuity of 20/800.

Not all patients who are contemplating ophthalmic surgical procedures are in great distress from a sight-threatening condition. Increasingly, patients are encouraged by friends and family or even by advertisement to have elective procedures such as refractive surgery. Patients are enticed by the thought of being free of eye-

glasses or contact lens. Refractive surgery sites are springing up in shopping malls and offering discounts and sales on procedures.

Some cataract surgeons remove cataracts before there is a visual deficit or with the full knowledge that such surgery may offer no increase in vision. Patients should be counseled before such procedures about the potential risk versus the potential benefit. Patients who have an ongoing retinal problem, such as AMD, should be evaluated by both a retinal expert and a cataract surgeon.

## Nursing Considerations

Fundamental goals in ophthalmic nursing should include the preservation of vision and the prevention of further visual loss in those patients who have already experienced some degree of loss. The maximal practical use should be sought for any remaining vision.

Skillful listening and interviewing on the part of the nurse or provider are critical tools for the rehabilitation of the distressed patient. The health care provider together with the patient should determine which goals are possible. A referral to a low-vision center for evaluation may be an appropriate intervention, but for some patients, it may be a signal that all hope of vision restoration is lost.

To be effective, the nurse listens to the patient, tries to determine his or her level of health care need, and makes suggestions and recommendations that can be of real value to the patient. Lines of communication must be kept open so that the patient is comfortable exploring all treatment modalities without fear of being ridiculed or patronized.

### Critical Thinking Exercises

**1.** You are making a home visit to a 73-year-old patient in an assisted living facility. She has had diabetes mellitus for many years. Her renal function has been deteriorating, and her blood pressure has become increasingly harder to control. She complains that, although her reading vision is better, her distance vision seems to be blurry most of the time. She asks whether she should get her glasses changed (it has been several years since her last eye examination) or wait until her blood pressure medication regimen is settled. How often should a patient with diabetes have a dilated eye examination? What could be the underlying reason for her decrease in distance acuity? How can her fluctuating renal and hypertensive status affect the condition of the retina?

**2.** A 19-year-old, female student arrives at the college infirmary with scratchy eyes, blurred vision, and photophobia. She has just returned to the campus after spring break. She states that her nose has been running, her eyelids have been stuck together in the mornings, and she has used some eye drops with a red cap that she found in her medicine cabinet at home. She denies any use of other medications. Examination reveals crusting on the lids and lashes, hyperemic conjunctiva, purulent discharge, and fixed, dilated pupils. What should be included in the differential diagnosis? What could account for the photophobia? For the unresponsive pupils? What eyelid hygiene measure will promote ocular comfort? What precautions should be taken to prevent the spread of ocular infection to other students in the dormitory?

# ● Assessment and Management of Patients With Hearing and Balance Disorders

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Describe methods used to assess hearing and diagnose hearing and balance disorders.
2. List the manifestations that may be exhibited by a person with a hearing disorder.
3. Identify ways to communicate effectively with a hearing-impaired person.
4. Differentiate problems of the external ear from those of the middle ear and inner ear.
5. Compare the various types of surgical procedures used for managing middle ear disorders, including appropriate nursing care.
6. Describe the teaching topics that need to be addressed for patients undergoing middle ear and mastoid surgery.
7. Describe the different types of inner ear disorders, including the clinical manifestations, diagnosis, and management.

The ear is a sensory organ with dual functions—hearing and balance. The sense of hearing is essential for normal development and maintenance of speech and the ability to communicate with others. Balance, or equilibrium, is essential for maintaining body movement, position, and coordination.

The delicate structure and function of the ear make early detection and accurate diagnosis of disorders necessary for preservation of normal hearing and balance. Among the professionals involved in the diagnosis and treatment of these disorders are otolaryngologists, pediatricians, internists, and nurses. Nurses involved in the specialty of otolaryngology can become certified through the Society of Otorhinolaryngology and Head-Neck Nurses, Inc.

This chapter addresses the assessment and management of hearing and balance disorders common to the adult population. The pediatric otolaryngology literature provides information on otologic disorders pertaining to that population.

## Anatomic and Physiologic Overview

The cranium encloses and protects the brain and surrounding structures, providing attachment for various muscles that control head and jaw movements. Eight bones form the cranium: the occipital bone, the frontal bone, two parietal bones, two temporal bones, the sphenoid bone, and the ethmoid bone. Some of these bones contain sinuses, which are cavities lined with mucous membranes and connected to the nasal cavity. The ears are located on either side of the cranium at approximately eye level.

## ANATOMY OF THE EXTERNAL EAR

The external ear, housed in the temporal bone, includes the auricle (i.e., pinna) and the external auditory canal (Fig. 59-1). The external ear is separated from the middle ear by a disklike structure called the tympanic membrane (ie, eardrum).

### Auricle

The auricle, attached to the side of the head by skin, is composed mainly of cartilage, except for the fat and subcutaneous tissue in the earlobe. The auricle collects the sound waves and directs vibrations into the external auditory canal.

## External Auditory Canal

The external auditory canal is approximately 2.5 cm long. The lateral third is an elastic cartilaginous and dense fibrous framework to which thin skin is attached. The medial two thirds is bone lined with thin skin. The external auditory canal ends at the tympanic membrane (Chart 59-1).

The skin of the canal contains hair, sebaceous glands, and ceruminous glands, which secrete a brown, waxlike substance called cerumen (ie, ear wax). The ear's self-cleaning mechanism moves old skin cells and cerumen to the outer part of the ear.

Just anterior to the external auditory canal is the temporomandibular joint. The head of the mandible can be felt by placing a fingertip in the external auditory canal while the patient opens and closes the mouth.

## ANATOMY OF THE MIDDLE EAR

The middle ear, an air-filled cavity, includes the tympanic membrane laterally and the otic capsule medially. The middle ear cleft lies between the two. The middle ear is connected by the eustachian tube to the nasopharynx and is continuous with air-filled cells in the adjacent mastoid portion of the temporal bone.

The eustachian tube, which is approximately 1 mm wide and 35 mm long, connects the middle ear to the nasopharynx. Normally, the eustachian tube is closed, but it opens by action of the tensor veli palatini muscle when performing a Valsalva maneuver or when yawning or swallowing. The tube serves as a drainage channel for normal and abnormal secretions of the middle ear and equalizes pressure in the middle ear with that of the atmosphere.

## Tympanic Membrane

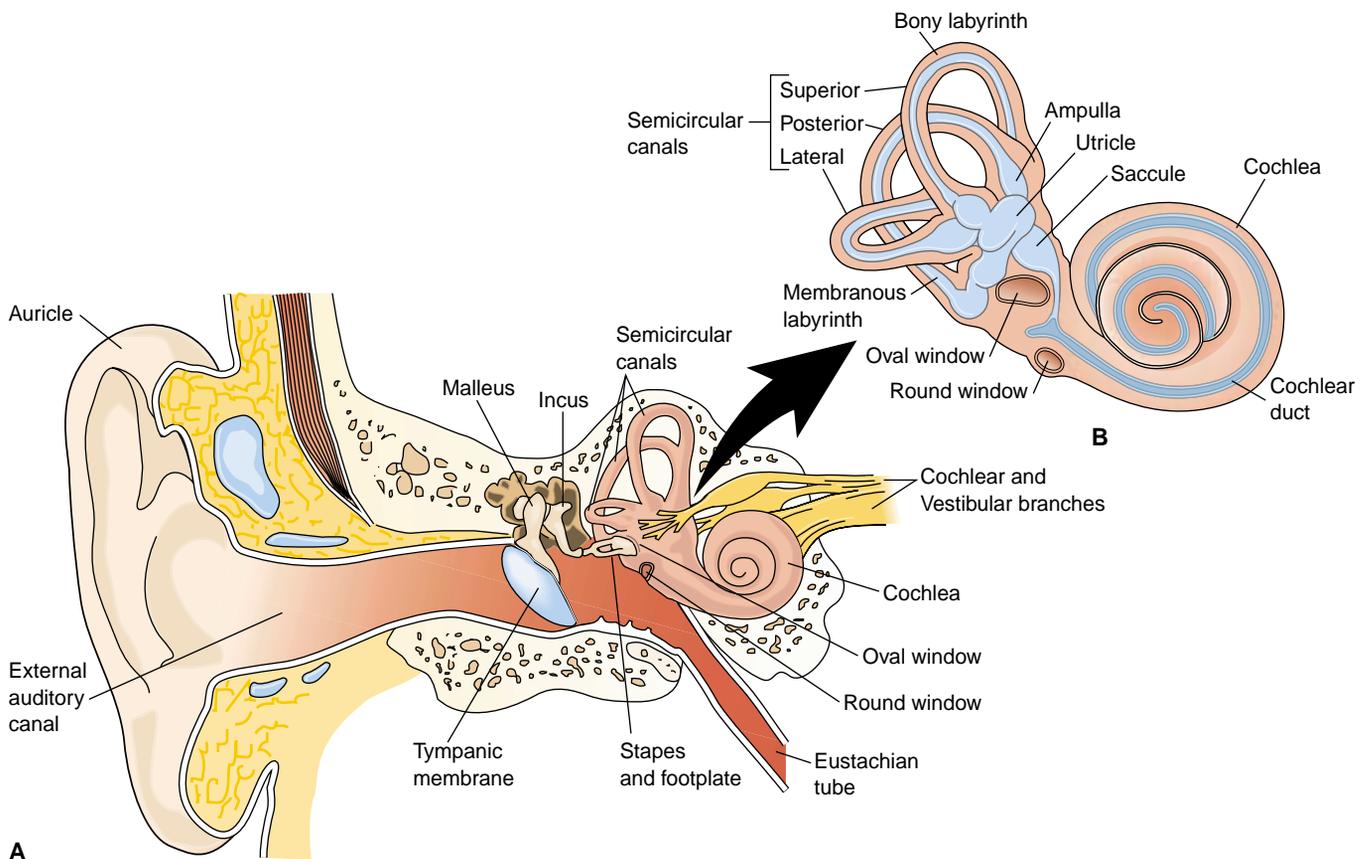

The tympanic membrane (ie, eardrum), about 1 cm in diameter and very thin, is normally pearly gray and translucent. The tympanic membrane consists of three layers of tissue: an outer layer, continuous with the skin of the ear canal; a fibrous middle layer; and an inner mucosal layer, continuous with the lining of the middle ear cavity. Approximately 80% of the tympanic membrane is composed of all three layers and is called the pars

## Glossary

**acute otitis media:** inflammation in the middle ear lasting less than 6 weeks  
**cholesteatoma:** tumor of the middle ear or mastoid, or both, that can destroy structures of the temporal bone  
**chronic otitis media:** repeated episodes of acute otitis media causing irreversible tissue damage and persistent tympanic membrane perforation  
**conductive hearing loss:** loss of hearing in which efficient sound transmission to the inner ear is interrupted by some obstruction or disease process  
**dizziness:** altered sensation of orientation in space  
**endolymphatic hydrops:** dilation of the endolymphatic space of the inner ear; the pathologic correlate of Ménière's disease

**exostoses:** small, hard, bony protrusions in the lower posterior bony portion of the ear canal  
**labyrinthitis:** inflammation of the labyrinth of the inner ear  
**Ménière's disease:** condition of the inner ear characterized by a triad of symptoms: episodic vertigo, tinnitus, and fluctuating sensorineural hearing loss  
**middle ear effusion:** fluid in the middle ear without evidence of infection  
**myringotomy (ie, tympanotomy):** incision in the tympanic membrane  
**nystagmus:** involuntary rhythmic eye movement  
**ossiculoplasty:** surgical reconstruction of the middle ear bones to restore hearing  
**otalgia:** sensation of fullness or pain in the ear  
**otitis externa (ie, external otitis):** inflammation of the external auditory canal

**otorrhea:** drainage from the ear  
**otosclerosis:** a condition characterized by abnormal spongy bone formation around the stapes  
**presbycusis:** progressive hearing loss associated with aging  
**rhinorrhea:** drainage from the nose  
**sensorineural hearing loss:** loss of hearing related to damage of the end organ for hearing or cranial nerve VIII, or both  
**tinnitus:** subjective perception of sound with internal origin; unwanted noises in the head or ear  
**tympanoplasty:** surgical repair of the tympanic membrane  
**vertigo:** illusion of movement in which the individual or the surroundings are sensed as moving

**FIGURE 59-1** (A) Anatomy of the ear. (B) The inner ear.

### Chart 59-1

#### Definition of Terms: Ear Anatomy

**Acoustic:** pertaining to sound or the sense of hearing

**Cerumen:** yellow or brown, waxlike secretion found in the external auditory canal

**Cochlea:** the winding, snail-shaped bony tube that forms a portion of the inner ear and contains the organ of Corti, the transducer for hearing

**Cochlear (acoustic) nerve:** the division of the eighth cranial (vestibulocochlear) nerve, which goes to the cochlea

**Eustachian tube:** the 3- to 4-cm tube that extends from the middle ear to the nasopharynx

**External auditory canal:** the canal leading from the external auditory meatus to the tympanic membrane; about 2.5 cm in length

**External ear:** the portion of the ear that consists of the auricle and external auditory canal; it is separated from the middle ear by the tympanic membrane

**Incus:** the second of the three ossicles in the middle ear; it articulates with the malleus and stapes; the anvil

**Inner ear:** the portion of the ear that consists of the cochlea, vestibule, and semicircular canals

**Internal auditory canal:** a canal in the petrous portion of the temporal bone, which houses the facial and vestibulocochlear nerves (cranial nerves VII and VIII)

**Malleus:** the first (most lateral) and largest of the three ossicles in the middle ear; it is connected to the tympanic membrane laterally and articulates with the incus; the hammer

**Middle ear:** the small, air-filled cavity in the temporal bone that contains the three ossicles

**Organ of Corti:** the end organ of hearing, located in the cochlea

**Ossicle:** a small bone; there are three in the middle ear: malleus, incus, and stapes

**Oval window:** a fenestra (aperture) between the vestibule of the inner ear and the middle ear, occupied by the base of the stapes

**Pinna:** the outer part of the external ear, which collects and directs sound waves into the external auditory canal; the auricle

**Round window:** a fenestra between the middle ear and the inner ear at the base of the cochlea, occupied by the round window membrane

**Semicircular canals:** the superior, posterior, and lateral bony tubes that form part of the inner ear; contain the receptor organs for balance

**Stapes:** the third (most medial) ossicle of the middle ear; it articulates with the incus, and its footplate fits into the oval window; the stirrup

**Temporal bone:** a bone on both sides of the skull at its base; composed of the squamous, mastoid, and petrous portions

**Tympanic membrane:** the membrane that separates the middle ear from the external auditory canal; also referred to as the eardrum

**Vestibulocochlear nerve:** cranial nerve VIII; cochlear (acoustic) nerve and vestibular nerve

tensa. The other 20% of the tympanic membrane lacks the middle layer and is called the pars flaccida. The absence of this fibrous middle layer makes the pars flaccida more vulnerable to pathologic disorders than the pars tensa. Distinguishing landmarks of the tympanic membrane include the annulus, the fibrous border that attaches the eardrum to the temporal bone; the short process of the malleus; the long process of the malleus; the umbo of the malleus, which attaches to the tympanic membrane in the center; the pars flaccida; and the pars tensa (Fig. 59-2).

The tympanic membrane protects the middle ear and conducts sound vibrations from the external canal to the ossicles. The sound pressure is magnified 22 times as a result of transmission from a larger area to a smaller one.

## Ossicles

The middle ear contains the three smallest bones (ie, ossicles) of the body: malleus, incus, and stapes. The ossicles, which are held in place by joints, muscles, and ligaments, assist in the transmission of sound. Two small fenestrae (ie, oval and round windows), located in the medial wall of the middle ear, separate the middle ear from the inner ear. The footplate of the stapes sits in the oval window, secured by a fibrous annulus, or ring-shaped structure. The footplate transmits sound to the inner ear. The round window, covered by a thin membrane, provides an exit for sound vibrations (see Fig. 59-1).

## ANATOMY OF THE INNER EAR

The inner ear is housed deep within the temporal bone. The organs for hearing (ie, cochlea) and balance (ie, semicircular canals), as well as cranial nerves VII (ie, facial nerve) and VIII (ie, vestibulocochlear nerve), are all part of this complex anatomy (see Fig. 59-1). The cochlea and semicircular canals are housed in the bony labyrinth. The bony labyrinth surrounds and pro-

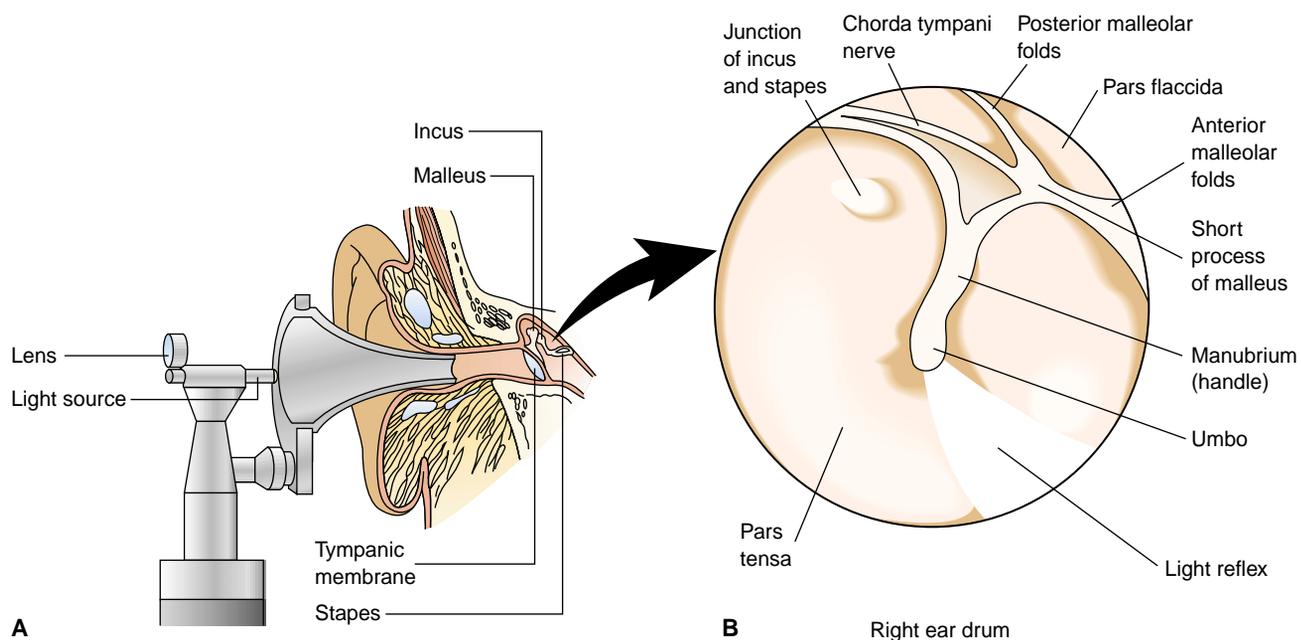

TECTS the membranous labyrinth, which is bathed in a fluid called perilymph.

## Membranous Labyrinth

The membranous labyrinth is composed of the utricle, the saccule, the cochlear duct, the semicircular canals, and the organ of Corti. The membranous labyrinth contains a fluid called endolymph. The three semicircular canals—posterior, superior, and lateral, which lie at 90-degree angles to one another—contain sensory receptor organs, arranged to detect rotational movement. These receptor end organs are stimulated by changes in the rate or direction of an individual's movement. The utricle and saccule are involved with linear movements.

## Organ of Corti

The organ of Corti is located in the cochlea, a snail-shaped, bony tube about 3.5 cm long with two and one-half spiral turns. Membranes separate the cochlear duct (ie, scala media) from the scala vestibuli, and the scala tympani from the basilar membrane. The organ of Corti is located on the basilar membrane stretching from the base to the apex of the cochlea. As sound vibrations enter the perilymph at the oval window and travel along the scala vestibuli, they pass through the scala tympani, enter the cochlear duct, and cause movement of the basilar membrane. The organ of Corti, also called the end organ for hearing, transforms mechanical energy into neural activity and separates sounds into different frequencies. This electrochemical impulse travels through the acoustic nerve to the temporal cortex of the brain to be interpreted as meaningful sound. In the internal auditory canal, the cochlear (acoustic) nerve, arising from the cochlea, joins the vestibular nerve, arising from the semicircular canals, utricle, and saccule, to become the vestibulocochlear nerve (cranial nerve VIII). This canal also houses the facial nerve and the blood supply from the ear to the brain.

**FIGURE 59-2** (A) Technique for using the otoscope to see (B) the tympanic membrane.

## FUNCTION OF THE EARS

### Hearing

Hearing is conducted over two pathways: air and bone. Sounds transmitted by air conduction travel over the air-filled external and middle ear through vibration of the tympanic membrane and ossicles. Sounds transmitted by bone conduction travel directly through bone to the inner ear, bypassing the tympanic membrane and ossicles. Normally, air conduction is the more efficient pathway. However, defects in the tympanic membrane or interruption of the ossicular chain disrupt normal air conduction, which results in a loss of the sound-to-pressure ratio and subsequently in a conductive hearing loss.

### SOUND CONDUCTION AND TRANSMISSION

Sound enters the ear through the external auditory canal and causes the tympanic membrane to vibrate. These vibrations transmit sound through the lever action of the ossicles to the oval window as mechanical energy. This mechanical energy is then transmitted through the inner ear fluids to the cochlea, stimulating the hair cells, and is subsequently converted to electrical energy. The electrical energy travels through the vestibulocochlear nerve to the central nervous system, where it is analyzed and interpreted in its final form as sound.

Vibrations transmitted by the tympanic membrane to the ossicles of the middle ear are transferred to the cochlea, lodged in the labyrinth of the inner ear. The stapes rocks, causing vibrations (ie, waves) in fluids contained in the inner ear. These fluid waves cause movement of the basilar membrane to occur that then stimulates the hair cells of the organ of Corti in the cochlea to move in a wavelike manner. The movements of the tympanic membrane set up electrical currents that stimulate the various areas of the cochlea. The hair cells set up neural impulses that are encoded and then transferred to the auditory cortex in the brain, where they are decoded into a sound message.

The footplate of the stapes receives impulses transmitted by the incus and the malleus from the tympanic membrane. The round window, which opens on the opposite side of the cochlear duct, is protected from sound waves by the intact tympanic membrane, permitting motion of the inner ear fluids by sound wave stimulation. For example, in the normally intact tympanic membrane, sound waves stimulate the oval window first, and a lag occurs before the terminal effect of the stimulus reaches the round window. This lag phase is changed, however, when a perforation of the tympanic membrane is large enough to allow sound waves to impinge on the oval and round windows simultaneously. This effect cancels the lag and prevents the maximal effect of inner ear fluid motility and its subsequent effect in stimulating the hair cells in the organ of Corti. The result is a reduction in hearing ability (Fig. 59-3).

### Balance and Equilibrium

Body balance is maintained by the cooperation of the muscles and joints of the body (ie, proprioceptive system), the eyes (ie, visual system), and the labyrinth (ie, vestibular system). These areas send their information about equilibrium, or balance, to the brain (ie, cerebellar system) for coordination and perception in the cerebral cortex. The brain obtains its blood supply from the heart and arterial system. A problem in any of these areas, such as arteriosclerosis or impaired vision, can cause a balance disturbance. The vestibular apparatus of the inner ear provides feedback regarding the movements and the position of the head and body in space.

## Assessment

The external ear is examined by inspection and direct palpation, and the tympanic membrane is inspected with an otoscope and indirect palpation with a pneumatic otoscope. Until the advent of middle ear endoscopy, inspection of the middle ear was impossible. Evaluation of gross auditory acuity also is included in every physical examination.

### INSPECTION OF THE EXTERNAL EAR

Inspection of the external ear is a simple procedure, but it is often overlooked. The auricle and surrounding tissues should be inspected for deformities, lesions, and discharge, as well as size, symmetry, and angle of attachment to the head. Manipulation of the auricle does not normally elicit pain. If this maneuver is painful, acute external otitis is suspected. Tenderness on palpation in the area of the mastoid may indicate acute mastoiditis or inflammation of the posterior auricular node. Occasionally, sebaceous cysts and tophi (ie, subcutaneous mineral deposits) are present on the pinna. A flaky scaliness on or behind the auricle usually indicates seborrheic dermatitis and can be present on the scalp and facial structures as well.

### OTOSCOPIC EXAMINATION

To examine the external auditory canal and tympanic membrane, the otoscope should be held in the examiner's right hand, in a pencil-hold position, with the bottom of the scope pointing up (Fig. 59-4). This position prevents the examiner from inserting the otoscope too far into the external canal. Using the opposite hand, the auricle is grasped and gently pulled back to straighten the canal in the adult. If the canal is not straightened with this technique, the tympanic membrane is harder to visualize because of the canal obstructing the view.

The speculum is slowly inserted into the ear canal, with the examiner's eye held close to the magnifying lens of the otoscope to visualize the canal and tympanic membrane. The largest speculum that the canal can accommodate (usually 5 mm in an adult) is guided gently down into the canal and slightly forward. Because the distal portion of the canal is bony and covered by a sensitive layer of epithelium, only light pressure can be used without causing pain. The examiner looks for any discharge, inflammation, or foreign body in the external auditory canal.

The healthy tympanic membrane is pearly gray and is positioned obliquely at the base of the canal. The landmarks are identified, if visible (see Fig. 59-2): the pars tensa, the umbo, the manubrium of the malleus, and its short process. A slow, circular movement of the speculum allows further visualization of the malleolar folds and periphery. The position and color of the membrane and any unusual markings or deviations from normal are documented. The presence of fluid, air bubbles, blood, or masses in the middle ear also are noted.

Proper otoscopic examination of the external auditory canal and tympanic membrane requires that the canal be free of large amounts of cerumen. Cerumen is normally present in the external canal, and small amounts should not interfere with otoscopic examination. If the tympanic membrane cannot be visualized because of cerumen, the cerumen may be removed by gently irrigating the external canal with warm water (if there are no contraindications to this). If adherent cerumen is present, a small amount of mineral oil or over-the-counter cerumen softener may be instilled within the ear canal, and the patient is instructed to

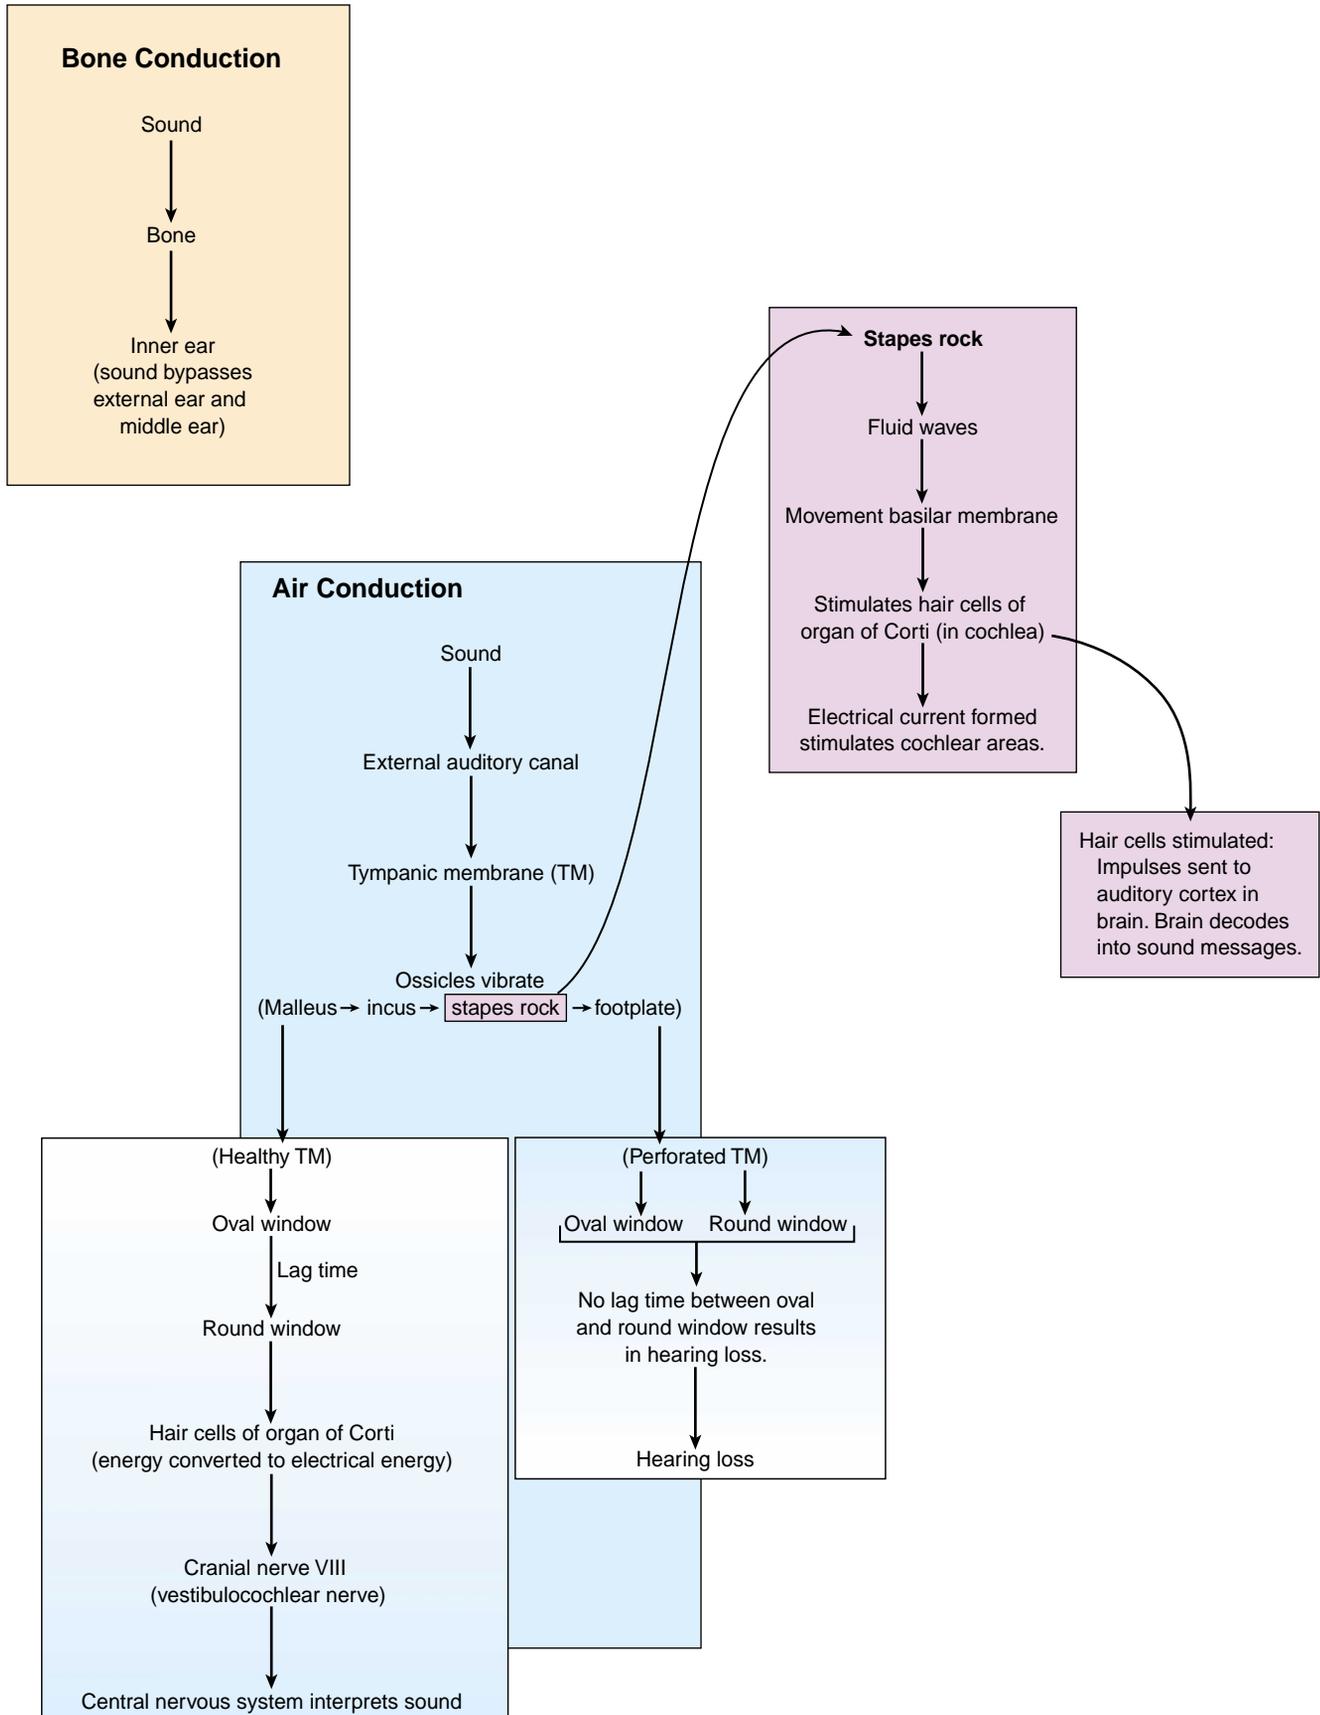

FIGURE 59-3 Bone conduction compared to air conduction.

**FIGURE 59-4** Proper technique for examining the ear. Hold the otoscope in the right or left hand, in a “pencil hold” position. Steady the hand against the patient’s head to avoid inserting the otoscope too far into the external canal.

return for subsequent removal of the cerumen and inspection of the ear. The use of instruments such as a cerumen curette for cerumen removal is reserved for otolaryngologists and nurses with specialized training because of the danger of perforating the tympanic membrane or excoriating the external auditory canal. Cerumen buildup is a common cause of hearing loss and local irritation.

## EVALUATION OF GROSS AUDITORY ACUITY

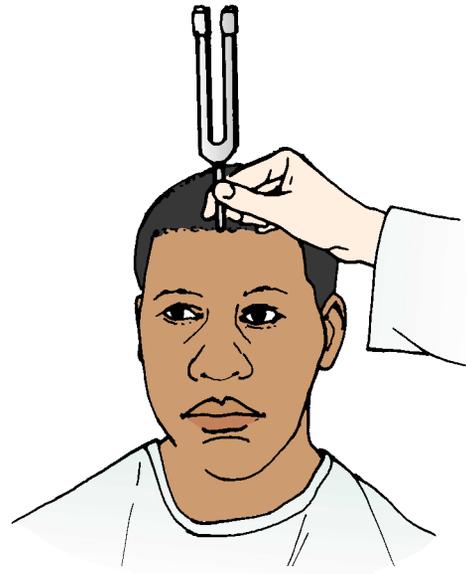

A general estimation of hearing can be made by assessing the patient’s ability to hear a whispered phrase or a ticking watch, testing one ear at a time. The Weber and Rinne tests may be used to distinguish conductive loss from sensorineural loss when hearing is impaired. These tests are part of the usual screening physical examination and are useful if a more specific assessment is needed, if hearing loss is detected, or if confirmation of audiometric results is desired.

### Whisper Test

To exclude one ear from the testing, the examiner covers the untested ear with the palm of the hand. Then the examiner whispers softly from a distance of 1 or 2 feet from the unoccluded ear and out of the patient’s sight. The patient with normal acuity can correctly repeat what was whispered.

### Weber Test

The Weber test uses bone conduction to test lateralization of sound. A tuning fork (ideally, 512 Hz), set in motion by grasping it firmly by its stem and tapping it on the examiner’s knee or hand, is placed on the patient’s head or forehead (Fig. 59-5). A person with normal hearing will hear the sound equally in both ears or describe the sound as centered in the middle of the head. In cases of **conductive hearing loss**, such as from otosclerosis or otitis media, the sound is heard better in the affected ear. In cases of **sen-**

**FIGURE 59-5** The Weber test assesses bone conduction of sound. From Weber, J. W., & Kelley, J. (2003). *Health assessment in nursing* (2nd ed.). Philadelphia: Lippincott Williams & Wilkins.

**sensorineural hearing loss**, resulting from damage to the cochlear or vestibulocochlear nerve, the sound lateralizes to the better-hearing ear. The Weber test is useful for detecting unilateral hearing loss (Table 59-1).

### Rinne Test

In the Rinne test (pronounced rin-ay), the examiner shifts the stem of a vibrating tuning fork between two positions: 2 inches from the opening of the ear canal (ie, for air conduction) and against the mastoid bone (ie, for bone conduction) (Fig. 59-6). As the position changes, the patient is asked to indicate which tone is louder or when the tone is no longer audible. Normally, sound heard by air conduction is audible longer than sound heard by bone conduction. The Rinne test is useful for distinguishing between conductive and sensorineural hearing losses. With a conductive hearing loss, bone-conducted sound is heard as long as or longer than air-conducted sound, whereas with a sensorineural hearing loss, air-conducted sound is audible longer than bone-conducted sound. In a normal hearing ear, air-conducted sound is louder than bone-conducted sound.

## Diagnostic Evaluation

Many diagnostic procedures are available to measure the auditory and vestibular systems indirectly. These tests are usually performed by an audiologist who is recognized by the American Speech-Language-Hearing Association with a certificate of clinical competence in audiology.

## AUDIOMETRY

In detecting hearing loss, audiometry is the single most important diagnostic instrument. Audiometric testing is of two kinds: pure-tone audiometry, in which the sound stimulus consists of a pure or musical tone (the louder the tone before the patient perceives it, the greater the hearing loss), and speech audiometry, in

**Table 59-1 • Comparison of Weber and Rinne Tests**

HEARING STATUS	WEBER	RINNE
Normal hearing	Sound is heard equally in both ears.	Air conduction is audible longer than bone conduction.
Conductive hearing loss	Sound heard best in affected ear (hearing loss).	Sound heard as long or longer in affected ear (hearing loss).
Sensorineural hearing loss	Sound heard best in normal hearing ear.	Air conduction is audible longer than bone conduction in affected ear.

which the spoken word is used to determine the ability to hear and discriminate sounds and words.

When evaluating hearing, three characteristics are important: frequency, pitch, and intensity. *Frequency* refers to the number of sound waves emanating from a source per second, measured as cycles per second, or Hertz (Hz). The normal human ear perceives sounds ranging in frequency from 20 to 20,000 Hz. The frequencies from 500 to 2,000 Hz are important in understanding everyday speech and are referred to as the speech range or speech frequencies. *Pitch* is the term used to describe frequency; a tone with 100 Hz is considered of low pitch, and a tone of 10,000 Hz is considered of high pitch.

The unit for measuring loudness (ie, *intensity* of sound) is the decibel (dB), the pressure exerted by sound. Hearing loss is measured in decibels, a logarithmic function of intensity that is not easily converted into a percentage. The critical level of loudness is approximately 30 dB. The shuffling of papers in quiet surroundings

is about 15 dB; a low conversation, 40 dB; and a jet plane 100 feet away, about 150 dB. Sound louder than 80 dB is perceived by the human ear to be harsh and can be damaging to the inner ear. Table 59-2 classifies hearing loss based on decibel level. In surgical treatment of patients with hearing loss, the aim is to improve the hearing level to 30 dB or better within the speech frequencies.

With audiometry, the patient wears earphones and signals to the audiologist when a tone is heard. When the tone is applied directly over the external auditory canal, air conduction is measured. When the stimulus is applied to the mastoid bone, bypassing the conductive mechanism (ie, ossicles), nerve conduction is tested. For accuracy, audiometric evaluations are performed in a sound-proof room. Responses are plotted on a graph known as an audiogram, which differentiates conductive from sensorineural hearing loss. Speech discrimination is also measured (Fig. 59-7).

## TYMPANOGRAM

A tympanogram, or impedance audiometry, measures middle ear muscle reflex to sound stimulation and compliance of the tympanic membrane by changing the air pressure in a sealed ear canal. Compliance is impaired with middle ear disease.

## AUDITORY BRAIN STEM RESPONSE

The auditory brain stem response is a detectable electrical potential from cranial nerve VIII and the ascending auditory pathways of the brain stem in response to sound stimulation. Electrodes are placed on the patient's forehead. Acoustic stimuli, usually in the form of clicks, are made in the ear. The resulting electrophysiologic measurements can determine at which decibel level a patient hears and whether there are any impairments along the nerve pathways (eg, tumor on cranial nerve VIII).

## ELECTRONYSTAGMOGRAPHY

Electronystagmography is the measurement and graphic recording of the changes in electrical potentials created by eye movements during spontaneous, positional, or calorically evoked nystagmus.

**FIGURE 59-6** The Rinne test assesses both air and bone conduction of sound. From Weber, J., & Kelley, J. (2003). *Health assessment in nursing* (2nd ed., p. 218). Philadelphia: Lippincott Williams & Wilkins. © B. Proud.

**Table 59-2 • Severity of Hearing Loss**

LOSS IN DECIBELS	INTERPRETATION
0–15	Normal hearing
>15–25	Slight hearing loss
>25–40	Mild hearing loss
>40–55	Moderate hearing loss
>55–70	Moderate to severe hearing loss
>70–90	Severe hearing loss
>90	Profound hearing loss

SPEECH HEARING TESTS					
TEST		R	L	BIN	SF
Sp. Reception Threshold (SRT)		10 db	10 db	db	db
Sp. Discrim. Scores (PB)	80 db HL	100%	100%	%	%
	___ db HL	%	%	%	%
	___ db HL	%	%	%	%

**FIGURE 59-7** The speech reception threshold is the sound intensity level at which a patient is just capable of correctly identifying simple speech stimuli. Speech discrimination determines the patient's ability to distinguish different sounds, in the form of words, at a decibel level where sound is heard.

It is also used to assess the oculomotor and vestibular systems and their corresponding interaction. It helps in diagnosing conditions such as **Ménière's disease** and tumors of the internal auditory canal or posterior fossa. Any vestibular suppressants, such as sedatives, tranquilizers, antihistamines, and alcohol are withheld for 24 hours before testing. Prior to the test the procedure is explained to the patient.

## PLATFORM POSTUROGRAPHY

Platform posturography is used to investigate postural control capabilities. The integration of visual, vestibular, and proprioceptive cues (ie, sensory integration) with motor response output and coordination of the lower limbs is tested. The patient stands on a platform, surrounded by a screen, and different conditions such as a moving platform with a moving screen or a stationary platform with a moving screen are presented. The responses from the patient on six different conditions are measured and indicate which of the anatomic systems may be impaired. Preparation for the testing is the same as for electronystagmography.

## SINUSOIDAL HARMONIC ACCELERATION

Sinusoidal harmonic acceleration, or a rotary chair, is used to assess the vestibulo-ocular system by analyzing compensatory eye movements in response to the clockwise and counterclockwise rotation of the chair. Although such testing cannot identify the side of the lesion in unilateral disease, it helps identify disease and evaluate the course of recovery. The same patient preparation is required as for electronystagmography.

## MIDDLE EAR ENDOSCOPY

With endoscopes with very small diameters and acute angles, the ear can be examined endoscopically by an endoscopist specializing in otolaryngology. Middle ear endoscopy is performed safely and effectively as an office procedure to evaluate suspected perilymphatic fistula and new-onset conductive hearing loss, the anatomy of the round window before transtympanic treatment of Ménière's disease, and the tympanic cavity before ear surgery to treat chronic middle ear and mastoid infections.

The tympanic membrane is anesthetized topically for about 10 minutes. Then, the external auditory canal is irrigated with sterile normal saline solution. With the aid of a microscope, a tympanotomy is created with a laser beam or a myringotomy knife, so that the endoscope can be inserted into the middle ear cavity. Video and photo documentation can be accomplished through the scope.

## Hearing Loss

More than 26 million people in the United States have some form of hearing impairment (Larson et al., 2000). Most can be helped with medical or surgical therapies or with a hearing aid. By the year 2050, about one of every five people in the United States, or almost 58 million people, will be 55 years of age or older. Of this population, almost one half can expect a hearing impairment (U.S. Public Health Service, 2000).

Approximately 10 million persons in the United States have irreversible hearing loss (National Strategic Research Plan of the National Institute on Deafness and Other Communication Disorders [NIDCD], 1998). It is estimated that more than 30 million people are exposed to noise levels that produce hearing loss on a daily basis. Occupations such as carpentry, plumbing, and coal mining have the highest risk of noise-induced hearing loss. Researchers report greater than 90% of coal miners are estimated to have hearing loss by the age of 52 years (Franks, 1996).

Conductive hearing loss usually results from an external ear disorder, such as impacted cerumen, or a middle ear disorder, such as otitis media or otosclerosis. In such instances, the efficient transmission of sound by air to the inner ear is interrupted. A sensorineural loss involves damage to the cochlea or vestibulocochlear nerve.

Mixed hearing loss and functional hearing loss also may occur. The patient with mixed hearing loss has conductive loss and sensorineural loss, resulting from dysfunction of air and bone conduction. A functional (or psychogenic) hearing loss is nonorganic and unrelated to detectable structural changes in the hearing mechanisms; it is usually a manifestation of an emotional disturbance.

## Clinical Manifestations

Early manifestations of hearing impairment and loss may include tinnitus, increasing inability to hear in groups, and a need to turn up the volume of the television. Hearing impairment can also trigger changes in attitude, the ability to communicate, the awareness of surroundings, and even the ability to protect oneself, affecting the person's quality of life. In a classroom, a student with impaired hearing may be disinterested and inattentive and have failing grades. A person at home may feel isolated because of an inability to hear the clock chime, the refrigerator hum, the birds sing, or the traffic pass. A hearing-impaired pedestrian may attempt to cross the street and fail to hear an approaching car. Hearing-impaired people may miss parts of a conversation. Many people are unaware of their gradual hearing impairment. Often, it is not the person with the hearing loss, but the people with whom he or she is communicating who recognize the impairment first (see Chart 59-2).

For various reasons, some people with hearing loss refuse to seek medical attention or wear a hearing aid. Others feel self-conscious wearing a hearing aid. Insightful patients generally ask those with whom they are trying to communicate to let them know whether difficulties in communication exist. These attitudes and behaviors should be taken into account when counseling patients who need hearing assistance. The decision to wear a hearing aid is a personal one that is affected by these attitudes and behaviors.

## Prevention

Many environmental factors have an adverse effect on the auditory system and, with time, result in permanent sensorineural hearing loss. The most common is noise.

### Chart 59-2 • ASSESSMENT

#### Symptoms of Hearing Loss

**Speech deterioration:** The person who slurs words or drops word endings, or produces flat-sounding speech, may not be hearing correctly. The ears guide the voice, both in loudness and in pronunciation.

**Fatigue:** If a person tires easily when listening to conversation or to a speech, fatigue may be the result of straining to hear. Under these circumstances, the person may become irritable very easily.

**Indifference:** It is easy for the person who cannot hear what others say to become depressed and disinterested in life in general.

**Social withdrawal:** Not being able to hear what is going on causes the hearing-impaired person to withdraw from situations that might prove embarrassing.

**Insecurity:** Lack of self-confidence and fear of mistakes create a feeling of insecurity in many hearing-impaired people. No one likes to say the wrong thing or do anything that might appear foolish.

**Indecision and procrastination:** Loss of self-confidence makes it increasingly difficult for a hearing-impaired person to make decisions.

**Suspiciousness:** The hearing-impaired person, who often hears only part of what is being said, may suspect that others are talking about him or her, or that portions of the conversation are deliberately spoken softly so that he or she will not hear them.

**False pride:** The hearing-impaired person wants to conceal the hearing loss and thus often pretends to be hearing when he or she actually is not.

**Loneliness and unhappiness:** Although everyone wishes for quiet now and then, *enforced* silence can be boring and even somewhat frightening. People with a hearing loss often feel isolated.

**Tendency to dominate the conversation:** Many hearing-impaired people tend to dominate the conversation, knowing that as long as it is centered on them and they can control it, they are not so likely to be embarrassed by some mistake.

Noise (ie, unwanted and unavoidable sound) has been identified as one of the environmental hazards of the 20th century. The sheer volume of noise that surrounds us daily has increased from a simple annoyance into a potentially dangerous source of physical and psychological damage.

In terms of physical impact, loud, persistent noise has been found to cause constriction of peripheral blood vessels, increased blood pressure and heart rate (because of increased secretion of adrenalin), and increased gastrointestinal activity. Additional research is needed to address the overall effects of noise on the human body. It seems certain, however, that a quiet environment is more conducive to peace of mind. A person who is ill feels more at ease when noise is kept to a minimum. There are numerous factors that contribute to hearing loss (see Chart 59-3).

The term *noise-induced hearing loss* is used to describe hearing loss that follows a long period of exposure to loud noise (eg, heavy machinery, engines, artillery). *Acoustic trauma* refers to the hearing loss caused by a single exposure to an extremely intense noise, such as an explosion. Usually, noise-induced hearing loss occurs at a high frequency (around 4,000 Hz). However, with continued noise exposure, the hearing loss can become more severe and include adjacent frequencies. The minimum noise level known to cause noise-induced hearing loss, regardless of duration, is about 85 to 90 dB.

Noise exposure is inherent in many jobs (eg, mechanics, printers, pilots, musicians) and in hobbies such as woodworking and

### Chart 59-3

#### Risk Factors for Hearing Loss

- Family history of sensorineural impairment
- Congenital malformations of the cranial structure (ear)
- Low birth weight (<1500 g)
- Use of ototoxic medications (eg, gentamicin, loop diuretics)
- Recurrent ear infections
- Bacterial meningitis
- Chronic exposure to loud noises
- Perforation of the tympanic membrane

hunting. The Occupational Safety and Health Administration requires that workers wear ear protection to prevent noise-induced hearing loss when exposed to noise above the legal limits. There are no medications that protect against noise-induced hearing loss; hearing loss is permanent because the hair cells in the organ of Corti are destroyed. Ear protection against noise is the most effective preventive measure available.

#### Gerontologic Considerations

About 30% of people 65 years of age and older and 50% of people 75 years and older have hearing difficulties. The cause is unknown; linkages to diet, metabolism, arteriosclerosis, stress, and heredity have been inconsistent (Cruickshanks et al., 1998).

With aging, changes occur in the ear that may eventually lead to hearing deficits. Although few changes occur in the external ear, cerumen tends to become harder and drier, posing a greater chance of impaction. In the middle ear, the tympanic membrane may atrophy or become sclerotic. In the inner ear, cells at the base of the cochlea degenerate. A familial predisposition to sensorineural hearing loss is also seen, manifested by a loss in the ability to hear high-frequency sounds, followed in time by the loss of middle and lower frequencies. The term **presbycusis** is used to describe this progressive hearing loss.

In addition to age-related changes, other factors can affect hearing in the elderly population, such as lifelong exposure to loud noises (eg, jets, guns, heavy machinery, circular saws). Certain medications, such as aminoglycosides and aspirin, have ototoxic effects when renal changes (eg, in the older person) result in delayed medication excretion and increased levels of the medications in the blood. Many older people take quinine for treatment of leg cramps; quinine can cause a hearing loss. Psychogenic factors and other disease processes (eg, diabetes) also may be partially responsible for sensorineural hearing loss.

When a hearing problem occurs, an evaluation is warranted. Even with the best medical care, the person must learn to adjust to various degrees of hearing loss. Care of elderly patients includes recognizing emotional reactions related to hearing loss, such as suspicion of others because of an inability to hear adequately; frustration and anger, with repeated statements such as, "I didn't hear what you said"; and feelings of insecurity because of the inability to hear the telephone or alarms.

#### Medical Management

If a hearing loss is permanent or untreatable with medical or surgical intervention or if the patient elects not to have surgery, aural rehabilitation (discussed at the end of the chapter) may be beneficial.

## GENETICS IN NURSING PRACTICE—Hearing Disorders

### SELECTED HEARING DISORDERS INFLUENCED BY GENETIC FACTORS

- Autosomal dominant hearing loss
- Autosomal recessive hearing loss (eg, connexin 26 gene)
- Otosclerosis
- Pendred syndrome
- Usher syndrome
- Waardenburg syndrome

### NURSING ASSESSMENTS

#### FAMILY HISTORY ASSESSMENT

- Assess for other family members in several generations with hearing loss (autosomal dominant hearing loss)
- Inquire about genetic relatedness (eg, individuals who are related, such as first cousins, have a higher chance to share the same recessive genes—autosomal recessive hearing loss)
- Inquire about age at onset of hearing loss

#### PHYSICAL ASSESSMENT

- Assess for related genetic conditions, such as vision impairment (eg, retinitis pigmentosa in Usher syndrome; thyroid disorder in Pendred syndrome)
- Assess for iris, pigmentary, and hair alterations (white forelock) seen in Waardenburg syndrome

### MANAGEMENT ISSUES SPECIFIC TO GENETICS

- Inquire whether DNA gene mutation or other genetic testing has been performed on affected family members.

- If indicated, refer for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, availability of genetic testing, and gene-based interventions.
- Offer appropriate genetics information and resources.
- Assess patient's understanding of genetics information.
- Provide support to families with newly diagnosed genetic-related sensorineural disorders.
- Participate in management and coordination of care of patients with genetic conditions, and individuals predisposed to develop or pass on a genetic condition.

### GENETICS RESOURCES

Genetic Alliance—a directory of support groups for patients and families with genetic conditions; <http://www.geneticalliance.org>

Gene Clinics—a listing of common genetic disorders with up-to-date clinical summaries, genetic counseling and testing information; <http://www.geneclinics.org>

National Organization of Rare Disorders—a directory of support groups and information for patients and families with rare genetic disorders; <http://www.rarediseases.org>

OMIM: Online Mendelian Inheritance in Man—a complete listing of inherited genetic conditions; <http://www.ncbi.nlm.nih.gov/omim/stats/html>

## Nursing Management

The nurse who understands the different types of hearing loss will be more successful in adopting a communication style to fit the patient's needs. Trying to speak in a loud voice to a person who cannot hear high-frequency sounds only makes understanding more difficult. However, strategies such as talking into the less-

impaired ear and using gestures and facial expressions can help (see Chart 59-4).

A major issue for many deaf and hearing-impaired people is that they have other health problems that often do not receive attention, in large part because of communication problems with their health care practitioners. To effectively meet the health care needs of these patients, practitioners are legally obligated to make

Chart  
59-4

### Guidelines for Communicating With the Hearing-Impaired Person

#### For the hearing-impaired person whose speech is difficult to understand:

- Devote full attention to what the person is saying. Look and listen—do not try to attend to another task while listening.
- Engage the speaker in conversation when it is possible for you to anticipate the replies. This enables you to become accustomed to any peculiarities in speech patterns.
- Try to determine the essential context of what is being said; you can often fill in the details from context.
- Do not try to appear as if you understand if you do not.
- If you cannot understand at all or have serious doubt about your ability to understand what is being said, have the person write the message rather than risk misunderstanding. Having the person repeat the message in speech, after you know its content, also aids you in becoming accustomed to the person's pattern of speech.

#### For the hearing-impaired person who speech reads:

- When speaking, always face the person as directly as possible.
- Make sure your face is as clearly visible as possible. Locate yourself so that your face is well lighted; avoid being silhouetted against strong light. Do not obscure the person's view of your mouth in any way; avoid talking with any object held in your mouth.
- Be sure that the patient knows the topic or subject before going ahead with what you plan to say. This enables the person to use contextual clues in speech reading.
- Speak slowly and distinctly, pausing more frequently than you would normally.
- If you question whether some important direction or instruction has been understood, check to be certain that the patient has the full meaning of your message.
- If for any reason your mouth must be covered (as with a mask) and you must direct or instruct the patient, write the message.

accommodations for the patient's inability to hear. Providing the services of interpreters or those who can communicate through sign language is essential in many situations so that the practitioner can effectively communicate with the patient.

During health care and screening procedures, the practitioner (eg, dentist, physician, nurse) must be aware that patients who are deaf or hearing impaired are unable to read lips, see a signer, or read written materials in dark rooms required during some diagnostic tests. The same situation exists if the practitioner is wearing a mask or not in sight (eg, x-ray studies, magnetic resonance imaging [MRI], colonoscopy).

Nurses and other health care practitioners must work with deaf and hearing-impaired patients and their families to identify workable and effective means of communication. Nurses can serve as catalysts throughout the health care system to ensure that accommodations are made to meet the communication needs of these patients.

## Conditions of the External Ear

### CERUMEN IMPACTION

Cerumen normally accumulates in the external canal in various amounts and colors. Although wax does not usually need to be removed, impaction occasionally occurs, causing **otalgia**, a sensation of fullness or pain in the ear, with or without a hearing loss. Accumulation of cerumen is especially significant in the geriatric population as a cause of hearing deficit. Attempts to clear the external auditory canal with matches, hairpins, and other implements are dangerous because trauma to the skin, infection, and damage to the tympanic membrane can occur.

### Management

Cerumen can be removed by irrigation, suction, or instrumentation. Unless the patient has a perforated eardrum or an inflamed external ear (ie, otitis externa), gentle irrigation usually helps remove impacted cerumen, particularly if it is not tightly packed in the external auditory canal. For successful removal, the water stream must flow behind the obstructing cerumen to move it first laterally and then out of the canal. To prevent injury, the lowest effective pressure should be used. If the eardrum behind the impaction is perforated, however, water can enter the middle ear, producing acute vertigo and infection. If irrigation is unsuccessful, direct visual, mechanical removal can be performed on a cooperative patient by a trained health care provider.

Instilling a few drops of warmed glycerin, mineral oil, or half-strength hydrogen peroxide into the ear canal for 30 minutes can soften cerumen before its removal. Ceruminolytic agents, such as peroxide in glyceryl (Debrox), are available; however, these compounds may cause an allergic dermatitis reaction. Using any softening solution two or three times a day for several days is generally sufficient. If the cerumen cannot be dislodged by these methods, instruments, such as a cerumen curette, aural suction, and a binocular microscope for magnification, can be used.

### FOREIGN BODIES

Some objects are inserted intentionally into the ear by adults who may have been trying to clean the external canal or relieve itching or by children who introduce the objects. Other objects, such as insects, peas, beans, pebbles, toys, and beads, may enter or be introduced into the ear canal. In either case, the effects may range from no symptoms to profound pain and decreased hearing.

### Management

Removing a foreign body from the external auditory canal can be quite challenging. The three standard methods for removing foreign bodies are the same as those for removing cerumen: irrigation, suction, and instrumentation. The contraindications for irrigation are also the same. Foreign vegetable bodies and insects tend to swell; thus, irrigation is contraindicated. Usually, an insect can be dislodged by instilling mineral oil, which will kill the insect and allow it to be removed.

Attempts to remove any foreign body from the external canal may be dangerous in unskilled hands. The object may be pushed completely into the bony portion of the canal, lacerating the skin and perforating the tympanic membrane. In difficult cases, the foreign body may have to be extracted in the operating room with the patient under general anesthesia.

### EXTERNAL OTITIS (OTITIS EXTERNA)

**External otitis**, or **otitis externa**, refers to an inflammation of the external auditory canal. Causes include water in the ear canal (ie, swimmer's ear); trauma to the skin of the ear canal, permitting entrance of organisms into the tissues; and systemic conditions, such as vitamin deficiency and endocrine disorders. Bacterial or fungal infections are most frequently encountered. The most common bacterial pathogens associated with external otitis are *Staphylococcus aureus* and *Pseudomonas* species. The most common fungus isolated in both normal and infected ears is *Aspergillus*. External otitis is often caused by a dermatosis such as psoriasis, eczema, or seborrheic dermatitis. Even allergic reactions to hair spray, hair dye, and permanent wave lotions can cause dermatitis, which clears when the offending agent is removed.

### Clinical Manifestations

The patient usually reports pain, discharge from the external auditory canal, aural tenderness (usually not present in middle ear infections), and occasionally fever, cellulitis, and lymphadenopathy. Other symptoms may include pruritus and hearing loss or a feeling of fullness. On otoscopic examination, the ear canal is erythematous and edematous. Discharge may be yellow or green and foul smelling. In fungal infections, the hairlike black spores may even be visible.

### Medical Management

The principles of therapy are aimed at relieving the discomfort, reducing the swelling of the ear canal, and eradicating the infection. Patients may require analgesics for the first 48 to 92 hours. If the tissues of the external canal are edematous, a wick should be inserted to keep the canal open so that liquid medications (eg, Burow's solution, antibiotic otic preparations) can be introduced. These medications may be administered by dropper at room temperature. Such medications usually combine antibiotic and corticosteroid agents to soothe the inflamed tissues. For cellulitis or fever, systemic antibiotics may be prescribed. For fungal disorders, antifungal agents are prescribed.

### Nursing Management

Nurses need to teach patients not to clean the external auditory canal with cotton-tipped applicators, to avoid swimming, and not to allow water to enter the ear when shampooing or shower-

ing. A cotton ball can be covered in a water-insoluble gel such as petroleum jelly and placed in the ear as a barrier to water contamination. Infection can be prevented by using antiseptic otic preparations after swimming (eg, Swim Ear, Ear Dry), unless there is a history of tympanic membrane perforation or a current ear infection.

## MALIGNANT EXTERNAL OTITIS

A more serious, although rare, external ear infection is malignant external otitis (ie, temporal bone osteomyelitis). This is a progressive, debilitating, and occasionally fatal infection of the external auditory canal, the surrounding tissue, and the base of the skull. *Pseudomonas aeruginosa* is usually the infecting organism in patients with low resistance to infection (eg, patients with diabetes). Successful treatment includes control of the diabetes, administration of antibiotics (usually intravenously), and aggressive local wound care. Standard parenteral antibiotic treatment includes the combination of an antipseudomonal agent and an aminoglycoside, both of which have potentially serious side effects. Because aminoglycosides are nephrotoxic and ototoxic, serum aminoglycoside levels and renal and auditory function must be monitored during therapy. Local wound care includes limited débridement of the infected tissue, including bone and cartilage, depending on the extent of the infection.

## MASSES OF THE EXTERNAL EAR

**Exostoses** are small, hard, bony protrusions found in the lower posterior bony portion of the ear canal; they usually occur bilaterally. The skin covering the exostosis is normal. Many people think exostoses are caused by an exposure to cold water, as in scuba diving or surfing. The usual treatment, if any, is surgical excision.

Malignant tumors also may be found in the external ear. Most common are basal cell carcinomas on the pinna and squamous cell carcinomas in the ear canal. If untreated, squamous cell carcinoma may spread through the temporal bone, causing facial nerve paralysis and hearing loss. Carcinomas must be treated surgically.

## GAPPING EARRING PUNCTURE

Gapping earring puncture results from wearing heavy pierced earrings for a long time or after an infection, or as a reaction from the earring or other impurities in the earring. One or more gapping punctures may result from wearing more than one earring. Whatever its cause, this deformity can only be corrected surgically. The edges of the perforations are excised on the lateral and medial surfaces of the earlobe. Next, the entire tract is removed, joining the above two incisions and resulting in a much larger defect that is closed separately on each surface. Then, an antibiotic dressing is applied.

## Conditions of the Middle Ear

### TYMPANIC MEMBRANE PERFORATION

Perforation of the tympanic membrane is usually caused by infection or trauma. Sources of trauma include skull fracture, explosive injury, or a severe blow to the ear. Less frequently, perforation is caused by foreign objects (eg, cotton-tipped applicators, bobby pins, keys) that have been pushed too far into the external auditory canal. In addition to tympanic membrane perforation, injury to the ossicles and even the inner ear may result from this type of

action. Attempts by patients to clear the external auditory canal should be discouraged. During infection, the tympanic membrane can rupture if the pressure in the middle ear exceeds the atmospheric pressure in the external auditory canal.

### Medical Management

Although most tympanic membrane perforations heal spontaneously within weeks after rupture, some may take several months to heal. Some perforations persist because scar tissue grows over the edges of the perforation, preventing extension of the epithelial cells across the margins and final healing. In the case of a head injury or temporal bone fracture, a patient is observed for evidence of cerebrospinal fluid **otorrhea** or **rhinorrhea**—a clear, watery drainage from the ear or nose, respectively. While healing, the ear must be protected from water.

### SURGICAL MANAGEMENT

Perforations that do not heal on their own may require surgery. The decision to perform a **tympanoplasty** (ie, surgical repair of the tympanic membrane) is usually based on the need to prevent potential infection from water entering the ear or the desire to improve the patient's hearing. Performed on an outpatient basis, tympanoplasty may involve a variety of surgical techniques. In all techniques, tissue is placed across the perforation to allow healing. Surgery is usually successful in closing the perforation permanently and improving hearing.

## ACUTE OTITIS MEDIA

**Acute otitis media** is an acute infection of the middle ear, usually lasting less than 6 weeks. The primary cause of acute otitis media is usually *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*, which enter the middle ear after eustachian tube dysfunction caused by obstruction related to upper respiratory infections, inflammation of surrounding structures (eg, sinusitis, adenoid hypertrophy), or allergic reactions (eg, allergic rhinitis). Bacteria can enter the eustachian tube from contaminated secretions in the nasopharynx and the middle ear from a tympanic membrane perforation. A purulent exudate is usually present in the middle ear, resulting in a conductive hearing loss.

### Clinical Manifestations

The symptoms of otitis media vary with the severity of the infection. The condition, usually unilateral in adults, may be accompanied by otalgia. The pain is relieved after spontaneous perforation or therapeutic incision of the tympanic membrane. Other symptoms may include drainage from the ear, fever, and hearing loss. On otoscopic examination, the external auditory canal appears normal. The patient reports no pain with movement of the auricle. The tympanic membrane is erythematous and often bulging. Table 59-3 differentiates acute external otitis from acute otitis media.

### Medical Management

The outcome of acute otitis media depends on the efficacy of therapy (ie, the prescribed dose of an oral antibiotic and the duration of therapy), the virulence of the bacteria, and the physical status of the patient. With early and appropriate broad-spectrum antibiotic therapy, otitis media may resolve with no serious sequelae.

Table 59-3 • Clinical Features of Otitis

FEATURE	ACUTE OTITIS EXTERNA	ACUTE OTITIS MEDIA
Otorrhea	May or may not be present	Present if tympanic membrane perforates; discharge is profuse
Otalgia	Persistent, may awaken patient at night	Relieved if tympanic membrane ruptures
Aural tenderness	Present on palpation of auricle	Usually absent
Systemic symptoms	Absent	Fever, upper respiratory infection, rhinitis
Edema of external auditory canal	Present	Absent
Tympanic membrane	May appear normal	Erythema, bulging, may be perforated
Hearing loss	Conductive type	Conductive type

If drainage occurs, an antibiotic otic preparation is usually prescribed. The condition may become subacute (lasting 3 weeks to 3 months), with persistent purulent discharge from the ear. Rarely does permanent hearing loss occur. Secondary complications involving the mastoid and other serious intracranial complications, such as meningitis or brain abscess, although rare, can occur.

### SURGICAL MANAGEMENT

An incision in the tympanic membrane is known as **myringotomy** or **tympanotomy**. The tympanic membrane is numbed with a local anesthetic such as phenol or by iontophoresis (ie, electrical current flows through a lidocaine-and-epinephrine solution to numb the ear canal and tympanic membrane). The procedure is painless and takes less than 15 minutes. Under microscopic guidance, an incision is made through the tympanic membrane to relieve pressure and to drain serous or purulent fluid from the middle ear.

Normally, this procedure is unnecessary for treating acute otitis media, but it may be performed if pain persists. Myringotomy also allows the drainage to be analyzed (by culture and sensitivity testing) so that the infecting organism can be identified and appropriate antibiotic therapy prescribed. The incision heals within 24 to 72 hours.

If episodes of acute otitis media recur and there is no contraindication, a ventilating, or pressure-equalizing, tube may be inserted. The ventilating tube, which temporarily takes the place of the eustachian tube in equalizing pressure, is retained for 6 to 18 months. The ventilating tube is then extruded with normal skin migration of the tympanic membrane, with the hole healing in nearly every case. Ventilating tubes are more commonly used to treat recurrent episodes of acute otitis media in children than in adults.

### SEROUS OTITIS MEDIA

Serous otitis media (ie, **middle ear effusion**) implies fluid, without evidence of active infection, in the middle ear. In theory, this fluid results from a negative pressure in the middle ear caused by eustachian tube obstruction. This condition is found primarily in children. When it occurs in adults, an underlying cause for the eustachian tube dysfunction must be sought. Middle ear effusion is frequently seen in patients after radiation therapy or barotrauma and in patients with eustachian tube dysfunction from a concurrent upper respiratory infection or allergy. Barotrauma results from sudden pressure changes in the middle ear caused by changes in barometric pressure, as in scuba diving or airplane descent. A carcinoma (eg, nasopharyngeal cancer) obstructing the

eustachian tube should be ruled out in an adult with persistent unilateral serous otitis media.

### Clinical Manifestations

Patients may complain of hearing loss, fullness in the ear or a sensation of congestion, and perhaps even popping and crackling noises, which occur as the eustachian tube attempts to open. The tympanic membrane appears dull on otoscopy, and air bubbles may be visualized in the middle ear. Usually, the audiogram shows a conductive hearing loss.

### Management

Serous otitis media need not be treated medically unless infection occurs (ie, acute otitis media). If the hearing loss associated with middle ear effusion is a problem for the patient, a myringotomy can be performed, and a tube may be placed to keep the middle ear ventilated. Corticosteroids in small doses sometimes decrease the edema of the eustachian tube in cases of barotrauma. Decongestants have not proved effective. A Valsalva maneuver, which forcibly opens the eustachian tube by increasing nasopharyngeal pressure, may be cautiously performed. Performing the Valsalva maneuver may cause worsening pain or perforation of the tympanic membrane.

### CHRONIC OTITIS MEDIA

**Chronic otitis media** is the result of repeated episodes of acute otitis media causing irreversible tissue pathology and persistent perforation of the tympanic membrane. Chronic infections of the middle ear damage the tympanic membrane, destroy the ossicles, and involve the mastoid. Before the discovery of antibiotics, infections of the mastoid were life-threatening. The use of medications in acute otitis media has made acute mastoiditis a rare condition in developed countries.

### Clinical Manifestations

Symptoms may be minimal, with varying degrees of hearing loss and the presence of a persistent or intermittent, foul-smelling otorrhea. Pain is not usually experienced, except in cases of acute mastoiditis, when the postauricular area is tender to the touch and may be erythematous and edematous. Otoscopic evaluation of the tympanic membrane may show a perforation, and cholesteatoma can be identified as a white mass behind the tympanic membrane or coming through to the external canal from a perforation.

**Cholesteatoma** is an ingrowth of the skin of the external layer of the eardrum into the middle ear. It is generally caused by a chronic retraction pocket of the tympanic membrane, creating a persistently high negative pressure of the middle ear. The skin forms a sac that fills with degenerated skin and sebaceous materials. The sac can attach to the structures of the middle ear or mastoid, or both. Cholesteatoma alone usually does not cause pain; however, if treatment or surgery is delayed, the cholesteatoma may destroy structures of the temporal bone. In cases of cholesteatoma, audiometric tests often show a conductive or mixed hearing loss.

## Medical Management

Local treatment of chronic otitis media consists of careful suctioning of the ear under microscopic guidance. Instillation of antibiotic drops or application of antibiotic powder is used to treat a purulent discharge. Systemic antibiotics are usually not prescribed except in cases of acute infection.

## SURGICAL MANAGEMENT

Surgical procedures, including tympanoplasty, ossiculoplasty, and mastoidectomy, are used after medical treatments are determined to be ineffective. Chronic otitis media can cause chronic mastoiditis and lead to the formation of cholesteatoma. It can occur in the middle ear, mastoid cavity, or both, often dictating the type of surgery to be performed. If untreated, cholesteatoma will continue to enlarge, possibly causing damage to the facial nerve and horizontal canal and destruction of other surrounding structures.

**Tympanoplasty.** The most common surgical procedure for chronic otitis media is a tympanoplasty, or surgical reconstruction of the tympanic membrane. Reconstruction of the ossicles may also be required. The purposes of a tympanoplasty are to reestablish middle ear function, close the perforation, prevent recurrent infection, and improve hearing.

There are five types of tympanoplasties. The simplest surgical procedure, type I (myringoplasty), is designed to close a perforation in the tympanic membrane. The other procedures, types II through V, involve more extensive repair of middle ear structures. The structures and the degree of involvement can differ, but all tympanoplasty procedures include restoring the continuity of the sound conduction mechanism.

Tympanoplasty is performed through the external auditory canal with a transcanal approach or through a postauricular incision. The contents of the middle ear are carefully inspected, and the ossicular chain is evaluated. Ossicular interruption is most frequent in chronic otitis media, but problems of reconstruction can also occur with malformations of the middle ear and ossicular dislocations due to head injuries. Dramatic improvement in hearing can result from closure of a perforation and reestablishment of the ossicles. Surgery is usually performed in an outpatient environment under moderate sedation or general anesthesia.

**Ossiculoplasty.** Many people use the term *tympanoplasty* to include **ossiculoplasty**, or surgical reconstruction of the middle ear bones to restore hearing. Prostheses made of materials such as Teflon, stainless steel, and hydroxyapatite are used to reconnect the ossicles, thereby reestablishing the sound conduction mechanism. However, the greater the damage, the lower the success rate for restoring normal hearing.

**Mastoidectomy.** The objectives of mastoid surgery are to remove the cholesteatoma, gain access to diseased structures, and create a dry and healthy ear. If possible, the ossicles are reconstructed during the initial surgical procedure. Occasionally, extensive disease dictates that this be performed as part of a planned second-stage operation.

A mastoidectomy is usually performed through a postauricular incision. Infection is eliminated by removing the mastoid air cells. Although infrequently injured, the facial nerve, which runs through the middle ear and mastoid, is at some risk for injury during mastoid surgery. As the patient awakens from anesthesia, any evidence of facial paresis should be reported to the physician. A second mastoidectomy may be necessary to check for recurrent or residual cholesteatoma. The hearing mechanism may be reconstructed at this time. The success rate for correcting this conductive hearing loss is approximately 75%. Surgery is usually performed in an outpatient setting. The patient has a mastoid pressure dressing, which can be removed 24 to 48 hours after surgery.

## NURSING PROCESS: THE PATIENT UNDERGOING MASTOID SURGERY

Although several otologic surgical procedures are performed under moderate sedation, mastoid surgery is performed using general anesthesia.

### Assessment

The health history includes a complete description of the ear problem, including infection, otalgia, otorrhea, hearing loss, and vertigo. Data are collected about the duration and intensity of the problem, its causes, and previous treatments. Information is obtained about other health problems and all medications that the patient is taking. Medication allergies and family history of ear disease also should be obtained.

Physical assessment includes observation for erythema, edema, otorrhea, lesions, and characteristics such as odor and color of discharge. The results of the audiogram should be reviewed.

### Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Anxiety related to surgical procedure, potential loss of hearing, potential taste disturbance, and potential loss of facial movement
- Acute pain related to mastoid surgery
- Risk for infection related to mastoidectomy, placement of grafts, prostheses, electrodes, and surgical trauma to surrounding tissues and structures
- Disturbed auditory sensory perception related to ear disorder, surgery, or packing
- Risk for trauma related to balance difficulties or vertigo during the immediate postoperative period
- Disturbed sensory perception related to potential damage to facial nerve (cranial nerve VII) and chorda tympani nerve
- Impaired skin integrity related to ear surgery, incisions, and graft sites
- Deficient knowledge about mastoid disease, surgical procedure, and postoperative care and expectations

## Planning and Goals

The major goals of caring for a patient undergoing mastoidectomy include reduction of anxiety; freedom from pain and discomfort; prevention of infection; stable or improved hearing and communication; absence of injury from vertigo; absence of or adjustment to sensory or perceptual alterations; return of skin integrity; and increased knowledge regarding the disease, surgical procedure, and postoperative care.

## Nursing Interventions

### REDUCING ANXIETY

Information that the otologic surgeon has discussed with the patient, including anesthesia, the location of the incision (postauricular), and expected surgical results (eg, hearing, balance, taste, facial movement), is reinforced. The patient also is encouraged to discuss any anxieties and concerns about the surgery.

### RELIEVING PAIN

Although most patients complain very little about incisional pain after mastoid surgery, they do have some ear discomfort. Aural fullness or pressure after surgery is caused by residual blood or fluid in the middle ear. The prescribed analgesic may be taken for the first 24 hours after surgery and then only as needed. The patient is instructed in the use of and side effects of the medication.

A tympanoplasty may also be performed at the time of the mastoidectomy. A wick or external auditory canal packing is used after a tympanoplasty to stabilize the tympanic membrane. Patients should be informed that they may experience intermittent sharp, shooting pains in the ear for 2 to 3 weeks after surgery as the eustachian tube opens and allows air to enter the middle ear.

### PREVENTING INFECTION

Measures are initiated to prevent infection in the operated ear. The external auditory canal wick, or packing, may be impregnated with an antibiotic solution before instillation. Prophylactic antibiotics are administered as prescribed, and the patient is instructed to prevent water from entering the external auditory canal for 6 weeks. A cotton ball or lamb's wool covered with a water-insoluble substance (eg, petroleum jelly) and placed loosely in the ear canal usually prevents water contamination. The postauricular incision should be kept dry for 2 days. Signs of infection such as an elevated temperature and purulent drainage are reported. Some serosanguineous drainage from the external auditory canal is normal after surgery.

### IMPROVING HEARING AND COMMUNICATION

Hearing in the operated ear may be reduced for several weeks because of edema, accumulation of blood and tissue fluid in the middle ear, and dressings or packing. Measures are initiated to improve hearing and communication, such as reducing environmental noise, facing the patient when speaking, speaking clearly and distinctly without shouting, providing good lighting if the patient relies on speech reading, and using nonverbal clues (eg, facial expression, pointing, gestures) and other forms of communication. Family members or significant others are instructed about effective ways to communicate with the patient. If the patient uses assistive hearing devices, one can be used in the unaffected ear.

### PREVENTING INJURY

Vertigo may occur after mastoid surgery if the semicircular canals or other areas of the inner ear are traumatized. This symp-

tom is relatively uncommon after this type of ear surgery and usually is temporary. Antiemetics or antivertiginous medications (eg, antihistamines) can be prescribed if a balance disturbance or vertigo occurs. The patient should be instructed about the expected effects and potential side effects. Safety measures such as assisted ambulation are implemented to prevent falls. Safety measures must also be implemented at home to prevent falls and injury.

### PREVENTING ALTERED SENSORY PERCEPTION

Facial nerve injury is a potential, although rare, complication of mastoid surgery. The patient is instructed to report immediately any evidence of facial nerve (cranial nerve VII) weakness, such as drooping of the mouth on the operated side. A more frequent occurrence is a temporary disturbance in the chorda tympani nerve, a small branch of the facial nerve that runs through the middle ear. Patients experience a taste disturbance and dry mouth on the side of surgery for several months until the nerve regenerates.

### PROMOTING WOUND HEALING

The patient is instructed to avoid heavy lifting, straining, exertion, and nose blowing for 2 to 3 weeks after surgery to prevent dislodging the tympanic membrane graft or ossicular prosthesis.

### INCREASING KNOWLEDGE

The patient is informed about the surgery and operating room environment. Discussing postoperative expectations helps to decrease anxiety about the unknown. Because postoperative instructions for mastoid surgery vary among otologic surgeons, it is important for the nurse to be aware of the surgeon's preferences when teaching the patient.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

Patients require instruction about prescribed medication therapy, such as analgesics, antivertiginous agents, and antihistamines prescribed for balance disturbance. Teaching includes information about the expected effects and potential side effects of the medication. Patients also need instruction about any activity restrictions. Possible complications such as infection, facial nerve weakness, or taste disturbances, including the signs and symptoms to report immediately, should be addressed (see Chart 59-5).

#### Continuing Care

Some patients, particularly elderly patients, who have had mastoid surgery may require the services of a home care nurse for a few days after returning home. However, most people find that assistance from a family member or a friend is sufficient. The caregiver and patient are cautioned that the patient may experience some vertigo and will therefore require help with ambulation to avoid falling. Any symptoms of complications are to be reported promptly to the surgeon. The importance of scheduling and keeping follow-up appointments is also stressed.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Demonstrates reduced anxiety about surgical procedure
  - a. Verbalizes and exhibits less stress, tension, and irritability
  - b. Verbalizes acceptance of the results of surgery and adjustment to possible hearing impairment

### Chart 59-5 • PATIENT EDUCATION Self-Care After Middle Ear or Mastoid Surgery

Postoperative instructions for patients who have had middle ear and mastoid surgery vary greatly among otolaryngologists. These patient teaching guidelines may require modification for the individual patient.

- Take antibiotics and other medications as prescribed.
- Blow nose gently one side at a time for 1 week after surgery.
- Sneeze and cough with the mouth open for a few weeks after surgery.
- Check with your health care provider about returning to work (usually 2 to 3 days postoperatively). Avoid heavy lifting (>25 lb), straining, and bending over for a few weeks after surgery.
- Know that popping and crackling in the operative ear is normal for approximately 3 to 5 weeks after surgery.
- Be aware that packing in the operated ear, as well as blood and fluid in the middle ear after surgery, will cause a hearing loss. You may also feel that you are talking in a well or hearing echoes.
- Remember that minor ear discomfort is normal; use the analgesics prescribed. Report any excessive ear pain to the surgeon.
- Note that some slightly bloody or serosanguineous drainage from the ear is normal after surgery. Report any excessive or purulent ear drainage to the surgeon.
- Change the cotton ball in the ear as needed.
- Check with the surgeon for instructions regarding air travel.
- Avoid getting water in the operated ear for 2 weeks after surgery. You may shampoo the hair 2 to 3 days postoperatively if the ear is protected from water by saturating a cotton ball with petroleum jelly (or some other water-insoluble substance) and loosely placing it in the ear. If the postauricular suture line becomes wet, pat (not rub) the area and cover it with a thin layer of antibiotic ointment.

2. Remains free of discomfort or pain
  - a. Exhibits no facial grimacing, moaning, or crying, and reports absence of pain
  - b. Uses analgesics appropriately
3. Demonstrates no signs or symptoms of infection
  - a. Has normal vital signs, including temperature
  - b. Demonstrates absence of purulent drainage from the external auditory canal
  - c. Describes method for preventing water from contaminating packing
4. Exhibits signs that hearing has stabilized or improved
  - a. Describes surgical goal for hearing and judges whether the goal has been met
  - b. Verbalizes that hearing has improved
5. Remains free of injury and trauma because of vertigo
  - a. Reports absence of vertigo or balance disturbance
  - b. Experiences no injury or fall
  - c. Modifies environment to avoid falls (eg, night light, no clutter on stairs)
6. Adjusts to or remains free from altered sensory perception
  - a. Reports no taste disturbance, mouth dryness, or facial weakness
7. Demonstrates no skin breakdown
  - a. Lists ways to prevent dislodging graft or prosthesis
  - b. Is aware of limitations in activities (eg, bathing, lifting, air travel) and for how long

8. Verbalizes the reasons for and methods of care and treatment
  - a. Shares knowledge with family about treatment protocol
  - b. Describes treatment and the time frame for the recovery phase
  - c. Discusses the discharge plan formulated with the nurse with regard to rest periods, medication, and activities permitted and restricted
  - d. Lists symptoms that should be reported to health care personnel
  - e. Keeps follow-up appointments

## OTOSCLEROSIS

**Otosclerosis** involves the stapes and is thought to result from the formation of new, abnormal spongy bone, especially around the oval window, with resulting fixation of the stapes. The efficient transmission of sound is prevented because the stapes cannot vibrate and carry the sound as conducted from the malleus and incus to the inner ear. More common in women and frequently hereditary, otosclerosis may be worsened by pregnancy.

### Clinical Manifestations

The condition can involve one or both ears and manifests as a progressive conductive or mixed hearing loss. The patient may or may not complain of tinnitus. Otoscopic examination usually reveals a normal tympanic membrane. Bone conduction is better than air conduction on Rinne testing. The audiogram confirms conductive hearing loss or mixed loss, especially in the low frequencies.

### Medical Management

There is no known nonsurgical treatment for otosclerosis. However, some physicians believe the use of Florical (a fluoride supplement) can mature the abnormal spongy bone growth. Amplification with a hearing aid also may help.

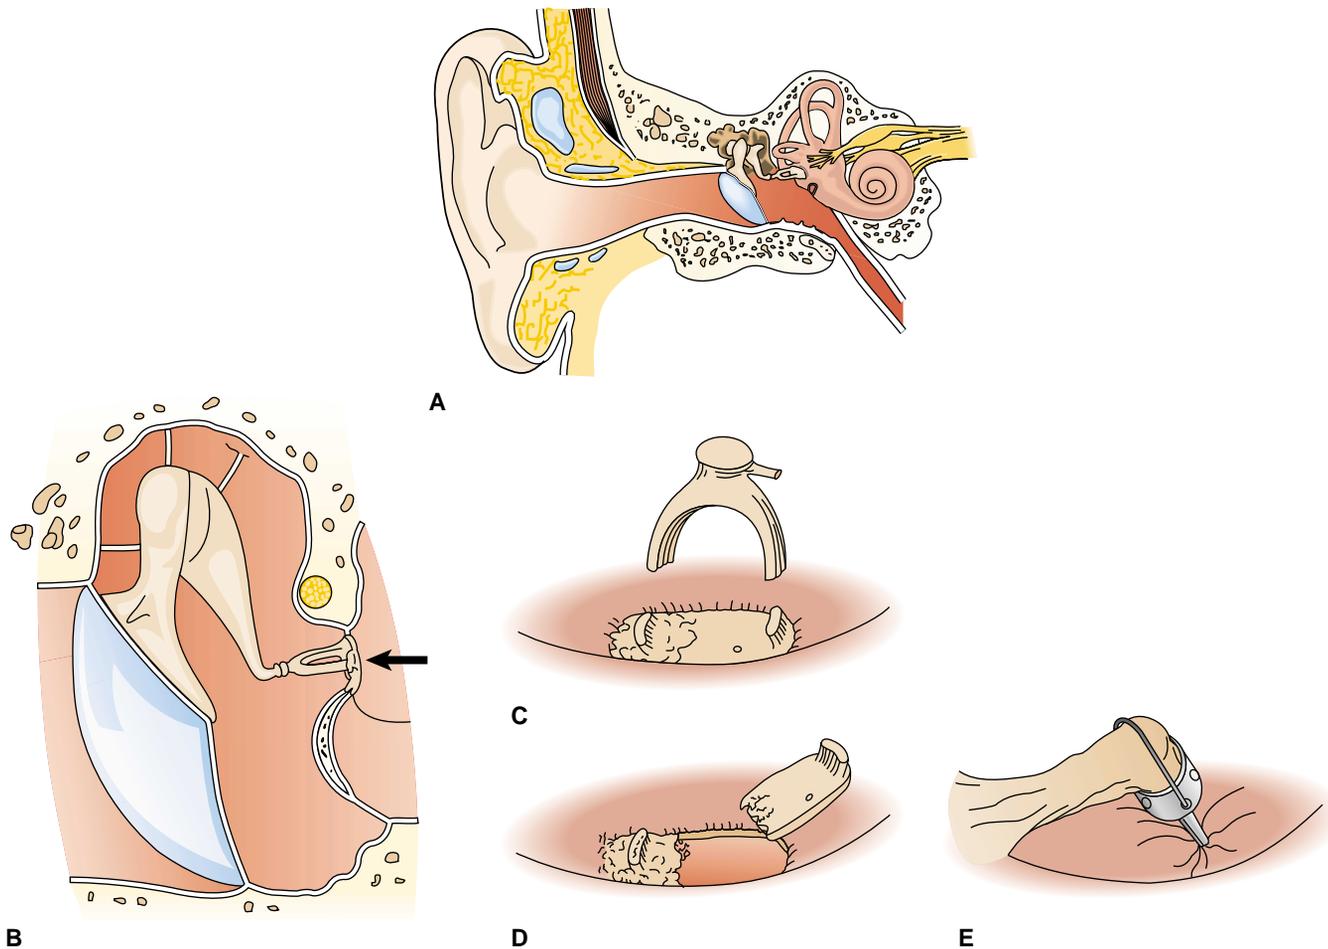

### SURGICAL MANAGEMENT

A stapedectomy, performed through the canal, involves removing the stapes superstructure and part of the footplate and inserting a tissue graft and a suitable prosthesis (Fig. 59-8). Some surgeons elect to remove only a small part of the stapes footplate (ie, stapedotomy). Regardless of the method used, the prosthesis bridges the gap between the incus and the inner ear, providing better sound conduction. Stapes surgery is very successful in improving hearing. Balance disturbance or true vertigo, which rarely occurs in other middle ear surgical procedures, can occur for a short time after stapedectomy.

## MIDDLE EAR MASSES

Other than cholesteatoma, masses in the middle ear are rare. Glomus jugulare is a tumor that arises from the jugular bulb. A histologically identical tumor that arises from Jacobson's nerve and remains limited to the middle ear is known as a glomus tympanicum. On otoscopy, a red blemish on or behind the tympanic membrane is indicative of a glomus tumor. The treatment for glomus tumors is surgical excision, except in poor surgical candidates, in whom radiation therapy is used.

A facial nerve neuroma is a tumor on cranial nerve VII, the facial nerve. These types of tumors are usually not visible on otoscopic examination but are suspected when a patient presents with a facial nerve paresis. X-ray evaluation is necessary to determine

**FIGURE 59-8** Stapedectomy for otosclerosis. (A) Normal anatomy. (B) Arrow points to sclerotic process at the foot of the stapes. (C) Stapes broken away surgically from its diseased base. The hole in the footplate provides an area where an instrument can grasp the plate. (D) The footplate is removed from its base. Some otosclerotic tissue may remain, and tissue is placed over it. (E) Robinson stainless-steel prosthesis in position.

the site of the tumor along the facial nerve. The treatment is surgical removal.

Other less common problems of the middle ear include cholesterol granuloma and tympanosclerosis. Cholesterol granuloma is an immune system reaction to the byproducts of blood (ie, cholesterol crystals) within the middle ear. Tympanosclerosis is a deposit of collagen and minerals within the middle ear that can harden around the ossicles as a result of repeated infections. It can also be found as plaque on the tympanic membrane; this can decrease hearing.

## Conditions of the Inner Ear

Disorders of balance and the vestibular system involving the inner ear afflict more than 30 million Americans 17 years of age or older. Falls resulting from these disorders account for more than 100,000 hip fractures in elderly people each year (NIDCD, 1998).

The term **dizziness** is used frequently by patients and health care providers to describe any altered sensation of orientation in space. **Vertigo** is defined as the misperception or illusion of motion of the person or the surroundings. Most people with vertigo describe a spinning sensation or say they feel as though objects are moving around them. Ataxia is a failure of muscular coordination

and may be present in patients with vestibular disease. Syncope, fainting, and loss of consciousness are not forms of vertigo, nor are they characteristic of an ear problem; they usually indicate disease in the cardiovascular system.

**Nystagmus** is an involuntary rhythmic movement of the eyes. Nystagmus occurs normally when a person watches a rapidly moving object (eg, through the side window of a moving car or train). However, pathologically it is an ocular disorder associated with vestibular dysfunction. Nystagmus can be horizontal, vertical, or rotary and can be caused by a disorder in the central or peripheral nervous system.

## MOTION SICKNESS

Motion sickness is a disturbance of equilibrium caused by constant motion. For example, it can occur aboard a ship, while riding on a merry-go-round or swing, or in the back seat of a car.

## Clinical Manifestations

The syndrome manifests itself in sweating, pallor, nausea, and vomiting caused by vestibular overstimulation. These manifestations may persist for several hours after the stimulation stops.

## Management

Over-the-counter antihistamines used to treat vertigo, such as dimenhydrinate (Dramamine) or meclizine hydrochloride (Bonine), provide some relief. Anticholinergic medications, such as scopolamine patches, may be helpful. These must be replaced every few days. Side effects such as dry mouth and drowsiness occur with these medications, which may prove to be more troublesome than helpful. Potentially hazardous activities such as driving a car or operating heavy machinery should be avoided if the patient experiences drowsiness.

## MÉNIÈRE'S DISEASE

Ménière's disease is an abnormal inner ear fluid balance caused by a malabsorption in the endolymphatic sac. Evidence indicates that many people with Ménière's disease may have a blockage in the endolymphatic duct. Regardless of the cause, **endolymphatic hydrops**, a dilation in the endolymphatic space, develops. Either increased pressure in the system or rupture of the inner ear membranes occurs, producing symptoms of Ménière's disease.

Ménière's disease affects more than 2.4 million people in the United States. More common in adults, it has an average age of onset in the 40s, with symptoms usually beginning between the ages of 20 and 60 years. However, the disease has been reported in children as young as age 4 years and in adults up to the 90s. Ménière's disease appears to be equally common in both genders. The right and left ears are affected with equal frequency; the disease occurs bilaterally in about 20% of patients. About 20% of the patients have a positive family history for the disease (Knox & McPherson, 1997).

## Clinical Manifestations

Ménière's disease involves the following symptoms: fluctuating, progressive sensorineural hearing loss; **tinnitus** or a roaring sound; a feeling of pressure or fullness in the ear; and episodic, incapacitating vertigo, often accompanied by nausea and vomiting. The effects of these symptoms range from a minor nuisance to extreme disability, especially if the attacks of vertigo are severe. At the onset of the disease, perhaps only one or two of the symptoms are manifested.

Some clinicians believe that there are two subsets of the disease, known as atypical Ménière's disease: cochlear and vestibular. Cochlear Ménière's disease is recognized as a fluctuating, progressive sensorineural hearing loss associated with tinnitus and aural pressure in the absence of vestibular symptoms or findings. Vestibular Ménière's disease is characterized as the occurrence of episodic vertigo associated with aural pressure but no cochlear symptoms. In some patients, cochlear or vestibular Ménière's disease develops first. In most patients, however, all of the symptoms develop eventually.

## Assessment and Diagnostic Findings

Vertigo is usually the most troublesome complaint. A careful history is taken to determine the frequency, duration, severity, and character of the vertigo attacks. Typically, the patient reports that vertigo lasts minutes to hours, possibly accompanied by nausea or vomiting. Patients also complain of diaphoresis and a persistent feeling of imbalance or disequilibrium, which may last for days. They may complain of attacks that awaken them at night. Between attacks, however, they usually feel well. The hearing loss may fluctuate, with tinnitus and aural pressure waxing and wan-

ing with changes in hearing. The tinnitus and feeling of aural pressure may occur only during or before attacks, or they may be constant.

Findings of the physical examination are usually normal, with the exception of the evaluation of cranial nerve VIII. Sounds from a tuning fork (ie, Weber test) may lateralize to the ear opposite the hearing loss, the one affected with Ménière's disease. An audiogram typically reveals a sensorineural hearing loss in the affected ear. This can be in the form of a "Pike's Peak" pattern, which looks like a hill or mountain, or it may show a sensorineural loss in the low frequencies. As the disease progresses, the hearing loss increases. The electronystagmogram may be normal or may show reduced vestibular response. There is, however, no absolute diagnostic test.

## Medical Management

Most patients with Ménière's disease can be successfully treated with diet and medication therapy. Many patients can control their symptoms by adhering to a low-sodium (2,000 mg/day) diet. The amount of sodium is one of many factors that regulate the balance of fluid within the body. Sodium and fluid retention disrupts the delicate balance between endolymph and perilymph in the inner ear. Psychological evaluation may be indicated if the patient is anxious, uncertain, fearful, or depressed.

## PHARMACOLOGIC THERAPY

Pharmacologic therapy for Ménière's disease consists of antihistamines such as meclizine (Antivert), which suppress the vestibular system. Tranquilizers such as diazepam (Valium) may be used in acute instances to help control vertigo. Antiemetics such as promethazine (Phenergan) suppositories help control the nausea and vomiting and the vertigo because of their antihistamine effect. Diuretic therapy (eg, hydrochlorothiazide) sometimes relieves symptoms by lowering the pressure in the endolymphatic system. Intake of foods containing potassium (eg, bananas, tomatoes, oranges) is necessary if the patient takes a diuretic that causes potassium loss.

Vasodilators, such as nicotinic acid, papaverine hydrochloride (Pavabid), and methantheline bromide (Banthine), have no scientific basis for alleviating the symptoms, but they are often used in conjunction with other therapies.

## SURGICAL MANAGEMENT

Although most patients respond well to conservative therapy, some continue to have disabling attacks of vertigo. If these attacks reduce their quality of life, patients may elect to undergo surgery for relief. However, hearing loss, tinnitus, and aural fullness may continue, because the surgical treatment of Ménière's disease is aimed at eliminating the attacks of vertigo.

**Endolymphatic Sac Decompression.** Endolymphatic sac decompression, or shunting, theoretically equalizes the pressure in the endolymphatic space. A shunt or drain is inserted in the endolymphatic sac through a postauricular incision. This procedure is favored by many otolaryngologists as a first-line surgical approach to treat the vertigo of Ménière's disease because it is relatively simple and safe and can be performed on an outpatient basis.

**Middle and Inner Ear Perfusion.** Ototoxic medications, such as streptomycin or gentamicin, can be given to patients by infusion into the middle and inner ear. These medications are used to decrease vestibular function and decrease vertigo. The success rate

for eliminating vertigo is high, about 85%, but the risk of significant hearing loss is also high. This procedure of inner ear perfusion usually requires an overnight stay in the hospital. After the procedure, many patients have a period of imbalance that lasts several weeks.

**Intraotologic Catheters.** In an attempt to deliver medication directly to the inner ear, catheters are being developed to provide a conduit from the outer ear to the inner ear. The route of the catheter is from the external ear canal through or around the tympanic membrane and to the round window niche or membrane. Medicinal fluids can be placed against the round window for a direct route to the inner ear fluids.

Potential uses of these catheters include treatment for sudden hearing loss and various disorders causing intractable vertigo. Future applications may include tinnitus and slowly progressing sensorineural hearing loss. Intratympanic injections of ototoxic medications for round window membrane diffusion can be used to decrease vestibular function. Established surgical techniques can be used for the patient with vertigo who has not responded to medical or physical therapeutic modalities.

**Vestibular Nerve Section.** Vestibular nerve section provides the greatest success rate (approximately 98%) in eliminating the attacks of vertigo. It can be performed by a translabyrinthine approach (ie, through the hearing mechanism) or in a manner that can conserve hearing (ie, suboccipital or middle cranial fossa), depending on the degree of hearing loss. Most patients with incapacitating Ménière's disease have little or no effective hearing. Cutting the nerve prevents the brain from receiving input from the semicircular canals. This procedure requires a brief hospital stay. Nursing care for the patient with vertigo is presented in Plan of Nursing Care 59-1.

## LABYRINTHITIS

**Labyrinthitis**, an inflammation of the inner ear, can be bacterial or viral in origin. Although rare because of antibiotic therapy, bacterial labyrinthitis usually occurs as a complication of otitis media. The infection can enter the inner ear by penetrating the membranes of the oval or round windows. Viral labyrinthitis is a common medical diagnosis, but little is known about this disorder, which affects hearing and balance. The most commonly identified viral causes are mumps, rubella, rubeola, and influenza. Viral illnesses of the upper respiratory tract and herpetiform disorders of the facial and acoustic nerves (ie, Ramsay Hunt syndrome) also cause labyrinthitis.

## Clinical Manifestations

Labyrinthitis is characterized by a sudden onset of incapacitating vertigo, usually with nausea and vomiting, various degrees of hearing loss, and possibly tinnitus. The first episode is usually the worst; subsequent attacks, which usually occur over a period of several weeks to months, are less severe.

## Management

Treatment of bacterial labyrinthitis includes intravenous antibiotic therapy, fluid replacement, and administration of a vestibular suppressant, such as meclizine, and antiemetic medications. Treatment of viral labyrinthitis is tailored to the patient's symptoms.

## BENIGN PAROXYSMAL POSITIONAL VERTIGO

Benign paroxysmal positional vertigo (BPPV) is a brief period of incapacitating vertigo that occurs when the position of the patient's head is changed with respect to gravity, typically by placing the head back with the affected ear turned down. The onset is sudden and followed by a predisposition for positional vertigo, usually for hours to weeks but occasionally for months or years.

It is speculated to be caused by the disruption of debris within the semicircular canal. This debris is formed from small crystals of calcium carbonate from the inner ear structure, the utricle. This is frequently stimulated by head trauma, infection, or other events. In severe cases, vertigo may easily be induced by any head movement. The vertigo is usually accompanied by nausea and vomiting; however, hearing impairment does not generally occur (Hain, 2002).

Bed rest is recommended for patients with acute symptoms. Canalith repositioning procedures (CRP) may be used to provide resolution of vertigo. The Epley procedure is a repositioning technique that is safe, inexpensive, and easy to perform for these patients. However, this procedure is not recommended for patients with acute vertigo or for patients diagnosed with vestibular neuronitis (a paroxysmal attack of severe vertigo).

Patients with acute vertigo may be medicated with meclizine for 1 to 2 weeks. After this time, the meclizine is stopped and the patient is reassessed. Patients who continue to have severe positional vertigo may be premedicated with prochlorperazine (Compazine) 1 hour before performing the CRP. The Dix-Hallpike test is used to assess for BPPV. When the Dix-Hallpike test results are positive on the right side, a left-sided CRP is used (Fig. 59-9).

Vestibular rehabilitation can be used in the management of vestibular disorders. This strategy promotes active use of the vestibular system through a multidisciplinary team approach, including medical and nursing care, stress management, biofeedback, vocational rehabilitation, and physical therapy. A physical therapist prescribes balance exercises that help the brain compensate for the impairment to the balance system.

## OTOTOXICITY

A variety of medications may have adverse effects on the cochlea, vestibular apparatus, or cranial nerve VIII. All but a few, such as aspirin and quinine, cause irreversible hearing loss. At high doses, aspirin toxicity also can produce tinnitus. Intravenous medications, especially the aminoglycosides, are the most common cause of ototoxicity, and they destroy the hair cells in the organ of Corti (see Chart 59-6).

To prevent loss of hearing or balance, patients receiving potentially ototoxic medications should be counseled about the side effects of these medications. Blood levels of the medications should be monitored and patients receiving long-term intravenous antibiotics should be monitored with an audiogram twice each week during therapy.

## ACOUSTIC NEUROMA

An acoustic neuroma is a slow-growing, benign tumor of cranial nerve VIII, usually arising from the Schwann cells of the vestibular portion of the nerve. Most acoustic tumors arise within the internal auditory canal and extend into the cerebellopontine angle to press on the brain stem. Acoustic neuromas account for 5% to 10% of all intracranial tumors and seem to occur with equal frequency in men and women at any age, although most occur during

*(text continues on page 1812)*

## Plan of Nursing Care

### Care of the Patient With Vertigo

#### Nursing Interventions

#### Rationale

#### Expected Patient Outcomes

**Nursing Diagnosis:** Risk for injury related to altered mobility because of gait disturbance and vertigo

**Goal:** Remains free of any injuries associated with imbalance and/or falls

1. Assess for vertigo, including history, onset, description of attacks, duration, frequency, and any associated ear symptoms (hearing loss, tinnitus, aural fullness).	1. History provides basis for interventions.	<ul style="list-style-type: none"> <li>Experiences no falls due to balance disturbance</li> <li>Fear and anxiety are reduced</li> <li>Performs exercises as prescribed</li> </ul>
2. Assess extent of disability in relation to activities of daily living.	2. Extent of disability indicates risk of falling.	<ul style="list-style-type: none"> <li>Takes prescribed medications appropriately</li> <li>Assumes safe position when vertigo is present</li> </ul>
3. Teach or reinforce vestibular/balance therapy as prescribed.	3. Exercises hasten labyrinthine compensation, which may decrease vertigo and gait disturbance.	<ul style="list-style-type: none"> <li>Keeps head still when vertigo is present</li> <li>Identifies a characteristic fullness or sense of pressure in the ear as occurring before a full-blown attack</li> </ul>
4. Administer, or teach administration of, antivertiginous medications and/or vestibular sedation medication; instruct patient about side effects.	4. Alleviates acute symptoms of vertigo	<ul style="list-style-type: none"> <li>Reports measures that help reduce vertigo</li> </ul>
5. Encourage patient to sit down when dizzy.	5. Decreases possibility of falling and injury	
6. Place pillow on each side of head to restrict movement.	6. Movement aggravates vertigo.	
7. Assist patient in identifying aura that suggests an impending attack.	7. Recognition of aura may trigger the need to take medication before an attack occurs, thereby minimizing the severity of effects.	
8. Recommend that the patient keep eyes open and stare straight ahead when lying down and experiencing vertigo.	8. Sensation of vertigo decreases and motion decelerates if eyes are kept in a fixed position.	

**Nursing Diagnosis:** Impaired adjustment related to disability requiring change in lifestyle due to unpredictability of vertigo

**Goal:** Modifies lifestyle to decrease disability and exert maximum control and independence within limits posed by chronic vertigo

1. Encourage patient to identify personal strengths and roles that can still be fulfilled.	1. Maximizes sense of regaining control and independence	<ul style="list-style-type: none"> <li>Exerts maximum control of environment and independence within limits imposed by vertigo</li> </ul>
2. Provide information about vertigo and what to expect.	2. Reduces fear and anxiety	<ul style="list-style-type: none"> <li>Is informed about condition</li> </ul>
3. Include family and significant others in rehabilitative process.	3. Perceived beliefs of significant others are important for patient's adherence to medical regimen.	<ul style="list-style-type: none"> <li>Family and significant others are included in rehabilitation process</li> </ul>
4. Encourage patient to maintain sense of control by making decisions and assuming more responsibility for care.	4. Reinforces positive psychological and social outcomes	<ul style="list-style-type: none"> <li>Uses strengths and potentials to engage in the most independent and constructive lifestyle</li> </ul>

**Nursing Diagnosis:** Risk for deficient fluid volume related to increased fluid output, altered intake, and medications

**Goal:** Maintains a normal fluid-electrolyte balance

1. Assess, or have patient assess, intake and output (including emesis, liquid stools, urine, and diaphoresis). Monitor laboratory values.	1. Accurate records provide basis for fluid replacement.	<ul style="list-style-type: none"> <li>Laboratory values within normal limits</li> <li>Alert and oriented; vital signs within normal limits, skin turgor normal; electrolytes normal</li> </ul>
2. Assess indicators of dehydration, including blood pressure (orthostasis), pulse, skin turgor, mucous membranes, and level of consciousness.	2. Prompt recognition of dehydration allows early intervention.	<ul style="list-style-type: none"> <li>Mucous membranes are moist</li> <li>Vomiting or diarrhea has stopped; usual oral intake resumed</li> </ul>

(continued)

## Plan of Nursing Care

### Care of the Patient With Vertigo (Continued)

Nursing Interventions	Rationale	Expected Patient Outcomes
3. Encourage oral fluids as tolerated; discourage beverages containing caffeine (a vestibular stimulant). 4. Administer, or teach administration of, antiemetics and antidiarrheal medication as prescribed and needed. Instruct patient in side effects.	3. Oral replacement is begun as soon as possible to replace losses. Caffeine may increase diarrhea. 4. Antiemetics reduce nausea and vomiting, reducing fluid losses and improving oral intake. Antidiarrheal medication reduces intestinal motility and fluid losses.	
<b>Nursing Diagnosis:</b> Anxiety related to threat of, or change in, health status and disability effects of vertigo <b>Goal:</b> Experiences less or no anxiety		
1. Assess level of anxiety. Help patient identify coping skills used successfully in the past. 2. Provide information about vertigo and its treatment. 3. Encourage patient to discuss anxieties and explore concerns about vertigo attacks. 4. Teach patient stress management techniques or make appropriate referral. 5. Provide comfort measures and avoid stress-producing activities. 6. Instruct patient in aspects of treatment regimen.	1. Guides therapeutic interventions and participation in self-care. Past coping skills can relieve anxiety. 2. Increased knowledge helps to decrease anxiety. 3. Promotes awareness and understanding of relationship between anxiety level and behavior 4. Improved stress management can reduce the frequency and severity of some vertiginous attacks. 5. Stressful situations may exacerbate symptoms of the condition. 6. Patient knowledge helps to decrease anxiety.	<ul style="list-style-type: none"> <li>• Fear and anxiety about attacks of vertigo reduced or eliminated</li> <li>• Acquires knowledge and skills to deal with vertigo</li> <li>• Feels less tension, apprehension, and uncertainty</li> <li>• Uses stress management techniques when needed</li> <li>• Avoids upsetting encounters</li> <li>• Repeats instructions given and verbalizes understanding of treatments</li> </ul>
<b>Nursing Diagnosis:</b> Risk for trauma related to impaired balance <b>Goal:</b> Reduces the risk of trauma by adapting the home environment and by using rehabilitative devices as necessary		
1. Assess for balance disturbance and/or vertigo by taking history and by examination for nystagmus, positive Romberg, and inability to perform tandem Romberg. 2. Assist with ambulation when indicated. 3. Assess for visual acuity and proprioceptive deficits. 4. Encourage increased activity level with or without use of assistive devices. 5. Help identify hazards in home environment.	1. Peripheral vestibular disorders cause these signs and symptoms. 2. Abnormal gait can predispose patient to unsteadiness and falls. 3. Balance depends on visual, vestibular, and proprioceptive systems. 4. Increased activity may help retrain balance system. 5. Adaptation of home environment can reduce risk of falls during rehabilitative process.	<ul style="list-style-type: none"> <li>• Has adapted home environment or uses rehabilitative devices to reduce risk of falling</li> <li>• Ambulates with needed assistance</li> <li>• Visual and proprioceptive risks identified</li> <li>• Activity level increased</li> <li>• Home environment free of hazards</li> </ul>
<b>Nursing Diagnosis:</b> Ineffective coping related to personal vulnerability and disabling effects of vertigo <b>Goal:</b> Develops coping skills necessary to decrease vulnerability and unmet needs and demonstrates effective coping		
1. Assess cognitive appraisal of illness and factors that may be contributing to inability to cope. 2. Provide factual information about treatment and future health status.	1. To improve patient's self-image and to enhance coping process 2. To clarify any misinformation or confusion	<ul style="list-style-type: none"> <li>• Copes effectively with vertigo</li> <li>• Has acquired knowledge and skills to cope with vertigo</li> <li>• Verbalizes less threatening appraisal of situation</li> </ul>

(continued)

## Plan of Nursing Care

### Care of the Patient With Vertigo (Continued)

Nursing Interventions	Rationale	Expected Patient Outcomes
-----------------------	-----------	---------------------------

- |  |   |  |
|--|---|--|
| <ol style="list-style-type: none"> <li>Encourage and help patient to participate in decision making about adjustments in lifestyle.</li> <li>Encourage patient to maintain diversional or recreational activities, exercise, and social events.</li> <li>Help patient identify personal strengths and develop coping strategies based on previous positive experiences in dealing with stress, and situational supports.</li> <li>Refer patient to support groups or counseling as indicated.</li> </ol> | <ol style="list-style-type: none"> <li>To help patient regain sense of power and control in self-care with activities of daily living</li> <li>Social isolation and avoiding pleasant activities intensify isolation and reduce ability to cope with vertigo.</li> <li>To enhance patient's strengths that help maintain hope</li> <li>May help patient feel less alone and isolated</li> </ol> | <ul style="list-style-type: none"> <li>Is involved in outside activities</li> <li>Identifies specific strategies for coping</li> <li>Uses support groups or counseling as appropriate</li> </ul> |

**Goal:** Experiences increased sense of control over life and activities despite vertigo/balance disturbance

- |  |   |  |
|--|---|--|
| <ol style="list-style-type: none"> <li>Assess patient's needs, values, attitudes, and readiness to initiate activities.</li> <li>Provide opportunities for patient to express feelings about self and illness.</li> <li>Help patient identify previous coping behaviors that were successful.</li> </ol> | <ol style="list-style-type: none"> <li>Involving patient in planning activities and care enhances potential for mastery.</li> <li>Expressing feelings increases understanding of individual coping styles and defense mechanisms.</li> <li>Awareness increases understanding of stressors that trigger feeling of powerlessness. Awareness of past successes enhances self-confidence.</li> </ol> | <ul style="list-style-type: none"> <li>Does not restrict activities unnecessarily due to vertigo</li> <li>Verbalizes positive feelings about own ability to achieve a sense of power and control</li> <li>Identifies previous successful coping behaviors</li> </ul> |
|--|---|--|

**FIGURE 59-9** The Dix-Hallpike maneuver is the test used to assess for benign paroxysmal positional vertigo (BPPV). (A) The patient sits on the examination table with the head turned to the left at a 45-degree angle. (B) The patient is lowered quickly to a supine position with the head turned to one side and slightly lower than the head of the examination table. The patient's eyes should remain open so that the examiner can observe for nystagmus. If the patient has BPPV, vertigo occurs within 5 to 10 seconds and lasts about 30 seconds. Rotary nystagmus and dizziness also occur. The procedure is repeated on the opposite side. Vertigo occurs when the affected ear faces toward the ground.

middle age. Most acoustic neuromas are unilateral, except in von Recklinghausen's disease (ie, neurofibromatosis type 2), in which bilateral tumors occur.

### Assessment and Diagnostic Findings

The most common findings of assessment of patients with an acoustic neuroma are unilateral tinnitus and hearing loss with or without vertigo or balance disturbance. It is important to identify asymmetry in audiovestibular test results so that further

workup can be performed to rule out an acoustic neuroma. MRI with a paramagnetic contrast agent (ie, gadolinium or Magnevist) is the imaging study of choice. If the patient is claustrophobic or cannot tolerate an MRI or if the scan is unavailable, a computed tomography (CT) scan with contrast dye is performed. However, MRI is more sensitive in delineating a small tumor than is CT.

### Management

Surgical removal of acoustic tumors is the treatment of choice because these tumors do not respond well to irradiation or chemotherapy. Because treatment of acoustic tumors crosses several specialties, the multidisciplinary treatment approach involves a neurotologist and a neurosurgeon. The objective of the surgery is to remove the tumor while preserving facial nerve function. Most acoustic tumors have damaged the cochlear portion of cranial nerve VIII, and no serviceable hearing exists before surgery. In these patients, the surgery is performed using a translabyrinthine approach, and the hearing mechanism is destroyed. If hearing is still good before surgery, a suboccipital or middle cranial fossa approach to removing the tumor may be used, and intraoperative monitoring of cranial nerve VIII is performed to save the hearing.

Complications of surgery for acoustic neuroma include facial nerve paralysis, cerebrospinal fluid leak, meningitis, and cerebral edema. Death from acoustic neuroma surgery is rare.

### Aural Rehabilitation

If hearing loss is permanent or cannot be treated by medical or surgical means or if the patient elects not to undergo surgery, aural rehabilitation may be beneficial. The purpose of aural rehabilitation is to maximize the hearing-impaired person's communication skills. Aural rehabilitation includes auditory training, speech reading, speech training, and the use of hearing aids and hearing guide dogs.

Auditory training emphasizes listening skills, so the hearing-impaired person concentrates on the speaker. Speech reading (formerly known as lip reading) can help fill the gaps left by missed or misheard words. Speech training attempts to conserve, develop, and prevent deterioration of current skills.

It is important to identify the type of hearing impairment a person has so that rehabilitative efforts can be directed at his or her particular need. Surgical correction may be all that is necessary to treat and improve a conductive hearing loss (Fig. 59-10). With advances in hearing aid technology, amplification for patients with sensorineural hearing loss is more helpful than ever before.

### HEARING AIDS

A hearing aid is a device through which speech and environmental sounds are received by a microphone, converted to electrical signals, amplified, and reconverted to acoustic signals. Many aids available for sensorineural hearing loss depress the low frequencies, or tones, and enhance hearing for the high frequencies. A general guideline for assessing the patient's need for a hearing aid is a hearing loss exceeding 30 dB in the range of 500 to 2000 Hz in the better-hearing ear.

The evolution in technology has led to the availability of many smaller and more effective hearing aids. It is estimated that 98% of all hearing aids sold today are behind-the-ear, in-the-ear, or in-the-canal types (Table 59-4).

A hearing aid should be fitted according to the patient's needs (eg, type of hearing loss, manual dexterity), rather than the brand

**Chart 59-6 • PHARMACOLOGY**

**Selected Ototoxic Substances**

**Diuretics:** ethacrynic acid, furosemide, acetazolamide

**Chemotherapeutic agents:** cisplatin, nitrogen mustard

**Antimalarial agents:** quinine, chloroquine

**Anti-inflammatory agents:** salicylates (aspirin), indomethacin

**Chemicals:** alcohol, arsenic

**Aminoglycoside antibiotics:** amikacin, gentamicin, kanamycin, netilmicin, neomycin, streptomycin, tobramycin

**Other antibiotics:** erythromycin, minocycline, polymyxin B, vancomycin

**Metals:** gold, mercury, lead

**FIGURE 59-10** Management flow chart for conductive hearing loss. The flow chart indicates how the diagnosis determines the management of the patient and predicts the outcome. From Jafek, B. W. & Balkany, T. J. Conductive hearing loss. In B. Eiseman (Ed.). *Prognosis of surgical disease*. Philadelphia: W. B. Saunders.

name, by a certified audiologist licensed to dispense hearing aids. Many states have a consumer protection law that allows the hearing aid to be returned after a trial use if the patient is not completely satisfied.

A hearing aid makes sounds louder, but it does not improve a patient's ability to discriminate words or understand speech. People

who have low discrimination scores (ie, 20%) on audiograms may derive little benefit from a hearing aid. Hearing aids amplify all sounds, including background noise, which may be disturbing to the wearer. Chart 59-7 identifies additional problems associated with hearing aid use. There are, however, computerized hearing aids available that compensate for background noise or allow

**Table 59-4 • Hearing Aids**

SITE (AND RANGE OF HEARING LOSS)	ADVANTAGES	DISADVANTAGES
Body (mild–profound)	Separation of receiver and microphone prevents acoustic feedback, allowing high amplification. Generally used in a school setting.	Bulky; requires long wire, which may be cosmetically displeasing; some loss of high-frequency response
Behind the ear (mild–profound)	Larger size permits use of larger components that enable the aid to provide more power and features; most versatile due to size; no long wires	Large size
In the ear (mild–moderately severe)	One-piece custom fit to contour of ear; no tubes or cords; miniature microphone is located in the ear, which is a more natural placement; more cosmetically appealing due to easy concealment	Smaller size limits output; patients who have arthritis or cannot perform tasks requiring good manual dexterity may have difficulty with the small size of aid and/or battery; can require more repair than the behind-the-ear aid
In the canal (mild–moderately severe)	Same as in-the-ear aids; less visible, so more cosmetically pleasing	Even smaller than in-the-ear aids; requires good manual dexterity

Ear tumor  
Unrelated conditions of the temporomandibular joint, throat, or larynx

amplification at certain programmed frequencies rather than at all frequencies. Occasionally, depending on the type of hearing loss, binaural aids (ie, one for each ear) may be indicated. Chart 59-8 provides tips for hearing aid care.

To protect the health and safety of people with hearing impairments, the U.S. Food and Drug Administration (FDA) has established certain regulations. A medical evaluation of the impairment by a licensed physician must be obtained within 6 months before the purchase of a hearing aid. The written statement from a physician may be waived, however, if the patient (a fully informed adult 18 years of age or older) signs a document to this effect.

**Chart 59-8 • PATIENT EDUCATION**  
**Tips for Hearing Aid Care****Cleaning**

The ear mold is the only part of the hearing aid that may be washed frequently (even daily if necessary) with soap and water. The ear mold must be dry before it is snapped into the receiver. The canula is cleaned with a small pipe cleaner–like device.

**Malfunctioning**

Inadequate amplification, a whistling noise, or pain from the mold can occur when a hearing aid is not functioning properly. Check for malfunctions: Is the switch on? Are the batteries charged and positioned correctly? If the hearing aid still does not work properly, the hearing aid dealer should be notified. If the unit requires extended time for repair, the dealer may lend the patient a hearing aid until the repair can be accomplished.

**Recognizing Complications**

When occluded by a hearing aid, the external auditory canal can become moist. Common medical problems among hearing aid wearers include external otitis and pressure ulcers in the external auditory canal or meatus.

Children must be evaluated by a physician. Health care professionals who dispense hearing aids are required to refer prospective users to a physician if any of the following otologic conditions are evident:

- Visible congenital or traumatic deformity of the ear
- Active drainage from the ear within the previous 90 days
- Sudden or rapidly progressive hearing loss within the previous 90 days
- Complaints of dizziness or tinnitus
- Unilateral hearing loss that occurred suddenly or within the previous 90 days
- Audiometric air–bone gap of 15 dB or more at 500, 1000, and 2000 Hz
- Significant accumulation of cerumen or a foreign body in the external auditory canal
- Pain or discomfort in the ear

A user instruction brochure is to accompany every hearing aid device. In this brochure, the following information is presented:

- Specification that good health practice requires a medical evaluation before purchasing a hearing aid
- Notification that any of the eight otologic conditions previously listed should be investigated by a physician before purchase of a hearing aid
- Instructions for proper use, maintenance, and care of the hearing aid, as well as instructions for replacing or recharging the batteries
- Repair service information
- Description of avoidable conditions that could damage the hearing aid
- List of any known side effects that may warrant physician consultation (eg, skin irritation, accelerated cerumen accumulation)

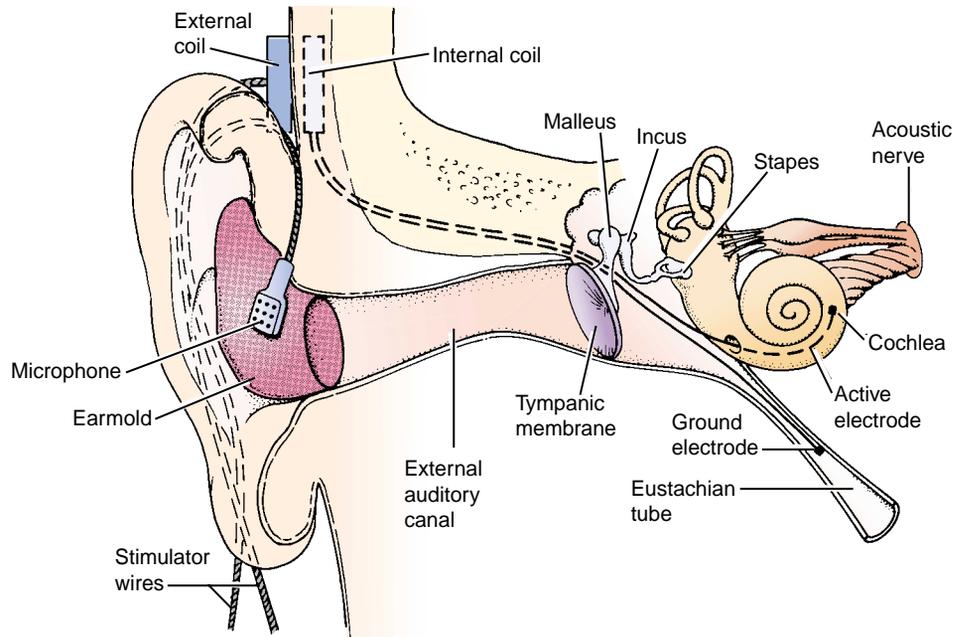

**IMPLANTED HEARING DEVICES**

Three types of implanted hearing devices are commercially available or in the investigational stage: the cochlear implant, the bone conduction device, and the semi-implantable hearing device. Cochlear implants are for patients with little or no hearing. Bone conduction devices, which transmit sound through the skull to the inner ear, are used in patients with a conductive hearing loss if a hearing aid is contraindicated (eg, those with chronic infection). The device is implanted postauricularly under the skin into the skull, and an external device—worn above the ear, not in the canal—transmits the sound through the skin. Semi-implantable hearing aids, although not yet approved by the FDA except in testing sites, still require the use of an external device. However, research to develop a fully implantable hearing aid continues.

**Cochlear Implant**

A cochlear implant is an auditory prosthesis used for people with profound sensorineural hearing loss bilaterally who do not benefit from conventional hearing aids. The hearing loss may be congenital or acquired. An implant does not restore normal hearing; rather, it helps the person detect medium to loud environmental sounds and conversation. The implant is designed to provide stimulation directly to the auditory nerve, bypassing the hair cells of the inner ear, which are not functioning. The microphone and signal processor are worn outside the body and transmit electrical stimuli inside the body to the implanted electrodes. The electrical signals stimulate the auditory nerve fibers and then the brain, where they are interpreted.

**FIGURE 59-11** The cochlear implant. The internal coil has a stranded electrode lead. The electrode is inserted through the round window into the scala tympani of the cochlea. The external coil (the transmitter) is held in alignment with the internal coil (the receiver) by a magnet. The microphone receives the sound. The stimulator wire receives the signal after it has been filtered, adjusted, and modified so that the sound is at a comfortable level for the patient. Sound is passed by the external transmitter to the inner coil receiver by magnetic conduction and is then carried by the electrode to the cochlea.

Candidates for a cochlear implant, who are usually at least 1 year old, are selected after careful screening by otologic history, physical examination, audiologic testing, x-rays, and psychological testing. Several criteria apply for choosing adults who may benefit from a cochlear implant:

- Profound sensorineural hearing loss in both ears
- Inability to hear and recognize speech well with hearing aids
- No medical contraindication to a cochlear implant or general anesthesia
- Indications that being able to hear would enhance the patient's life

The surgery involves implanting a small receiver in the temporal bone through a postauricular incision and placing electrodes into the inner ear (Fig. 59-11). The microphone and transmitter are worn on an external unit. The patient undergoes extensive cochlear rehabilitation with the multidisciplinary team, which includes an audiologist and speech pathologist. Several months may be needed to learn to interpret the sounds heard. Children and adults who lost their hearing before they learned to speak take much longer to acquire speech. There are wide variations of success with cochlear implants, and there is also controversy about their use, especially among the Deaf community. Patients who have had a cochlear implant are cautioned that an MRI will cause the implant to become inactivated; MRI is to be used only when unavoidable.

## HEARING GUIDE DOGS

Specially trained dogs are available to assist the person with a hearing loss. People who live alone are eligible to apply for a dog trained by International Hearing Dog, Inc. At home, the dog reacts to the sound of a telephone, a doorbell, an alarm clock, a baby's cry, a knock at the door, a smoke alarm, or an intruder. The dog does not bark but alerts its master by physical contact; the dog then runs to the source of the noise. In public, the dog positions itself between the hearing-impaired person and any potential hazard that the person cannot hear, such as an oncoming vehicle or a loud, hostile person. In many states, a hearing-impaired person with a certified hearing guide dog is legally permitted access to public transportation, public eating places, and stores, including food markets.

## Critical Thinking Exercises

1. An 82-year-old patient in an extended care facility appears withdrawn and distrustful of others. She does not participate in conversations with other residents. You suspect that she has a hearing loss. Describe the strategies you would use to assess this patient's hearing. What intervention strategies would you implement if your assessment confirms that the woman has a hearing loss? What intervention strategies would you implement if your assessment indicates that she does not have a hearing loss?
2. An antiemetic and a tranquilizer have been prescribed for a patient with Ménière's disease. You realize that safety precautions are indicated. Devise a teaching plan for this patient, and explain the reasons behind each part of the plan.
3. A teenage boy has decided to play the drums in a local band. The music consists of loud, hard rock music. The group practices for 2 to 3 hours each day, approximately 4 nights per week. Describe the teaching plan you would devise for this teenage boy, including rationale.
4. A patient presents with severe vertigo. She lives alone and is afraid of injuring herself because of her dizziness, which is unpredictable. Devise a teaching plan for this patient, including methods to prevent injury. Include interventions and outcomes that will address her fears and anxiety.
5. A patient with severe hearing loss is admitted for abdominal surgery to treat a bowel obstruction. It is anticipated that a colostomy will be created. Explain modifications in preoperative, intraoperative, and postoperative nursing care needed because of her impaired hearing.

# ● Assessment of Neurologic Function

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Describe the structures and functions of the central and peripheral nervous systems.
2. Differentiate between pathologic changes that affect motor control and those that affect sensory pathways.
3. Compare the functioning of the sympathetic and parasympathetic nervous systems.
4. Describe the significance of physical assessment to the diagnosis of neurologic dysfunction.
5. Describe changes in neurologic function associated with aging and their impact on neurologic assessment findings.
6. Describe diagnostic tests used for assessment of suspected neurologic disorders and the related nursing implications.

**N**urses in many types of practice settings encounter patients with altered neurologic function. Disorders of the nervous system can occur at any time during the life span and can vary from mild, self-limiting symptoms to devastating, life-threatening disorders. The nurse must be skilled in the assessment of the neurologic system whether the assessment is generalized or focused on specific areas of function. Assessment in either case requires knowledge of the anatomy and physiology of the nervous system and an understanding of the array of tests and procedures used to diagnose neurologic disorders. Knowledge about the nursing implications and interventions related to assessment and diagnostic testing is also essential.

## Anatomic and Physiologic Overview

The nervous system consists of two divisions: the central nervous system (CNS), including the brain and spinal cord, and the peripheral nervous system, made up of the cranial and spinal nerves. The peripheral nervous system can be further divided into the somatic, or voluntary, nervous system, and the autonomic, or involuntary, nervous system. The function of the nervous system is to control all motor, sensory, autonomic, cognitive, and behavioral activities. The nervous system has approximately 10 million sensory neurons that send information about the internal and external environment to the brain and 500,000 motor neurons that control the muscles and glands. The brain itself contains more than 20 billion nerve cells that link the motor and sensory pathways, monitor the body's processes, respond to the internal and external environment, maintain homeostasis, and direct all psychological, biologic, and physical activity through complex chemical and electrical messages (Bradley, Daroff, Fenichel & Marsden, 2000).

## ANATOMY OF THE NERVOUS SYSTEM

### Cells of the Nervous System

The basic functional unit of the brain is the neuron (Fig. 60-1). It is composed of a cell body, a dendrite, and an axon. The **dendrite** is a branch-type structure with synapses for receiving electrochemical messages. The **axon** is a long projection that carries

impulses away from the cell body. Nerve cell bodies occurring in clusters are called ganglia or nuclei. A cluster of cell bodies with the same function is called a center (eg, the respiratory center). Neuroglial cells, another type of nerve cell, support, protect, and nourish neurons.

### Neurotransmitters

Neurotransmitters communicate messages from one neuron to another or from a neuron to a specific target tissue. Neurotransmitters are manufactured and stored in synaptic vesicles. They enable conduction of impulses across the synaptic cleft. The neurotransmitter has an affinity for specific receptors in the postsynaptic bulb. When released, the neurotransmitter crosses the synaptic cleft and binds to receptors in the postsynaptic cell membrane. The action of a neurotransmitter is to potentiate, terminate, or modulate a specific action and can either excite or inhibit the target cell's activity. There are usually multiple neurotransmitters at work in the neural synapse. There are various types of neurotransmitters (Bradley et al., 2000; Hickey, 2003); major neurotransmitters are described in Table 60-1.

Many neurologic disorders are due, at least in part, to an imbalance in neurotransmitters—that is, a lack of gamma-aminobutyric acid (GABA) and acetylcholine in Huntington's disease (Bradley et al., 2000), low serotonin levels in some forms of epilepsy (Blows, 2000), and a decrease in dopamine in Parkinson's disease. In fact, probably all brain functions are modulated through neurotransmitter receptor site activity, including memory and other cognitive processes.

There are two types of receptors: direct and indirect. Direct receptors are also known as inotropic because they are linked to ion channels and allow passage of ions when opened. They can be excitatory or inhibitory and are rapid-acting (measured in milliseconds). Indirect receptors affect metabolic processes in the cell, which can take from seconds to hours to occur. Receptor sites are an expanding area of research because they are often the target for the action and development of new medications. These medications either block or stimulate neurotransmitters at receptor sites and thus provide relief from symptoms (Blows, 2000). Receptor sites are also sites for the action of addictive drugs.

## Glossary

**agnosia:** loss of ability to recognize objects through a particular sensory system; may be visual, auditory, or tactile

**ataxia:** inability to coordinate muscle movements, resulting in difficulty in walking, talking, and performing self-care activities

**autonomic nervous system:** division of the nervous system that regulates the involuntary body functions

**axon:** portion of the neuron that conducts impulses away from the cell body

**Babinski reflex (sign):** a reflex action of the toes, indicative of abnormalities in the motor control pathways leading from the cerebral cortex

**clonus:** abnormal movement marked by alternating contraction and relaxation of a muscle occurring in rapid succession

**delirium:** transient loss of intellectual function, usually due to systemic problems

**dendrite:** portion of the neuron that conducts impulses toward the cell body

**dysphagia:** difficulty swallowing

**flaccid:** displaying lack of muscle tone; limp, floppy

**myelography (myelogram):** x-ray study of the spinal cord after injection of a contrast agent into the subarachnoid space

**parasympathetic nervous system:** division of the autonomic nervous system active primarily during nonstressful conditions, controlling mostly visceral functions

**photophobia:** inability to tolerate light

**position (postural) sense:** awareness of position of parts of the body without looking at them; also referred to as proprioception

**rigidity:** increase in muscle tone at rest characterized by increased resistance to passive stretch

**reflex:** an automatic response to stimuli

**Romberg test:** test for cerebellar dysfunction requiring the patient to stand with feet together, eyes closed and arms extended; inability to maintain the position, with either significant stagger or sway, is a positive test

**spasticity:** sustained increase in tension of a muscle when it is passively lengthened or stretched

**sympathetic nervous system:** division of the autonomic nervous system with predominantly excitatory responses, the "fight-or-flight" system

**tone:** tension present in a muscle at rest

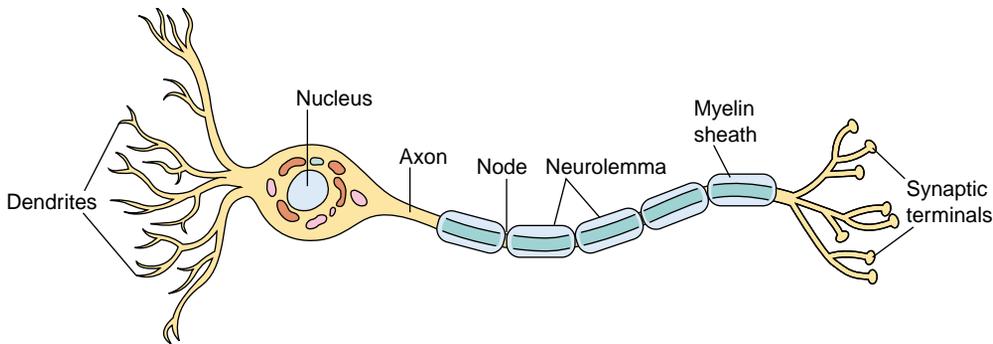

FIGURE 60-1 Neuron.

Another important area of ongoing research is diagnostic testing that can detect abnormal levels of neurotransmitters in the brain. Positron emission tomography (PET), for example, can detect dopamine, serotonin, and acetylcholine (Gjedde et al., 2001). Single photon emission computed tomography (SPECT) is similar to PET. Both PET and SPECT are discussed in more detail later in this chapter.

## The Central Nervous System

### ANATOMY OF THE BRAIN

The brain is divided into three major areas: the cerebrum, the brain stem, and the cerebellum. The cerebrum is composed of two hemispheres, the thalamus, the hypothalamus, and the basal ganglia. Additionally, connections for the olfactory (cranial nerve I) and optic (cranial nerve II) nerves are found in the cerebrum. The brain stem includes the midbrain, pons, medulla, and connections for cranial nerves III and IV through XII. The cerebellum is located under the cerebrum and behind the brain stem (Fig. 60-2). The brain accounts for approximately 2% of the total body weight; it weighs approximately 1,400 g in an average young adult (Hickey, 2003). In the elderly, the average brain weighs approximately 1,200 g.

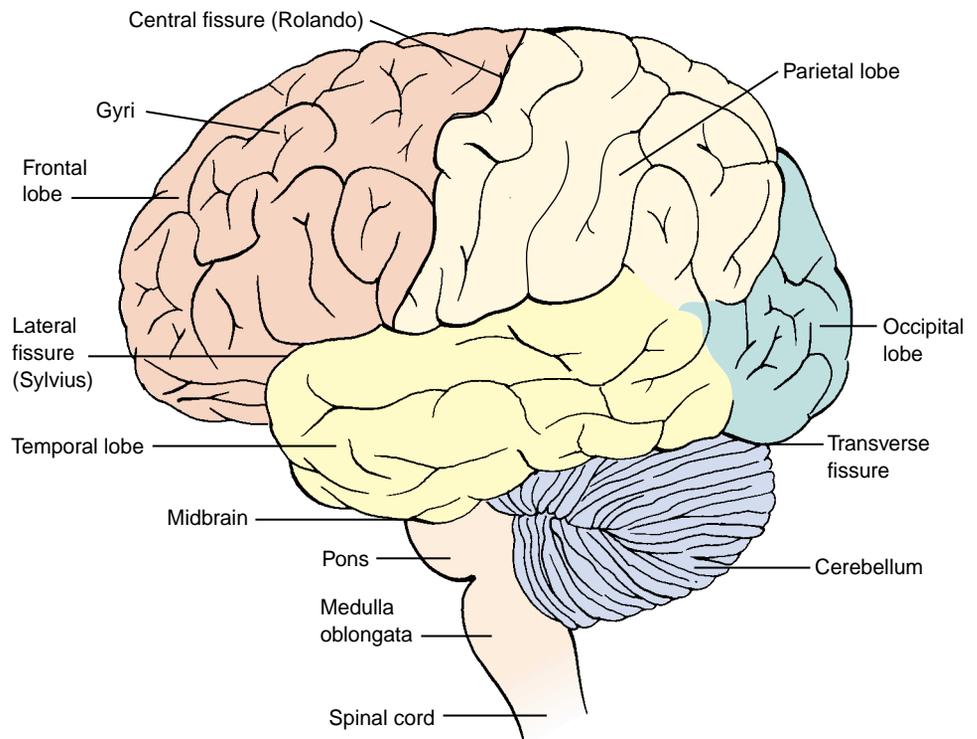

**Cerebrum.** The cerebrum consists of two hemispheres that are incompletely separated by the great longitudinal fissure. This sulcus separates the cerebrum into the right and left hemispheres. The two hemispheres are joined at the lower portion of the fis-

sure by the corpus callosum. The outside surface of the hemispheres has a wrinkled appearance that is the result of many folded layers or convolutions called gyri, which increase the surface area of the brain, accounting for the high level of activity carried out by such a small-appearing organ. The external or outer portion of the cerebrum (the cerebral cortex) is made up of gray matter approximately 2 to 5 mm in depth; it contains billions of neurons/cell bodies, giving it a gray appearance. White matter makes up the innermost layer and is composed of nerve fibers and neuroglia (support tissue) that form tracts or pathways connecting various parts of the brain with one another (transverse and association pathways) and the cortex to lower portions of the brain and spinal cord (projection fibers). The cerebral hemispheres are divided into pairs of frontal, parietal, temporal, and occipital lobes. The four lobes are as follows (see Fig. 60-2):

- **Frontal**—the largest lobe. The major functions of this lobe are concentration, abstract thought, information storage or memory, and motor function. It also contains Broca's area, critical for motor control of speech. The frontal lobe is also responsible in large part for an individual's affect, judgment, personality, and inhibitions.
- **Parietal**—a predominantly sensory lobe. The primary sensory cortex, which analyzes sensory information and relays the interpretation of this information to the thalamus and other cortical areas, is located in the parietal lobe. It is also essential to an individual's awareness of the body in space, as well as orientation in space and spatial relations.

Table 60-1 • Major Neurotransmitters

NEUROTRANSMITTER	SOURCE	ACTION
Acetylcholine (major transmitter of the parasympathetic nervous system)	Many areas of the brain; autonomic nervous system	Usually excitatory; parasympathetic effects sometimes restrain (stimulation of heart by vagal nerve)
Serotonin	Brain stem, hypothalamus, dorsal horn of the spinal cord	Restraining, helps control mood and sleep, inhibits pain pathways
Dopamine	Substantia nigra and basal ganglia	Usually restrains, affects behavior (attention, emotions) and fine movement
Norepinephrine (major transmitter of the sympathetic nervous system)	Brain stem, hypothalamus, postganglionic neurons of the sympathetic nervous system	Usually excitatory; affects mood and overall activity
Gamma-aminobutyric acid (GABA)	Spinal cord, cerebellum, basal ganglia, some cortical areas	Excitatory amino acid
Enkephalin, endorphin	Nerve terminals in the spine, brain stem, thalamus and hypothalamus, pituitary gland	Excitatory; pleasurable sensation, inhibits pain transmission

**FIGURE 60-2** View of the external surface of the brain showing lobes, cerebellum, and brain stem.

- Temporal—contains the auditory receptive areas. Contains a vital area called the interpretive area that provides integration of somatization, visual, and auditory areas and plays the most dominant role of any area of the cortex in cerebration.
- Occipital—the posterior lobe of the cerebral hemisphere is responsible for visual interpretation.

The corpus callosum (Fig. 60-3) is a thick collection of nerve fibers that connects the two hemispheres of the brain and is responsible for the transmission of information from one side of the brain to the other. Information transferred includes sensation, memory, and learned discrimination. Right-handed people and some left-handed people have cerebral dominance on the left side of the brain for verbal, linguistic, arithmetical, calculating, and

analytic functions. The nondominant hemisphere is responsible for geometric, spatial, visual, pattern, and musical functions.

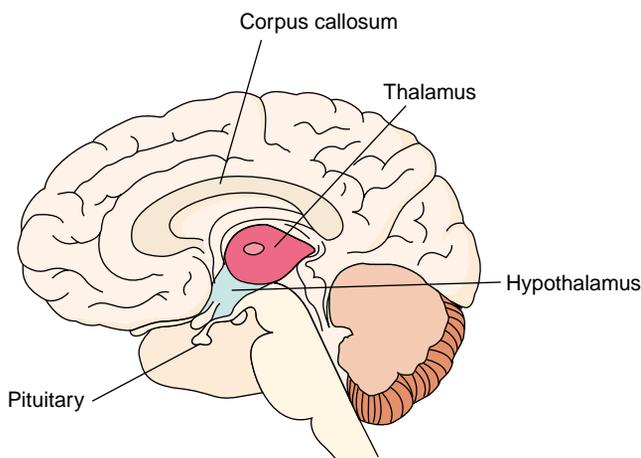

The basal ganglia are masses of nuclei located deep in the cerebral hemispheres that are responsible for control of fine motor movements, including those of the hands and lower extremities.

The thalamus (see Fig. 60-3) lies on either side of the third ventricle and acts primarily as a relay station for all sensation except smell. All memory, sensation, and pain impulses also pass through this section of the brain.

The hypothalamus is located anterior and inferior to the thalamus. The hypothalamus lies immediately beneath and lateral to the lower portion of the wall of the third ventricle. It includes the optic chiasm (the point at which the two optic tracts cross) and the mamillary bodies (involved in olfactory reflexes and emotional response to odors). The infundibulum of the hypothalamus connects it to the posterior pituitary gland. The hypothalamus plays an important role in the endocrine system because it regulates the pituitary secretion of hormones that influence metabolism, reproduction, stress response, and urine production. It works with the pituitary to maintain fluid balance and maintains temperature regulation by promoting vasoconstriction or vasodilatation.

The hypothalamus is the site of the hunger center and is involved in appetite control. It contains centers that regulate the sleep-wake cycle, blood pressure, aggressive and sexual behavior, and emotional responses (ie, blushing, rage, depression, panic, and fear). The hypothalamus also controls and regulates the autonomic nervous system.

The pituitary gland is located in the sella turcica at the base of the brain and is connected to the hypothalamus. The pituitary is a common site for brain tumors in adults; frequently they are detected by physical signs and symptoms that can be traced to the pituitary, such as hormonal imbalance or visual disturbances

**FIGURE 60-3** Medial view of the brain.

secondary to pressure on the optic chiasm (further information on brain tumors is found later in this unit in Chap. 65).

Nerve fibers from all portions of the cortex converge in each hemisphere and exit in the form of a tight bundle of nerve fibers known as the internal capsule. Having entered the pons and the medulla, each bundle crosses to the corresponding bundle from the opposite side. Some of these axons make connections with axons from the cerebellum, basal ganglia, thalamus, and hypothalamus; some connect with the cranial nerve cells. Other fibers from the cortex and the subcortical centers are channeled through the pons and the medulla into the spinal cord.

Although the various cells in the cerebral cortex are quite similar in appearance, their functions vary widely, depending on location. The topography of the cortex in relation to certain of its functions is shown in Figure 60-4. The posterior portion of each hemisphere (ie, the occipital lobe) is devoted to all aspects of visual perception. The lateral region, or temporal lobe, incorporates the auditory center. The midcentral zone, or parietal zone, posterior to the fissure of Rolando, is concerned with sensation; the anterior portion is concerned with voluntary muscle movements. The large area behind the forehead (ie, the frontal lobes) contains the association pathways that determine emotional attitudes and responses and contribute to the formation of thought processes. Damage to the frontal lobes as a result of trauma or disease is by no means incapacitating from the standpoint of muscular control or coordination, but it affects a person's personality, as reflected by basic attitudes, sense of humor and propriety, self-restraint, and motivations. (Neurologic trauma and disease states that may result in frontal damage are discussed in later chapters in this unit.)

**Brain Stem.** The brain stem consists of the midbrain, pons, and medulla oblongata (see Fig. 60-2). The midbrain connects the

pons and the cerebellum with the cerebral hemispheres; it contains sensory and motor pathways and serves as the center for auditory and visual reflexes. Cranial nerves III and IV originate in the midbrain. The pons is situated in front of the cerebellum between the midbrain and the medulla and is a bridge between the two halves of the cerebellum, and between the medulla and the cerebrum. Cranial nerves V through VIII connect to the brain in the pons. The pons contains motor and sensory pathways. Portions of the pons also control the heart, respiration, and blood pressure.

The medulla oblongata contains motor fibers from the brain to the spinal cord and sensory fibers from the spinal cord to the brain. Most of these fibers cross, or decussate, at this level. Cranial nerves IX through XII connect to the brain in the medulla.

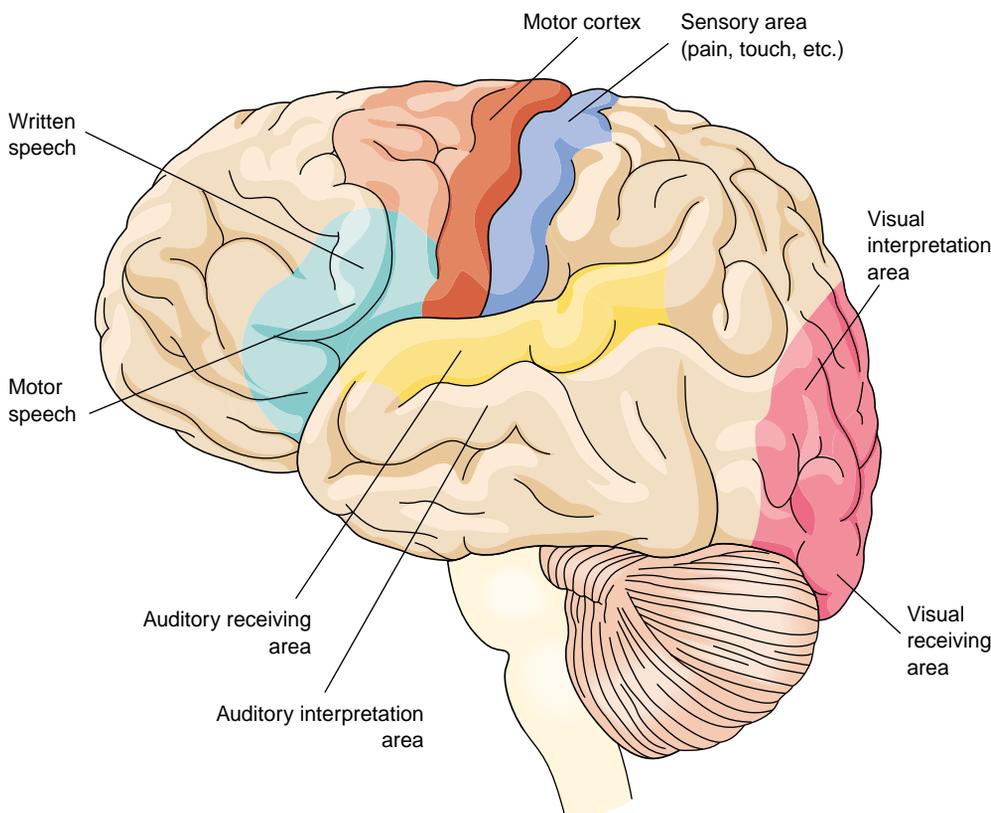

**Cerebellum.** The cerebellum is separated from the cerebral hemispheres by a fold of dura mater, the tentorium cerebelli. The cerebellum has both excitatory and inhibitory actions and is largely responsible for coordination of movement. It also controls fine movement, balance, **position sense** (awareness of where each part of the body is), and integration of sensory input.

### STRUCTURES PROTECTING THE BRAIN

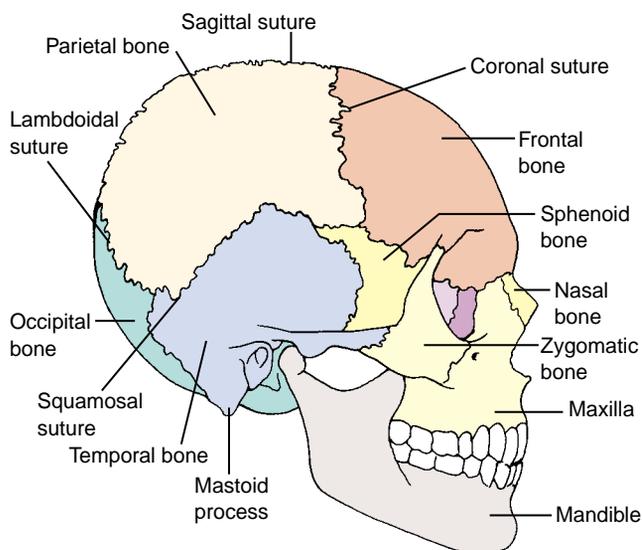

The brain is contained in the rigid skull, which protects it from injury. The major bones of the skull are the frontal, temporal, parietal, and occipital bones. These bones join at the suture lines (Fig. 60-5).

The meninges (fibrous connective tissues that cover the brain and spinal cord) provide protection, support, and nourishment to the brain and spinal cord. The layers of the meninges are the dura, arachnoid, and pia mater (Fig. 60-6).

- Dura mater—the outermost layer; covers the brain and the spinal cord. It is tough, thick, inelastic, fibrous, and gray.

**FIGURE 60-4** Topography of the cortex as it relates to function.

**FIGURE 60-5** Bones and sutures of the skull.

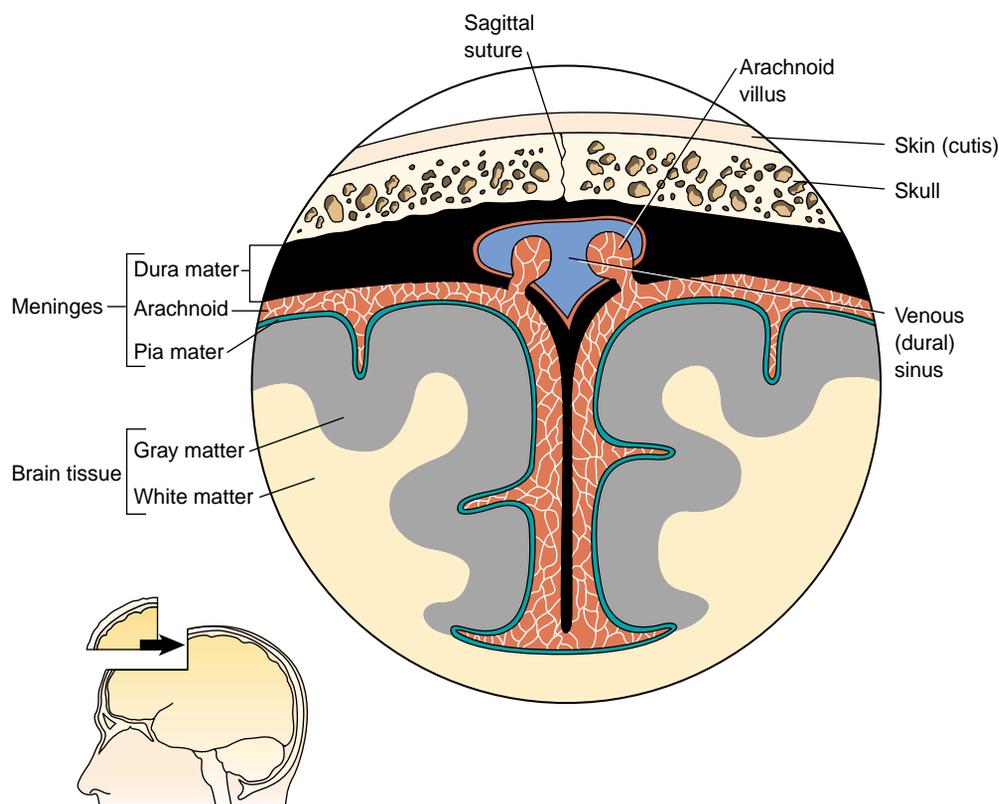

There are four extensions of the dura: the falx cerebri, which separates the two hemispheres in a longitudinal plane; the tentorium, which is an infolding of the dura that forms a tough membranous shelf; the falx cerebelli, which is between the two lateral lobes of the cerebellum; and the diaphragm sellae, which provides a “roof” for the sella turcica. The tentorium supports the hemispheres and separates them from the lower part of the brain. When excess pressure occurs in the cranial cavity, brain tissue may be compressed against the tentorium or displaced downward, a

process called herniation. Between the dura mater and the skull in the cranium, and between the periosteum and the dura in the vertebral column, is the epidural space, a potential space.

- **Arachnoid**—the middle membrane; an extremely thin, delicate membrane that closely resembles a spider web (hence the name arachnoid). It appears white because it has no blood supply. The arachnoid layer contains the choroid plexus, which is responsible for the production of cerebrospinal fluid (CSF). This membrane also has unique finger-like projections, arachnoid villi, that absorb CSF. In the normal adult, approximately 500 mL of CSF is produced each day; all but 125 to 150 mL is absorbed by the villi (Hickey, 2003). When blood enters the system (from trauma or hemorrhagic stroke), the villi become obstructed and hydrocephalus (increased size of ventricles) may result. The subdural space is between the dura and the arachnoid layer, and the subarachnoid space is located between the arachnoid and pia layers and contains the CSF.
- **Pia mater**—the innermost membrane; a thin, transparent layer that hugs the brain closely and extends into every fold of the brain’s surface.

### CEREBROSPINAL FLUID

CSF, a clear and colorless fluid with a specific gravity of 1.007, is produced in the ventricles and is circulated around the brain and the spinal cord through the ventricular system. There are four ventricles: the right and left lateral, and the third and fourth ventricles. The two lateral ventricles open into the third ventricle at the interventricular foramen or the foramen of Monro. The third and fourth ventricles connect via the aqueduct of Sylvius. The fourth ventricle supplies CSF to the subarachnoid space and

**FIGURE 60-6** Meninges and related structures.

down the spinal cord on the dorsal surface. CSF is returned to the brain and is then circulated around the brain, where it is absorbed by the arachnoid villi.

CSF is produced in the choroid plexus of the lateral, third, and fourth ventricles. The ventricular and subarachnoid system contains approximately 125 to 150 mL of fluid, while 15 to 25 mL of CSF is located in each lateral ventricle.

The composition of CSF is similar to other extracellular fluids (such as blood plasma), but the concentrations of the various constituents are different. The analysis and laboratory report of CSF usually contains information on color, specific gravity, protein count, white blood cell count, glucose, and other electrolyte levels; it may also be tested for immunoglobulins or lactate (Hickey, 2003). Normal CSF contains a minimal number of white blood cells and no red blood cells.

### CEREBRAL CIRCULATION

The cerebral circulation receives approximately 15% of the cardiac output, or 750 mL per minute. The brain does not store nutrients and has a high metabolic demand that requires the high blood flow. The brain's blood pathway is unique because it flows against gravity; its arteries fill from below and the veins drain from above. In contrast to other organs that may tolerate decreases in blood flow because of their adequate collateral circulation, the brain lacks additional collateral blood flow, which may result in irreversible tissue damage when blood flow is occluded for even short periods of time.

**Arteries.** Two internal carotid arteries and two vertebral arteries and their extensive system of branches provide the blood supply to the brain. The internal carotids arise from the bifurcation of the common carotid and supply much of the anterior circulation of the brain. The vertebral arteries branch from the subclavian arteries, flow back and upward on either side of the cervical vertebrae, and enter the cranium through the foramen magnum. The vertebral arteries join to become the basilar artery at the level of the brain stem; the basilar artery divides to form the two branches of the posterior cerebral arteries. The vertebrobasilar arteries supply most of the posterior circulation of the brain.

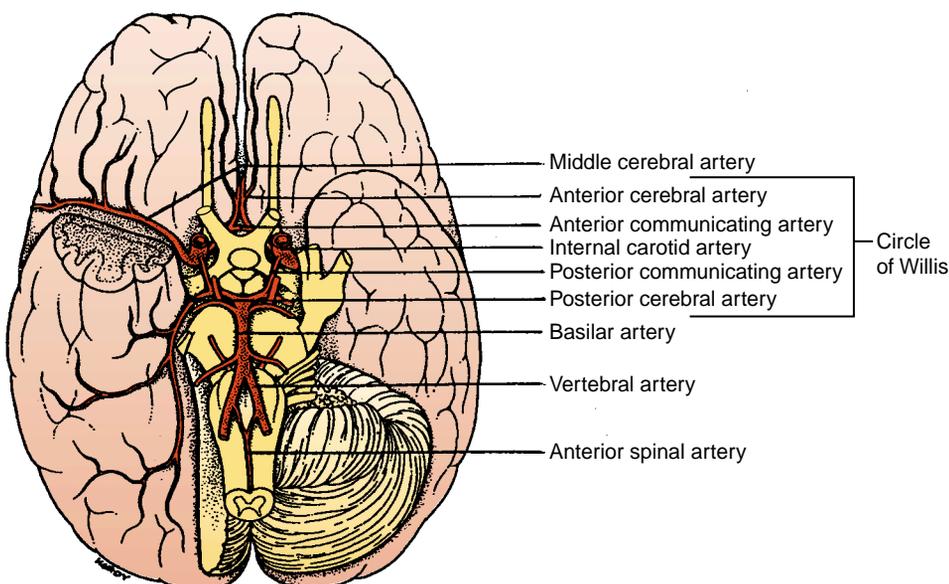

At the base of the brain surrounding the pituitary gland, a ring of arteries is formed between the vertebral and internal carotid arterial chains. This ring is called the circle of Willis and is formed from the branches of the internal carotid arteries, anterior and middle cerebral arteries, and anterior and posterior communicating arteries (Fig. 60-7). Functionally, the posterior portion of the circulation and the anterior or carotid circulation usually remain separate. The arteries of the circle of Willis can provide collateral circulation if one or more of the four vessels supplying it become occluded or are ligated.

The arterial anastomoses along the circle of Willis are frequent sites of aneurysms. These can be formed when the pressure at a weakened arterial wall causes the artery to balloon out. Aneurysms may be congenital or the result of degenerative changes in the vessel wall associated with arteriosclerotic vascular disease. If an artery with an aneurysm bursts or becomes occluded by vasospasm, an embolus, or a thrombus, the neurons distal to the occlusion are deprived of their blood supply and the cells quickly die. The result is a hemorrhagic stroke (cerebrovascular accident or infarction). The effects of the occlusion depend on which vessels are involved and which areas of the brain these vessels supply. Aneurysms and cerebrovascular accidents are discussed in more detail in Chapter 62.

**Veins.** Venous drainage for the brain does not follow the arterial circulation as in other body structures. The veins reach the brain's surface, join larger veins, then cross the subarachnoid space and empty into the dural sinuses, which are the vascular channels lying within the tough dura mater (see Fig. 60-6). The network of the sinuses carries venous outflow from the brain and empties into the internal jugular vein, returning the blood to the heart. Cerebral veins and sinuses are unique because, unlike other veins in the body, they do not have valves to prevent blood from flowing backward and depend on both gravity and blood pressure.

### BLOOD–BRAIN BARRIER

The CNS is inaccessible to many substances that circulate in the blood plasma (eg, dyes, medications, and antibiotics). After being injected into the blood, many substances cannot reach the neu-

**FIGURE 60-7** Arterial blood supply of the brain, including the circle of Willis, as viewed from the ventral surface.

rons of the CNS because of the blood–brain barrier. This barrier is formed by the endothelial cells of the brain’s capillaries, which form continuous tight junctions, creating a barrier to macromolecules and many compounds. All substances entering the CSF must filter through the capillary endothelial cells and astrocytes (Hickey, 2003). Often altered by trauma, cerebral edema, and cerebral hypoxemia, the blood–brain barrier has implications in the treatment and selection of medication for CNS disorders as well as serving a protective function.

### ANATOMY OF THE SPINAL CORD

The spinal cord and medulla form a continuous structure extending from the cerebral hemispheres and serving as the connection between the brain and the periphery. Approximately 45 cm (18 in) long and about the thickness of a finger, it extends from the foramen magnum at the base of the skull to the lower border of the first lumbar vertebra, where it tapers to a fibrous band called the conus medullaris. Continuing below the second lumbar space are the nerve roots that extend beyond the conus, which are called the cauda equina because they resemble a horse’s tail. Similar to the brain, the spinal cord consists of gray and white matter. Gray matter in the brain is external and white matter is internal; in the spinal cord, gray matter is in the center and is surrounded on all sides by white matter (Fig. 60-8).

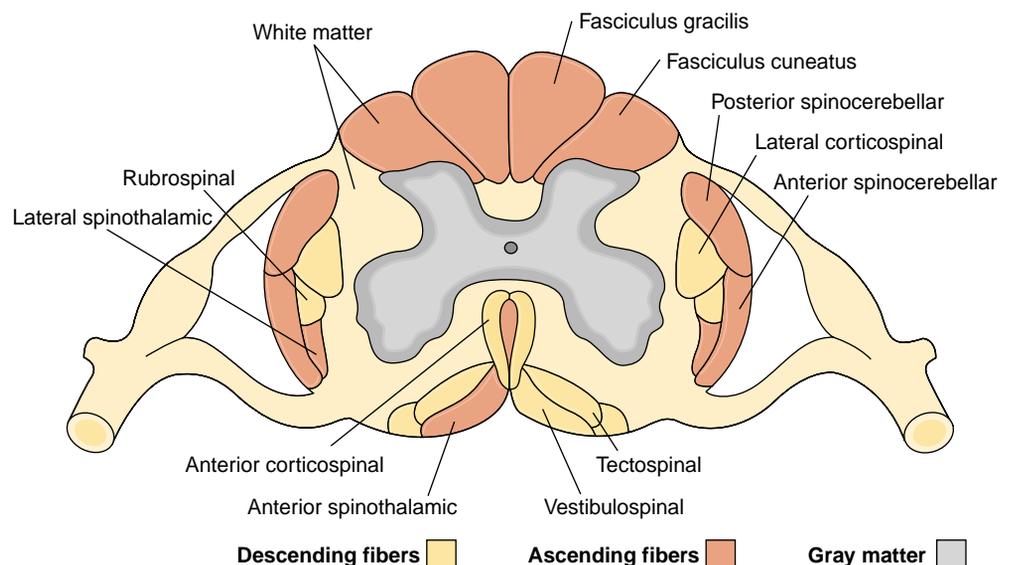

The spinal cord is surrounded by the meninges, dura, arachnoid, and pia layers. Between the dura mater and the vertebral canal is the epidural space. The spinal cord is an H-shaped structure with nerve cell bodies (gray matter) surrounded by ascending and descending tracts (white matter) (see Fig. 60-8). The lower portion of the H is broader than the upper portion and corresponds to the anterior horns. The anterior horns contain cells with fibers that form the anterior (motor) root end and are essential for the voluntary and reflex activity of the muscles they innervate. The thinner posterior (upper horns) portion contains cells with fibers that enter over the posterior (sensory) root end and thus serve as a relay station in the sensory/reflex pathway.

The thoracic region of the spinal cord has a projection from each side at the crossbar of the H of gray matter called the lateral horn. It contains the cells that give rise to the autonomic fibers of the sympathetic division. The fibers leave the spinal cord through the anterior roots in the thoracic and upper lumbar segments.

**Sensory and Motor Pathways: The Spinal Tracts.** The white matter of the cord is composed of myelinated and unmyelinated nerve fibers. The fast-conducting myelinated fibers form bundles that also contain glial cells. Fiber bundles with a common function are called tracts. There are six ascending tracts. Two conduct sensation, principally the perception of touch, pressure, vibration, position, and passive motion from the same side of the body. Before reaching the cerebral cortex, these fibers cross to the opposite side in the medulla. The two spinocerebellar tracts conduct sensory impulses from muscle spindles, providing necessary input for coordinated muscle contraction. They ascend essentially uncrossed and terminate in the cerebellum. The last two spinothalamic tracts are responsible for conduction of pain, temperature, proprioception, fine touch, and vibratory sense from the upper body to the brain. They ascend, cross to the opposite side of the brain, and terminate in the thalamus (Hickey, 2003).

There are eight descending tracts, seven of which are engaged in motor function. The two corticospinal tracts conduct motor impulses to the anterior horn cells from the opposite side of the brain and control voluntary muscle activity. The three vestibulospinal tracts descend uncrossed and are involved in some autonomic functions (sweating, pupil dilation, and circulation) and involuntary muscle control. The corticobulbar tract conducts impulses responsible for voluntary head and facial muscle movement and crosses at the level of the brain stem. The rubrospinal and reticulospinal tracts conduct impulses involved with involuntary muscle movement.

**Vertebral Column.** The bones of the vertebral column surround and protect the spinal cord and normally consist of 7 cervical, 12 thoracic, and 5 lumbar vertebrae, as well as the sacrum (a fused mass of five vertebrae), and terminate in the coccyx. Nerve roots exit from the vertebral column through the intervertebral foramina (openings). The vertebrae are separated by disks, except for the first and second cervical, the sacral, and the coccygeal vertebrae. Each vertebra has a ventral solid body and a dorsal segment or arch, which is posterior to the body. The arch is composed of two pedicles and two laminae supporting seven processes. The vertebral body, arch, pedicles, and laminae all encase the vertebral canal.

**FIGURE 60-8** Cross-sectional diagram of the spinal cord showing major spinal tracts.

## The Peripheral Nervous System

The peripheral nervous system includes the cranial nerves, the spinal nerves, and the autonomic nervous system.

### CRANIAL NERVES

There are 12 pairs of cranial nerves that emerge from the lower surface of the brain and pass through the foramina in the skull. Three are entirely sensory (I, II, VIII), five are motor (III, IV, VI, XI, and XII), and four are mixed (V, VII, IX, and X) as they have both sensory and motor functions (Downey & Leigh, 1998; Hickey, 2003). The cranial nerves are numbered in the order in which they arise from the brain. For example, cranial nerves I and II attach in the cerebral hemispheres, whereas cranial nerves IX, X, XI, and XII attach at the medulla (Fig. 60-9). Most cranial nerves innervate the head, neck, and special sense structures. Table 60-2 lists the names and primary functions of the cranial nerves.

### SPINAL NERVES

The spinal cord is composed of 31 pairs of spinal nerves: 8 cervical, 12 thoracic, 5 lumbar, 5 sacral, and 1 coccygeal. Each spinal nerve has a ventral root and a dorsal root (Fig. 60-10).

The dorsal roots are sensory and transmit sensory impulses from specific areas of the body known as dermatomes (Fig. 60-11) to the dorsal ganglia. The sensory fiber may be somatic, carrying information about pain, temperature, touch, and position sense (proprioception) from the tendons, joints, and body surfaces; or visceral, carrying information from the internal organs.

The ventral roots are motor and transmit impulses from the spinal cord to the body. These fibers are also either somatic or visceral. The visceral fibers include autonomic fibers that control the cardiac muscles and glandular secretions.

### AUTONOMIC NERVOUS SYSTEM

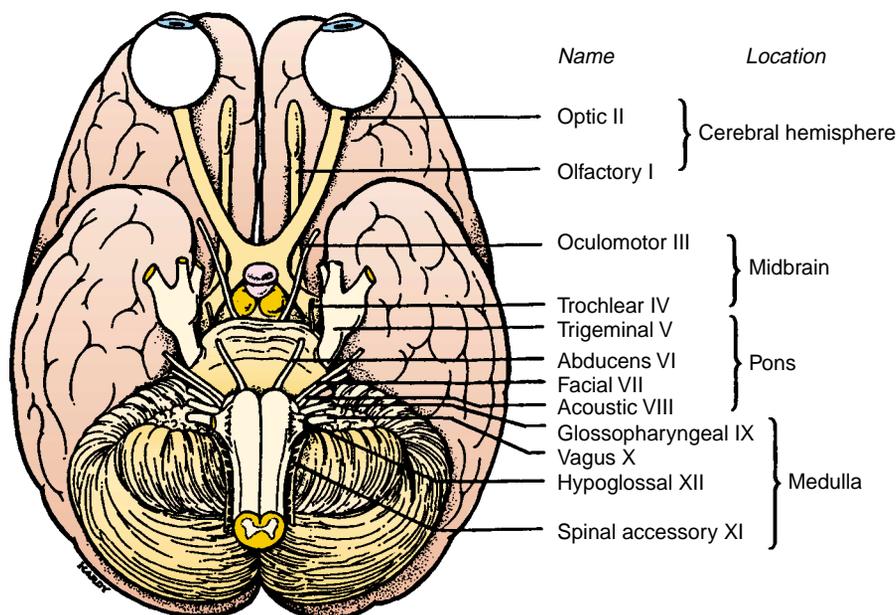

The **autonomic nervous system** regulates the activities of internal organs such as the heart, lungs, blood vessels, digestive organs, and glands. Maintenance and restoration of internal homeostasis is largely the responsibility of the autonomic nervous system. There are two major divisions: the **sympathetic nervous system**,

**Table 60-2 • Cranial Nerves**

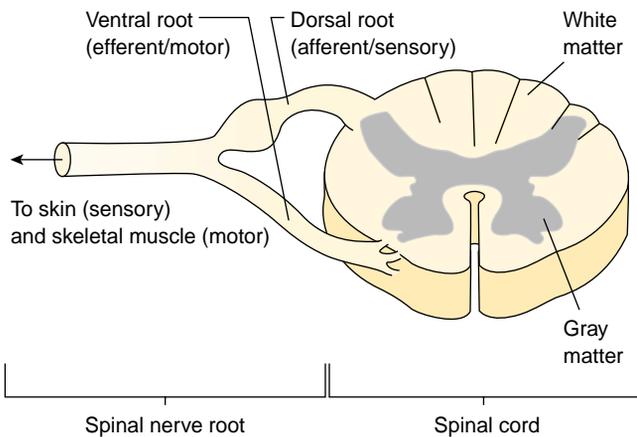

CRANIAL NERVE	TYPE	FUNCTION
I (olfactory)	Sensory	Sense of smell
II (optic)	Sensory	Visual acuity
III (oculomotor)	Motor	Muscles that move the eye and lid, pupillary constriction, lens accommodation
IV (trochlear)	Motor	Muscles that move the eye
V (trigeminal)	Mixed	Facial sensation, corneal reflex, mastication
VI (abducens)	Motor	Muscles that move the eye
VII (facial)	Mixed	Facial expression and muscle movement, salivation and tearing, taste, sensation in the ear
VIII (acoustic)	Sensory	Hearing and equilibrium
IX (glossopharyngeal)	Mixed	Taste, sensation in pharynx and tongue, pharyngeal muscles
X (vagus)	Mixed	Muscles of pharynx, larynx, and soft palate; sensation in external ear, pharynx, larynx, thoracic and abdominal viscera; parasympathetic innervation of thoracic and abdominal organs
XI (spinal accessory)	Motor	Sternocleidomastoid and trapezius muscles
XII (hypoglossal)	Motor	Movement of the tongue

with predominantly excitatory responses, most notably the “fight or flight” response, and the **parasympathetic nervous system**, which controls mostly visceral functions.

The autonomic nervous system innervates most body organs. Although usually considered part of the peripheral nervous system, it is regulated by centers in the spinal cord, brain stem, and

**FIGURE 60-9** Diagram of the base of the brain showing entrance or exit of the cranial nerves. The right column shows the anatomic location of the connection of each cranial nerve to the central nervous system.

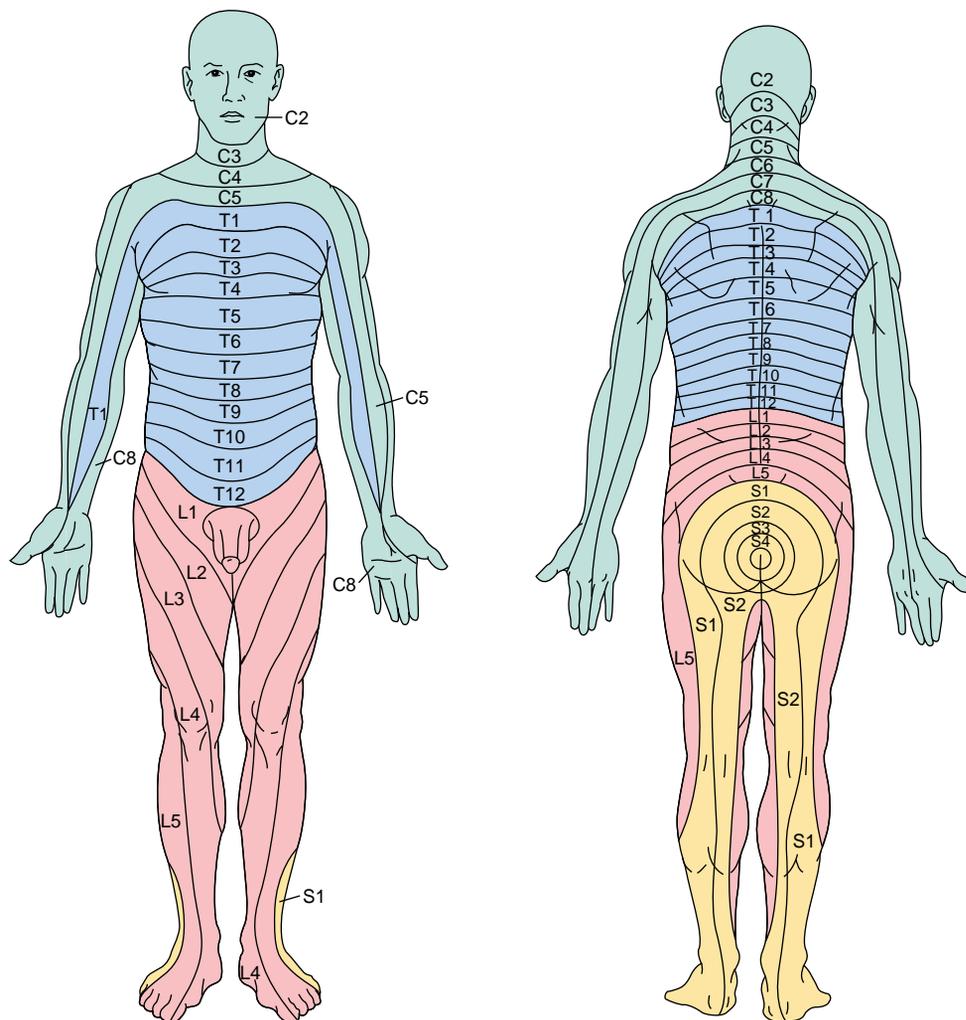

**FIGURE 60-10** Cross-section of the spinal cord showing dorsal and ventral roots of a spinal nerve.

hypothalamus. The autonomic nervous system has two neurons in a series extending between the centers in the CNS and the organs innervated. The first neuron, the preganglionic neuron, is located in the brain or spinal cord, and its axon extends to the autonomic ganglia. There, it synapses with the second neuron, the postganglionic neuron, located in the autonomic ganglia, and its axon synapses with the target tissue and innervates the effector

organ. Its regulatory effects are exerted not on individual cells but on large expanses of tissue and on entire organs. The responses elicited do not occur instantaneously but after a lag period. These responses are sustained far longer than other neurogenic responses to ensure maximal functional efficiency on the part of receptor organs, such as blood vessels.

The quality of these responses is explained by the fact that the autonomic nervous system transmits its impulses by way of nerve pathways, enhanced by chemical mediators, resembling in this respect the endocrine system. Electrical impulses, conducted through nerve fibers, stimulate the formation of specific chemical agents at strategic locations within the muscle mass; the diffusion of these chemicals within the muscle is responsible for the contraction.

The hypothalamus is the major subcortical center for the regulation of visceral and somatic activities, with an inhibitory–excitatory role in the autonomic nervous system. The hypothalamus has connections that link the autonomic system with the thalamus, the cortex, the olfactory apparatus, and the pituitary gland. Located here are the mechanisms for the control of visceral and somatic reactions that were originally important for defense or attack, and are associated with emotional states (eg, fear, anger, anxiety); for the control of metabolic processes, including fat, carbohydrate, and water metabolism; for the regulation of body temperature, arterial pressure, and all muscular and glandular activities of the gastrointestinal tract; for control of genital functions; and for the sleep cycle.

**FIGURE 60-11** Dermatome distribution.

The autonomic nervous system is separated into the anatomically and functionally distinct sympathetic and parasympathetic divisions. Most of the tissues and the organs under autonomic control are innervated by both systems. Sympathetic stimuli are mediated by norepinephrine and parasympathetic impulses are mediated by acetylcholine. These chemicals produce opposing and mutually antagonistic effects. Both divisions produce stimulatory and inhibitory effects. For example, the parasympathetic division causes contraction (stimulation) of the urinary bladder muscles and a decrease (inhibition) in heart rate, whereas the sympathetic division produces relaxation (inhibition) of the urinary bladder and an increase (stimulation) in the rate and force of the heartbeat. Table 60-3 compares the sympathetic and the parasympathetic effects on the different systems of the body.

**Sympathetic Nervous System.** The sympathetic division of the autonomic nervous system is best known for its role in the body's "fight-or-flight" response. Under stress conditions from either physical or emotional causes, sympathetic impulses increase greatly. As a result, the bronchioles dilate for easier gas exchange; the heart's contractions are stronger and faster; the arteries to the heart and voluntary muscles dilate, carrying more blood to these organs; peripheral blood vessels constrict, making the skin feel cool but shunting blood to essential organs; the pupils dilate; the liver releases glucose for quick energy; peristalsis slows; hair stands on end; and perspiration increases. The sympathetic neurotransmitter is norepinephrine (noradrenaline), and this increase in sympathetic discharge is the same as if the body has been given an injection of adrenalin—hence, the term adrenergic is often used to refer to this division.

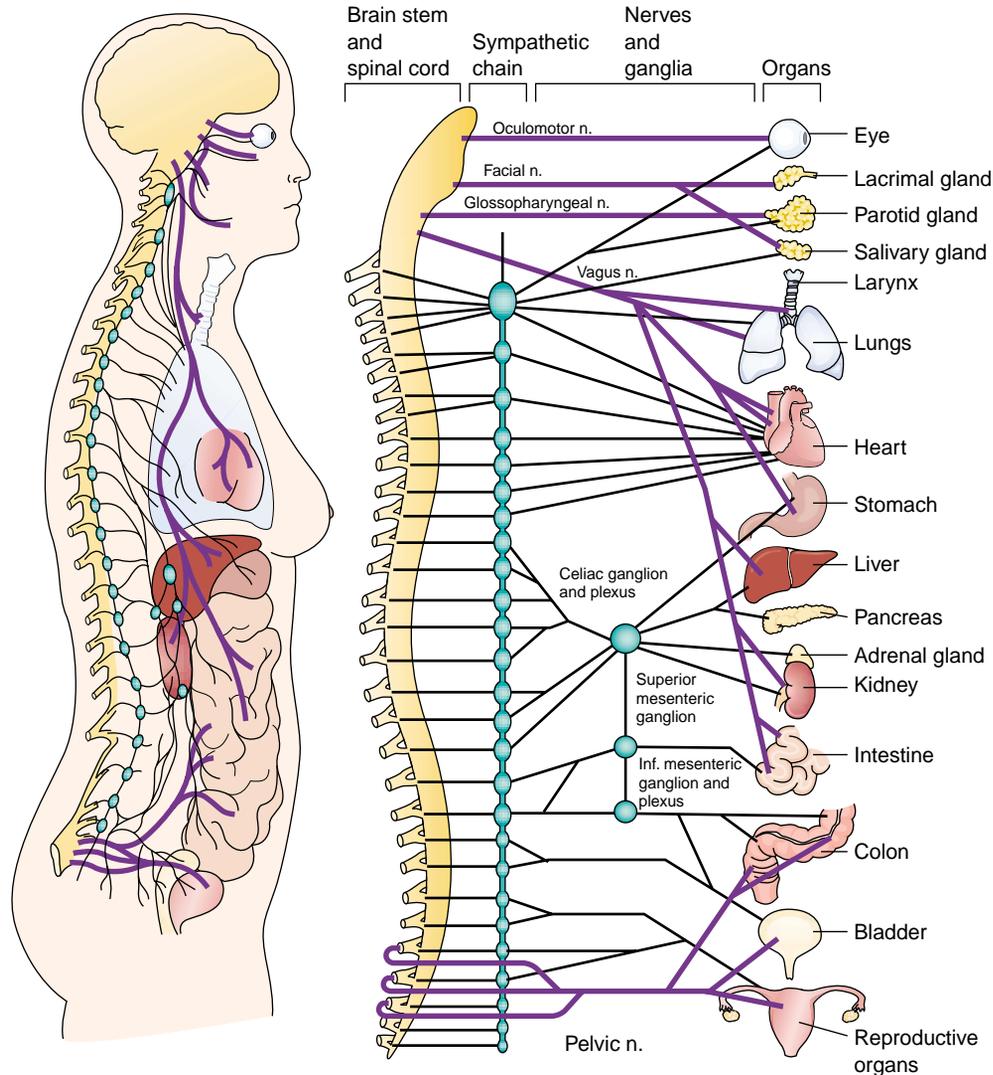

Sympathetic neurons are located in the thoracic and the lumbar segments of the spinal cord; their axons, or the preganglionic fibers, emerge by way of anterior nerve roots from the eighth cervical or first thoracic segment to the second or third lumbar segment. A short distance from the cord, these fibers diverge to join a chain, composed of 22 linked ganglia, that extends the entire length of the spinal column, adjacent to the vertebral bodies on both sides. Some form multiple synapses with nerve cells within the chain. Others traverse the chain without making connections or losing continuity to join large "prevertebral" ganglia in the thorax, the abdomen, or the pelvis or one of the "terminal" ganglia in the vicinity of an organ, such as the bladder or the rectum (Fig. 60-12). Postganglionic nerve fibers originating in the sympathetic chain rejoin the spinal nerves that supply the extremities and are distributed to blood vessels, sweat glands, and smooth muscle tissue in the skin. Postganglionic fibers from the prevertebral plexuses (eg, the cardiac, pulmonary, splanchnic, and pelvic plexuses) supply structures in the head and neck, thorax, abdomen, and pelvis, respectively, having been joined in these plexuses by fibers from the parasympathetic division.

The adrenal glands, kidneys, liver, spleen, stomach, and duodenum are under the control of the giant celiac plexus, commonly known as the solar plexus. This receives its sympathetic nerve components by way of the three splanchnic nerves, composed of preganglionic fibers from nine segments of the spinal cord (T4 to L1), and is joined by the vagus nerve, representing the parasympathetic division. From the celiac plexus, fibers of both divisions travel along the course of blood vessels to their target organs.

**Sympathetic Syndromes.** Certain syndromes are distinctive to diseases of the sympathetic nerve trunks. Among these are dilation of the pupil of the eye on the same side as a penetrating wound of the neck (evidence of disturbance of the cervical sympathetic cord); temporary paralysis of the bowel (indicated by the

absence of peristaltic waves and the distention of the intestine by gas) after fracture of any one of the lower dorsal or upper lumbar vertebrae with hemorrhage into the base of the mesentery; and the marked variations in pulse rate and rhythm that often follow compression fractures of the upper six thoracic vertebrae.

**Parasympathetic Nervous System.** The parasympathetic nervous system functions as the dominant controller for most visceral effectors. During quiet, nonstressful conditions, impulses from parasympathetic fibers (cholinergic) predominate. The fibers of the parasympathetic system are located in two sections, one in the

**FIGURE 60-12** Anatomy of the autonomic nervous system.

brain stem and the other from spinal segments below L2. Because of the location of these fibers, the parasympathetic system is referred to as the craniosacral division, as distinct from the thoracolumbar (sympathetic) division of the autonomic nervous system.

The parasympathetic nerves arise from the midbrain and the medulla oblongata. Fibers from cells in the midbrain travel with the third oculomotor nerve to the ciliary ganglia, where postganglionic fibers of this division are joined by those of the sympathetic system, creating controlled opposition, with a delicate balance maintained between the two at all times.

## Motor and Sensory Functions of the Nervous System

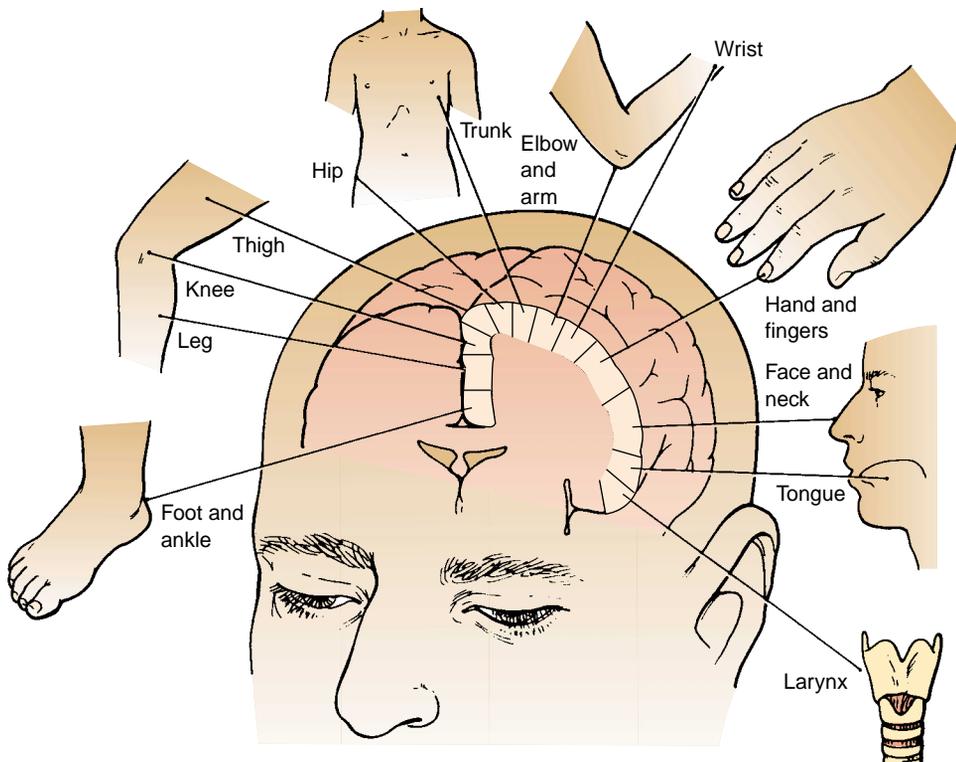

### MOTOR SYSTEM FUNCTION

The motor cortex, a vertical band within each cerebral hemisphere, controls the voluntary movements of the body. The exact locations within the brain at which the voluntary movements of the muscles of the face, thumb, hand, arm, trunk, and leg originate are known (Fig. 60-13). To initiate muscle movement, these particular cells must send the stimulus down along their fibers. Stimulation of these cells with an electric current will also result in muscle contraction. En route to the pons, the motor fibers con-

verge into a tight bundle known as the internal capsule. A comparatively small injury to the capsule causes paralysis in more muscles than does a much larger injury to the cortex itself.

Within the medulla, the motor axons from the cortex form the motor pathways or tracts, notably the corticospinal or pyramidal tracts. Here, most of the fibers cross (or decussate) to the opposite side, continuing as a crossed pyramidal tract. The remaining fibers enter the spinal cord on the same side as the direct pyramidal tract. Each fiber in this tract finally crosses to the opposite side of the cord and terminates within the gray matter of the anterior horn on that side, in proximity to a motor nerve cell. Fibers of the crossed pyramidal tract terminate within the anterior horn and make connections with anterior horn cells on the same side. All of the motor fibers of the spinal nerves represent extensions of these anterior horn cells, with each of these fibers communicating with only one particular muscle fiber.

The motor system is complex, and motor function depends on the integrity of the corticospinal tracts, the extrapyramidal system, and cerebellar function. A motor impulse consists of a two-neuron pathway (described below). The motor nerve pathways are contained in the spinal cord. Some represent the pathways of the so-called extrapyramidal system, establishing connections between the anterior horn cells and the automatic control centers located in the basal ganglia and the cerebellum. Others are

**FIGURE 60-13** Diagrammatic representation of the cerebrum showing locations for control of motor movement of various parts of the body.

components of reflex arcs, forming synaptic connections between anterior horn cells and sensory fibers that have entered adjacent or neighboring segments of the cord.

**Upper and Lower Motor Neurons.** The voluntary motor system consists of two groups of neurons: upper motor neurons and lower motor neurons. Upper motor neurons originate in the cerebral cortex, the cerebellum, and the brain stem and modulate the activity of the lower motor neurons. Upper motor neuron fibers make up the descending motor pathways and are located entirely within the CNS. Lower motor neurons are located either in the anterior horn of the spinal cord gray matter or within cranial nerve nuclei in the brain stem. Axons of both extend through peripheral nerves and terminate in skeletal muscle. Lower motor neurons are located in both the CNS and the peripheral nervous system.

The motor pathways from the brain to the spinal cord, as well as from the cerebrum to the brain stem, are formed by upper motor neurons. They begin in the cortex of one side of the brain, descend through the internal capsule, cross to the opposite side in the brain stem, descend through the corticospinal tract, and synapse with the lower motor neurons in the cord. The lower motor neurons receive the impulse in the posterior part of the cord and run to the myoneural junction located in the peripheral muscle. The clinical features of lesions of upper and lower motor neurons are discussed in the sections that follow and in Table 60-4.

**Upper Motor Neuron Lesions.** Upper motor neuron lesions can involve the motor cortex, the internal capsule, the spinal cord, and other structures of the brain through which the corticospinal tract descends. If the upper motor neurons are damaged or destroyed, as frequently occurs with stroke or spinal cord injury, paralysis (loss of voluntary movement) results. However, because the inhibitory influences of intact upper motor neurons are now impaired, **reflex** (involuntary) movements are uninhibited, and

hence hyperactive deep tendon reflexes, diminished or absent superficial reflexes, and pathologic reflexes such as a Babinski response occur. Severe leg spasms can occur as the result of an upper motor neuron lesion; the spasms result from the preserved reflex arc, which lacks inhibition along the spinal cord below the level of injury.

There is little or no muscle atrophy, and muscles remain permanently tense, exhibiting spastic paralysis or paresis (weakness). Paralysis associated with upper motor neuron lesions usually affects a whole extremity, both extremities, and an entire half of the body. Hemiplegia (paralysis of an arm and leg on the same side of the body) can be the result of an upper motor neuron lesion. If hemorrhage, an embolus, or a thrombus destroys the fibers from the motor area in the internal capsule, the arm and the leg of the opposite side become stiff and very weak or paralyzed, and the reflexes are hyperactive (further discussion of hemiplegia is found in Chap. 62). When both legs are paralyzed, the condition is called paraplegia; paralysis of all four extremities is quadriplegia (more discussion of these can be found in Chap. 63).

**Lower Motor Neuron Lesions.** A patient is considered to have lower motor neuron damage if a motor nerve is severed between

**Table 60-4 • Comparison of Upper Motor Neuron and Lower Motor Neuron Lesions**

UPPER MOTOR NEURON LESIONS	LOWER MOTOR NEURON LESIONS
Loss of voluntary control	Loss of voluntary control
Increased muscle tone	Decreased muscle tone
Muscle spasticity	Flaccid muscle paralysis
No muscle atrophy	Muscle atrophy
Hyperactive and abnormal reflexes	Absent or decreased reflexes

the muscle and the spinal cord. The result of lower motor neuron damage is muscle paralysis. Reflexes are lost, and the muscle becomes **flaccid** (limp) and atrophied from disuse. If the patient has injured the spinal trunk and it can heal, use of the muscles connected to that section of the spinal cord may be regained. If the anterior horn motor cells are destroyed, however, the nerves cannot regenerate and the muscles are never useful again. Flaccid paralysis and atrophy of the affected muscles are the principal signs of lower motor neuron disease. Lower motor neuron lesions can be the result of trauma, infection (poliomyelitis), toxins, vascular disorders, congenital malformations, degenerative processes, and neoplasms. Compression of nerve roots by herniated intervertebral disks is a common cause of lower motor neuron dysfunction.

**Coordination of Movement.** The smoothness, accuracy, and strength that characterize the muscular movements of a normal person are attributable to the influence of the cerebellum and the basal ganglia.

The cerebellum (refer to Fig. 60-2), described earlier, is located beneath the occipital lobe of the cerebrum; it is responsible for the coordination, balance, and timing of all muscular movements that originate in the motor centers of the cerebral cortex. Through the action of the cerebellum, the contractions of opposing muscle groups are adjusted in relation to each other to maximal mechanical advantage; muscle contractions can be sustained evenly at the desired tension and without significant fluctuation, and reciprocal movements can be reproduced at high and constant speed, in stereotyped fashion and with relatively little effort.

The basal ganglia, masses of gray matter in the midbrain beneath the cerebral hemispheres, border the lateral ventricles and lie in proximity to the internal capsule. The basal ganglia play an important role in planning and coordinating motor movements and posture. Complex neural connections link the basal ganglia with the cerebral cortex. The major effect of these structures is to inhibit unwanted muscular activity; disorders of the basal ganglia result in exaggerated, uncontrolled movements.

Impaired cerebellar function, which may occur as a result of an intracranial injury or some type of an expanding mass (eg, a hemorrhage, abscess, or tumor), results in loss of muscle tone, weakness, and fatigue. Depending on the area of the brain affected, the patient has different motor symptoms or responses. The patient may demonstrate decorticate, decerebrate, or flaccid posturing, usually as a result of cerebral trauma (Bateman, 2001). For further explanation of this, see Figure 61-1 in Chapter 61. Decortication (decorticate posturing) is the result of lesions of the internal capsule or cerebral hemispheres; the patient has flexion and internal rotation of the arms and wrists and extension, internal rotation, and plantar flexion of the feet. Decerebration (decerebrate posturing), the result of lesions at the midbrain, is more ominous than decortication. The patient has extension and external rotation of the arms and wrists and extension, plantar flexion, and internal rotation of the feet. Flaccid posturing is usually the result of lower brain stem dysfunction; the patient has no motor function, is limp, and lacks motor tone.

Flaccidity preceded by decerebration in a patient with cerebral injury indicates severe neurologic impairment, which may herald brain death. However, before the declaration of brain death, the patient must have spinal cord injury ruled out, the effects of all neuromuscular paralyzing agents must have worn off, and any other possible treatable causes of neurologic impairment must be investigated.

Tumors, infection, or abscess and increased intracranial pressure can all affect the cerebellum. Cerebellar signs, such as ataxia, incoordination, and seizures, as well as CSF obstruction and compression of the brain stem may be seen. Signs of increased intracranial pressure, including vomiting, headache, and changes in vital signs and level of consciousness, are especially common when CSF flow is obstructed.

Destruction or dysfunction of the basal ganglia leads not to paralysis but to muscle rigidity, with disturbances of posture and movement. Such patients tend to have involuntary movements. These may take the form of coarse tremors, most often in the upper extremities, particularly in the distal portions; athetosis, movement of a slow, squirming, writhing, twisting type; or chorea, marked by spasmodic, purposeless, irregular, uncoordinated motions of the trunk and the extremities, and facial grimacing. Disorders due to lesions of the basal ganglia include Parkinson's disease, Huntington's disease (see Chap. 65), and spasmodic torticollis.

## SENSORY SYSTEM FUNCTION

**Integrating Sensory Impulses.** The thalamus, a major receiving and transmitting center for the afferent sensory nerves, is a large structure connected to the midbrain. It lies next to the third ventricle and forms the floor of the lateral ventricle (see Fig. 60-3). The thalamus integrates all sensory impulses except olfaction. It plays a role in the conscious awareness of pain and the recognition of variation in temperature and touch. The thalamus is responsible for the sense of movement and position and the ability to recognize the size, shape, and quality of objects.

**Receiving Sensory Impulses.** Afferent impulses travel from their points of origin to their destinations in the cerebral cortex via the ascending pathways directly, or they may cross at the level of the spinal cord or in the medulla, depending on the type of sensation that is registered. Sensory information may be integrated at the level of the spinal cord or may be relayed to the brain. Knowledge of these pathways is important for neurologic assessment and for understanding symptoms and their relationship to various lesions.

Sensory impulses enter the spinal cord by way of the posterior root. These axons convey sensations of heat, cold, and pain and enter the posterior gray column of the cord, where they make connections with the cells of secondary neurons. Pain and temperature fibers cross immediately to the opposite side of the cord and course upward to the thalamus. Fibers carrying sensations of touch, light pressure, and localization do not connect immediately with the second neuron but ascend the cord for a variable distance before entering the gray matter and completing this connection. The axon of the secondary neuron crosses the cord and proceeds upward to the thalamus.

Position and vibratory sensation are produced by stimuli arising from muscles, joints, and bones. These stimuli are conveyed, uncrossed, all the way to the brain stem by the axon of the primary neuron. In the medulla, synaptic connections are made with cells of the secondary neurons, whose axons cross to the opposite side and then proceed to the thalamus.

**Sensory Losses.** Destruction of a sensory nerve results in total loss of sensation in its area of distribution. Transection of the spinal cord yields complete anesthesia below the level of injury. Selective destruction or degeneration of the posterior columns of the spinal cord is responsible for a loss of position and vibratory sense in segments distal to the lesion, without loss of touch, pain, or temperature perception. A lesion, such as a cyst, in the center of the spinal cord causes dissociation of sensation—loss of pain

at the level of the lesion. This occurs because the fibers carrying pain and temperature cross within the cord immediately on entering; thus, any lesion that divides the cord longitudinally divides these fibers. Other sensory fibers ascend the cord for variable distances, some even to the medulla, before crossing, thereby bypassing the lesion and avoiding destruction.

Lesions affecting the posterior spinal nerve roots may cause impairment of tactile sensation, including intermittent severe pain that is referred to their areas of distribution. Tingling of the fingers and the toes can be a prominent symptom of spinal cord disease, presumably due to degenerative changes in the sensory fibers that extend to the thalamus (ie, belonging to the spinothalamic tract).

## Assessment: The Neurologic Examination

### HEALTH HISTORY

An important aspect of the neurologic assessment is the history of the present illness. The initial interview provides an excellent opportunity to systematically explore the patient's current condition and related events while simultaneously observing overall appearance, mental status, posture, movement and affect. Depending on the patient's condition, the nurse may need to rely on yes-or-no answers to questions, on a review of the medical record, or input from the family or a combination of these.

Neurologic disease may be stable or progressive, with both intermittent symptom-free periods as well as times with fluctuations in symptoms. The health history therefore includes details about the onset, character, severity, location, duration, and frequency of symptoms and signs; associated complaints; precipitating, aggravating, and relieving factors; progression, remission, and exacerbation; and the presence or absence of similar symptoms among family members. The nurse may also use the interview to inquire about any family history of genetic diseases. See the Genetics chart for assessment guidelines and Chapter 9 for additional information about genetics.

Included in the health history is a review of the medical history, including a system-by-system evaluation. The nurse should be aware of any history of trauma or falls that may have involved the head or spinal cord. Questions regarding the use of alcohol, medications, and recreational drugs are also included. The history-taking portion of the neurologic examination is critical and, in many cases of neurologic disease, leads to an accurate diagnosis.

### CLINICAL MANIFESTATIONS

The clinical manifestations of neurologic disease are as varied as the disease processes themselves. Symptoms can be subtle or intense, fluctuating or permanent, an inconvenience or devastating. An introduction to some of the most common symptoms associ-

## GENETICS IN NURSING PRACTICE—Neurologic Disorders

### DISEASES AND CONDITIONS INFLUENCED BY GENETIC FACTORS

- Alzheimer's disease
- Amyotrophic lateral sclerosis (ALS)
- Duchenne muscular dystrophy
- Epilepsy
- Friedrich ataxia
- Huntington disease
- Myotonic dystrophy
- Neurofibromatosis type I
- Parkinson's disease
- Spina bifida
- Tourette syndrome

### NURSING ASSESSMENTS

#### FAMILY HISTORY ASSESSMENT

- Assess for other similarly affected relatives with neurologic impairment.
- Inquire about age of onset (eg, present at birth—spina bifida; developed in childhood—Duchenne muscular dystrophy; developed in adulthood—Huntington disease, Alzheimer's disease, amyotrophic lateral sclerosis)
- Inquire about the presence of related conditions such as mental retardation and/or learning disabilities (neurofibromatosis type I).

#### PHYSICAL ASSESSMENT

- Assess for the presence of other physical features suggestive of an underlying genetic condition, such as skin lesions seen in neurofibromatosis type I (café-au-lait spots).
- Assess for other congenital abnormalities (eg, cardiac, ocular).

### MANAGEMENT SPECIFIC TO GENETICS

- Inquire whether DNA mutation or other genetic testing has been performed on affected family members.
- If indicated, refer for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, availability of genetic testing and gene-based interventions.
- Offer appropriate genetics information and resources.
- Assess patient's understanding of genetics information.
- Provide support to families with newly diagnosed genetic-related neurologic disorders.
- Participate in management and coordination of care of patients with genetic conditions and individuals predisposed to develop or pass on a genetic condition.

### GENETICS RESOURCES FOR NURSES AND THEIR PATIENTS ON THE WEB

Genetic Alliance: <http://www.geneticalliance.org>—a directory of support groups for patients and families with genetic conditions

Gene Clinics: <http://www.geneclinics.org>—a listing of common genetic disorders with up-to-date clinical summaries, genetic counseling and testing information

National Organization of Rare Disorders: <http://www.rarediseases.org>—a directory of support groups and information for patients and families with rare genetic disorders

OMIM: Online Mendelian Inheritance in Man: <http://www.ncbi.nlm.nih.gov/omim/stats/html>—a complete listing of inherited genetic conditions

ated with neurologic disease follows; detailed discussions regarding how specific symptoms relate to a particular disorder will be covered in later chapters in this unit.

## Pain

Pain is considered an unpleasant sensory perception and emotional experience associated with actual or potential tissue damage or described in terms of such damage. Pain is therefore considered multidimensional and entirely subjective (Loeser, 2001). Pain can be acute or chronic. In general, acute pain lasts for a relatively short period of time and remits as the pathology resolves. In neurologic disease, this type of pain is often associated with spinal disc disease, trigeminal neuralgia, or other neuropathic pathology (eg, post-herpetic neuralgia, or painful neuropathies). In contrast, chronic pain extends for long periods of time and may represent a low level of pathology. This type of pain might also occur with discogenic disease.

## Seizures

Seizures are the result of abnormal paroxysmal discharges in the cerebral cortex, which then manifest as an alteration in sensation, behavior, movement, perception, or consciousness (Hickey, 2003). The alteration may be short, as in a blank stare lasting only a second, or of longer duration, such as a tonic-clonic grand mal seizure that can last several minutes. The type of seizure activity is a direct result of the area of the brain affected. Seizures can occur as isolated events, such as when induced by a high fever, alcohol or drug withdrawal, or hypoglycemia. A seizure may also be the first obvious sign of a brain lesion.

## Dizziness

Dizziness is an abnormal sensation of imbalance or movement. It is fairly common in the elderly and one of the most common complaints encountered by health professionals. Dizziness can have a variety of causes, including viral syndromes, hot weather, roller coaster rides, and middle ear infections, to name a few. One difficulty confronting health care providers when assessing dizziness is the vague and varied terms patients use to describe the sensation. *Vertigo*, a specific form of dizziness, is defined as a sensation that is usually a manifestation of vestibular dysfunction. It can be so severe as to result in spatial disorientation, loss of equilibrium, and nausea and vomiting (Greenberg, Aminoff, & Simon, 2002).

## Visual Disturbances

Visual defects that cause people to seek health care can range from the decreased visual acuity associated with aging to sudden blindness caused by glaucoma. Normal vision depends upon functioning visual pathways through the retina and optic chiasm and the radiations into the visual cortex in the occipital lobes. Lesions of the eye itself (eg, cataract), lesions along the pathway (eg, tumor), or lesions in the visual cortex (from stroke) interfere with normal visual acuity. Abnormalities of eye movement (as in the nystagmus associated with multiple sclerosis) can also compromise vision by causing diplopia or double vision.

## Weakness

Weakness, specifically muscle weakness, is a common manifestation of neurologic disease. Weakness frequently coexists with other symptoms of disease and can affect a variety of muscles, causing a

wide range of disability. Weakness can be sudden and permanent, as in stroke, or progressive, as in many neuromuscular diseases such as amyotrophic lateral sclerosis. Any muscle group can be affected.

## Abnormal Sensation

Numbness, abnormal sensation, or loss of sensation is a neurologic manifestation of both central and peripheral nervous system disease. Altered sensation can affect small or large areas of the body. It is frequently associated with weakness or pain and is potentially disabling. Both numbness and weakness can significantly affect balance and coordination.

## PHYSICAL EXAMINATION

The neurologic examination is a systematic process that includes a variety of clinical tests, observations, and assessments designed to evaluate a complex system. Although the neurologic examination is often limited to a simple screening, the examiner must be able to conduct a thorough neurologic assessment when the patient's history or other physical findings warrant it. Many neurologic rating scales exist; some of the more common ones are discussed here, but an in-depth discussion is beyond the scope of this chapter (see Herndon [1997] and Rapp, Wakefield, Kundrat et al. [2000] for full descriptions of neurologic rating scales).

The brain and spinal cord cannot be examined as directly as other systems of the body. Thus, much of the neurologic examination is an indirect evaluation that assesses the function of the specific body part or parts controlled or innervated by the nervous system. A neurologic assessment is divided into five components: cerebral function, cranial nerves, motor system, sensory system, and reflexes. As in other parts of the physical assessment, the neurologic examination follows a logical sequence and progresses from higher levels of cortical function such as abstract thinking to lower levels of function such as the determination of the integrity of peripheral nerves.

## Assessing Cerebral Function

Cerebral abnormalities may cause disturbances in mental status, intellectual functioning, and thought content and in patterns of emotional behavior. There may also be alterations in perception, motor and language abilities, as well as lifestyle.

## MENTAL STATUS

An assessment of mental status begins by observing the patient's appearance and behavior, noting dress, grooming, and personal hygiene. Posture, gestures, movements, facial expressions, and motor activity often provide important information about the patient. The patient's manner of speech and level of consciousness are also assessed. Is the patient's speech clear and coherent? Is the patient alert and responsive, or drowsy and stuporous?

Assessing orientation to time, place, and person assists in evaluating mental status. Does the patient know what day it is, what year it is, and the name of the president of the United States? Is the patient aware of where he or she is? Is the patient aware of who the examiner is and of his or her purpose for being in the room? Is the capacity for immediate memory intact? (See Chart 12-1: Mini-Mental State Examination in Chap. 12.)

## INTELLECTUAL FUNCTION

A person with an average IQ can repeat seven digits without faltering and can recite five digits backward. The examiner might

ask the patient to count backward from 100 or to subtract 7 from 100, then 7 from that, and so forth (called serial 7s) (Johnson, 2001). The capacity to interpret well-known proverbs tests abstract reasoning, which is a higher intellectual function; for example, does the patient know what is meant by “the early bird catches the worm”? Patients with damage to the frontal cortex appear superficially normal until one or more tests of integrative capacity are performed. Questions designed to assess this capacity might include the ability to recognize similarities: how are a mouse and dog or pen and pencil alike? Can the patient make judgements about situations—for instance, if the patient arrived home without a house key, what alternatives are there?

### THOUGHT CONTENT

During the interview, it is important to assess the patient’s thought content. Are the patient’s thoughts spontaneous, natural, clear, relevant, and coherent? Does the patient have any fixed ideas, illusions, or preoccupations? What are his or her insights into these thoughts? Preoccupation with death or morbid events, hallucinations, and paranoid ideation are examples of unusual thoughts or perceptions that require further evaluation.

### EMOTIONAL STATUS

An assessment of cerebral functioning also includes the patient’s emotional status. Is the patient’s affect (external manifestation of mood) natural and even, or irritable and angry, anxious, apathetic or flat, or euphoric? Does his or her mood fluctuate normally, or does the patient unpredictably swing from joy to sadness during the interview? Is affect appropriate to words and thought content? Are verbal communications consistent with nonverbal cues?

### PERCEPTION

The examiner may now consider more specific areas of higher cortical function. **Agnosia** is the inability to interpret or recognize objects seen through the special senses. The patient may see a pencil but not know what it is called or what to do with it. The patient may even be able to describe it but not to interpret its function. The patient may experience auditory or tactile agnosia as well as visual agnosia. Each of the dysfunctions implicates a different part of the cortex (Chart 60-1).

Screening for visual and tactile agnosia provides insight into the patient’s cortical interpretation ability. The patient is shown a familiar object and asked to identify it by name. Placing a familiar object (eg, key, coin) in the patient’s hand and having him or her identify it with both eyes closed is an easy way to assess tactile interpretation.

### MOTOR ABILITY

Assessment of cortical motor integration is carried out by asking the patient to perform a skilled act (throw a ball, move a chair).

Successful performance requires the ability to understand the activity desired and normal motor strength. Failure signals cerebral dysfunction.

### LANGUAGE ABILITY

The person with normal neurologic function can understand and communicate in spoken and written language. Does the patient answer questions appropriately? Can he or she read a sentence from a newspaper and explain its meaning? Can the patient write his or her name or copy a simple figure that the examiner has drawn? A deficiency in language function is called aphasia. Different types of aphasia result from injury to different parts of the brain (Chart 60-2). Aphasia is discussed in detail in Chapter 62.

### IMPACT ON LIFESTYLE

The nurse assesses the impact the neurologic impairment has on the patient’s lifestyle. Issues to consider include the limitations imposed on the patient by any deficit and the patient’s role in society, including family and community roles. The plan of care that the nurse develops needs to address and support adaptation to the neurologic deficit and continued function to the extent possible within the patient’s support system.

### DOCUMENTATION OF FINDINGS

Interpretation and documentation of neurologic abnormalities, particularly mental status abnormalities, should be specific and nonjudgmental. Lengthy descriptions and the use of terms such as “inappropriate” or “demented” should be avoided. Terms such as these often mean different things to different people and are therefore not useful when describing behavior. The examiner records and reports specific observations regarding orientation, level of consciousness, emotional state, or thought content, all of which permit comparison by others over time. Analysis and the conclusions that may be drawn from these findings usually depend on the examiner’s knowledge of neuroanatomy, neurophysiology, and neuropathology.

### Examining the Cranial Nerves

Table 60-5 describes how to assess the cranial nerves. Opposite sides of the face and neck are compared throughout the examination.

### Examining the Motor System

A thorough examination of the motor system includes an assessment of muscle size, tone, and strength, coordination, and balance. The patient is instructed to walk across the room while the examiner observes posture and gait. The muscles are inspected, and palpated if necessary, for their size and symmetry. Any evidence of atrophy or involuntary movements (tremors, tics) is noted. Muscle **tone** (the tension present in a muscle at rest) is evaluated by palpating various muscle groups at rest and during passive movement. Resistance to these movements is assessed and documented.

Chart  
60-1

#### Types of Agnosia and Corresponding Sites of Lesions

Type of Agnosia	Affected Cerebral Area
Visual	Occipital lobe
Auditory	Temporal lobe (lateral and superior portions)
Tactile	Parietal lobe
Body parts and relationships	Parietal lobe (posteroinferior regions)

Chart  
60-2

#### Types of Aphasia and Region of Brain Involved

Type of Aphasia	Brain Area Involved
Auditory-receptive	Temporal lobe
Visual-receptive	Parietal-occipital area
Expressive speaking	Inferior posterior frontal areas
Expressive writing	Posterior frontal area

Table 60-5 • Assessing Cranial Nerve Function

CRANIAL NERVE	CLINICAL EXAMINATION
I (olfactory)	With eyes closed, the patient identifies familiar odors (coffee, tobacco). Each nostril is tested separately.
II (optic)	Snellen eye chart; visual fields; ophthalmoscopic examination
III (oculomotor)	For cranial nerves III, IV, and VI: test for ocular rotations, conjugate movements, nystagmus. Test for pupillary reflexes, and inspect eyelids for ptosis.
IV (trochlear)	
VI (abducens)	
V (trigeminal)	Have patient close the eyes. Touch cotton to forehead, cheeks, and jaw. Sensitivity to superficial pain is tested by using the sharp and dull ends of a broken tongue blade. Alternate between the sharp point and the dull end. Patient reports “sharp” or “dull” with each movement. If responses are incorrect, test for temperature sensation. Test tubes of cold and hot water are used alternately. While the patient looks up, <i>lightly</i> touch a wisp of cotton against the temporal surface of each cornea. A blink and tearing are normal responses. Have the patient clench and move the jaw from side to side. Palpate the masseter and temporal muscles, noting strength and equality.
VII (facial)	Observe for symmetry while the patient performs facial movements: smiles, whistles, elevates eyebrows, frowns, tightly closes eyelids against resistance (examiner attempts to open them). Observe face for flaccid paralysis (shallow nasolabial folds). Patient extends tongue. Ability to discriminate between sugar and salt is tested.
VIII (acoustic)	Whisper or watch-tick test Test for lateralization (Weber) Test for air and bone conduction (Rinne)
IX (glossopharyngeal)	Assess patient’s ability to discriminate between sugar and salt on posterior third of the tongue.
X (vagus)	Depress a tongue blade on posterior tongue, or stimulate posterior pharynx to elicit gag reflex. Note any hoarseness in voice. Have patient say “ah.” Observe for symmetric rise of uvula and soft palate.
XI (spinal accessory)	Palpate and note strength of trapezius muscles while patient shrugs shoulders against resistance. Palpate and note strength of each sternocleidomastoid muscle as patient turns head against opposing pressure of the examiner’s hand.
XII (hypoglossal)	While the patient protrudes the tongue, any deviation or tremors are noted. The strength of the tongue is tested by having the patient move the protruded tongue from side to side against a tongue depressor.

Abnormalities in tone include **spasticity** (increased muscle tone), **rigidity** (resistance to passive stretch), and flaccidity.

### MUSCLE STRENGTH

Assessing the patient’s ability to flex or extend the extremities against resistance tests muscle strength. The function of an individual muscle or group of muscles is evaluated by placing the muscle at a disadvantage. The quadriceps, for example, is a powerful muscle responsible for straightening the leg. Once the leg is straightened, it is exceedingly difficult for the examiner to flex the knee. Conversely, if the knee is flexed and the patient is asked to straighten the leg against resistance, a more subtle disability can be elicited. The evaluation of muscle strength compares the sides of the body to each other. For example, the right upper extremity is compared to the left upper extremity. In this way, subtle differences in muscle strength can be more easily detected and accurately described.

Clinicians use a five-point scale to rate muscle strength (O’Hanlon-Nichols, 1999). A 5 indicates full power of contraction against gravity and resistance or normal muscle strength; 4 indicates fair but not full strength against gravity and a moderate amount of resistance or slight weakness; 3 indicates just sufficient strength to overcome the force of gravity or moderate weakness; 2 indicates the ability to move but not to overcome the force of gravity or severe weakness; 1 indicates minimal contractile power—weak muscle contraction can be palpated but no move-

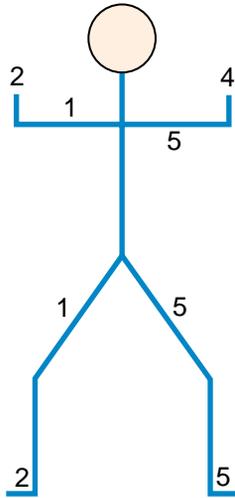

ment is noted—or very severe weakness; and 0 indicates complete paralysis. A stick figure may be used to record muscle strength and is a precise form of documenting findings. Distal and proximal strength in both upper and lower extremities is recorded using the five-point scale (Fig. 60-14).

Assessment of muscle strength can be as detailed as necessary. One may quickly test the strength of the proximal muscles of the upper and lower extremities, always comparing both sides. The strength of the finer muscles that control the function of the hand (hand grasp) and the foot (dorsiflexion and plantar flexion) can then be assessed.

### BALANCE AND COORDINATION

Cerebellar influence on the motor system is reflected in balance control and coordination. Coordination in the hands and upper extremities is tested by having the patient perform rapid, alternating movements and point-to-point testing. First, the patient is instructed to pat his or her thigh as fast as possible with each hand separately. Then the patient is instructed to alternately pronate and supinate the hand as rapidly as possible. Lastly, the patient is asked to touch each of the fingers with the thumb in a consecutive motion. Speed, symmetry, and degree of difficulty are noted.

Point-to-point testing is accomplished by having the patient touch the examiner’s extended finger and then his or her own nose. This is repeated several times. This assessment is then carried out with the patient’s eyes closed.

**FIGURE 60-14** A stick figure may be used to record muscle strength as follows: 5, full range of motion against gravity and resistance; 4, full range of motion against gravity and a moderate amount of resistance; 3, full range of motion against gravity only; 2, full range of motion when gravity is eliminated; 1, a weak muscle contraction when muscle is palpated, but no movement; and 0, complete paralysis.

Coordination in the lower extremities is tested by having the patient run the heel down the anterior surface of the tibia of the other leg. Each leg is tested in turn. **Ataxia** is defined as incoordination of voluntary muscle action, particularly of the muscle groups used in activities such as walking or reaching for objects. The presence of ataxia or tremors (rhythmic, involuntary movements) during these movements suggests cerebellar disease.

It is not necessary to carry out each of these assessments for coordination. During a routine examination, it is advisable to perform a simple screening of the upper and lower extremities by having the patient perform either rapid, alternating movements or point-to-point testing. When abnormalities are observed, a more thorough examination is indicated.

The **Romberg test** is a screening test for balance. The patient stands with feet together and arms at the side, first with eyes open and then with both eyes closed for 20 to 30 seconds. The examiner stands close to reassure the patient of support if he or she begins to fall. Slight swaying is normal, but a loss of balance is abnormal and is considered a positive Romberg test. Additional cerebellar tests for balance in the ambulatory patient include hopping in place, alternating knee bends, and heel-to-toe walking (both forward and backward).

## Examining the Reflexes

The motor reflexes are involuntary contractions of muscles or muscle groups in response to abrupt stretching near the site of the muscle's insertion. The tendon is struck directly with a reflex hammer or indirectly by striking the examiner's thumb, which is placed firmly against the tendon. Testing these reflexes enables the examiner to assess involuntary reflex arcs that depend on the presence of afferent stretch receptors, spinal synapses, efferent motor fibers, and a variety of modifying influences from higher levels. Common reflexes that may be tested include the deep tendon reflexes (biceps, brachioradialis, triceps, patellar, and ankle reflexes) and superficial or cutaneous reflexes (abdominal reflexes and plantar or Babinski response) (Fig. 60-15).

## TECHNIQUE

A reflex hammer is used to elicit a deep tendon reflex. The handle of the hammer is held loosely between the thumb and index finger, allowing a full swinging motion. The wrist motion is similar to that used during percussion. The extremity is positioned so that the tendon is slightly stretched. This requires a sound knowledge of the location of muscles and their tendon attachments. The tendon is then struck briskly, and the response is compared with that on the opposite side of the body. A wide variation in reflex response may be considered normal; it is more important, however, that the reflexes be symmetrically equivalent. When the comparison is made, both sides should be equivalently relaxed and each tendon struck with equal force.

Valid findings depend on several factors: proper use of the reflex hammer, proper positioning of the extremity, and a relaxed patient. If the reflexes are symmetrically diminished or absent, the examiner may use reinforcement to increase reflex activity. This involves the isometric contraction of other muscle groups. If lower extremity reflexes are diminished or absent, the patient is instructed to lock the fingers together and pull in opposite directions. Having the patient clench the jaw or press the heels against the floor or examining table may similarly elicit more reliable biceps, triceps, and brachioradialis reflexes.

## GRADING THE REFLEXES

The absence of reflexes is significant, although ankle jerks (Achilles reflex) may be normally absent in older people. Deep tendon reflex responses are often graded on a scale of 0 to 4+. A 4+ indicates a hyperactive reflex, often indicating pathology; 3+ indicates a response that is more brisk than average but may be normal or indicative of disease; 2+ indicates an average or normal response; 1+ indicates a hypoactive or diminished response; and 0 indicates no response. As stated previously, scale ratings are highly subjective. Findings can be recorded as a fraction, indicating the scale range (eg, 2/4). Some examiners prefer to use the terms present, absent, and diminished when describing reflexes. As with muscle strength recording, a stick figure such as the one shown in Chart 60-3 may also be used to record numerical findings.

## BICEPS REFLEX

The biceps reflex is elicited by striking the biceps tendon of the flexed elbow. The examiner supports the forearm with one arm while placing the thumb against the tendon and striking the thumb with the reflex hammer. The normal response is flexion at the elbow and contraction of the biceps (see Fig. 60-15A).

## TRICEPS REFLEX

To elicit a triceps reflex, the patient's arm is flexed at the elbow and positioned in front of the chest. The examiner supports the patient's arm and identifies the triceps tendon by palpating 2.5 to 5 cm (1 to 2 in) above the elbow. A direct blow on the tendon normally produces contraction of the triceps muscle and extension of the elbow (see Fig. 60-15B).

## BRACHIORADIALIS REFLEX

With the patient's forearm resting on the lap or across the abdomen, the brachioradialis reflex is assessed. A gentle strike of the hammer 2.5 to 5 cm (1 to 2 in) above the wrist results in flexion and supination of the forearm.

## PATELLAR REFLEX

The patellar reflex is elicited by striking the patellar tendon just below the patella. The patient may be in a sitting or a lying posi-

**FIGURE 60-15** Techniques for eliciting major reflexes. (A) Biceps reflex. (B) Triceps reflex. (C) Patellar reflex. (D) Ankle or Achilles reflex. (E) Babinski response. From Weber, J. & Kelley, J. (2003). *Health assessment in nursing* (2nd ed.). Philadelphia: Lippincott Williams & Wilkins. © B. Proud.

tion. If the patient is supine, the examiner supports the legs to facilitate relaxation of the muscles. Contractions of the quadriceps and knee extension are normal responses (see Fig. 60-15C).

#### ANKLE REFLEX

To elicit an ankle (Achilles) reflex, the foot is dorsiflexed at the ankle and the hammer strikes the stretched Achilles tendon (see Fig. 60-15D). This reflex normally produces plantar flexion. If the examiner cannot elicit the ankle reflex and suspects that the patient cannot relax, the patient is instructed to kneel on a chair or similar elevated, flat surface. This position places the ankles in dorsiflexion and reduces any muscle tension in the gastrocnemius. The Achilles tendons are struck in turn, and plantar flexion is usually demonstrated.

#### CLONUS

When reflexes are very hyperactive, a phenomenon called **clonus** may be elicited. If the foot is abruptly dorsiflexed, it may continue to “beat” two or three times before it settles into a position of rest. Occasionally with central nervous system disease this activity persists and the foot does not come to rest while the tendon is being stretched but persists in repetitive activity. The unsustained clonus associated with normal but hyperactive reflexes is not considered pathologic. Sustained clonus always indicates the presence of central nervous system disease and requires further evaluation.

#### SUPERFICIAL REFLEXES

The major superficial reflexes include corneal, gag or swallowing, upper/lower abdominal, cremasteric (men only), plantar, and

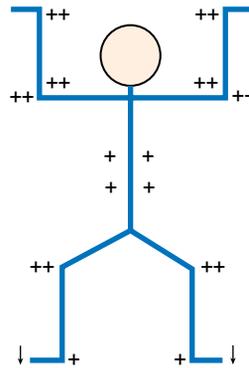

Chart  
60-3

## Documenting Reflexes

Deep tendon reflexes are graded on a scale of 0 to 4:

- 0 No response
- 1+ Diminished (hypoactive)
- 2+ Normal
- 3+ Increased (may be interpreted as normal)
- 4+ Hyperactive (hyperreflexia)

The deep tendon responses and plantar reflexes are commonly recorded on stick figures. The arrow points downward if the plantar response is normal and upward if the response is abnormal.

perianal. These reflexes are graded differently than the motor reflexes and are noted to be present (+) or absent (-). Of these, only three are tested commonly. The corneal reflex is tested carefully using a clean wisp of cotton and lightly touching the outer corner of each eye on the sclera. The reflex is present if the action elicits a blink. Conditions such as a cerebrovascular accident or coma might result in loss of this reflex, either unilaterally or bilaterally. Loss of this reflex indicates the need for eye protection and possible lubrication to prevent corneal damage.

The gag reflex is elicited by gently touching the posterior pharynx with a cotton-tipped applicator; first on one side of the uvula and then the other. Positive response is an equal elevation of the uvula and “gag” with stimulation. Absent response on one or both sides can be seen following a cerebrovascular accident and requires careful evaluation and treatment of the resultant swallowing dysfunction to prevent aspiration of food and fluids into the lungs.

The plantar reflex is elicited by stroking the lateral side of the foot with a tongue blade or the handle of a reflex hammer. Stimulation normally causes toe flexion. Toe fanning (positive Babinski) is an abnormal response and is discussed below (O’Hanlon-Nichols, 1999).

### BABINSKI RESPONSE

A well-known reflex indicative of central nervous system disease affecting the corticospinal tract is the **Babinski reflex**. In someone with an intact central nervous system, if the lateral aspect of the sole of the foot is stroked, the toes contract and are drawn together (see Fig. 60-15E). In patients who have central nervous system disease of the motor system, however, the toes fan out and are drawn back. This is normal in newborns but represents a serious abnormality in adults. Several other reflexes convey similar information. Many of them are interesting but not particularly informative.

### Sensory Examination

The sensory system is even more complex than the motor system because sensory modalities are carried in different tracts located in different portions of the spinal cord. The sensory examination is largely subjective and requires the cooperation of the patient. The examiner should be familiar with dermatomes that represent the distribution of the peripheral nerves that arise from the spinal

cord (see Fig. 60-11). Most sensory deficits result from peripheral neuropathy and follow anatomic dermatomes. Exceptions to this include major destructive lesions of the brain; loss of sensation, which may affect an entire side of the body; and the neuropathies associated with alcoholism, which occur in a glove-and-stocking distribution or over the entire hand or foot in areas traditionally covered by a glove or sock.

Assessment of the sensory system involves tests for tactile sensation, superficial pain, vibration, and position sense (proprioception). During the sensory assessment, the patient’s eyes are closed. Simple directions and reassurance that the examiner will not hurt or startle the patient encourage the cooperation of the patient.

Tactile sensation is assessed by lightly touching a cotton wisp to corresponding areas on each side of the body. The sensitivity of proximal parts of the extremities is compared with that of distal parts.

Pain and temperature sensations are transmitted together in the lateral part of the spinal cord, so it is unnecessary to test for temperature sense in most circumstances. Determining the patient’s sensitivity to a sharp object can assess superficial pain perception. The patient is asked to differentiate between the sharp and dull ends of a broken wooden cotton swab or tongue blade; using a safety pin is inadvisable because it breaks the integrity of the skin. Both the sharp and dull sides of the object are applied with equal intensity at all times, and as with the motor evaluation the two sides are compared.

Vibration and proprioception are transmitted together in the posterior part of the cord. Vibration may be evaluated through the use of a low-frequency (128- or 256-Hz) tuning fork. The handle of the vibrating fork is placed against a bony prominence, and the patient is asked whether he or she feels a sensation and is instructed to signal the examiner when the sensation ceases. Common locations used to test for vibratory sense include the distal joint of the great toe and the proximal thumb joint. If the patient does not perceive the vibrations at the distal bony prominences, the examiner progresses upward with the tuning fork until the patient perceives the vibrations. As with all measurements of sensation, a side-to-side comparison is made.

Position sense or proprioception may be determined by asking the patient to close both eyes and indicate, as the great toe is alternately moved up and down, in which direction movement has taken place. Vibration and position sense are often lost

together, frequently in circumstances in which all others remain intact.

Integration of sensation in the brain is evaluated next. This may be performed by testing two-point discrimination—when the patient is touched with two sharp objects simultaneously, are they perceived as two or as one? If touched simultaneously on opposite sides of the body, the patient should normally report being touched in two places. If only one site is reported, the one not being recognized is said to demonstrate extinction. Another test of higher cortical sensory ability is stereognosis. The patient is instructed to close both eyes and identify a variety of objects (eg, keys, coins) that are placed in one hand by the examiner.

### Gerontologic Considerations

The nervous system undergoes many changes during the normal aging process and is extremely vulnerable to general systemic illness. Changes throughout the nervous system vary in degree as the person ages. Nerve fibers that connect directly to muscles show little decline in function with age, as do simple neurologic functions that involve a number of connections in the spinal cord. Disease in the elderly often makes it difficult to distinguish normal from abnormal changes. However, it is important for clinicians not to attribute abnormality or dysfunction to aging without appropriate investigation (Kaye & Quinn, 2000).

**Structural Changes.** There are a number of alterations that occur with increasing age. Brain weight decreases, as does the number of synapses. A loss of neurons occurs in select regions of the brain. There is a reduction in cerebral blood flow and metabolism. Temperature regulation becomes less efficient. In the peripheral nervous system, myelin is lost, resulting in a decrease in conduction velocity in some nerves. There is an overall reduction in muscle bulk and the electrical activity within muscles. Taste buds atrophy and nerve cell fibers in the olfactory bulb degenerate. Nerve cells in the vestibular system of the inner ear, cerebellum, and proprioceptive pathways also degenerate. Deep tendon reflexes can be decreased or in some cases absent. Hypothalamic function is modified such that stage IV sleep is reduced. There is an overall slowing of autonomic nervous system responses. Pupillary responses are reduced or may not appear at all in the presence of cataracts (Kaye & Quinn, 2000).

**Motor Alterations.** There is an overall reduction in muscle bulk, with atrophy most easily noted in the hands (Kaye & Quinn, 2000). Changes in motor function often result in a flexed posture, shuffling gait, and rigidity of movement. These changes can create difficulties for the older person in maintaining or recovering balance. Strength and agility are diminished, and reaction time and movement time are decreased. Repetitive movements and mild tremors may be noted during an examination and may be of concern to the individual. Observation of gait may reveal a wide-based gait with balance difficulties.

**Sensory Alterations.** Sensory isolation due to visual and hearing loss can cause confusion, anxiety, disorientation, misinterpretation of the environment, and feelings of inadequacy. Sensory alterations may require modification of the home environment, such as large-print reading materials or sound enhancement for the telephone, as well as extra orientation to new surroundings. Simple explanations of routines, the location of the bathroom, and how to operate the call bell are just a few examples of information the elderly patient needs when hospitalized.

**Temperature Regulation and Pain Perception.** Other manifestations of neurologic changes are related to temperature regulation and pain. The elderly patient may feel cold more readily than heat and may require extra covering when in bed; a room temperature somewhat higher than usual may be desirable. Reaction to painful stimuli may be decreased with age. Because pain is an important warning signal, caution must be used when hot or cold packs are used. The older patient may be burned or suffer frostbite before being aware of any discomfort. Complaints of pain, such as abdominal discomfort or chest pain, may be more serious than the patient's perception might indicate and thus require careful evaluation.

**Taste and Smell Alterations.** The acuity of the taste buds decreases with age; along with an altered olfactory sense, this may cause a decreased appetite and subsequent weight loss. Extra seasoning often increases food intake as long as it does not cause gastric irritation. A decreased sense of smell due to atrophy of olfactory organs may present a safety hazard, because elderly people living alone may be unable to detect household gas leaks or fires. Smoke and carbon monoxide detectors, important for all, are critical for the elderly.

**Tactile and Visual Alterations.** Another neurologic alteration in the elderly patient is the dulling of tactile sensation due to a decrease in the number of areas of the body responding to all stimuli and in the number and sensitivity of sensory receptors. There may be difficulty in identifying objects by touch, and because fewer tactile cues are received from the bottom of the feet, the person may get confused as to body position and location.

These factors, combined with sensitivity to glare, decreased peripheral vision, and a constricted visual field, may result in disorientation, especially at night when there is little or no light in the room. Because the elderly person takes longer to recover visual sensitivity when moving from a light to dark area, night-lights and a safe and familiar arrangement of furniture are essential.

**Mental Status.** Mental status is evaluated while the history is obtained, and areas of judgment, intelligence, memory, affect, mood, orientation, speech, and grooming are assessed. Family members who bring the patient to the attention of the health care provider may have noticed changes in the patient's mental status. Drug toxicity should always be suspected as a causative factor when the patient has a change in mental status. **Delirium** (mental confusion, usually with delusions and hallucinations) is seen in elderly patients who have underlying central nervous system damage or are experiencing an acute condition such as infection, adverse medication reaction, or dehydration. About 25% of patients over the age of 70 admitted to the hospital have delirium (Johnson, 2001). The cause is often reversible and treatable (as in drug toxicity, vitamin B deficiency, or thyroid disease). Depression may produce impairment of attention and memory. For elderly patients, delirium, which is an acute change in mental status attributable to a treatable medical problem, must be differentiated from dementia, which is a chronic and irreversible deterioration of cognitive status.

**Nursing Implications.** Nursing care for patients with age-related changes to the nervous system and for patients with long-term neurologic disability who are aging should include the modifications previously described. In addition, the consequences of any neurologic deficit and its impact on overall function such as activities of daily living, use of assistive devices, and individual

coping need to be assessed and considered in planning care for patients.

Patient teaching is also affected because the nurse must understand the altered responses and the changing needs of the elderly patient before beginning to teach. When caring for the elderly patient, the nurse adapts activities such as preoperative teaching, diet therapy, and instruction about new medications, their timing, and doses to the patient's needs and capabilities. The nurse considers the presence of decline in fine motor movement and failing vision. When using visual materials for teaching or menu selection, adequate lighting without glare, contrasting colors, and large print are used to offset visual difficulties caused by rigidity and opacity of the lens in the eye and slower pupillary reaction.

Procedures and preparations needed for diagnostic tests are explained, taking into account the possibility of impaired hearing and slowed responses in the elderly. Even with hearing loss, the elderly patient often hears adequately if the speaker uses a low-pitched, clear voice; shouting only makes it harder for the patient to understand the speaker. Providing auditory and visual cues aids understanding; if the patient has a significant hearing or visual loss, assistive devices, a signer, or a translator may be needed.

Teaching at an unrushed pace and using reinforcement enhance learning and retention. Material should be short, concise, and concrete. Vocabulary is matched to the patient's ability, and terms are clearly defined. The elderly patient requires adequate time to receive and respond to stimuli, to learn, and to react. These measures allow comprehension, memory, and formation of association and concepts.

## Diagnostic Evaluation

### COMPUTED TOMOGRAPHY SCANNING

Computed tomography (CT) makes use of a narrow x-ray beam to scan the head in successive layers. The images provide cross-sectional views of the brain, with distinguishing differences in tissue densities of the skull, cortex, subcortical structures, and ventricles. The brightness of each slice of the brain in the final image is proportional to the degree to which it absorbs x-rays. The image is displayed on an oscilloscope or TV monitor and is photographed and stored digitally (Hinkle, 1999a).

Lesions in the brain are seen as variations in tissue density differing from the surrounding normal brain tissue. Abnormalities of tissue indicate possible tumor masses, brain infarction, displacement of the ventricles, and cortical atrophy. Whole-body CT scanners allow sections of the spinal cord to be visualized. The injection of a water-soluble iodinated contrast agent into the subarachnoid space through lumbar puncture improves the visualization of the spinal and intracranial contents on these images. The CT scan, along with magnetic resonance imaging (MRI), has largely replaced myelography as a diagnostic procedure for the diagnosis of herniated lumbar disks.

CT scanning is usually performed first without contrast material and then with intravenous contrast enhancement. The patient lies on an adjustable table with the head held in a fixed position, while the scanning system rotates around the head and produces cross-sectional images. The patient must lie with the head held perfectly still without talking or moving the face, because head motion will distort the image.

CT scanning is noninvasive and painless and has a high degree of sensitivity for detecting lesions. With advances in CT scan-

ning, the number of disorders and injuries that can be diagnosed is increasing.

### Nursing Interventions

Essential nursing interventions include preparation for the procedure and patient monitoring. Preparation includes teaching the patient about the need to lie quietly throughout the procedure. A review of relaxation techniques may be helpful for claustrophobic patients.

Sedation can be used if agitation, restlessness, or confusion will interfere with a successful study (Hinkle, 1999a). Ongoing patient monitoring during sedation is necessary. If a contrast agent is used, the patient must be assessed before the CT scan for an iodine/shellfish allergy, as the contrast agent is iodine-based. An intravenous line for injection of the contrast agent and a period of fasting (usually 4 hours) are required prior to the study. Patients who receive an intravenous or inhalation contrast agent are monitored during and after the procedure for allergic reactions and other side effects, including flushing, nausea, and vomiting.

### POSITRON EMISSION TOMOGRAPHY

Positron emission tomography (PET) is a computer-based nuclear imaging technique that produces images of actual organ functioning. The patient either inhales a radioactive gas or is injected with a radioactive substance that emits positively charged particles. When these positrons combine with negatively charged electrons (normally found in the body's cells), the resultant gamma rays can be detected by a scanning device that produces a series of two-dimensional views at various levels of the brain. This information is integrated by a computer and gives a composite picture of the brain at work.

PET permits the measurement of blood flow, tissue composition, and brain metabolism and thus indirectly evaluates brain function. The brain is one of the most metabolically active organs, consuming 80% of the glucose the body uses. PET measures this activity in specific areas of the brain and can detect changes in glucose use.

This test is useful in showing metabolic changes in the brain (Alzheimer's disease), locating lesions (brain tumor, epileptogenic lesions), identifying blood flow and oxygen metabolism in patients with strokes, evaluating new therapies for brain tumors, and revealing biochemical abnormalities associated with mental illness. The isotopes used have a very short half-life and are expensive to produce, requiring specialized equipment for production. PET scanning has been useful in research settings for the last 20 years and is now becoming more available in clinical settings. Improvements in scanning itself and the production of isotopes, as well as the advent of reimbursement by third-party payers, has increased the availability of PET studies (Gjedde et al., 2001).

### Nursing Interventions

Key nursing interventions include patient preparation, which involves explaining the test and teaching the patient about inhalation techniques and the sensations (eg, dizziness, lightheadedness, and headache) that may occur. The intravenous injection of the radioactive substance produces similar side effects. Relaxation exercises may reduce anxiety during the test.

## SINGLE PHOTON EMISSION COMPUTED TOMOGRAPHY

Single photon emission computed tomography (SPECT) is a three-dimensional imaging technique that uses radionuclides and instruments to detect single photons. It is a perfusion study that captures a moment of cerebral blood flow at the time of injection of a radionuclide (Huntington, 1999). Gamma photons are emitted from a radiopharmaceutical agent administered to the patient and are detected by a rotating gamma camera or cameras; the image is sent to a minicomputer. This approach allows areas behind overlying structures or background to be viewed, greatly increasing the contrast between normal and abnormal tissue. It is relatively inexpensive, and the duration is similar to that of a CT scan.

SPECT is useful in detecting the extent and location of abnormally perfused areas of the brain, thus allowing detection, localization, and sizing of stroke (before it is visible by CT scan), localization of seizure foci in epilepsy, and evaluation of perfusion before and after neurosurgical procedures. Pregnancy and breastfeeding are contraindications to SPECT.

### Nursing Interventions

The nursing interventions for SPECT primarily include patient preparation and patient monitoring. Teaching about what to expect before the test can allay anxiety and ensure patient cooperation during the test. Premenopausal women are advised to practice effective contraception before and for several days after testing, and the woman who is breastfeeding is instructed to stop nursing for the period of time recommended by the nuclear medicine department.

The nurse may need to accompany and monitor the patient during transport to the nuclear medicine department for the scan. Patients are monitored during and after the procedure for allergic reactions to the radiopharmaceutical agent. In a few institutions nurses with special education and training inject the contrast agent before a SPECT scan (Fischbach, 2002; Huntington, 1999).

## MAGNETIC RESONANCE IMAGING

Magnetic resonance imaging (MRI) uses a powerful magnetic field to obtain images of different areas of the body (Fig. 60-16). This diagnostic test involves altering hydrogen ions in the body. Placing the patient into a powerful magnetic field causes the hydrogen nuclei (protons) within the body to align like small

**FIGURE 60-16** Technician explains what to expect during an MRI.

magnets in a magnetic field. In combination with radiofrequency pulses, the protons emit signals, which are converted to images. MRI has the potential for identifying a cerebral abnormality earlier and more clearly than other diagnostic tests. It can provide information about the chemical changes within cells, allowing the clinician to monitor a tumor's response to treatment. It is particularly useful in the diagnosis of multiple sclerosis and can describe the activity and extent of disease in the brain and spinal cord. MRI does not involve ionizing radiation.

Several newer MRI techniques, including magnetic resonance angiography (MRA), diffusion-weighted imaging (DWI), perfusion-weighted imaging (PWI), and fluid attenuation inversion recovery (FLAIR), are becoming more widely used (Hinkle, 1999b; Shellock, 2001). The use of MRA allows visualization of the cerebral vasculature without the administration of an arterial contrast agent. A substantial amount of research on the techniques of DWI, PWI, and FLAIR shows promise for clearer visualization and the early diagnosis of ischemic stroke (Hinkle, 1999b). At present MRI is most valuable in the diagnosis of nonacute conditions, as the test takes up to an hour to complete.

### Nursing Interventions

Patient preparation should include teaching relaxation techniques and informing the patient that he or she will be able to talk to the staff by means of a microphone located inside the scanner. Many MRI suites provide headphones so patients can listen to the music of their choice during the procedure.

Before the patient enters the room where the MRI is to be performed, all metal objects and credit cards (the magnetic field can erase them) are removed. No metal objects may be brought into the room where the MRI is located (Shellock, 2001): this includes oxygen tanks, traditional ventilators, or even stethoscopes. The magnetic field generated by the unit is so strong that any metal-containing items will be strongly attracted and literally can be pulled away with such force that they fly like projectiles toward the magnet. There is a risk of severe injury and death; furthermore, damage to a very expensive piece of equipment may occur. A patient history is obtained to determine the presence of any metal objects (eg, aneurysm clips, orthopedic hardware, pacemakers, artificial heart valves, intrauterine devices). These objects could malfunction, be dislodged, or heat up as they absorb energy. Cochlear implants will be inactivated by MRI; therefore, other imaging procedures are considered.

**NURSING ALERT** For patient safety, the nurse must make sure no patient care equipment (eg, portable oxygen tanks) that contains metal or metal parts enters the room where the MRI is located.

The patient lies on a flat platform that is moved into a tube housing the magnet. The scanning process is painless, but the patient hears loud thumping of the magnetic coils as the magnetic field is being pulsed. Because the MRI scanner is a narrow tube, patients may experience claustrophobia; sedation may be prescribed in these circumstances. Newer versions of MRI machines are less claustrophobic than the earlier devices and are available in some locations. However, the images produced on these machines are not optimal, and the traditional device is preferable for accurate diagnosis.

## CEREBRAL ANGIOGRAPHY

Cerebral angiography is an x-ray study of the cerebral circulation with a contrast agent injected into a selected artery. Cerebral angiography is a valuable tool to investigate vascular disease, aneurysms, and arteriovenous malformations. It is frequently performed before craniotomy to assess the patency and adequacy of the cerebral circulation and to determine the site, size, and nature of the pathologic processes (Fischbach, 2002; Frizzell, 1998).

Most cerebral angiograms are performed by threading a catheter through the femoral artery in the groin and up to the desired vessel. Alternatively, direct puncture of the carotid or vertebral artery or retrograde injection of a contrast agent into the brachial artery may be performed.

In digital subtraction angiography (DSA), x-ray images of the area in question are obtained before and after the injection of a contrast agent. The computer analyzes the differences between the two images and produces an enhanced image of the carotid and vertebral arterial systems. The injection for a DSA can be given through a peripheral vein (Fischbach, 2002; Rowland, 2000).

### Nursing Interventions

The patient should be well hydrated, and clear liquids are usually permitted up to the time of a regular arteriogram or DSA. Before going to the x-ray department, the patient is instructed to void. The locations of the appropriate peripheral pulses are marked with a felt-tip pen. The patient is instructed to remain immobile during the angiogram process and is told to expect a brief feeling of warmth in the face, behind the eyes, or in the jaw, teeth, tongue, and lips, and a metallic taste when the contrast agent is injected.

After the groin is shaved and prepared, a local anesthetic is administered to prevent pain at the insertion site and to reduce arterial spasm. A catheter is introduced into the femoral artery, flushed with heparinized saline, and filled with contrast agent. Fluoroscopy is used to guide the catheter to the appropriate vessels. During injection of the contrast agent, images are made of the arterial and venous phases of circulation through the brain.

Nursing care after cerebral angiography includes observation for signs and symptoms of altered cerebral blood flow. In some instances, patients may experience major or minor arterial blockage due to embolism, thrombosis, or hemorrhage, producing a neurologic deficit. Signs of such an occurrence include alterations in the level of responsiveness and consciousness, weakness on one side of the body, motor or sensory deficits, and speech disturbances. Therefore, it is necessary to observe the patient frequently for these signs and to report them immediately if they occur.

The injection site is observed for hematoma formation (a localized collection of blood), and an ice bag may be applied intermittently to the puncture site to relieve swelling and discomfort. Because a hematoma at the puncture site or embolization to a distant artery affects the peripheral pulses, these pulses are monitored frequently. The color and temperature of the involved extremity are assessed to detect possible embolism.

## MYELOGRAPHY

A **myelogram** is an x-ray of the spinal subarachnoid space taken after the injection of a contrast agent into the spinal subarachnoid space through a lumbar puncture. It outlines the spinal subarachnoid space and shows any distortion of the spinal cord or spinal dural sac caused by tumors, cysts, herniated vertebral disks,

or other lesions. Water-based agents have replaced oil-based agents and their use has reduced side effects and complications; these agents disperse upward through the CSF. Myelography is performed less frequently today because of the sensitivity of CT scanning and MRI (Hickey, 2003).

### Nursing Interventions

Because many patients have misconceptions about this procedure, the nurse clarifies the explanation given by the physician and answers questions. The patient is informed about what to expect during the procedure and should be aware that changes in position may be made during the procedure. The meal that normally would be eaten before the procedure is omitted. A sedative may be prescribed to help the patient cope with this rather lengthy test. Patient preparation for lumbar puncture is discussed later in this chapter.

After myelography, the patient lies in bed with the head of the bed elevated 30 to 45 degrees. The patient is advised to remain in bed in the recommended position for 3 hours or as prescribed by the physician. The patient is encouraged to drink liberal amounts of fluid for rehydration and replacement of CSF and to decrease the incidence of postlumbar puncture headache. The blood pressure, pulse, respiratory rate, and temperature are monitored, as well as the patient's ability to void. Untoward signs include headache, fever, stiff neck, **photophobia** (sensitivity to light), seizures, and signs of chemical or bacterial meningitis.

## NONINVASIVE CAROTID FLOW STUDIES

Noninvasive carotid flow studies use ultrasound imagery and Doppler measurements of arterial blood flow to evaluate carotid and deep orbital circulation. The graph produced indicates blood velocity. Increased blood velocity can indicate stenosis or partial obstruction. These tests are often obtained before arteriography, which carries a higher risk of stroke or death (Fischbach, 2002; Hickey, 2003). Carotid Doppler, carotid ultrasonography, oculo-plethysmography, and ophthalmodynamometry are four common noninvasive vascular techniques that permit evaluation of arterial blood flow and detection of arterial stenosis, occlusion, and plaques.

## TRANSCRANIAL DOPPLER

Transcranial Doppler uses the same noninvasive techniques as carotid flow studies except that it records the blood flow velocities of the intracranial vessels. Flow velocities of the basal artery can be measured through thin areas of the temporal and occipital bones of the skull. A hand-held Doppler probe emits a pulsed beam; the signal is reflected by the moving red blood cells within the blood vessels (Falyar, 1999). Transcranial Doppler sonography is a noninvasive technique that is helpful in assessing vasospasm (a complication following subarachnoid hemorrhage), altered cerebral blood flow found in occlusive vascular disease or stroke, and other cerebral pathology.

### Nursing Interventions

When a carotid flow study or transcranial Doppler is scheduled, the procedure is described to the patient. The patient is informed that this is a noninvasive test, that a hand-held transducer will be placed over the neck and orbits of the eyes, and that some type of water-soluble jelly is used on the transducer. Either one of these low-risk tests can be performed at the patient's bedside.

## ELECTROENCEPHALOGRAPHY

An electroencephalogram (EEG) represents a record of the electrical activity generated in the brain. It is obtained through electrodes applied on the scalp or through microelectrodes placed within the brain tissue. It provides a physiologic assessment of cerebral activity.

The EEG is a useful test for diagnosing and evaluating seizure disorders, coma, or organic brain syndrome. Tumors, brain abscesses, blood clots, and infection may cause abnormal patterns in electrical activity. The EEG is also used in making a determination of brain death.

Electrodes are applied to the scalp to record the electrical activity in various regions of the brain. The amplified activity of the neurons between any two of these electrodes is recorded on continuously moving paper; this record is called the encephalogram.

For a baseline recording, the patient lies quietly with both eyes closed. The patient may be asked to hyperventilate for 3 to 4 minutes and then look at a bright, flashing light for photic stimulation. These activation procedures are performed to evoke abnormal electrical discharges, such as seizure potentials. A sleep EEG may be recorded after sedation because some abnormal brain waves are seen only when the patient is asleep. If the epileptogenic area is inaccessible to conventional scalp electrodes, nasopharyngeal electrodes may be used.

Depth recording of EEG is performed by introducing electrodes stereotactically (radiologically placed using instrumentation) into a target area of the brain, as indicated by the patient's seizure pattern and scalp EEG. It is used to identify patients who may benefit from surgical excision of epileptogenic foci.

Special transsphenoidal, mandibular, and nasopharyngeal electrodes can be used, and video recording combined with EEG monitoring and telemetry is used in hospital settings to capture epileptiform abnormalities and their sequelae. Some epilepsy centers provide long-term ambulatory EEG monitoring with portable recording devices.

### Nursing Interventions

To increase the chances of recording seizure activity, it is sometimes recommended that the patient be deprived of sleep on the night before the EEG. Antiseizure agents, tranquilizers, stimulants, and depressants should be withheld 24 to 48 hours before an EEG because these medications can alter the EEG wave patterns or mask the abnormal wave patterns of seizure disorders (Hickey, 2003). Coffee, tea, chocolate, and cola drinks are omitted in the meal before the test because of their stimulating effect. The meal is not omitted, however, because an altered blood glucose level can also cause changes in the brain wave patterns.

The patient is informed that the standard EEG takes 45 to 60 minutes, 12 hours for a sleep EEG. The patient is assured that the procedure does not cause an electric shock and that the EEG is a diagnostic test, not a form of treatment. An EEG requires patient cooperation and ability to lie quietly during the test. Sedation is not advisable as it may lower the seizure threshold in patients with a seizure disorder and alter brain wave activity in all patients. Patients with seizures do not stop taking their anti-seizure medication prior to testing.

Routine EEGs use a water-soluble lubricant for electrode contact, which at the conclusion of the study can be wiped off and removed by shampooing. Sleep EEGs involve the use of colloid glue for electrode contact, which requires acetone for removal.

## EVOKED POTENTIAL STUDIES

In evoked potential studies, electrodes are applied to the scalp and an external stimulus is applied to peripheral sensory receptors to elicit changes in the brain waves. Evoked changes are detected with the aid of computerized devices that extract the signal, display it on an oscilloscope, and store the data on magnetic tape or disk. These studies are based on the concept that any insult or dysfunction that can alter neuronal metabolism or disturb membrane function may change evoked responses in brain waves. In neurologic diagnosis, they reflect conduction times in the peripheral nervous system. In clinical practice, the visual, auditory, and somatosensory systems are most often tested.

In visual evoked responses, the patient looks at a visual stimulus (flashing lights, a checkerboard pattern on a screen). The average of several hundred stimuli is recorded by EEG leads placed over the occiput. The transit time from the retina to the occipital area is measured using computer-averaging methods.

Auditory evoked responses or brain stem evoked responses are measured by applying an auditory stimulus (a repetitive auditory click) and measuring the transit time up the brain stem into the cortex. Specific lesions in the auditory pathway modify or delay the response.

In somatosensory evoked responses, the peripheral nerves are stimulated (electrical stimulation through skin electrodes) and the transit time up the spinal cord to the cortex is measured and recorded from scalp electrodes.

This test is used to detect a deficit in spinal cord conduction and to monitor spinal cord function during operative procedures. Because myelinated fibers conduct impulses at a higher rate of speed, nerves with an intact myelin sheath record the highest velocity. Demyelination of nerve fibers leads to a decrease in speed of conduction, as found in Guillain-Barré syndrome, multiple sclerosis, and polyneuropathies.

### Nursing Interventions

There is no specific patient preparation other than to explain the procedure and to reassure the patient and encourage him or her to relax. The patient is advised to remain perfectly still throughout the recording to prevent artifacts (signals not generated by the brain) that interfere with the recording and interpretation of the test.

## ELECTROMYOGRAPHY

An electromyogram (EMG) is obtained by introducing needle electrodes into the skeletal muscles to measure changes in the electrical potential of the muscles and the nerves leading to them. The electrical potentials are shown on an oscilloscope and amplified by a loudspeaker so that both the sound and appearance of the waves can be analyzed and compared simultaneously.

An EMG is useful in determining the presence of a neuromuscular disorder and myopathies. They help to distinguish weakness due to neuropathy (functional or pathologic changes in the peripheral nervous system) from weakness due to other causes.

### Nursing Interventions

The procedure is explained and the patient is warned to expect a sensation similar to that of an intramuscular injection as the needle is inserted into the muscle. The muscles examined may ache for a short time after the procedure.

## NERVE CONDUCTION STUDIES

Nerve conduction studies are performed by stimulating a peripheral nerve at several points along its course and recording the muscle action potential or the sensory action potential that results. Surface or needle electrodes are placed on the skin over the nerve to stimulate the nerve fibers. This test is useful in the study of peripheral neuropathies.

## LUMBAR PUNCTURE AND EXAMINATION OF CEREBROSPINAL FLUID

A lumbar puncture (spinal tap) is carried out by inserting a needle into the lumbar subarachnoid space to withdraw CSF. The test may be performed to obtain CSF for examination, to measure and reduce CSF pressure, to determine the presence or absence of blood in the CSF, to detect spinal subarachnoid block, and to administer antibiotics intrathecally (into the spinal canal) in certain cases of infection.

The needle is usually inserted into the subarachnoid space between the third and fourth or fourth and fifth lumbar vertebrae. Because the spinal cord divides into a sheaf of nerves at the first lumbar vertebra, insertion of the needle below the level of the third lumbar vertebra prevents puncture of the spinal cord.

A successful lumbar puncture requires that the patient be relaxed; an anxious patient is tense, and this may increase the pressure reading. CSF pressure with the patient in a lateral recumbent position is normally 70 to 200 mm H<sub>2</sub>O. Pressures of more than 200 mm H<sub>2</sub>O are considered abnormal.

A lumbar puncture may be risky in the presence of an intracranial mass lesion because intracranial pressure is decreased by the removal of CSF, and the brain may herniate downward through the tentorium and the foramen magnum.

### Queckenstedt's Test

A lumbar manometric test (Queckenstedt's test) may be performed by compressing the jugular veins on each side of the neck during the lumbar puncture. The increase in pressure caused by the compression is noted; then the pressure is released and pressure readings are made at 10-second intervals. Normally, CSF pressure rises rapidly in response to compression of the jugular veins and returns quickly to normal when the compression is released. A slow rise and fall in pressure indicates a partial block due to a lesion compressing the spinal subarachnoid pathways. If there is no pressure change, a complete block is indicated. This test is not performed if an intracranial lesion is suspected.

See Chart 60-4 for nursing guidelines for assisting with a lumbar puncture.

### Cerebrospinal Fluid Analysis

The CSF should be clear and colorless. Pink, blood-tinged, or grossly bloody CSF may indicate a cerebral contusion, laceration, or subarachnoid hemorrhage. Sometimes with a difficult lumbar puncture, the CSF initially is bloody because of local trauma but then becomes clearer.

Usually, specimens are obtained for cell count, culture, and glucose and protein testing. The specimens should be sent to the laboratory immediately because changes will take place and alter

the result if the specimens are allowed to stand. (See Appendix B for the normal values of CSF.)

### Post-Lumbar Puncture Headache

A post-lumbar puncture headache, ranging from mild to severe, may appear a few hours to several days after the procedure. This is the most common complication, occurring in 15% to 30% of patients (Connolly, 1999). It is a throbbing bifrontal or occipital headache, dull and deep in character. It is particularly severe on sitting or standing but lessens or disappears when the patient lies down.

The headache is caused by CSF leakage at the puncture site. The fluid continues to escape into the tissues by way of the needle track from the spinal canal. It is then absorbed promptly by the lymphatics. As a result of this leak, the supply of CSF in the cranium is depleted to a point at which it is insufficient to maintain proper mechanical stabilization of the brain. This leakage of CSF allows settling of the brain when the patient assumes an upright position, producing tension and stretching the venous sinuses and pain-sensitive structures. Both traction and pain are lessened and the leakage is reduced when the patient lies down.

Post-lumbar puncture headache may be avoided if a small-gauge needle is used and if the patient remains prone after the procedure. When a large volume of fluid (more than 20 mL) is removed, the patient is positioned prone for 2 hours, then flat in a side-lying position for 2 to 3 hours, and then supine or prone for 6 more hours. Keeping the patient flat overnight may reduce the incidence of headaches.

The postpuncture headache is usually managed by bed rest, analgesic agents, and hydration (Connolly, 1999). Occasionally, if the headache persists, the epidural blood patch technique may be used. Blood is withdrawn from the antecubital vein and injected into the epidural space, usually at the site of the previous spinal puncture. The rationale is that the blood acts as a gelatinous plug to seal the hole in the dura, preventing further loss of CSF.

### Other Complications of Lumbar Puncture

Herniation of the intracranial contents, spinal epidural abscess, spinal epidural hematoma, and meningitis are rare but serious complications of lumbar puncture. Other complications include temporary voiding problems, slight elevation of temperature, backache or spasms, and stiffness of the neck.

## HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

Many diagnostic tests that were once performed as part of a hospital stay are now carried out in short-procedure units or outpatient testing settings or units. As a result, family members often provide the postprocedure care. Therefore, the patient and family must receive clear verbal and written instructions about precautions to take after the procedure, complications to watch for, and steps to take if complications occur. Because many patients undergoing neurologic diagnostic studies are elderly or have neurologic deficits, provisions must be made to ensure that transportation and postprocedure care and monitoring are available.

Chart  
60-4

## Guidelines for Assisting with a Lumbar Puncture

A needle is inserted into the subarachnoid space through the third and fourth or fourth and fifth lumbar interspace to withdraw spinal fluid.

**Preprocedure**

1. Determine whether written consent for the procedure has been obtained.
2. Explain the procedure to the patient and describe sensations that are likely during the procedure (ie, a sensation of cold as the site is cleansed with solution, a needle prick when local anesthetic is injected).
3. Determine whether the patient has any questions or misconceptions about the procedure; reassure the patient that the needle will not enter the spinal cord or cause paralysis.
4. Instruct the patient to void before the procedure.

**Procedure (performed by the physician)**

1. The patient is positioned on one side at the edge of the bed or examining table with back toward the physician; the thighs and legs are flexed as much as possible to increase the space between the spinous processes of the vertebrae, for easier entry into the subarachnoid space.

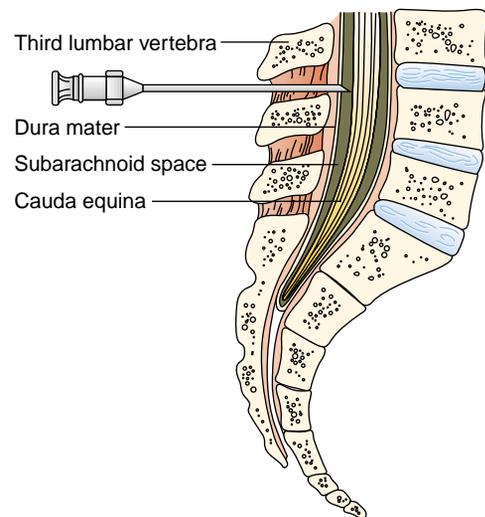

© B. Proud.

2. A small pillow may be placed under the patient's head to maintain the spine in a horizontal position; a pillow may be placed between the legs to prevent the upper leg from rolling forward.
3. The nurse assists the patient to maintain the position to avoid sudden movement, which can produce a traumatic (bloody) tap.
4. The patient is encouraged to relax and is instructed to breathe normally, because hyperventilation may lower an elevated pressure.

5. The nurse describes the procedure step by step to the patient as it proceeds.
6. The physician cleanses the puncture site with an antiseptic solution and drapes the site.
7. Local anesthetic is injected to numb the puncture site, and then a spinal needle is inserted into the subarachnoid space through the third and fourth or fourth and fifth lumbar interspace.
8. A specimen of CSF is removed and usually collected in three test tubes, labeled in order of collection. A pressure reading may be obtained. The needle is withdrawn.
9. A small dressing is applied to the puncture site.
10. The tubes of CSF are sent to the laboratory immediately.

**Postprocedure**

1. Instruct the patient to lie prone for 2 to 3 hours to separate the alignment of the dural and arachnoid needle punctures in the meninges, to reduce leakage of CSF.

2. Monitor the patient for complications of lumbar puncture; notify physician if complications occur.
3. Encourage increased fluid intake to reduce the risk of post-procedure headache.

**Continuing Care**

Contacting the patient and family after diagnostic testing enables the nurse to determine whether they have any questions about the procedure or whether the patient had any untoward results. During these phone calls, teaching is reinforced and the patient and family are reminded to make and keep follow-up appointments. Patients, family members, and health care providers are focused on the immediate needs, issues, or deficits that necessitated the diagnostic testing. This is also a good time to remind them of the need for and importance of continuing health promotion and screening practices and make referrals to appropriate health care providers.

**Critical Thinking Exercises**

1. A 68-year old patient with a long history of type 1 diabetes is admitted to the hospital to rule out an ischemic stroke and is scheduled for an MRI. Explain why the MRI is indicated for this patient and what, if any, precautions must be taken because this patient is diabetic. What nursing observations and assessments are indicated because of the occurrence of these two disorders? What safety precautions are essential in the MRI suite, and why?

2. Your clinic patient will be having an EEG. Describe the procedure, its duration, and preparation for this test, including medication/diet restrictions, if any. How would the presence of a seizure disorder alter your plan of care?

3. Your patient is scheduled to undergo digital subtraction angiography (DSA). He tells you that he recently had an angiogram. What explanation can you give to the patient and his wife regarding the difference between the two procedures? What additional information will help prepare the patient to undergo this procedure?

# ● Management of Patients With Neurologic Dysfunction

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Describe the special nursing needs of patients with varied neurologic dysfunction.
2. Describe the multiple needs of the patient with altered level of consciousness.
3. Use the nursing process as a framework for care of the patient with altered level of consciousness.
4. Identify the early and late clinical manifestations of increased intracranial pressure.
5. Use the nursing process as a framework for care of the patient with increased intracranial pressure.
6. Describe the needs of the patient undergoing intracranial or transsphenoidal surgery.
7. Use the nursing process as a framework for care of the patient undergoing intracranial/transsphenoidal surgery.
8. Identify the various types and causes of seizures.
9. Use the nursing process to develop a plan of care for the patient experiencing seizures.
10. Identify the needs of the patient experiencing headaches.

This chapter discusses care of the patient with an altered level of consciousness, the patient with increased **intracranial pressure** (ICP), and the patient undergoing neurosurgical procedures, experiencing seizures, or experiencing headaches. Some of the topics in this chapter, such as headaches and seizures, may be symptoms of dysfunction in another body system. Conversely, headaches and seizures can be quite serious symptoms of a severe disruption of the neurologic system. These disorders can also be diagnosed at times as “idiopathic,” or without an identifiable cause. The commonality in these disorders is not in the diagnosis or the medical treatment; it is in the behaviors and needs of the patient and the manner in which nurses can best support the patient through these episodes.

The central nervous system contains a vast network of neurons controlling the body’s vital functions. Yet this system is vulnerable, and its optimal function depends on several key factors. First, the neurologic system relies on its own structural integrity for support and homeostasis. Examples of structural disruption include head injury, brain tumor, intracranial hemorrhage, infection, and stroke. As brain tissue expands in the inflexible cranium, ICP rises and cerebral perfusion is impaired. Further expansion places pressure on vital centers, which can cause permanent neurologic deficits or lead to brain death.

Second, the neurologic system also relies on the body’s ability to maintain a homeostatic environment. It requires the body to deliver the essential elements of oxygen and glucose and to filter out substrates toxic to the neurons. Sepsis, hypovolemia, myocardial infarction, respiratory arrest, hypoglycemia, electrolyte imbalance, drug and/or alcohol overdose, encephalopathy, and ketoacidosis are all examples of circumstances in which the neurologic system is depressed due to a toxic metabolic effect or due to the body’s mechanical inability to provide essential substrates.

Some conditions can be treated and neurologic impairments can be reversed; others result in permanent deficits.

Although neuroscience nursing is a specialty requiring an understanding of neuroanatomy, neurophysiology, neurodiagnostic testing, critical care nursing, and rehabilitation nursing, nurses in all settings care for patients with neurologic disorders. Ongoing assessment of the patient’s neurologic function and health needs, identification of problems, mutual goal setting, development and implementation of care plans (including teaching, counseling, and coordinating activities), and evaluation of the outcomes of care are nursing actions integral to the recovery of the patient. The nurse also collaborates with other members of the health care team to provide essential care, offer a variety of solutions to problems, help patients and families gain control of their lives, and explore the educational and supportive resources available in the community. The goals are to achieve as high a level of function as possible and to enhance the quality of life for the patient with neurologic impairment and his or her family.

## Altered Level of Consciousness

An **altered level of consciousness** (LOC) is apparent in the patient who is not oriented, does not follow commands, or needs persistent stimuli to achieve a state of alertness. LOC is gauged on a continuum with a normal state of alertness and full cognition (consciousness) on one end and coma on the other end. **Coma** is a clinical state of unconsciousness in which the patient is unaware of self or the environment for prolonged periods (days to months or even years). **Akinetic mutism** is a state of unresponsiveness to the environment in which the patient makes no movement or sound but sometimes opens the eyes. **Persistent vegetative state** is a condition in which the patient is described as wakeful but de-

## Glossary

**akinetic mutism:** unresponsiveness to the environment; the patient makes no movement or sound but sometimes opens the eyes

**altered level of consciousness:** condition of being less responsive to and aware of environmental stimuli

**autoregulation:** ability of cerebral blood vessels to dilate or constrict to maintain stable cerebral blood flow despite changes in systemic arterial blood pressure

**brain death:** irreversible loss of all functions of the entire brain, including the brain stem

**coma:** prolonged state of unconsciousness

**craniotomy:** a surgical procedure that involves entry into the cranial vault

**craniectomy:** a surgical procedure that involves removing a portion of the skull

**Cushing’s response:** brain’s attempt to restore blood flow by increasing arterial pressure to overcome the increased intracranial pressure

**Cushing’s triad:** three classic signs—bradycardia, hypertension, and bradypnea—seen with pressure on the medulla as a result of brain stem herniation

**decerebration:** an abnormal body posture associated with a severe brain injury, char-

acterized by extreme extension of the upper and lower extremities

**decortication:** an abnormal posture associated with severe brain injury, characterized by abnormal flexion of the upper extremities and extension of the lower extremities

**epidural monitor:** a sensor placed between the skull and the dura to monitor intracranial pressure

**epilepsy:** a group of syndromes characterized by paroxysmal transient disturbances of brain function.

**fiberoptic monitor:** a system that uses light refraction to determine intracranial pressure

**herniation:** abnormal protrusion of tissue through a defect or natural opening

**intracranial pressure:** pressure exerted by the volume of the intracranial contents within the cranial vault

**migraine headache:** a severe, unrelenting headache often accompanied by symptoms such as nausea, vomiting, and visual disturbances

**Monro-Kellie hypothesis:** theory that states that due to limited space for expansion within the skull, an increase in any one of

the cranial contents—brain tissue, blood, or CSF—causes a change in the volume of the others

**persistent vegetative state:** condition in which the patient is wakeful but devoid of conscious content, without cognitive or affective mental function

**primary headache:** a headache for which no specific organic cause can be found

**seizures:** paroxysmal transient disturbance of the brain resulting from a discharge of abnormal electrical activity

**status epilepticus:** episode in which the patient experiences multiple seizure bursts with no recovery time in between

**secondary headache:** headache identified as a symptom of another organic disorder (eg, brain tumor, hypertension)

**subarachnoid screw or bolt:** device placed into the subarachnoid space to measure intracranial pressure

**transsphenoidal:** surgical approach to the pituitary via the sphenoid sinuses

**ventriculostomy:** a catheter placed in one of the lateral ventricles of the brain to measure intracranial pressure and allow for drainage of fluid

void of conscious content, without cognitive or affective mental function. The level of responsiveness and consciousness is the most important indicator of the patient's condition.

## Pathophysiology

Altered LOC is not a disorder itself; rather, it is a function and symptom of multiple pathophysiologic phenomena. The cause may be neurologic (head injury, stroke), toxicologic (drug overdose, alcohol intoxication), or metabolic (hepatic or renal failure, diabetic ketoacidosis).

The underlying causes of neurologic dysfunction are disruption in the cells of the nervous system, neurotransmitters, or brain anatomy (see Chap. 60).

A disruption in the basic functional units (neurons) or neurotransmitters results in faulty impulse transmission, impeding communication within the brain or from the brain to other parts of the body. These disruptions are caused by cellular edema and other mechanisms such as antibodies disrupting chemical transmission at receptor sites.

Intact anatomic structures of the brain are needed for proper function. The two hemispheres of the cerebrum must communicate, via an intact corpus callosum, and the lobes of the brain (frontal, parietal, temporal, and occipital) must communicate and coordinate their specific functions (see Chap. 60). Additional anatomic structures of importance are the cerebellum and the brain stem. The cerebellum has both excitatory and inhibitory actions and is largely responsible for coordination of movement. The brain stem contains areas that control the heart, respiration, and blood pressure. Disruptions in the anatomic structures are caused by trauma, edema, pressure from tumors as well as other mechanisms such as an increase or decrease in blood or cerebrospinal fluid (CSF) circulation.

## Clinical Manifestations

Alterations in LOC occur along a continuum, and the clinical manifestations depend on where the patient is along this continuum. As the patient's state of alertness and consciousness decreases, there will be changes in the pupillary response, eye opening response, verbal response, and motor response. Initial changes may be reflected by subtle behavioral changes such as restlessness or increased anxiety. The pupils, normally round and quickly reactive to light, become sluggish (response is slower); as the patient becomes comatose, the pupils become fixed (no response to light). The patient in a coma does not open the eyes, respond verbally, or move the extremities in response to a request to do so.

## Assessment and Diagnostic Findings

The patient with an altered LOC is at risk for alterations in every body system. A complete assessment is performed, with particular attention to the neurologic system. The neurologic examination should be as complete as the LOC allows. It includes an evaluation of mental status, cranial nerve function, cerebellar function (balance and coordination), reflexes, and motor and sensory function. LOC, a sensitive indicator of neurologic function, is assessed based on the criteria in the Glasgow Coma Scale: eye opening, verbal response, and motor response (Bateman, 2001). The patient's responses are rated on a scale from 3 to 15. A score of 3 indicates severe impairment of neurologic function; a score of 15 indicates that the patient is fully responsive (see Chap. 63 for more discussion about the Glasgow Coma Scale).

If the patient is comatose, with localized signs such as abnormal pupillary and motor responses, it is assumed that neurologic disease is present until proven otherwise. If the patient is comatose and pupillary light reflexes are preserved, a toxic or metabolic disorder is suspected.

Procedures used to identify the cause of unconsciousness include scanning, imaging, tomography (eg, computed tomography, magnetic resonance imaging, positron emission tomography), and electroencephalography. Laboratory tests include analysis of blood glucose, electrolytes, serum ammonia, and blood urea nitrogen levels, as well as serum osmolality, calcium level, and partial thromboplastin and prothrombin times. Other studies may be used to evaluate serum ketones and alcohol, drug levels, and arterial blood gas levels.

## Complications

Potential complications for the patient with altered LOC include respiratory failure, pneumonia, pressure ulcers, and aspiration. Respiratory failure may develop shortly after the patient becomes unconscious. If the patient cannot maintain effective respirations, supportive care is initiated to provide adequate ventilation. Pneumonia is common in patients receiving mechanical ventilation or in those who cannot maintain and clear the airway. The patient with altered LOC is subject to all the complications associated with immobility, such as pressure ulcers, venous stasis, musculoskeletal deterioration, and disturbed gastrointestinal functioning. Pressure ulcers may become infected and act as a source of sepsis. Aspiration of gastric contents or feedings may occur, precipitating the development of pneumonia or airway occlusion.

## Medical Management

The first priority of treatment for the patient with altered LOC is to obtain and maintain a patent airway. The patient may be orally or nasally intubated, or a tracheostomy may be performed. Until the patient's ability to breathe on his or her own is determined, a mechanical ventilator is used to maintain adequate oxygenation. The circulatory status (blood pressure, heart rate) is monitored to ensure adequate perfusion to the body and brain. An intravenous catheter is inserted to provide access for fluids and intravenous medications. Neurologic care focuses on the specific neurologic pathology, if any. Nutritional support, using either a feeding tube or a gastrostomy tube, is initiated as soon as possible. In addition to measures to determine and treat the underlying causes of altered LOC, other medical interventions are aimed at pharmacologic management of complications and strategies to prevent complications.

## NURSING PROCESS: THE PATIENT WITH AN ALTERED LEVEL OF CONSCIOUSNESS

### Assessment

Where to begin assessing the patient with an altered LOC depends somewhat on each patient's circumstances, but clinicians often start by assessing the verbal response. Determining the patient's orientation to time, person, and place assesses verbal response. The patient is asked to identify the day, date, or season of the year and to identify where he or she is or to identify the clinicians, family members, or visitors present. Other questions such as, "Who is the president?" or "What is the next holiday?"

are also helpful in determining the patient's processing of information in the environment. (Verbal response cannot be evaluated when the patient is intubated or has a tracheostomy, and this should be clearly documented.)

Alertness is measured by the patient's ability to open the eyes spontaneously or to a stimulus. Patients with severe neurologic dysfunction cannot do this. The nurse should assess for periorbital edema or trauma, which may prevent the patient from opening the eyes, and document if this interferes with eye opening.

Motor response includes spontaneous, purposeful movement (eg, the awake patient can move all four extremities with equal strength), movement only in response to noxious stimuli (eg, pressure/pain), or abnormal posturing (Bateman, 2001). If the patient is not responding to commands, the motor response is tested by applying a painful stimulus (firm but gentle pressure) to the nailbed or by squeezing a muscle. If the patient attempts to push away or withdraw, the response is recorded as purposeful or appropriate ("patient withdraws to painful stimuli"). This response is considered purposeful if the patient can cross from one side of the body to the other in response to noxious stimuli. An inappropriate or nonpurposeful response is random and aimless. Posturing may be decorticate or decerebrate (Fig. 61-1; see Chap. 60). The most severe neurologic impairment results in flaccidity. Occasionally, posturing cannot be elicited if the patient has been given pharmacologic paralyzing agents.

In addition to LOC, the nurse monitors parameters such as respiratory status, eye signs, and reflexes on an ongoing basis. Table 61-1 summarizes the assessment and the clinical significance of the findings. Body functions (circulation, respiration, elimination, fluid and electrolyte balance) are examined in a systematic and ongoing manner.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the major nursing diagnoses may include the following:

- Ineffective airway clearance related to altered level of consciousness
- Risk of injury related to decreased level of consciousness
- Deficient fluid volume related to inability to take in fluids by mouth

- Impaired oral mucous membranes related to mouth-breathing, absence of pharyngeal reflex, and altered fluid intake
- Risk for impaired skin integrity related to immobility
- Impaired tissue integrity of cornea related to diminished or absent corneal reflex
- Ineffective thermoregulation related to damage to hypothalamic center
- Impaired urinary elimination (incontinence or retention) related to impairment in neurologic sensing and control
- Bowel incontinence related to impairment in neurologic sensing and control and also related to transitions in nutritional delivery methods
- Disturbed sensory perception related to neurologic impairment
- Interrupted family processes related to health crisis

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

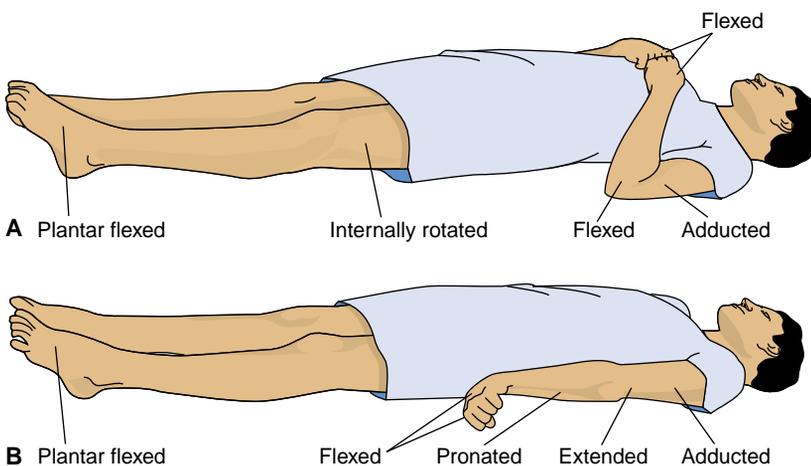

Based on the assessment data, potential complications may include:

- Respiratory distress or failure
- Pneumonia
- Aspiration
- Pressure ulcer
- Deep vein thrombosis

### Planning and Goals

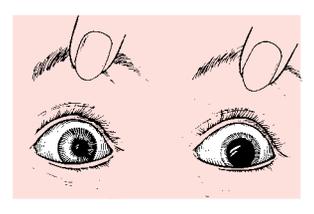

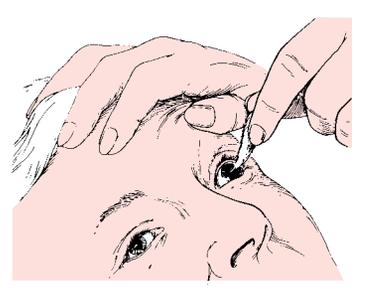

The goals of care for the patient with altered LOC include maintenance of a clear airway, protection from injury, attainment of fluid volume balance, achievement of intact oral mucous membranes, maintenance of normal skin integrity, absence of corneal irritation, attainment of effective thermoregulation, and effective urinary elimination. Additional goals include bowel continence, accurate perception of environmental stimuli, maintenance of intact family or support system, and absence of complications (Jacobson & Winslow, 2000).

Because the unconscious patient's protective reflexes are impaired, the quality of nursing care provided literally may mean the difference between life and death. The nurse must assume responsibility for the patient until the basic reflexes (coughing, blinking, and swallowing) return and the patient becomes conscious and oriented. Thus, the major nursing goal is to compensate for the absence of these protective reflexes.

**FIGURE 61-1** Abnormal posture response to stimuli. (A) Decorticate posturing, involving adduction and flexion of the upper extremities, internal rotation of the lower extremities, and plantar flexion of the feet. (B) Decerebrate posturing, involving extension and outward rotation of upper extremities and plantar flexion of the feet.

**Table 61-1 • Nursing Assessment of the Unconscious Patient**

EXAMINATION	CLINICAL ASSESSMENT	CLINICAL SIGNIFICANCE
Level of responsiveness or consciousness Pattern of respiration	Eye opening; verbal and motor responses; pupils (size, equality, reaction to light) Respiratory pattern  Cheyne-Stokes respiration  Hyperventilation  Ataxic respiration with irregularity in depth/rate	Obeying commands is a favorable response and demonstrates a return to consciousness. Disturbances of respiratory center of brain may result in various respiratory patterns. Suggests lesions deep in both hemispheres; area of basal ganglia and upper brain stem Suggests onset of metabolic problem or brain stem damage Ominous sign of damage to medullary center
Eyes Pupils (size, equality, reaction to light)	Equal, normally reactive pupils Equal or unequal diameter Progressive dilation Fixed dilated pupils	Suggests that coma is toxic or metabolic in origin Helps determine location of lesion Indicates increasing ICP Indicates injury at level of midbrain
		
Eye movements	Normally, eyes should move from side to side.	Functional and structural integrity of brain stem is assessed by inspection of extraocular movements; usually absent in deep coma.
Corneal reflex	When cornea is touched with a wisp of clean cotton, blink response is normal.	Tests cranial nerves V and VII; helps determine location of lesion if unilateral; absent in deep coma
		
Facial symmetry Swallowing reflex	Asymmetry (sagging, decrease in wrinkles) Drooling versus spontaneous swallowing	Sign of paralysis Absent in coma Paralysis of cranial nerves X and XII Subarachnoid hemorrhage, meningitis Fracture or dislocation of cervical spine Asymmetric response in paralysis
Neck	Stiff neck Absence of spontaneous neck movement	
Response of extremity to noxious stimuli	Firm pressure on a joint of the upper and lower extremity Observe spontaneous movements.	
Deep tendon reflexes	Tap patellar and biceps tendons.	Absent in deep coma Brisk response may have localizing value. Asymmetric response in paralysis Absent in deep coma
Pathologic reflexes	Firm pressure with blunt object on sole of foot, moving along lateral margin and crossing to the ball of foot	Flexion of the toes, especially the great toe, is normal except in newborn. Dorsiflexion of toes (especially great toe) indicates contralateral pathology of corticospinal tract (Babinski reflex). Helps determine location of lesion in brain
		
Abnormal posture	Observation for posturing (spontaneous or in response to noxious stimuli) Flaccidity with absence of motor response Decorticate posture (flexion and internal rotation of forearms and hands) Decerebrate posture (extension and external rotation)	Deep extensive brain lesion Seen with cerebral hemisphere pathology and in metabolic depression of brain function Decerebrate posturing indicates deeper and more severe dysfunction than does decorticate posturing; implies brain pathology; poor prognostic sign.

## Nursing Interventions

### MAINTAINING THE AIRWAY

The most important consideration in managing the patient with altered LOC is to establish an adequate airway and ensure ventilation. Obstruction of the airway is a risk because the epiglottis and tongue may relax, occluding the oropharynx, or the patient may aspirate vomitus or nasopharyngeal secretions.

The accumulation of secretions in the pharynx presents a serious problem. Because the patient cannot swallow and lacks pharyngeal reflexes, these secretions must be removed to eliminate the danger of aspiration. Elevating the head of the bed to 30 degrees helps prevent aspiration. Positioning the patient in a lateral or semiprone position will also help as it permits the jaw and tongue to fall forward, thus promoting drainage of secretions.

Positioning alone is not always adequate, however. The patient may require suctioning and oral hygiene. Suctioning is performed to remove secretions from the posterior pharynx and upper trachea. With the suction off, a whistle-tip catheter is lubricated with a water-soluble lubricant and inserted to the level of the posterior pharynx and upper trachea. Continuous suction is applied as the catheter is withdrawn using a twisting motion of the thumb and forefinger. This twisting maneuver prevents the suctioning end of the catheter from causing irritation, which increases secretions and causes mucosal trauma and bleeding. Before and after suctioning, the patient is hyperoxygenated and hyperventilated to prevent hypoxia (Hickey, 2003). In addition to these interventions, chest physiotherapy and postural drainage may be initiated to promote pulmonary hygiene, unless contraindicated by the patient's underlying condition. Also, the chest should be auscultated at least every 8 hours to detect adventitious breath sounds or absence of breath sounds.

Despite these measures, or because of the severity of impairment, the patient with altered LOC often requires intubation and mechanical ventilation. Nursing actions for the mechanically ventilated patient include maintaining the patency of the endotracheal tube or tracheostomy, providing frequent oral care, monitoring arterial blood gas measurements, and maintaining ventilator settings (see Chap. 25).

### PROTECTING THE PATIENT

For the protection of the patient, padded siderails are provided and raised at all times. Care should be taken to prevent injury from invasive lines and equipment, and other potential sources of injury should be identified (eg, restraints, tight dressings, environmental irritants, damp bedding or dressings, tubes and drains).

**NURSING ALERT** If the patient begins to emerge from unconsciousness, every measure that is available and appropriate for calming and quieting him or her should be used. Any form of restraint is likely to be countered by the patient with resistance, leading to self-injury or to a dangerous increase in ICP. Therefore, physical restraints should be avoided if possible; a written prescription must be obtained if their use is essential for the patient's well-being.

Protection also encompasses the concept of protecting the patient's dignity during altered LOC. Simple measures such as providing privacy and speaking to the patient during nursing care activities preserve the patient's humanity. Not speaking negatively about the patient's condition or prognosis is also important, because patients in a light coma may be able to hear. The comatose patient has an increased need for advocacy, and it is the

nurse's responsibility to see that these advocacy needs are met (Elliott & Wright, 1999; Villanueva, 1999).

### MAINTAINING FLUID BALANCE AND MANAGING NUTRITIONAL NEEDS

Hydration status is assessed by examining tissue turgor and mucous membranes, assessing intake and output trends, and analyzing laboratory data. Fluid needs are met initially by giving the required fluids intravenously. However, intravenous solutions (and blood transfusions) for patients with intracranial conditions must be administered slowly. If given too rapidly, they may increase ICP. The quantity of fluids administered may be restricted to minimize the possibility of producing cerebral edema.

If the patient does not recover quickly and sufficiently enough to take adequate fluids and calories by mouth, a feeding tube will be inserted for the administration of fluids and enteral feedings (Day, Stotts, Frankfurt et al., 2001).

### PROVIDING MOUTH CARE

The mouth is inspected for dryness, inflammation, and crusting. The unconscious patient requires conscientious oral care because there is a risk of parotitis if the mouth is not kept scrupulously clean. The mouth is cleansed and rinsed carefully to remove secretions and crusts and to keep the mucous membranes moist. A thin coating of petrolatum on the lips prevents drying, cracking, and encrustations. If the patient has an endotracheal tube, the tube should be moved to the opposite side of the mouth daily to prevent ulceration of the mouth and lips.

### MAINTAINING SKIN AND JOINT INTEGRITY

Preventing skin breakdown requires continuing nursing assessment and intervention. Special attention is given to unconscious patients because they cannot respond to external stimuli. Assessment includes a regular schedule of turning to avoid pressure, which can cause breakdown and necrosis of the skin. Turning also provides kinesthetic (sensation of movement), proprioceptive (awareness of position), and vestibular (equilibrium) stimulation. After turning, the patient is carefully repositioned to prevent ischemic necrosis over pressure areas. Dragging the patient up in bed must be avoided, because this creates a shearing force and friction on the skin surface.

Maintaining correct body position is important; equally important is passive exercise of the extremities to prevent contractures. The use of splints or foam boots aids in the prevention of footdrop and eliminates the pressure of bedding on the toes. Trochanter rolls supporting the hip joints keep the legs in proper alignment. The arms should be in abduction, the fingers lightly flexed, and the hands in slight supination. The heels of the feet should be assessed for pressure areas. Specialty beds, such as fluidized or low-air-loss beds, may be used to decrease pressure on bony prominences.

### PRESERVING CORNEAL INTEGRITY

Some unconscious patients have their eyes open and have inadequate or absent corneal reflexes. The cornea is likely to become irritated or scratched, leading to keratitis and corneal ulcers. The eyes may be cleansed with cotton balls moistened with sterile normal saline to remove debris and discharge. If artificial tears are prescribed, they may be instilled every 2 hours. Periocular edema (swelling around the eyes) often occurs after cranial surgery. Cold compresses may be prescribed, and care must be exerted to avoid contact with the cornea. Eye patches should be used cautiously

because of the potential for corneal abrasion from the cornea coming in contact with the patch.

### ACHIEVING THERMOREGULATION

High fever in the unconscious patient may be caused by infection of the respiratory or urinary tract, drug reactions, or damage to the hypothalamic temperature-regulating center. A slight elevation of temperature may be caused by dehydration. The environment can be adjusted, depending on the patient's condition, to promote a normal body temperature. If body temperature is elevated, a minimum amount of bedding—a sheet or perhaps only a small drape—is used. The room may be cooled to 18.3°C (65°F). However, if the patient is elderly and does not have an elevated temperature, a warmer environment is needed.

**NURSING ALERT** The body temperature of an unconscious patient is never taken by mouth. Rectal or tympanic (if not contraindicated) temperature measurement is preferred to the less accurate axillary temperature.

Because of damage to the heat-regulating center in the brain or severe intracranial infection, unconscious patients often develop very high temperatures. Such temperature elevations must be controlled because the increased metabolic demands of the brain can overburden cerebral circulation and oxygenation, resulting in cerebral deterioration (Hickey, 2003). Persistent hyperthermia with no identified clinical source of infection indicates brain stem damage and a poor prognosis.

Strategies for reducing fever include:

- Removing all bedding over the patient (with the possible exception of a light sheet or small drape)
- Administering repeated doses of acetaminophen as prescribed
- Giving a cool sponge bath and allowing an electric fan to blow over the patient to increase surface cooling
- Using a hypothermia blanket

Frequent temperature monitoring is indicated to assess the response to the therapy and to prevent an excessive decrease in temperature and shivering.

### PREVENTING URINARY RETENTION

The patient with an altered LOC is often incontinent or has urinary retention. The bladder is palpated or scanned at intervals to determine whether urinary retention is present, because a full bladder may be an overlooked cause of overflow incontinence. A portable bladder ultrasound instrument is a useful tool in bladder management and retraining programs (O'Farrell, Vandervoort, Bisnaire et al., 2001).

If there are signs of urinary retention, initially an indwelling urinary catheter attached to a closed drainage system is inserted. A catheter may be inserted during the acute phase of illness to monitor urinary output. Because catheters are a major factor in causing urinary tract infection, the patient is observed for fever and cloudy urine. The area around the urethral orifice is inspected for drainage. The urinary catheter is usually removed when the patient has a stable cardiovascular system and if no diuresis, sepsis, or voiding dysfunction existed before the onset of coma. Although many unconscious patients urinate spontaneously after catheter removal, the bladder should be palpated or scanned with a portable ultrasound device periodically for urinary retention (O'Farrell et al., 2001). An intermittent catheterization

program may be initiated to ensure complete emptying of the bladder at intervals, if indicated.

An external catheter (condom catheter) for the male patient and absorbent pads for the female patient can be used for the unconscious patient who can urinate spontaneously although involuntarily. As soon as consciousness is regained, a bladder-training program is initiated. The incontinent patient is monitored frequently for skin irritation and skin breakdown. Appropriate skin care is implemented to prevent these complications.

### PROMOTING BOWEL FUNCTION

The abdomen is assessed for distention by listening for bowel sounds and measuring the girth of the abdomen with a tape measure. There is a risk of diarrhea from infection, antibiotics, and hyperosmolar fluids. Frequent loose stools may also occur with fecal impaction. Commercial fecal collection bags are available for patients with fecal incontinence.

Immobility and lack of dietary fiber may cause constipation. The nurse monitors the number and consistency of bowel movements and performs a rectal examination for signs of fecal impaction. Stool softeners may be prescribed and can be administered with tube feedings. To facilitate bowel emptying, a glycerine suppository may be indicated. The patient may require an enema every other day to empty the lower colon.

### PROVIDING SENSORY STIMULATION

Sensory stimulation is provided at the appropriate time to help overcome the profound sensory deprivation of the unconscious patient. Efforts are made to maintain the sense of daily rhythm by keeping the usual day and night patterns for activity and sleep. The nurse touches and talks to the patient and encourages family members and friends to do so. Communication is extremely important and includes touching the patient and spending enough time with him or her to become sensitive to his or her needs. It is also important to avoid making any negative comments about the patient's status or prognosis in the patient's presence.

The nurse orients the patient to time and place at least once every 8 hours. Sounds from the patient's home and workplace may be introduced using a tape recorder. Family members can read to the patient from a favorite book and may suggest radio and television programs that the patient previously enjoyed as a means of enriching the environment and providing familiar input (Hickey, 2003).

When arousing from coma, many patients experience a period of agitation, indicating that they are becoming more aware of their surroundings but still cannot react or communicate in an appropriate fashion. Although disturbing for many family members, this is actually a good clinical sign. At this time, it is necessary to minimize the stimulation to the patient by limiting background noises, having only one person speak to the patient at a time, giving the patient a longer period of time to respond, and allowing for frequent rest or quiet times.

When the patient has regained consciousness, videotaped family or social events may assist the patient in recognizing family and friends and allow him or her to experience missed events.

### MEETING FAMILIES' NEEDS

The family of the patient with altered LOC may be thrown into a sudden state of crisis and go through the process of severe anxiety, denial, anger, remorse, grief, and reconciliation. Depending on the disorder that caused the altered LOC and the extent of the patient's recovery, the family may be unprepared for the changes in the cognitive and physical status of their loved one. If the

patient has significant residual deficits, the family may require considerable time, assistance, and support to come to terms with these changes. To help family members mobilize their adaptive capacities, the nurse can reinforce and clarify information about the patient's condition, permit the family to be involved in care, and listen to and encourage ventilation of feelings and concerns while supporting them in their decision-making process about posthospitalization management and placement (Hauber & Testani-Dufour, 2000). Families may benefit from participation in support groups offered through the hospital, rehabilitation facility, or community organizations.

In some circumstances, the family may need to face the death of their loved one. The neurologic patient is often pronounced brain dead before physiologic death occurs. The term **brain death** describes irreversible loss of all functions of the entire brain, including the brain stem. The term may be misleading to the family because although brain function has ceased, the patient appears to be alive, with the heart rate and blood pressure sustained by vasoactive medications, and breathing continues by mechanical ventilation. When discussing a patient who is brain dead with family members, it is important to use the term "dead"; the term "brain dead" may confuse them (Shewmon, 1998). Chart 61-1 discusses ethical issues related to patients with severe neurologic damage. End-of-life care is discussed in Chapter 17.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Pneumonia, aspiration, and respiratory failure are potential complications in any patient who has a depressed LOC and who cannot protect the airway or turn, cough, and take deep breaths. The longer the period of unconsciousness, the greater the risk for pulmonary complications.

Vital signs and respiratory function are monitored closely to detect any signs of respiratory failure or distress. Total blood

count and arterial blood gas measurements are assessed to determine whether there are adequate red blood cells to carry oxygen and whether ventilation is effective. Chest physiotherapy and suctioning are initiated to prevent respiratory complications such as pneumonia. If pneumonia develops, cultures are obtained to identify the organism so that appropriate antibiotics can be administered.

The patient with altered LOC is monitored closely for evidence of impaired skin integrity, and strategies to prevent skin breakdown and pressure ulcers are continued through all phases of care, including hospital, rehabilitation, and home care. Factors that contribute to impaired skin integrity (eg, incontinence, inadequate dietary intake, pressure on bony prominences, edema) are addressed. If pressure ulcers develop, strategies to promote healing are undertaken. Care is taken to prevent bacterial contamination of pressure ulcers, which may lead to sepsis and septic shock. Assessment and management of pressure ulcers are discussed in Chapter 11.

The patient should also be monitored for signs and symptoms of deep vein thrombosis. Patients who develop deep vein thrombosis are at risk for pulmonary embolism. Prophylaxis such as subcutaneous heparin or low-molecular-weight heparin (Fragmin, Orgaran) should be prescribed (Karch, 2002). Thigh-high elastic compression stockings or pneumatic compression stockings should also be prescribed to reduce the risk for clot formation. Measures to assess for deep vein thrombosis, such as Homans' sign, may be clinically unreliable in this population, and the nurse should observe for redness and swelling in the lower extremities.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Maintains clear airway and demonstrates appropriate breath sounds
2. Experiences no injuries
3. Attains/maintains adequate fluid status
  - a. Has no clinical signs or symptoms of dehydration
  - b. Demonstrates normal range of serum electrolytes
  - c. Has no clinical signs or symptoms of overhydration
4. Attains/maintains healthy oral mucous membranes
5. Maintains normal skin integrity
6. Has no corneal irritation
7. Attains or maintains thermoregulation
8. Has no urinary retention
9. Has no diarrhea or fecal impaction
10. Receives appropriate sensory stimulation
11. Family members cope with crisis
  - a. Verbalize fears and concerns
  - b. Participate in patient's care and provide sensory stimulation by talking and touching
12. Is free of complications
  - a. Has arterial blood gas values within normal range
  - b. Displays no signs or symptoms of pneumonia
  - c. Exhibits intact skin over pressure areas
  - d. Does not develop deep vein thrombosis

### Increased Intracranial Pressure

The rigid cranial vault contains brain tissue (1,400 g), blood (75 mL), and CSF (75 mL) (Hickey, 2003). The volume and pressure of these three components are usually in a state of equi-

#### Chart 61-1 • Ethics and Related Issues

##### *What Ethical Principles Apply When Treatment Is Withdrawn From the Patient in a Persistent Vegetative State?*

###### Situation

The family of a 55-year-old woman who has been diagnosed as being in a persistent vegetative state wants to withdraw tube feedings and let her die. The nursing staff express concern about removing the feeding tube, relating that the patient has wakeful periods and sometimes seems to move her eyes toward them when they care for her. The family's wishes, however, are honored and the medical team discontinues all tube feedings and intravenous lines and orders comfort measures only. The patient dies 7 days later.

###### Dilemma

How do nurses reconcile their ethical obligations of respect for persons and sanctity of life in the face of a decision to withdraw treatment? Is the ethical principle of justice upheld?

###### Discussion

Is the maintenance of medical treatment obligatory in patients in a persistent vegetative state to provide respect for the patient and the sanctity of life? What mechanisms can the nursing staff use to assist them in resolving these dilemmas?

librium and produce the ICP. ICP is usually measured in the lateral ventricles; normal ICP is 10 to 20 mm Hg (Hickey, 2003).

The **Monro-Kellie hypothesis** states that because of the limited space for expansion within the skull, an increase in any one of the components causes a change in the volume of the others. Because brain tissue has limited space to change, compensation typically is accomplished by displacing or shifting CSF, increasing the absorption of CSF, or decreasing cerebral blood volume. Without such changes, ICP will begin to rise. Under normal circumstances, minor changes in blood volume and CSF volume occur constantly due to alterations in intrathoracic pressure (coughing, sneezing, straining), posture, blood pressure, and systemic oxygen and carbon dioxide levels.

## Pathophysiology

Increased ICP is a syndrome that affects many patients with acute neurologic conditions. This is because pathologic conditions alter the relationship between intracranial volume and pressure. Although an elevated ICP is most commonly associated with head injury, it also may be seen as a secondary effect in other conditions, such as brain tumors, subarachnoid hemorrhage, and toxic and viral encephalopathies. Increased ICP from any cause decreases cerebral perfusion, stimulates further swelling (edema), and shifts brain tissue through openings in the rigid dura, resulting in **herniation**, a dire, frequently fatal event.

### DECREASED CEREBRAL BLOOD FLOW

Increased ICP may significantly reduce cerebral blood flow, resulting in ischemia and cell death. In the early stages of cerebral ischemia, the vasomotor centers are stimulated and the systemic pressure rises to maintain cerebral blood flow. Usually a slow bounding pulse and respiratory irregularities accompany this. These changes in blood pressure, pulse, and respiration are important clinically because they suggest increased ICP.

The concentration of carbon dioxide in the blood and in the brain tissue also has a role in the regulation of cerebral blood flow. A rise in carbon dioxide partial pressure ( $\text{PaCO}_2$ ) causes cerebral vasodilatation, leading to increased cerebral blood flow and increased ICP; a fall in  $\text{PaCO}_2$  has a vasoconstrictive effect (Young, Ropper & Bolton, 1998). Decreased venous outflow may also increase cerebral blood volume, thus raising ICP.

### CEREBRAL EDEMA

Cerebral edema or swelling is defined as an abnormal accumulation of water or fluid in the intracellular space, extracellular space,

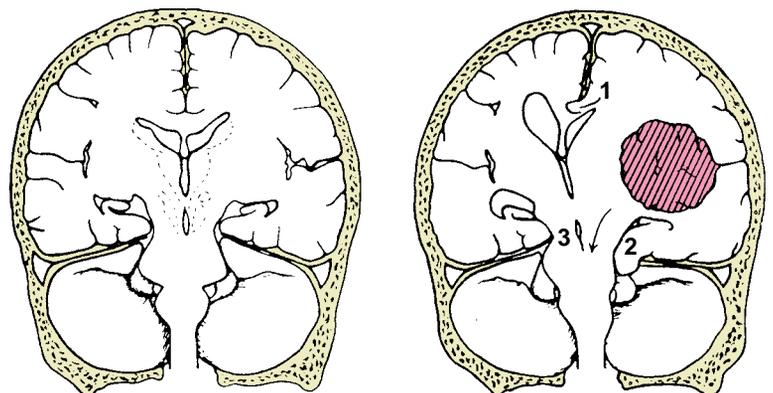

or both, associated with an increase in brain tissue volume. Edema can occur in the gray, white, or interstitial matter. As brain tissue swells within the rigid skull, several mechanisms attempt to compensate for the increasing ICP. These mechanisms include autoregulation and decreasing the production and flow of CSF. **Autoregulation** refers to the brain's ability to change the diameter of its blood vessels automatically to maintain a constant cerebral blood flow during alterations in systemic blood pressure.

### CEREBRAL RESPONSE TO INCREASED ICP

As ICP rises, compensatory mechanisms in the brain work to maintain blood flow and prevent tissue damage. The brain can maintain a steady perfusion pressure when the arterial systolic blood pressure is 50 to 150 mm Hg and ICP is less than 40 mm Hg. The cerebral perfusion pressure is calculated by subtracting the ICP from the mean arterial pressure. For example, if the mean arterial pressure is 100 and the ICP is 15, then the cerebral perfusion pressure is 85 mm Hg. The normal cerebral perfusion pressure is 70 to 100 mm Hg (Hickey, 2003; Young et al., 1998). As ICP rises, however, and the autoregulatory mechanism of the brain is overwhelmed, cerebral perfusion pressure can rise to greater than 100 mm Hg or fall to less than 50 mm Hg. Patients with a cerebral perfusion pressure less than 50 mm Hg experience irreversible neurologic damage. If ICP equals mean arterial pressure, cerebral circulation ceases (Porth, 2002).

A clinical phenomenon known as the **Cushing's response** (or Cushing's reflex) is seen when cerebral blood flow decreases significantly. When ischemic, the vasomotor center triggers a rise in arterial pressure in an effort to overcome the increased ICP. A sympathetically mediated response causes a rise in the systolic blood pressure with a widening of the pulse pressure and cardiac slowing. This response, which is mediated by the sympathetic nervous system, is seen clinically as a rise in systolic blood pressure, widening of the pulse pressure, and reflex slowing of the heart rate. This is a sign requiring immediate intervention; however, perfusion may be recoverable if treated rapidly.

At a certain volume or pressure, the brain's ability to autoregulate becomes ineffective and decompensation (ischemia and infarction) begins (Young et al., 1998). When this occurs, the patient exhibits significant changes in mental status and vital signs. The bradycardia, hypertension, and bradypnea associated with this deterioration are known as **Cushing's triad**, a grave sign. At this point, herniation of the brain stem and occlusion of the cerebral blood flow occur if therapeutic intervention is not initiated. Herniation refers to the shifting of brain tissue from an area of high pressure to an area of lower pressure (Fig. 61-2). The herniated

**FIGURE 61-2** Cross section of normal brain (*left*) and brain with intracranial shifts from supratentorial lesions (*right*). (1) Herniation of the cingulate gyrus. (2) Herniation of the temporal lobe into the tentorial notch. (3) Downward displacement of the brainstem through the notch.

tissue exerts pressure on the brain area to which it has herniated or shifted, interfering with the blood supply in that area. Cessation of cerebral blood flow results in cerebral ischemia and infarction and brain death.

## Clinical Manifestations

When ICP increases to the point at which the brain's ability to adjust has reached its limits, neural function is impaired; this may be manifested by clinical changes first in LOC and later by abnormal respiratory and vasomotor responses.

**NURSING ALERT** The earliest sign of increasing ICP is a change in LOC. Slowing of speech and delay in response to verbal suggestions are other early indicators.

Any sudden change in the patient's condition, such as restlessness (without apparent cause), confusion, or increasing drowsiness, has neurologic significance. These signs may result from compression of the brain due to swelling from hemorrhage or edema, an expanding intracranial lesion (hematoma or tumor), or a combination of both.

As ICP increases, the patient becomes stuporous, reacting only to loud auditory or painful stimuli. At this stage, serious impairment of brain circulation is probably taking place, and immediate intervention is required. As neurologic function deteriorates further, the patient becomes comatose and exhibits abnormal motor responses in the form of **decortication**, **decerebration**, or flaccidity (see Fig. 61-1). When the coma is profound, with the pupils dilated and fixed and respirations impaired, death is usually inevitable.

## Assessment and Diagnostic Findings

The diagnostic studies used to determine the underlying cause of increased ICP are discussed in detail in Chapter 60. The patient may undergo cerebral angiography, computed tomography (CT) scanning, magnetic resonance imaging (MRI), or positron emission tomography (PET). Transcranial Doppler studies provide information about cerebral blood flow. The patient with increased ICP may also undergo electrophysiologic monitoring to monitor cerebral blood flow indirectly. Evoked potential monitoring measures the electrical potentials produced by nerve tissue in response to external stimulation (auditory, visual, or sensory). Lumbar puncture is avoided in patients with increased ICP because the sudden release of pressure can cause the brain to herniate.

## Complications

Complications of increased ICP include brain stem herniation, diabetes insipidus, and syndrome of inappropriate antidiuretic hormone (SIADH).

Brain stem herniation results from an excessive increase in ICP, when the pressure builds in the cranial vault and the brain tissue presses down on the brain stem. This increasing pressure on the brain stem results in the cessation of blood flow to the brain, causing irreversible brain anoxia and brain death.

Diabetes insipidus is the result of decreased secretion of antidiuretic hormone. The patient has excessive urine output, and hyperosmolarity results (Young et al., 1998). Therapy consists of administration of fluid volume, electrolyte replacement, and vasopressin (desmopressin, DDAVP) therapy. Diabetes insipidus is discussed in Chapters 14 and 42.

SIADH is the result of increased secretion of antidiuretic hormone. The patient becomes volume-overloaded, urine output diminishes, and serum sodium concentration becomes dilute. Treatment of SIADH includes fluid restriction, which is usually sufficient to correct the hyponatremia; severe cases call for judicious administration of a 3% hypertonic saline solution (Hickey, 2003). Patients with chronic SIADH may respond to lithium carbonate or demeclocycline, which reduces renal tubule responsiveness to antidiuretic hormone. Further discussion of SIADH is presented in Chapters 14 and 42.

## Management

Increased ICP is a true emergency and must be treated promptly. Invasive monitoring of ICP is an important component of management, but immediate management to relieve increased ICP involves decreasing cerebral edema, lowering the volume of CSF, or decreasing cerebral blood volume while maintaining cerebral perfusion (Cunning & Houdek, 1999). These goals are accomplished by administering osmotic diuretics and corticosteroids, restricting fluids, draining CSF, controlling fever, maintaining systemic blood pressure and oxygenation, and reducing cellular metabolic demands. Judicious use of hyperventilation is recommended only if the ICP is refractory to other measures.

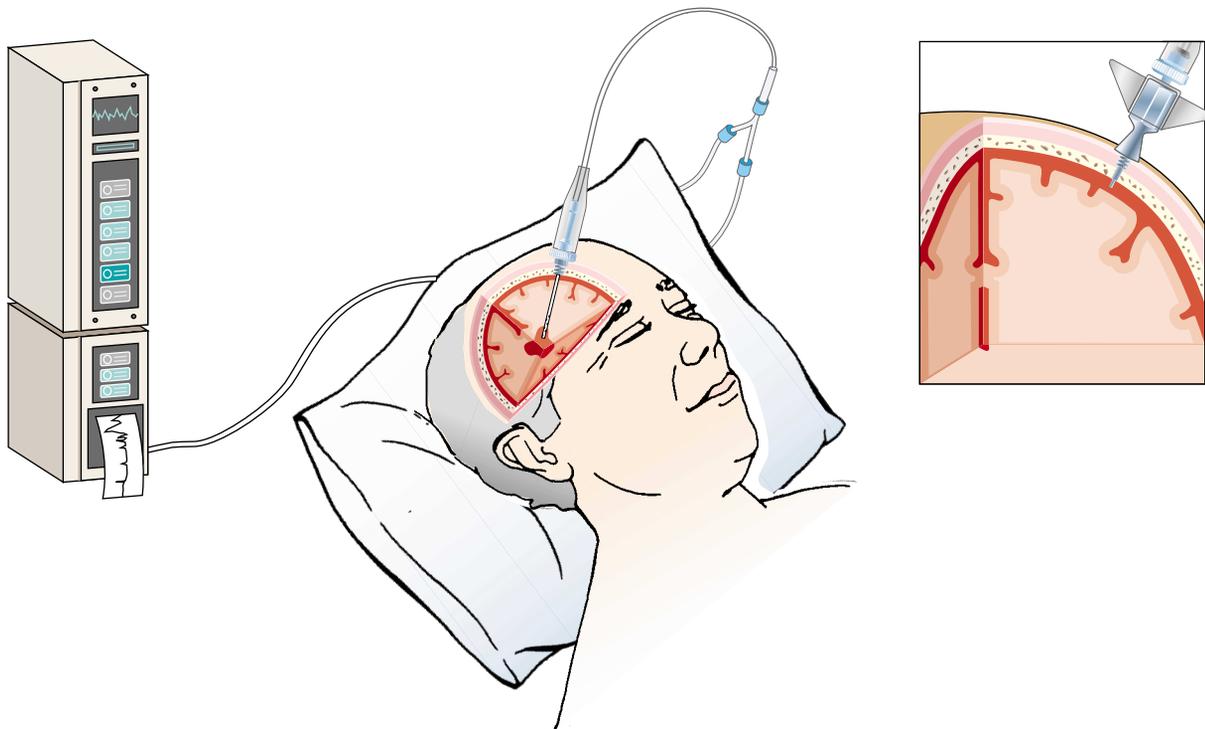

### MONITORING ICP

The purposes of ICP monitoring are to identify increased pressure early in its course (before cerebral damage occurs), to quantify the degree of elevation, to initiate appropriate treatment, to provide access to CSF for sampling and drainage, and to evaluate the effectiveness of treatment. An intraventricular catheter (ventriculostomy), a subarachnoid bolt, an epidural or subdural catheter, or a fiberoptic transducer-tipped catheter placed in the subdural space or the ventricle can be used to monitor ICP (Fig. 61-3).

When a **ventriculostomy** or ventricular catheter monitoring device is used for monitoring ICP, a fine-bore catheter is inserted into a lateral ventricle, usually in the nondominant hemisphere of the brain (Hickey, 2003). The catheter is connected by a fluid-filled system to a transducer, which records the pressure in the form of an electrical impulse. In addition to obtaining continuous ICP recordings, the ventricular catheter allows CSF to drain, particularly during acute rises in pressure. The ventriculostomy also can be used to drain the ventricle of blood. Also, continuous drainage of ventricular fluid under pressure control is an effective method of treating intracranial hypertension. Another advantage of an indwelling ventricular catheter is the access it provides for the intraventricular administration of medications and the instillation of air or a contrast agent for ventriculography. Complications include ventricular infection, meningitis, ventricular collapse, occlusion of the catheter by brain tissue or blood, and problems with the monitoring system.

The **subarachnoid bolt** (or screw) is a hollow device inserted through the skull and dura mater into the cranial subarachnoid space (Hickey, 2003). It has the advantage of not requiring a ventricular puncture. The subarachnoid screw is attached to a pressure transducer, and the output is recorded on an oscilloscope. The hollow screw technique has the advantage of avoiding complications from brain shift and small ventricle size. Complications include blockage of the screw by clot or brain tissue, which leads to a loss of pressure tracing and a decrease in accuracy at high ICP readings.

An **epidural monitor** uses a pneumatic flow sensor that functions on a nonelectrical basis. This pneumatic epidural ICP mon-

**FIGURE 61-3** ICP monitoring. A fiber-optic, transducer-tipped device placed in (A) the ventricle or (B) the subarachnoid space. These devices connect to a pressure transducer and a display system.

itoring system has a low incidence of infection and complications and appears to read pressures accurately. Calibration of the system is maintained automatically, and abnormal pressure waves trigger an alarm system. One disadvantage of the epidural catheter is the inability to withdraw CSF for analysis.

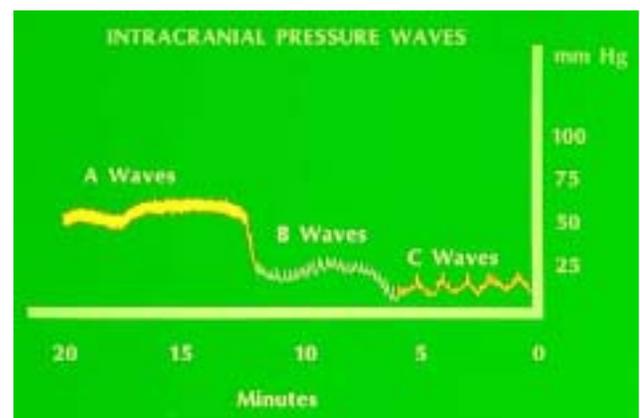

A **fiberoptic monitor**, or transducer-tipped catheter, is becoming a widely used alternative to standard intraventricular, subarachnoid, and subdural systems (Hickey, 2003). The miniature transducer reflects pressure changes, which are converted to electrical signals in an amplifier and displayed on a digital monitor. The catheter can be inserted into the ventricle, subarachnoid space, subdural space, or brain parenchyma or under a bone flap. If inserted into the ventricle, it can also be used in conjunction with a CSF drainage device.

Waves of high pressure and troughs of relatively normal pressure indicate changes in ICP. Waveforms are captured and recorded on an oscilloscope. These waves have been classified as A waves (plateau waves), B waves, and C waves (Fig. 61-4). The plateau waves (A waves) are transient, paroxysmal, recurring elevations of ICP that may last 5 to 20 minutes and range in amplitude from 50 to 100 mm Hg (Hickey, 2003). Plateau waves have clinical significance and indicate changes in vascular volume within the intracranial compartment that are beginning to compromise cerebral perfusion. A waves may increase in amplitude and frequency, reflecting cerebral ischemia and brain damage that can occur before overt signs and symptoms of raised ICP are seen clinically. B waves are shorter (30 seconds to 2 minutes), with smaller amplitude (up to 50 mm Hg). They have less clinical significance, but if seen in runs in a patient with depressed consciousness, they may precede the appearance of A waves. B waves may be seen in patients with intracranial hypertension and decreased intracranial compliance. C waves are small, rhythmic oscillations with frequencies of approximately six per minute. They

appear to be related to rhythmic variations of the systemic arterial blood pressure and respirations.

#### DECREASING CEREBRAL EDEMA

Osmotic diuretics (mannitol) may be given to dehydrate the brain tissue and reduce cerebral edema. They act by drawing water across intact membranes, thereby reducing the volume of brain and extracellular fluid. An indwelling urinary catheter is usually inserted to monitor urinary output and to manage the resulting diuresis. When a patient is receiving osmotic diuretics, serum osmolality should be determined to assess hydration status. Corticosteroids (eg, dexamethasone) help reduce the edema

**FIGURE 61-4** Intracranial pressure waves. Composite diagram of A (plateau) waves, which indicate cerebral ischemia; B waves, which indicate intracranial hypertension and variations in the respiratory cycle; and C waves, which relate to variations in systemic arterial pressure and respirations.

surrounding brain tumors when a brain tumor is the cause of increased ICP.

Another method for decreasing cerebral edema is fluid restriction (Hickey, 2003). Limiting overall fluid intake leads to dehydration and hemoconcentration, drawing fluid across the osmotic gradient and decreasing cerebral edema. Conversely, overhydration of the patient with increased ICP is avoided, as this will increase cerebral edema.

It has been hypothesized that lowering body temperature will decrease cerebral edema, reduce the oxygen and metabolic requirements of the brain, and protect the brain from continued ischemia. If body metabolism can be reduced by lowering body temperature, the collateral circulation in the brain may be able to provide an adequate blood supply to the brain. The effect of hypothermia on ICP requires more study (Slade, Kerr & Marion, 1999), but as yet induced hypothermia has not been proven to be beneficial in the brain-injured patient (Clifton, Miller, Choi et al., 2001). Inducing and maintaining hypothermia is a major clinical procedure and requires knowledge and skilled nursing observation and management.

### MAINTAINING CEREBRAL PERFUSION

The cardiac output may be manipulated to provide adequate perfusion to the brain. Improvements in cardiac output are made using fluid volume and inotropic agents such as dobutamine hydrochloride. The effectiveness of the cardiac output is reflected in the cerebral perfusion pressure, which is maintained at greater than 70 mm Hg (Young et al., 1998). A lower cerebral perfusion pressure indicates that the cardiac output is insufficient to maintain adequate cerebral perfusion.

### REDUCING CSF AND INTRACRANIAL BLOOD VOLUME

CSF drainage is frequently performed because the removal of CSF with a ventriculostomy drain may dramatically reduce ICP and restore cerebral perfusion pressure. Caution should be used in draining CSF because excessive drainage may result in collapse of the ventricles.

Hyperventilation, which results in vasoconstriction, has been used for many years in patients with increased ICP. Recent research has demonstrated that hyperventilation may not be as beneficial as once thought (Hickey, 2003). The reduction in the PaCO<sub>2</sub> may result in hypoxia, ischemia, and an increase in cerebral lactate levels. Maintaining the PaCO<sub>2</sub> at 30 to 35 mm Hg may prove beneficial. Hyperventilation is indicated in patients whose ICP is unresponsive to conventional therapies, but it should be used judiciously.

### CONTROLLING FEVER

Preventing a temperature elevation is critical because fever increases cerebral metabolism and the rate at which cerebral edema forms. Strategies to reduce temperature include administration of antipyretic medications, as prescribed, and use of a cooling blanket. Additional strategies for reducing fever are included in the Nursing Process: The Patient With an Altered Level of Consciousness section of this chapter. The patient's temperature is monitored closely, and the patient is observed for shivering, which should be avoided because it increases ICP (Sund-Levander & Wahren, 2000).

### MAINTAINING OXYGENATION

Arterial blood gases must be monitored to ensure that systemic oxygenation remains optimal. Hemoglobin saturation can also be optimized to provide oxygen more efficiently at the cellular level.

### REDUCING METABOLIC DEMANDS

Cellular metabolic demands may be reduced through the administration of high doses of barbiturates when the patient is unresponsive to conventional treatment. The mechanism by which barbiturates decrease ICP and protect the brain is uncertain, but the resultant comatose state is thought to reduce the metabolic requirements of the brain, thus providing some protection (Greenberg, 2001).

Another method of reducing cellular metabolic demand and improving oxygenation is the administration of pharmacologic paralyzing agents. The patient who receives these agents cannot move, decreasing the metabolic demands and resulting in a decrease in cerebral oxygen demand. Because the patient cannot respond or report pain, sedation and analgesia must be provided because the paralyzing agents do not provide either.

Patients receiving high doses of barbiturates or pharmacologic paralyzing agents require continuous cardiac monitoring, endotracheal intubation, mechanical ventilation, ICP monitoring, and arterial pressure monitoring. Pentobarbital (Nembutal), thiopental (Pentothal), and propofol (Diprivan) are the most common agents used for high-dose barbiturate therapy (Greenberg, 2001). Serum barbiturate levels must be monitored (Hickey, 2003).

The ability to perform serial neurologic assessments on the patient is lost with the use of barbiturates or paralyzing agents (Greenberg, 2001). Therefore, other monitoring tools are needed to assess the patient's status and response to therapy. Important parameters that must be assessed include ICP, blood pressure, heart rate, respiratory rate, and response to ventilator therapy (eg, bucking the ventilator). The level of pharmacologic paralysis is adjusted based on serum levels and the assessed parameters. Potential complications include hypotension due to decreased sympathetic tone and myocardial depression (Greenberg, 2001).

### TRENDS IN NEUROLOGIC MONITORING

One controversial trend in cerebral monitoring is the ongoing measurement of venous oxygen saturation in the jugular bulb (SjO<sub>2</sub>). Readings taken from a catheter residing in the jugular outflow tract theoretically allow for a comparison of arterial and venous oxygen saturation, and the balance of cerebral oxygen supply and demand is demonstrated. Venous jugular desaturations can reflect early cerebral ischemia, alerting the clinician prior to a rise in ICP. Minimizing elevations in ICP can potentially improve outcome (Clay, 2000). This type of monitoring appears beneficial in the management of patients at risk for cerebral ischemia; however, the invasive nature of this type of monitoring and current limitations in technology mandate caution in its use. More study is needed before SjO<sub>2</sub> monitoring can be considered a valid and reliable tool for the management of cerebral ischemia (Clay, 2000).

## NURSING PROCESS: THE PATIENT WITH INCREASED ICP

### Assessment

Initial assessment of the patient with increased ICP includes obtaining a history of events leading to the present illness and other subjective data; it may be necessary to obtain this information from family or friends. The neurologic examination should be as complete as the patient's condition allows. It includes an evaluation of mental status, LOC, cranial nerve function, cerebellar function (balance and coordination), reflexes, and motor and sensory function. Because the patient is critically ill, ongoing assessment will

be more focused, including pupil checks, assessment of selected cranial nerves, frequent measurements of vital signs and intracranial pressure, and use of the Glasgow Coma Scale. Assessment of the patient with altered LOC is summarized in Table 61-1.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the major nursing diagnoses for patients with increased ICP include the following:

- Ineffective airway clearance related to diminished protective reflexes (cough, gag)
- Ineffective breathing patterns related to neurologic dysfunction (brain stem compression, structural displacement)
- Ineffective cerebral tissue perfusion related to the effects of increased ICP
- Deficient fluid volume related to fluid restriction
- Risk for infection related to ICP monitoring system (fiberoptic or intraventricular catheter)

Other relevant nursing diagnoses are included in the section on caring for patients with altered LOC.

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications include:

- Brain stem herniation
- Diabetes insipidus
- SIADH

## Planning and Goals

The goals for the patient include maintenance of a patent airway, normalization of respiration, adequate cerebral tissue perfusion through reduction in ICP, restoration of fluid balance, absence of infection, and absence of complications.

## Nursing Interventions

### MAINTAINING A PATENT AIRWAY

The patency of the airway is assessed. Secretions obstructing the airway must be suctioned with care, because transient elevations of ICP occur with suctioning (Hickey, 2003). The patient is hyperoxygenated before and after suctioning to maintain adequate oxygenation. Hypoxia caused by poor oxygenation leads to cerebral ischemia and edema. Coughing is discouraged because coughing and straining also increase ICP. The lung fields are auscultated at least every 8 hours to determine the presence of adventitious sounds or any areas of congestion. Elevating the head of the bed may aid in clearing secretions as well as improving venous drainage of the brain.

### ACHIEVING AN ADEQUATE BREATHING PATTERN

The patient must be monitored constantly for respiratory irregularities. Increased pressure on the frontal lobes or deep midline structures may result in Cheyne-Stokes respirations, whereas pressure in the midbrain may cause hyperventilation. When the lower portion of the brain stem (the pons and medulla) is involved, respirations become irregular and eventually cease.

If hyperventilation therapy is deemed appropriate to reduce ICP (by causing cerebral vasoconstriction and a decrease in cerebral blood volume), the nurse collaborates with the respiratory

therapist in monitoring PaCO<sub>2</sub>, which is usually maintained at 35 to 45 mm Hg (Hickey, 2003).

A neurologic observation record (Fig. 61-5) is maintained, and all observations are made in relation to the patient's baseline condition. Repeated assessments of the patient are made (sometimes minute by minute) so that improvement or deterioration may be noted immediately. If the patient's condition deteriorates, preparations are made for surgical intervention.

### OPTIMIZING CEREBRAL TISSUE PERFUSION

In addition to ongoing nursing assessment, strategies are initiated to reduce factors contributing to the elevation of ICP (Table 61-2).

Proper positioning helps to reduce ICP. The head is kept in a neutral (midline) position, maintained with the use of a cervical collar if necessary, to promote venous drainage. Elevation of the head is maintained at 0 to 60 degrees to aid in venous drainage unless otherwise prescribed (Sullivan, 2000). Extreme rotation of the neck and flexion of the neck are avoided because compression or distortion of the jugular veins increases ICP. Extreme hip flexion is also avoided because this position causes an increase in intra-abdominal and intrathoracic pressures, which can produce a rise in ICP. Relatively minor changes in position may significantly affect ICP (Sullivan, 2000). If monitoring parameters demonstrate that turning the patient raises ICP, rotating beds, turning sheets, and holding the patient's head during turning may minimize the stimuli that increase ICP.

The Valsalva maneuver, which can be produced by straining at defecation or even moving in bed, raises ICP and is to be avoided. Stool softeners may be prescribed. If the patient is alert and able to eat, a diet high in fiber may be indicated. Abdominal distention, which increases intra-abdominal and intrathoracic pressure and ICP, should be noted. Enemas and cathartics are avoided if possible. When moving or being turned in bed, the patient can be instructed to exhale (which opens the glottis) to avoid the Valsalva maneuver.

Mechanical ventilation presents unique problems for the patient with increased ICP. Before suctioning, the patient should be preoxygenated and hyperventilated using 100% oxygen on the ventilator (Hickey, 2003). Suctioning should not last longer than 15 seconds. High levels of positive end-expiratory pressure are avoided because they may decrease venous return to the heart and decrease venous drainage from the brain through increased intrathoracic pressure (Hickey, 2003).

Activities that raise ICP, as indicated by changes in waveforms, should be avoided if possible. Spacing nursing interventions may prevent transient increases in ICP. During nursing interventions, the ICP should not rise above 25 mm Hg and should return to baseline levels within 5 minutes. Patients with increased ICP should not demonstrate a significant increase in pressure or change in the ICP waveform. Patients with the potential for a significant increase in ICP should receive sedation or "paralyzation" before initiation of many nursing activities (Hickey, 2003; McConnell, 2001).

Emotional stress and frequent arousal from sleep are avoided. A calm atmosphere is maintained. Environmental stimuli (noise, conversation) should be minimal. Isometric muscle contractions are also contraindicated because they raise the systemic blood pressure and hence the ICP.

### MAINTAINING NEGATIVE FLUID BALANCE

The administration of various osmotic and loop diuretics is part of the treatment protocol to reduce ICP. Corticosteroids are used

**Table 61-2 • Increased ICP and Interventions**

FACTOR	PHYSIOLOGY	INTERVENTIONS	RATIONALE
Cerebral edema	Can be caused by contusion, tumor, or abscess; water intoxication (hypo-osmolality); alteration in the blood–brain barrier (protein leaks into the tissue, causing water to follow)	Administer osmotic diuretics as prescribed (monitor serum osmolality). Maintain head of bed elevated 30 degrees. Maintain alignment of the head.	Promotes venous return  Prevents impairment of venous return through the jugular veins
Hypoxia	A decrease in the PaO <sub>2</sub> causes cerebral vasodilation at less than 60 mm Hg.	Maintain PaO <sub>2</sub> greater than 60 mm Hg. Maintain oxygen therapy. Monitor arterial blood gas values. Suction when needed. Maintain a patent airway.	Prevents hypoxia and vasodilation
Hypercapnia (elevated PaCO <sub>2</sub> )	Causes vasodilation	Maintain PaCO <sub>2</sub> (normally 35–45 mm Hg) through hyperventilation.	Decreased PaCO <sub>2</sub> prevents vasodilation and thus reduces the cerebral blood volume.
Impaired venous return	Increases the cerebral blood volume	Maintain head alignment. Elevate head of bed 30 degrees.	Hyperextension, rotation, or hyperflexion of the neck causes decreased venous return.
Increase in intrathoracic or abdominal pressure	Increase in these pressures due to coughing, PEEP, Valsalva maneuver causes a decrease in venous return.	Monitor arterial blood gas values and keep PEEP as low as possible. Provide humidified oxygen. Administer stool softeners as prescribed.	To keep secretions loose and easy to suction or expectorate  Soft bowel movements will prevent straining or Valsalva maneuver.

to reduce cerebral edema, and fluids may be restricted. All of these treatment modalities promote dehydration.

Skin turgor, mucous membranes, and serum and urine osmolality are monitored to assess fluid status. If fluids are given intravenously, the nurse ensures they are administered at a slow to moderate rate with an intravenous infusion pump to prevent too-rapid administration and avoid overhydration. For the patient receiving mannitol, the nurse observes for the possible development of heart failure and pulmonary edema, because the intent of treatment is for fluid to shift from the intracellular compartment to the intravascular system, thus controlling cerebral edema.

For patients undergoing dehydrating procedures, vital signs, including blood pressure, must be monitored to assess fluid volume status. An indwelling urinary catheter is inserted to permit assessment of renal function and fluid status. During the acute phase, urine output should be monitored every hour. An output greater than 200 mL/hr for 2 consecutive hours may indicate the onset of diabetes insipidus (Cruz, 1998). These patients also need careful oral hygiene because mouth dryness is associated with dehydration. Frequently rinsing the mouth, lubricating the lips, and removing encrustations relieve dryness and promote comfort.

### PREVENTING INFECTION

Risk for infection is greatest when ICP is monitored with an intraventricular catheter. Most health care facilities have written protocols for managing these systems and maintaining their sterility; strict adherence to them is essential.

The dressing over the ventricular catheter must be kept dry because a wet dressing is conducive to bacterial growth. Aseptic technique must be used when managing the system and changing the ventricular drainage bag. The drainage system is also checked

for loose connections because they cause leakage and contamination of the CSF as well as inaccurate readings of ICP. The nurse should observe the character of the CSF drainage and report observations of increasing cloudiness or blood. The patient is monitored for signs and symptoms of meningitis: fever, chills, nuchal (neck) rigidity, and increasing or persisting headache.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

The primary complication of increased ICP is brain herniation resulting in death (see Fig. 61-2). Nursing management focuses on detecting early signs of increasing ICP because medical interventions are usually ineffective once later signs develop. Frequent neurologic assessment and documentation and analysis of trends will reveal the subtle changes that may herald rising ICP.

#### Detecting Early Indications of Increasing ICP

The nurse assesses for and immediately reports any of the following early signs or symptoms of increasing ICP:

- Disorientation, restlessness, increased respiratory effort, purposeless movements, and mental confusion; these are early clinical indications of rising ICP because the brain cells responsible for cognition are extremely sensitive to decreased oxygenation
- Pupillary changes and impaired extraocular movements; these occur as the increasing pressure displaces the brain against the oculomotor and optic nerves (cranial nerves II, III, IV, and VI) arising from the midbrain and brain stem (see Chap. 60)
- Weakness in one extremity or on one side of the body; this occurs as increasing ICP compresses the pyramidal tracts

- Headache that is constant, increasing in intensity, and aggravated by movement or straining; this occurs as increasing ICP causes pressure and stretching of venous and arterial vessels in the base of the brain

### Detecting Later Signs of Increased ICP

As ICP rises, the patient's condition worsens, as manifested by the following later signs and symptoms:

- LOC continues to deteriorate until the patient is comatose.
- The pulse rate and respiratory rate decrease or become erratic, and the blood pressure and temperature rise. The pulse pressure (the difference between the systolic and the diastolic pressures) widens. The pulse fluctuates rapidly, varying from bradycardia to tachycardia.
- Altered respiratory patterns develop, including Cheyne-Stokes breathing (rhythmic waxing and waning of rate and depth of respirations alternating with brief periods of apnea) and ataxic breathing (irregular breathing with a random sequence of deep and shallow breaths).
- Projectile vomiting may occur with increased pressure on the reflex center in the medulla.
- Hemiplegia or decorticate or decerebrate posturing may develop as pressure on the brain stem increases. Bilateral flaccidity occurs before death.
- Loss of brain stem reflexes, including pupillary, corneal, gag, and swallowing reflexes, is an ominous sign.

### Monitoring ICP

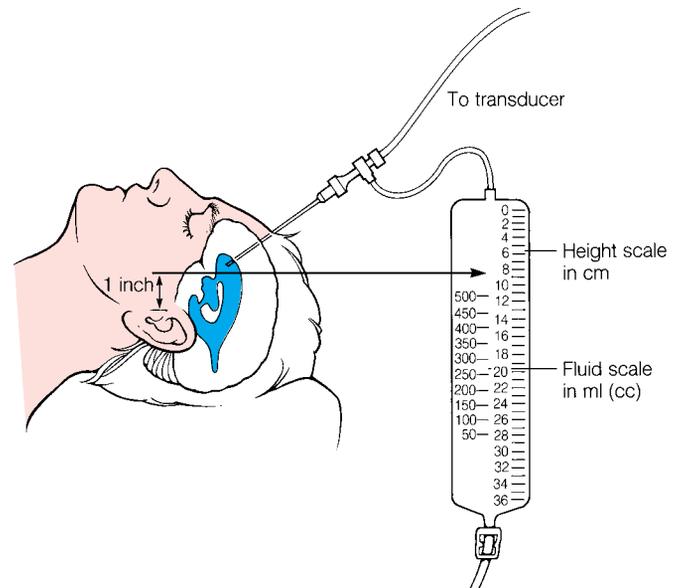

Because clinical assessment is not always a reliable guide in recognizing increased ICP, especially in comatose patients, ICP monitoring is an essential part of management (Hickey, 2003). ICP is monitored closely for continuous elevation or significant increase over baseline. The trend of ICP measurements over time is an important indication of the patient's underlying status. Vital signs are assessed when the increase in ICP is noted.

Strict aseptic technique is used when handling any part of the monitoring system. The insertion site is inspected for signs of infection. Temperature, pulse, and respirations are closely monitored for systemic signs of infection. All connections and stopcocks are checked for leaks, because even small leaks can distort pressure readings.

When ICP is monitored with a fluid system, the transducer is calibrated at a particular reference point, usually 2.5 cm (1 in) above the ear with the patient in the supine position; this point corresponds to the level of the foramen of Monro (Fig. 61-6). (CSF pressure readings depend on the patient's position.) For subsequent pressure readings, the head should be in the same position relative to the transducer. Fiberoptic catheters are calibrated before insertion and do not require further referencing; they do not require the head of the bed to be at a specific position to obtain an accurate reading.

Whenever technology is associated with patient management, the nurse must be certain that the technology is functioning properly. The most important concern, however, must be the patient who is attached to the technology. The patient and family must be informed about the technology and the goals of its use. The patient's response is monitored and appropriate comfort measures are implemented to ensure that the patient's stress is minimized.

ICP measurement is only one parameter: repeated neurologic checks and clinical examinations remain important measures. As-

**FIGURE 61-6** Location of the foramen of Monro for calibration of intracranial pressure monitoring system.

tute observation, comparison of findings with previous observations, and interventions can assist in preventing life-threatening ICP elevations.

### Monitoring for Secondary Complications

The nurse also assesses for complications of increased ICP, including diabetes insipidus and SIADH (see Chaps. 14 and 42). Urine output should be monitored closely. Diabetes insipidus requires fluid and electrolyte replacement, along with the administration of vasopressin, to replace and slow the urine output. Serum electrolyte levels should be monitored for imbalances. SIADH requires fluid restriction and monitoring of serum electrolyte levels.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Maintains patent airway
2. Attains optimal breathing pattern
  - a. Breathes in a regular pattern
  - b. Attains or maintains arterial blood gas values within acceptable range
3. Demonstrates optimal cerebral tissue perfusion
  - a. Increasingly oriented to time, place, and person
  - b. Follows verbal commands; answers questions correctly
4. Attains desired fluid balance
  - a. Maintains fluid restriction
  - b. Demonstrates serum and urine osmolality values within acceptable range
5. Has no signs or symptoms of infection
  - a. Has no fever
  - b. Shows no signs of infection at arterial, intravenous, and urinary catheter sites
  - c. Has no purulent drainage from invasive intracranial monitoring device

6. Absence of complications
  - a. Has ICP values that remain within normal limits
  - b. Demonstrates urine output and serum electrolyte levels within acceptable limits

## Intracranial Surgery

A **craniotomy** involves opening the skull surgically to gain access to intracranial structures. This procedure is performed to remove a tumor, relieve elevated ICP, evacuate a blood clot, and control hemorrhage. The surgeon cuts the skull to create a bony flap, which can be repositioned after surgery and held in place by periosteal or wire sutures. One of two approaches through the skull is used: (1) above the tentorium (supratentorial craniotomy) into the supratentorial compartment, or (2) below the tentorium into the infratentorial (posterior fossa) compartment. A **transsphenoidal** approach through the mouth and nasal sinuses is used to gain access to the pituitary gland. Table 61-3 compares the three different surgical approaches: supratentorial, infratentorial, and transsphenoidal.

Alternatively, intracranial structures may be approached through burr holes (Fig. 61-7), which are circular openings made in the skull by either a hand drill or an automatic craniotome

(which has a self-controlled system to stop the drill when the bone is penetrated). Burr holes are made for exploration or diagnosis. They may be used to determine the presence of cerebral swelling and injury and the size and position of the ventricles. They are also a means of evacuating an intracranial hematoma or abscess and for making a bone flap in the skull and allowing access to the ventricles for decompression, ventriculography, or shunting procedures. Other cranial procedures include **craniectomy** (excision of a portion of the skull) and cranioplasty (repair of a cranial defect using a plastic or metal plate).

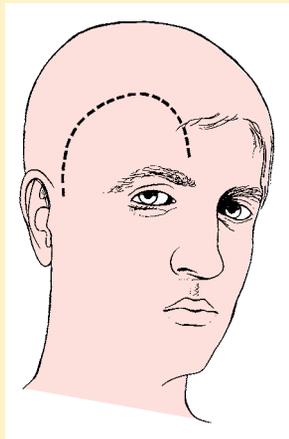

## Preoperative Management

Preoperative diagnostic procedures may include CT scanning to demonstrate the lesion and show the degree of surrounding brain edema, the ventricular size, and the displacement. MRI provides information similar to that of the CT scan and examines the lesion in other planes (Tornqvist, 2001). Cerebral angiography may be used to study the tumor's blood supply or give information about vascular lesions. Transcranial Doppler flow studies are used to evaluate the blood flow of intracranial blood vessels.

Most patients are placed on an antiseizure medication such as phenytoin (Dilantin) or a phenytoin metabolite (Cerebyx) before surgery to reduce the risk of postoperative **seizures** (paroxysmal

**Table 61-3 • Comparison of Cranial Surgical Approaches**

### SUPRATENTORIAL

#### Site of Surgery

Above the tentorium

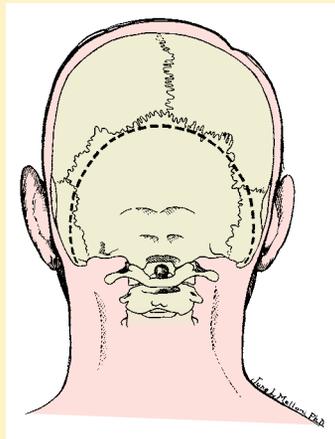

#### Incision Location

Incision is made above the area to be operated on; is usually located behind the hairline.

#### Selected Nursing Interventions

Maintain head of bed elevated 30 to 45 degrees, with neck in neutral alignment. Position patient on either side or back. (Avoid positioning patient on operative side if a large tumor has been removed.)

### INFRATENTORIAL

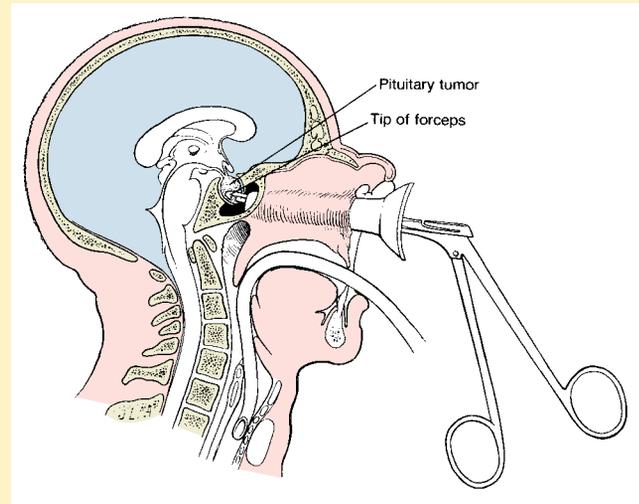

Below the tentorium, brain stem

Incision is made at the nape of the neck, around the occipital lobe.

Maintain neck in straight alignment. Avoid flexion of the neck to prevent possible tearing of the suture line. Position the patient on either side. (Check surgeon's preference for positioning of patient.)

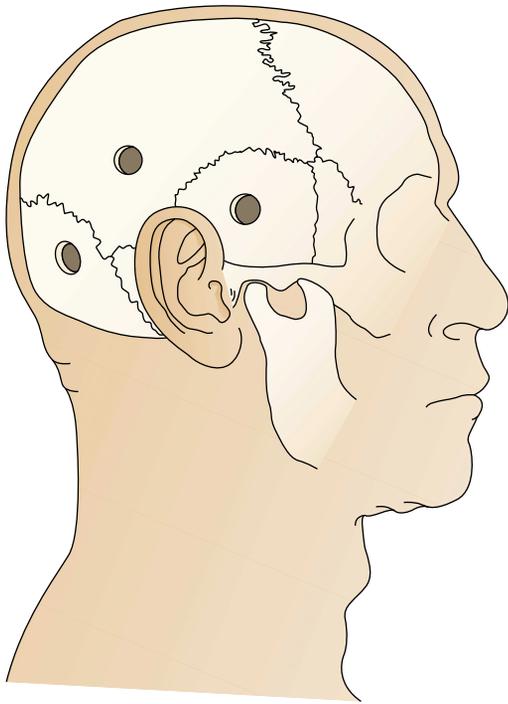

### TRANSPHENOIDAL

Sella turcica

Incision is made beneath the upper lip to gain access into the nasal cavity.

Maintain nasal packing in place and reinforce as needed. Instruct patient to avoid blowing the nose. Provide frequent oral care. Keep head of bed elevated to promote venous drainage and drainage from the surgical site.

**FIGURE 61-7** Burr holes may be used in neurosurgical procedures to make a bone flap in the skull, to aspirate a brain abscess, or to evacuate a hematoma.

transient disturbances of the brain resulting from a discharge of abnormal electrical activity) (Hickey, 2003; Karch, 2002). Before surgery, corticosteroids such as dexamethasone (Decadron) may be administered to reduce cerebral edema. Fluids may be restricted. A hyperosmotic agent (mannitol) and a diuretic agent such as furosemide (Lasix) may be given intravenously immediately before and sometimes during surgery if the patient tends to retain fluid, as do many who have intracranial dysfunction. The patient may be given antibiotics if there is a chance of cerebral contamination; diazepam may be prescribed before surgery to allay anxiety.

### Preoperative Nursing Management

The preoperative assessment serves as a baseline against which postoperative status and recovery are compared. This assessment includes evaluating LOC and responsiveness to stimuli and identifying any neurologic deficits, such as paralysis, visual dysfunction, alterations in personality or speech, and bladder and bowel disorders. Distal and proximal motor strength in both upper and lower extremities is recorded using the 5-point scale. Testing of motor function is discussed in Chapter 60 (see Fig. 60-14).

The patient's and family's understanding of and reactions to the anticipated surgical procedure and its possible sequelae are assessed, as is the availability of support systems for the patient and family. Adequate preparation for surgery, with attention to the patient's physical and emotional status, can reduce the risk for anxiety, fear, and postoperative complications. The patient is assessed for neurologic deficits and their potential impact after surgery. If there are motor deficits or weakness or paralysis of the arms or legs, trochanter rolls are applied to the extremities and the feet are positioned against a footboard. A patient who can ambulate is encouraged to do so. If the patient is aphasic, writing materials or picture and word cards showing the bedpan, glass of

water, blanket, and other frequently used items may help improve communication.

Preparation of the patient and family includes providing information about what to expect during and after surgery. The surgical site is shaved immediately before surgery (usually in the operating room) so that any resultant superficial abrasions do not have time to become infected. An indwelling urinary catheter is inserted in the operating room to drain the bladder during the administration of diuretics and to permit urinary output to be monitored. The patient may have a central and arterial line placed for fluid administration and monitoring of pressures after surgery. The large head dressing applied after surgery may impair hearing temporarily. Vision may be limited if the eyes are swollen shut. If a tracheostomy or endotracheal tube is in place, the patient will be unable to speak until the tube is removed, so an alternative method of communication should be established.

An altered cognitive state may make the patient unaware of the impending surgery. Even so, encouragement and attention to the patient's needs are necessary. Whatever the state of awareness of the patient, the family needs reassurance and support because they recognize the seriousness of brain surgery.

### Postoperative Management

Postoperatively, an arterial line and a central venous pressure line may be in place to monitor and manage blood pressure and central venous pressure. The patient may be intubated and may receive supplemental oxygen therapy. Ongoing postoperative management is aimed at detecting and reducing cerebral edema, relieving pain and preventing seizures, and monitoring ICP.

#### REDUCING CEREBRAL EDEMA

Medications to reduce cerebral edema include mannitol, which increases serum osmolality and draws free water from areas of the brain (with an intact blood-brain barrier). The fluid is then excreted by osmotic diuresis. Dexamethasone (Decadron) may be administered intravenously every 6 hours for 24 to 72 hours; the route is switched to oral as soon as possible and dosage is tapered over 5 to 7 days (Karch, 2002).

#### RELIEVING PAIN AND PREVENTING SEIZURES

Acetaminophen is usually prescribed for temperature exceeding 99.6°F (37.5°C) and for pain. Commonly, the patient has a headache after a craniotomy, usually as a result of the scalp nerves being stretched and irritated during surgery. Codeine, given parenterally, is often sufficient to relieve headache. Morphine sulfate may also be used in the management of postoperative pain in the craniotomy patient (Leith, 1998).

Antiseizure medication (phenytoin, diazepam) is prescribed for patients who have undergone supratentorial craniotomy because of the high risk of seizures after supratentorial neurosurgical procedures. Serum levels are monitored to keep the medications within the therapeutic range.

#### MONITORING ICP

A ventricular catheter or other type of drain frequently is inserted in patients undergoing intracranial surgery. The catheter is connected to an external drainage system. The patency of the catheter is noted by the pulsations of the fluid in the tubing. The ICP can be assessed using a stopcock attached to the pressure tubing and transducer. The ICP is measured by turning the three-way stopcock to the appropriate position (Hickey, 2003). Care is required to ensure that the system is tight at all connections and that the

stopcock is in the proper position to avoid drainage of CSF; collapse of the ventricles and brain herniation may result if fluid is removed too rapidly (Hickey, 2003). The catheter is removed when the ventricular pressure is normal and stable. The neurosurgeon must be notified if the catheter appears to be obstructed.

## NURSING PROCESS: THE PATIENT UNDERGOING INTRACRANIAL SURGERY

### Assessment

After surgery, the frequency of postoperative monitoring is based on the patient's clinical status. Assessing respiratory function is essential because even a small degree of hypoxia can increase cerebral ischemia. The respiratory rate and pattern are monitored, and arterial blood gas values are assessed frequently. Fluctuations in vital signs are carefully monitored and documented because they indicate increased ICP. The patient's temperature is measured at intervals to assess for hyperthermia secondary to damage to the hypothalamus. Neurologic checks are made frequently to detect increased ICP resulting from cerebral edema or bleeding. A change in LOC or response to stimuli may be the first sign of increasing ICP.

The surgical dressing is inspected for evidence of bleeding and CSF drainage. The nurse must be alert to the development of complications; all assessments are carried out with these problems in mind. Chart 61-2 provides an overview of the nursing management of the patient after intracranial surgery. Seizures are a potential complication, and any seizure activity is carefully recorded and reported. Restlessness may occur as the patient becomes more responsive or may be due to pain, confusion, hypoxia, or other stimuli.

### Diagnosis

#### NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses after intracranial surgery may include the following:

- Ineffective cerebral tissue perfusion related to cerebral edema
- Potential for ineffective thermoregulation related to damage to the hypothalamus, dehydration, and infection
- Potential for impaired gas exchange related to hypoventilation, aspiration, and immobility
- Disturbed sensory perception related to periorbital edema, head dressing, endotracheal tube, and effects of ICP
- Body image disturbance related to change in appearance or physical disabilities

Other nursing diagnoses may include impaired communication (aphasia) related to insult to brain tissue and high risk for impaired skin integrity related to immobility, pressure, and incontinence. There may be impaired physical mobility related to a neurologic deficit secondary to the neurosurgical procedure or to the underlying disorder.

#### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Potential complications include:

- Increased ICP
- Bleeding and hypovolemic shock
- Fluid and electrolyte disturbances

- Infection
- Seizures

### Planning and Goals

The major goals for the patient include neurologic homeostasis to improve cerebral tissue perfusion, adequate thermoregulation, normal ventilation and gas exchange, ability to cope with sensory deprivation, adaptation to changes in body image, and absence of complications.

### Nursing Interventions

#### MAINTAINING CEREBRAL TISSUE PERFUSION

Attention to the patient's respiratory status is essential because even slight decreases in the oxygen level (hypoxia) can cause cerebral ischemia and can affect the clinical course and outcome. The endotracheal tube is left in place until the patient shows signs of awakening and has adequate spontaneous ventilation, as evaluated clinically and by arterial blood gas analysis. Secondary brain damage can result from impaired cerebral oxygenation.

Some degree of cerebral edema occurs after brain surgery; it tends to peak 24 to 36 hours after surgery, producing decreased responsiveness on the second postoperative day. The control of cerebral edema is discussed in the earlier section of this chapter on management of increased ICP. Nursing strategies used to control factors that may raise ICP are found earlier in this chapter in Nursing Process: The Patient With Increased ICP. Intraventricular drainage is carefully monitored, using strict asepsis when any part of the system is handled.

Vital signs and neurologic status (LOC and responsiveness, pupillary and motor responses) are assessed every 15 minutes to every 1 hour. Extreme head rotation is avoided because this raises ICP. After supratentorial surgery, the patient is placed on his or her back or side (unoperated side if a large lesion was removed) with one pillow under the head. The head of the bed may be elevated 30 degrees, depending on the level of the ICP and the neurosurgeon's preference. After posterior fossa (infratentorial) surgery, the patient is kept flat on one side (off the back) with the head on a small, firm pillow. The patient may be turned on either side, keeping the neck in a neutral position. When the patient is being turned, the body should be turned as a unit to prevent placing strain on the incision and possibly tearing the sutures. The head of the bed may be elevated slowly as tolerated by the patient.

The patient's position is changed every 2 hours, and skin care is given frequently. During position changes, care is taken to prevent disrupting the ICP monitoring system. A turning sheet placed under the head to the mid thigh makes it easier to move and turn the patient safely.

#### REGULATING TEMPERATURE

Moderate temperature elevation can be expected after intracranial surgery because of the reaction to blood at the operative site or in the subarachnoid space. Injury to the hypothalamic centers that regulate body temperature can occur during surgery. High fever is treated vigorously to combat the effect of an elevated temperature on brain metabolism and function.

Nursing interventions include monitoring the patient's temperature and using the following measures to reduce body temperature: removing blankets, applying ice bags to axilla and groin areas, using a hypothermia blanket as prescribed, and administering prescribed medications to reduce fever.

Chart  
61-2

## Overview of Nursing Management for the Patient After Intracranial Surgery

**Postoperative Interventions**

*Nursing Diagnosis:* Risk for ineffective breathing pattern related to postoperative cerebral edema

*Goal:* Achievement of adequate respiratory function

1. Establish proper respiratory exchange to eliminate systemic hypercapnia and hypoxia, which increase cerebral edema.
  - a. Unless contraindicated, place the patient in a lateral or a semiprone position to facilitate respiratory gas exchange until consciousness returns.
  - b. Suction trachea and pharynx *cautiously* to remove secretions; suctioning can raise ICP.
  - c. Maintain patient on controlled ventilation if prescribed to maintain normal ventilatory status; monitor arterial blood gas results to determine respiratory status.
  - d. Elevate the head of the bed 30.5 cm (12 in) after patient is conscious to aid venous drainage of the brain.
  - e. Administer nothing by mouth until active coughing and swallowing reflexes are demonstrated, to prevent aspiration.

*Nursing Diagnosis:* Risk for imbalanced fluid volume related to intracranial pressure or diuretics

*Goal:* Attainment of fluid and electrolyte balance

1. Monitor for polyuria, especially during first postoperative week; diabetes insipidus may develop in patients with lesions around the pituitary or hypothalamus.
  - a. Measure urinary specific gravity at intervals.
  - b. Monitor serum and urinary electrolyte levels.
2. Evaluate patient's electrolyte status; patients may retain water and sodium.
  - a. Early postoperative weight gain indicates fluid retention; a greater-than-estimated weight loss indicates negative water balance.
  - b. Loss of sodium and chloride will produce weakness, lethargy, and coma.
  - c. Low potassium levels will cause confusion and decreased level of responsiveness.
3. Weigh patient daily; keep intake and output record.
4. Administer prescribed intravenous fluids cautiously—rate and composition depend on fluid deficit, urine output, and blood loss. Fluid intake and fluid losses should remain relatively equal.

*Nursing Diagnosis:* Disturbed sensory perception (visual/auditory) related to periorbital edema and head dressings

*Goal:* Compensate for sensory deprivation; prevention of injury

1. Perform supportive measures until the patient can care for self.
  - a. Change position as indicated; position changes can increase ICP.
  - b. Administer prescribed analgesics (codeine) that do not mask the level of responsiveness.
2. Use measures prescribed to relieve signs of periorbital edema.
  - a. Lubricate eyelids and around eyes with petrolatum.
  - b. Apply light, cold compresses over eyes at specified intervals.
  - c. Observe for signs of keratitis if cornea has no sensation.
3. Put extremities through range-of-motion exercises.
4. Evaluate and support patient during episodes of restlessness.
  - a. Evaluate for airway obstruction, distended bladder, meningeal irritation from bloody CSF.
  - b. Pad patient's hands and bed rails to prevent injury.
5. Reinforce blood-stained dressings with sterile dressing; blood-soaked dressings act as a culture medium for bacteria.
6. Orient patient frequently to time, place, and person.

**Monitor and Manage Complications**

1. Cerebral edema
  - a. Assess patient's level of responsiveness/consciousness; decreased level of consciousness may be the first sign of increased ICP.

- (1) Eye opening (spontaneous, to sound, to pain); pupillary reactions to light
- (2) Response to commands
- (3) Assessment of spinal motor reflexes (pinch Achilles tendon, arm, or other body site)
- (4) Observation of patient's spontaneous activity
- b. Maintain a neurologic flow sheet to assess and document neurologic status, fluid administration, laboratory data, medications, and treatments.
- c. Evaluate for signs and symptoms of increasing ICP, which can lead to ischemia and further impairment of brain function.
  - (1) Assess patient minute by minute, hour by hour, for:
    - Diminished response to stimuli
    - Fluctuations of vital signs
    - Restlessness
    - Weakness and paralysis of extremities
    - Increasing headache
    - Changes or disturbances of vision; pupillary changes
  - (2) Modify nursing management to prevent further increases in ICP.
- d. Control postoperative cerebral edema as prescribed.
  - (1) Administer corticosteroids and osmotic diuretics as prescribed to reduce brain swelling.
  - (2) Monitor fluid intake; avoid overhydration.
  - (3) Maintain a normal temperature. Temperature control may be impaired in certain neurologic states, and fever increases the metabolic demands of the brain.
    - Monitor rectal temperature at specified intervals. Assess temperature of extremities, which may be cold and dry due to impaired heat-losing mechanisms (vasodilation and sweating).
    - Employ measures as prescribed to reduce fever: ice bags to axillae and groin; hypothermia blanket. Use ECG monitoring to detect dysrhythmias during hypothermia procedures.
  - (4) Employ hyperventilation when prescribed and indicated (results in respiratory alkalosis, which causes cerebral vasoconstriction and reduces intracranial pressure).
  - (5) Elevate head of bed to reduce ICP and facilitate respirations.
  - (6) Avoid excessive stimuli.
  - (7) Use ICP monitoring if patient is at risk for intracranial hypertension.
2. Intracranial hemorrhage
  - a. Postoperative bleeding may be intraventricular, intracerebellar, subdural, or extradural.
  - b. Observe for progressive impairment of state of consciousness and other signs of increasing ICP.
  - c. Prepare deteriorating patient for return to surgery for evacuation of hematoma.
3. Seizures (greater risk with supratentorial operations)
  - a. Administer prescribed antiseizure agents; monitor anti-seizure medication blood levels.
  - b. Observe for status epilepticus, which may occur after any intracranial surgery.
4. Infections
  - a. Urinary tract infections
  - b. Pulmonary infections related to aspiration secondary to depressed level of responsiveness; may result in atelectasis and aspiration pneumonia
  - c. CNS infections (postoperative meningitis, CSF shunt infection)
  - d. Surgical site infections/septicemia

## Overview of Nursing Management for the Patient After Intracranial Surgery (Continued)

5. Venous thrombosis
  - a. Assess for Homans' sign.
  - b. Apply elastic compression stockings.
  - c. Administer anticoagulant therapy as prescribed.
6. Leakage of CSF
  - a. Differentiate between CSF and mucus.
    - (1) Collect fluid on Dextrostix; if CSF is present, the indicator will have a positive reaction, as CSF contains glucose.
    - (2) Assess for moderate elevation of temperature and mild neck rigidity.
  - b. Caution patient against nose blowing or sniffing.
  - c. Elevate head of bed as prescribed.
  - d. Assist with insertion of lumbar CSF drainage system if inserted to reduce CSF pressure.
    - (1) Ventricular catheters may be inserted in the patient undergoing surgery of the posterior fossa (ventriculostomy); the catheter is connected to a closed drainage system.
    - (2) Administer antibiotics as prescribed.
7. Gastrointestinal ulceration; monitor for signs and symptoms of hemorrhage, perforation, or both (probably caused by stress response).

## Evaluation

## Expected patient outcomes

1. Demonstrates normal breathing pattern
  - a. Absence of crackles
  - b. Demonstrates active swallowing and coughing reflexes
2. Attains/maintains fluid balance
  - a. Takes fluids orally
  - b. Maintains weight within expected range
3. Compensates for sensory deprivation
  - a. Makes needs known
  - b. Demonstrates improvement of vision
4. Exhibits absence of complications
  - a. No evidence of increased ICP
  - b. Opens eyes on request
  - c. Obeys commands
  - d. Has appropriate motor responses
  - e. Shows increasing alertness
  - f. No evidence of rhinorrhea, otorrhea, or CSF leakage
  - g. Absence of fever
  - h. No evidence of inflammation or infection at surgical site
  - i. Absence of seizures

Conversely, hypothermia may be seen after lengthy neurosurgical procedures. Therefore, frequent measurements of rectal temperature are necessary. Rewarming should occur slowly to prevent shivering, which increases cellular oxygen demands.

## IMPROVING GAS EXCHANGE

The patient undergoing neurosurgery is at risk for impaired gas exchange and pulmonary infections because of immobility, immunosuppression, decreased LOC, and fluid restriction. Immobility compromises the respiratory system by causing pooling and stasis of secretions in dependent areas and the development of atelectasis. The patient whose fluid intake is restricted may be more vulnerable to atelectasis as a result of inability to expectorate thickened secretions. Pneumonia is frequently seen in neurosurgical patients, possibly related to aspiration and restricted mobility.

The nurse assesses the patient for signs of respiratory infection, which include temperature elevation, increased pulse rate, and changes in respirations, and auscultates the lungs for decreased breath sounds and adventitious sounds.

Repositioning the patient every 2 hours will help to mobilize pulmonary secretions and prevent stasis. When the patient regains consciousness, additional measures to expand collapsed alveoli can be instituted, such as yawning, sighing, deep breathing, incentive spirometry, and coughing (unless contraindicated). If necessary, the oropharynx and trachea are suctioned to remove secretions that cannot be raised by coughing; however, coughing and suctioning increase ICP. Therefore, suctioning should be used cautiously. Increasing the humidity in the oxygen delivery system may help to loosen secretions. The nurse and the respiratory therapist work together to monitor the effects of chest physical therapy.

## MANAGING SENSORY DEPRIVATION

Periorbital edema is a common consequence of intracranial surgery because fluid drains into the dependent periorbital areas when the patient has been positioned in a prone position during

surgery. A hematoma may form under the scalp and spread down to the orbit, producing an area of ecchymosis (black eye).

Before surgery, the patient and family should be informed that one or both eyes may be edematous temporarily after surgery. After surgery, placing the patient in a head-up position (if not contraindicated) and applying cold compresses over the eyes will help reduce the edema. If periorbital edema increases significantly, the surgeon is notified because it may indicate that a postoperative clot is developing or that there is increasing ICP and poor venous drainage. Health care personnel should announce their presence when entering the room to avoid startling the patient whose vision is impaired due to periorbital edema or neurologic deficits.

Additional factors that can affect sensation include a bulky head dressing, the presence of an endotracheal tube, and effects of increased ICP. The first postoperative dressing change is usually performed by the neurosurgeon. In the absence of bleeding or a CSF leak, every effort is made to minimize the size of the head dressing. If the patient requires an endotracheal tube for mechanical ventilation, every effort is made to extubate the patient as soon as clinical signs indicate it is possible. The patient is monitored closely for the effects of elevated ICP.

## ENHANCING SELF-IMAGE

The patient is encouraged to verbalize feelings and frustrations about any change in appearance. Nursing support is based on the patient's reactions and feelings. Factual information may need to be provided if the patient has misconceptions about puffiness about the face, periorbital bruising, and hair loss. Attention to grooming, the use of the patient's own clothing, and covering the head with a turban (and ultimately a wig until hair growth occurs) are encouraged. Social interaction with close friends, family, and hospital personnel may increase the patient's sense of self-worth.

As the patient assumes more responsibility for self-care and participates in more activities, a sense of control and personal competence will develop. The family and social support system can be of assistance while the patient recovers from surgery.

## MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Complications that may develop within hours after surgery include increased ICP, bleeding and hypovolemic shock, altered fluid and electrolyte balance (including water intoxication), infection, and seizures. These complications require close collaboration between the nurse and the surgeon.

### Monitoring for Increased ICP and Bleeding

Increased ICP and bleeding are life-threatening to the patient who has undergone intracranial neurosurgery. The following must be kept in mind when caring for all patients who undergo such surgery:

- An increase in blood pressure and decrease in pulse with respiratory failure may indicate increased ICP.
- An accumulation of blood under the bone flap (extradural, subdural, intracerebral) may pose a threat to life. A clot must be suspected in any patient who does not awaken as expected or whose condition deteriorates. An intracranial hematoma is suspected if the patient has any new postoperative neurologic deficits (especially a dilated pupil on the operative side). In these events, the patient is returned to the operating room immediately for evacuation of the clot if indicated.
- Cerebral edema, infarction, metabolic disturbances, and hydrocephalus are conditions that may mimic the clinical manifestations of a clot.

The patient is monitored closely for indicators of complications, and early signs and trends in clinical status are reported to the surgeon. Treatments are initiated promptly, and the nurse assists in evaluating the response to treatment. The nurse also provides support to the patient and family.

Should signs and symptoms of increased ICP occur, efforts to decrease the ICP are initiated: alignment of the head in a neutral position without flexion to promote venous drainage, elevation of the head of the bed to 30 degrees, administration of mannitol (an osmotic diuretic), and possible administration of pharmacologic paralyzing agents.

### Managing Fluid and Electrolyte Disturbances

Fluid and electrolyte imbalances may occur because of the patient's underlying condition and its management or as complications of surgery. Fluid and electrolyte disturbances can contribute to the development of cerebral edema.

The postoperative fluid regimen depends on the type of neurosurgical procedure and is determined on an individual basis. The volume and composition of fluids are adjusted according to daily serum electrolyte values, along with fluid intake and output.

Sodium retention may occur in the immediate postoperative period. Serum and urine electrolytes, blood urea nitrogen, blood glucose, weight, and clinical status are monitored. Intake and output are measured in view of losses associated with fever, respiration, and CSF drainage. Fluids may have to be restricted in patients with cerebral edema.

Oral fluids are usually resumed after the first 24 hours (Hickey, 2003). The presence of gag and swallowing reflexes must be checked before initiation of oral fluids. Some patients with posterior fossa tumors may have impaired swallowing, so fluids may need to be administered by alternative routes. The patient should be observed for signs and symptoms of nausea and vomiting as the diet is progressed (Hickey, 2003).

Patients undergoing surgery for brain tumors often receive large doses of corticosteroids and thus tend to develop hyperglycemia. Therefore, serum glucose levels are measured every 4 hours. These patients are prone to gastric ulcers, and therefore histamine-2 receptor antagonists (H<sub>2</sub> blockers) are prescribed to suppress the secretion of gastric acid. The patient is monitored for bleeding and assessed for gastric pain.

If the surgical site is near, or causes edema to, the pituitary gland and hypothalamus, the patient may develop symptoms of diabetes insipidus, which is characterized by excessive urinary output. The urine specific gravity is measured hourly, and fluid intake and output are monitored. Fluid replacement must compensate for urine output, and serum potassium levels must be monitored.

SIADH, which results in water retention with hyponatremia and serum hypo-osmolality, occurs in a wide variety of central nervous system disorders (brain tumor, head trauma) causing fluid disturbances. Nursing management includes careful intake and output measurements, specific gravity determinations of urine, and monitoring of serum and urine electrolyte studies, while following directives for fluid restriction. SIADH is usually self-limiting.

### Preventing Infection
