artery, which also increases the possibility of arterial obstruction. Brachytherapy reduces the recurrence of obstruction, preventing vessel restenosis by inhibiting smooth muscle cell proliferation (Leon et al., 2001). Brachytherapy (from the Greek word, *brachys*, meaning *short*) involves the delivery of gamma or beta radiation by placing a radioisotope close to the lesion (Teirstein & Kuntz, 2001). The radioisotope may be delivered by a catheter or implanted with the stent. Long-term studies are needed to identify if the beneficial effects of radiation therapy are sustained and to determine the optimal dose and type of isotope to use for brachytherapy.

## Transmyocardial Revascularization

Patients who have cardiac ischemia and who are not candidates for CABG may benefit from transmyocardial laser revascularization (TMR) (Burkhoff et al., 1999). The procedure may be performed percutaneously in the cardiac catheterization laboratory (percutaneous transmyocardial revascularization [PTMR]) or through a midsternal or thoracotomy incision in the operating room (Acorda et al., 2000). The tip of a fiberoptic catheter is held firmly against the ischemic area of the heart while a laser burns a channel into but not through the muscle. If the procedure is percutaneous, the catheter is positioned inside the ventricle. If the procedure is surgical, the catheter is positioned on the outer surface of the ventricle. Each procedure usually involves making 20 to 40 channels. It is thought that some blood flows into the channels, decreasing the ischemia directly. Within the next few days to months, the channels close as a result of the body's inflammatory process of healing a wound (Platek & Atzori, 1999). The long-term result is the formation of new blood vessels (angiogenesis) during the inflammatory process that follows the laser burns (Anderson, 2000; Braunwald et al., 2001; Fuster et al., 2001; Hayden, 1998; Platek, & Atzori, 1999). The new blood vessels provide enough blood to decrease the symptoms of cardiac ischemia. Nursing care before, during, and after the procedure depends on the approach: if the approach was percutaneous, the patient care is the same as following a PTCA; if the approach was surgical, the patient care is the same as following CABG.

**FIGURE 28-6** Intracoronary artery stent. (A) Stent closed, before balloon inflation. (B) Stent open, balloon inflated; stent will remain expanded after balloon is deflated and removed. (C) Stent open, balloon removed.

## SURGICAL PROCEDURES

### Coronary Artery Revascularization

Advances in diagnostics, medical management, surgical and anesthesia techniques, and cardiopulmonary bypass (CPB), as well as the care provided in critical care and surgical units, home care, and rehabilitation programs, have helped make surgery a viable treatment option for patients with cardiac disease. CAD has been treated by some form of myocardial revascularization since the 1960s; the most common CABG techniques have been performed for approximately 35 years. CABG is a surgical procedure in which a blood vessel from another part of the body is grafted to the occluded coronary artery so that blood can flow beyond the occlusion; it is also called a *bypass graft*.

Candidates for CABG are usually patients with the following conditions (Eagle et al., 1999):

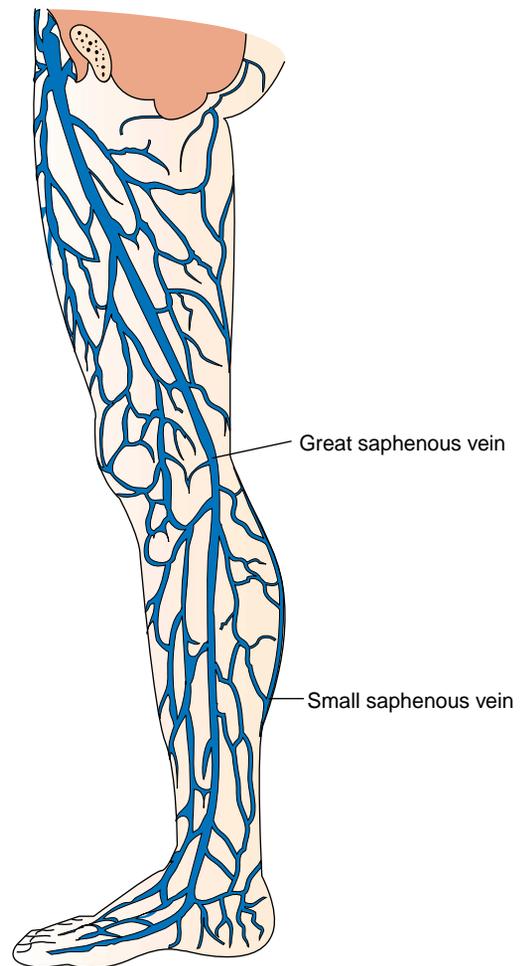

- Angina that cannot be controlled by medical therapies
- Unstable angina
- A positive exercise tolerance test and lesions or blockage that cannot be treated by PCI
- A left main coronary artery lesion or blockage of more than 60%
- Blockage of two or three coronary arteries, one of which is the proximal left anterior descending artery
- Left ventricular dysfunction with blockages in two or more coronary arteries
- Complications from or unsuccessful PCIs

For a patient to be considered for CABG, the coronary arteries to be bypassed must have at least a 70% occlusion (60% if it is the left main coronary artery). If the lesion involves less than 70% of the artery, enough blood can flow through the blocked artery to prevent adequate blood flow through the bypass graft. As a result, the graft would clot, effectively negating the surgery.

The vessel most commonly used for CABG is the greater saphenous vein, followed by the lesser saphenous vein (Fig. 28-7). Cephalic and basilic veins are used also. The vein is removed from the leg (or arm) and grafted to the ascending aorta and to the coronary artery distal to the lesion. The saphenous veins are used in emergency CABG procedures because they can be obtained by one surgical team while another team performs the chest surgery. One side effect of using a large vein is edema, which may develop in the extremity from which it was taken. The degree of edema varies and may diminish over time. Approximately 5 to 10 years after CABG, symptomatic atherosclerotic changes develop in saphenous veins used for grafting. In arm veins, the same changes develop more quickly, approximately 3 to 6 years after the surgery.

The right and left internal mammary arteries and, occasionally, radial arteries are also used for CABG. Arterial grafts are preferred to vein grafts because they do not develop atherosclerotic changes as quickly and remain patent longer. In general, the surgeon leaves the proximal end of the mammary artery intact and detaches the distal end of the artery from the chest wall. This distal end of the artery is then grafted to the coronary artery distal to the occlusion. Disadvantages of using the internal mammary arteries are that they may not be long enough or wide enough for the bypass and ulnar nerve damage may result.

The gastroepiploic artery (located along the greater curvature of the stomach) may also be used, although it does not respond as well when used as a graft. It has a more extensive blood supply to its wall than the internal mammary arteries, making dissection from the stomach difficult and increasing the potential for injury

**FIGURE 28-7** The greater and lesser saphenous veins are the vessels most commonly used in bypass graft procedures.

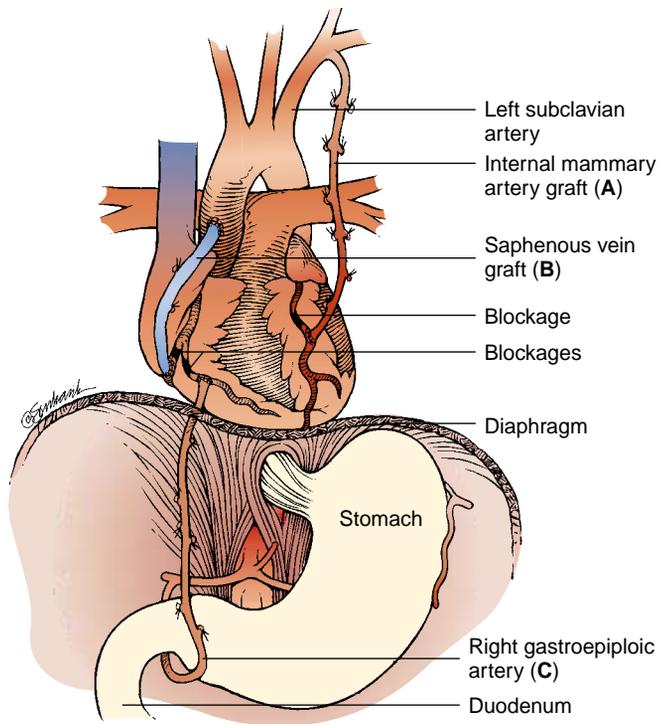

and ischemia of the graft. Use of the gastroepiploic artery requires the surgeon to extend the chest incision to the abdomen, thereby exposing the patient to the additional risks of an abdominal incision and infection at the surgical site from contamination by the gastrointestinal tract.

#### TRADITIONAL CORONARY ARTERY BYPASS GRAFT

The traditional CABG procedure is performed with the patient under general anesthesia. Usually, the surgeon makes a median sternotomy incision and connects the patient to the CPB machine. Next, a blood vessel from another part of the patient's body (eg, saphenous vein, left internal mammary artery) is grafted distal to the coronary artery lesion, bypassing the obstruction (Fig. 28-8). CPB is then discontinued and the incision is closed. The patient then is admitted to a critical care unit.

**Cardiopulmonary Bypass (CPB).** Many cardiac surgical procedures are possible because of CPB (ie, extracorporeal circulation). The procedure mechanically circulates and oxygenates blood for the body while bypassing the heart and lungs. CPB uses a heart-lung machine to maintain perfusion to other body organs and tissues while the surgeon works in a bloodless surgical field.

CPB, a common but complex technique, is accomplished by placing a cannula in the right atrium, vena cava, or femoral vein

**FIGURE 28-8** Three coronary artery bypass grafts. One or more procedures may be performed using various veins and arteries. (A) Left internal mammary artery, popular because of its functional longevity. (B) Saphenous vein, the most frequently constructed bypass. (C) Right gastroepiploic artery, rarely used because this artery has a more extensive blood supply to its wall (increasing the risk of bleeding and necrosis of the artery) and because of the risk of gastrointestinal tract contamination of the abdominal or mediastinal wound.

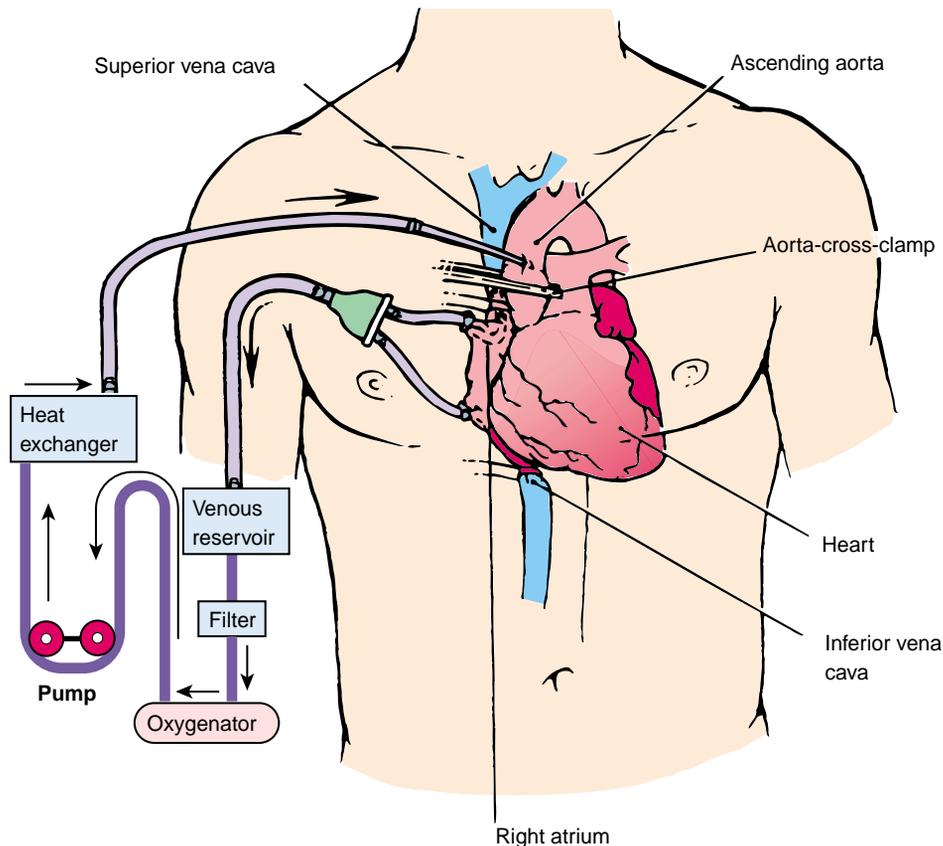

to withdraw blood from the body. The cannula is connected to tubing filled with an isotonic crystalloid solution (usually 5% dextrose in lactated Ringer's solution). Venous blood removed from the body by the cannula is filtered, oxygenated, cooled or warmed, and then returned to the body. The cannula used to return the oxygenated blood is usually inserted in the ascending aorta, but it may be inserted in the femoral artery (Fig. 28-9).

The patient receives heparin, an anticoagulant, to prevent thrombus formation and possible embolization that may occur when blood contacts the foreign surfaces of the CPB circuit and is pumped into the body by a mechanical pump (not the normal blood vessels and heart). After the patient is disconnected from the bypass machine, protamine sulfate is administered to reverse the effects of heparin.

During the procedure, hypothermia is maintained, usually 28°C to 32°C (82.4°F to 89.6°F). The blood is cooled during CPB and returned to the body. The cooled blood slows the body's basal metabolic rate, thereby decreasing its demand for oxygen. Cooled blood usually has a higher viscosity, but the crystalloid solution used to prime the bypass tubing dilutes the blood. When the surgical procedure is completed, the blood is rewarmed as it passes through the CPB circuit. Urine output, blood pressure, arterial blood gas measurements, electrolytes, coagulation studies, and the ECG are monitored to assess the patient's status during CPB.

#### MINIMALLY INVASIVE DIRECT CABG (MIDCAB)

For patients with single coronary artery blockages who cannot be treated by PTCA or with contraindications for CPB, an alternative to traditional CABG is minimally invasive direct CABG (MIDCAB). With the patient under general anesthesia, the surgeon makes one or more 2- to 4-inch (5- to 10-cm) incisions in

**FIGURE 28-9** The cardiopulmonary bypass system, in which cannulae are placed through the right atrium into the superior and inferior vena cavae to divert blood from the body and into the bypass system. The pump system creates a vacuum, pulling blood into the venous reservoir. The blood is cleared of air bubbles, clots, and particulates by the filter, and then is passed through the oxygenator, releasing carbon dioxide and obtaining oxygen. Next, the blood is pulled to the pump and pushed out to the heat exchanger, where its temperature is regulated. The blood is then returned to the body via the ascending aorta.

the chest wall for a left or right anterior thoracotomy or for a mid-sternal or midline upper laparotomy. The graft is prepared for the bypass (see previous graft selection description). The surgeon identifies the location of the coronary artery for the CAB, and a special instrument, a myocardial stabilizer, is put around the site. The stabilizer holds the graft site still for the surgeon while the heart continues to beat. Other techniques to minimize movement of the beating heart are to temporarily collapse the lung on the side of the chest where the surgery is being performed, decrease the respiratory rate and the volume of each breath, and give medications to cause bradycardia or up to 20 seconds of asystole.

Patients treated with MIDCAB may recover from anesthesia in the postanesthesia care unit (PACU) and then be admitted to a telemetry unit for 1 to 3 days. Nursing care is often directed toward routine postoperative pulmonary interventions (especially if a lung was collapsed during the MIDCAB) and incisional pain management (especially if a thoracotomy incision was made).

### PORT ACCESS CORONARY ARTERY BYPASS GRAFT

Port access CABG is another alternative to traditional CABG. With the patient under general anesthesia, the surgeon makes three or more incisions (ports) to perform the CABG. One 0.5- to 1-inch (1.3- to 2.5-cm) incision in the groin provides access to a femoral artery and vein. The femoral artery is used for a multi-purpose catheter threaded retrograde through the aorta to the ascending aorta. The catheter is used to return blood from CPB to the patient, to occlude the aorta by inflating a balloon near the end of the catheter, to provide a cardioplegia solution to the coronary arteries, and to vent air from the aortic root during the surgical procedure. The femoral vein is used for a catheter threaded through the vena cava to the right atrium to drain blood from the patient for CPB. Another 0.5- to 1-inch (1.3- to 2.5-cm) incision in the neck provides access to the jugular vein for two catheters. One catheter is threaded into the pulmonary artery to remove air, fluid, and blood that may enter the right heart during surgery. The other catheter is threaded into the right atrium and the tip positioned in the coronary sinus for retrograde infusion of the cardioplegia solution. One or more thoracotomy incisions, usually 2 to 3.5 inches (5 to 9 cm) long, are made for insertion of the surgical instruments. One of the thoracotomy ports may be used for video-assisted imaging equipment.

CPB is begun when the equipment is in place through the groin, neck, and thoracotomy incisions. The balloon on the aortic catheter is inflated, and the cardioplegia solution is injected into the coronary arteries. Cardioplegia solution is a crystalloid and electrolyte liquid used to stop the heart and protect the myocardium during cardiac surgical procedures. One lung may be temporarily collapsed to assist with exposing the surgical site. The CABG is performed through a thoracotomy incision. When the CABG is complete, air is vented from the pulmonary artery and aorta. The balloon on the aortic catheter is deflated, and CPB is discontinued. The surgical instruments and the catheters are removed. The incisions are closed. The patient's postoperative care is similar to that after traditional CABG.

### COMBINATION PERCUTANEOUS TRANSLUMINAL CORONARY ANGIOPLASTY AND CORONARY ARTERY BYPASS GRAFT

Patients who have blockages in the left anterior descending and at least one other coronary artery who are not candidates for traditional CABG or prefer less invasive procedures may be treated with both MIDCAB and PTCA. Because patients need their blood to

be able to clot after MIDCAB, but require anticoagulation after PTCA, the sequence and timing of providing both treatments to the same patient are being investigated.

### COMPLICATIONS

CABG may result in complications such as MI, dysrhythmias, and hemorrhage (see Table 28-2; these complications are discussed in depth in this chapter, in Chapter 27, and in Chapters 20 and 71). The patient's underlying heart disease remains, and angina, exercise intolerance, or other symptoms experienced before CABG may develop again. Medications required before surgery may need to be continued. Lifestyle modifications recommended before surgery remain important to treat the underlying CAD and for the continued viability of the newly implanted grafts (see Plan of Nursing Care, pp. 740–745).

### NURSING PROCESS: THE PATIENT AWAITING CARDIAC SURGERY

The cardiac surgery patient has many of the same needs and requires the same perioperative care as other surgical patients (see Chaps. 18 through 20). The patient and family are experiencing a major life crisis. The association of the heart with life and death intensifies their emotional and psychological needs. Patients frequently are admitted the same day as the procedure. For these patients, the nurse must prioritize needs carefully; in the time allowed, the nurse focuses on the needs that have the highest priority.

Before surgery, physical and psychological assessments establish the baselines for future reference. The patient's understanding of the surgical procedure, informed consent, and adherence to treatment protocols are evaluated. Helping the patient to cope, understand the procedure, and maintain dignity are nursing responsibilities.

The preoperative phase of cardiac surgery begins before hospitalization. The nurse assesses the patient for other disorders, such as diabetes, hypertension, and respiratory, gastrointestinal, and hematologic diseases, and documents their treatment.

The nurse clarifies how the medication regimen is to be altered before surgery, such as tapering corticosteroids and digoxin, decreasing or discontinuing anticoagulants, and maintaining medications for treatment of blood pressure, angina, diabetes, and dysrhythmias. The nurse also clarifies the need to maintain activity patterns, a healthy diet, healthful sleep habits, and cessation of smoking to minimize the risks of surgery.

### Assessment

Patients with nonacute heart disease may be admitted to the hospital the day of or the day before the surgery. Most of the preoperative evaluation is completed before the patient enters the hospital. Many surgeons' offices or hospitals mail an information packet to the patient's home.

A history and physical examination are performed by nursing and medical personnel. A chest x-ray, ECG, laboratory tests, blood typing and crossmatching, and autologous blood donation (patient's own blood) may also be performed. The health assessment focuses on obtaining baseline physiologic, psychological, and social information. The patient's and family's learning needs are identified and addressed as necessary. Of particular importance are the patient's usual functional level, coping mechanisms, and support systems. These are important because the support of the family or

## Plan of Nursing Care

### Care of the Patient After Cardiac Surgery

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Decreased cardiac output related to blood loss and compromised myocardial function

**Goal:** Restoration of cardiac output to maintain/attain desired lifestyle

<p>1. Monitor cardiovascular status. Serial readings of blood pressures (arterial, left atrial, pulmonary artery, pulmonary artery wedge pressure [PAWP], central venous pressure [CVP]), cardiac output/index, systemic and pulmonary vascular resistance, and cardiac rhythm and rate are obtained, recorded, and correlated with the patient's condition.</p> <p>a. Assess arterial blood pressure every 15 minutes until stable; then arterial or cuff blood pressure every 1–4 hours × 24 hours; then every 8–12 hours until hospital discharge; then every visit.</p> <p>b. Auscultate for heart sounds and rhythm.</p> <p>c. Assess peripheral pulses (pedal, tibial, radial, carotid).</p> <p>d. Measure left atrial pressure, pulmonary artery diastolic (PAD) pressure, and PAWP to determine left ventricular end-diastolic volume and to assess cardiac output.</p> <p>e. Monitor PAWP, PAD, left atrial pressure, and CVP to assess blood volume, vascular tone, and pumping effectiveness of the heart. <i>Remember: Trends are more important than isolated readings.</i> Mechanical ventilation may elevate CVP.</p> <p>f. Monitor ECG pattern for cardiac dysrhythmias (see Chap. 27 for discussion of dysrhythmias).</p> <p>g. Assess cardiac enzyme test results when available.</p> <p>h. Measure urine output every ½ hour to 1 hour at first, then with vital signs.</p> <p>i. Observe buccal mucosa, nailbeds, lips, earlobes, and extremities.</p> <p>j. Assess skin; note temperature and color.</p>	<p>1. Effectiveness of cardiac output is determined by hemodynamic monitoring.</p> <p>a. Blood pressure is one of the most important physiologic parameters to follow; vasoconstriction after cardiopulmonary bypass may make auscultatory blood pressure unobtainable.</p> <p>b. Auscultation provides evidence of cardiac tamponade (muffled distant heart sounds), pericarditis (precordial rub), dysrhythmias.</p> <p>c. Presence or absence and quality of pulses provide data about cardiac output as well as obstructive lesions.</p> <p>d. Rising pressures may indicate congestive heart failure or pulmonary edema.</p> <p>e. High PAWP, PAD, left atrial pressure, or CVP may result from hypervolemia, heart failure, cardiac tamponade. If blood pressure drop is due to low blood volume, PAWP, PAD, left atrial pressure, and CVP will show corresponding drop.</p> <p>f. Dysrhythmias may occur with coronary ischemia, hypoxia, alterations in serum potassium, edema, bleeding, acid-base or electrolyte disturbances, digitalis toxicity, cardiac failure. ST-segment changes may indicate myocardial ischemia or coronary artery spasm. Pacemaker capture and antiarrhythmic medication effects are used to maintain a heart rate and rhythm to support stable blood pressures.</p> <p>g. Elevations may indicate myocardial infarction.</p> <p>h. Urine output less than 25 mL/h indicates decreased renal perfusion and may reflect decreased cardiac output.</p> <p>i. Dusky skin and cyanosis may indicate decreased cardiac output.</p> <p>j. Cool moist skin indicates vasoconstriction and decreased cardiac output.</p>	<p>The following parameters are within the patient's normal ranges:</p> <ul style="list-style-type: none"> <li>• Arterial pressure</li> <li>• Left atrial pressures</li> <li>• PAWP</li> <li>• Pulmonary artery pressures</li> <li>• CVP</li> <li>• Heart sounds</li> <li>• Pulmonary and systemic vascular resistance</li> <li>• Cardiac output and cardiac index</li> <li>• Peripheral pulses</li> <li>• Cardiac rate and rhythm</li> <li>• Cardiac enzymes</li> <li>• Urine output</li> <li>• Skin and mucosal color</li> <li>• Skin temperature</li> </ul>
---	---	--

(continued)

## Plan of Nursing Care

### Care of the Patient After Cardiac Surgery (Continued)

#### Nursing Interventions

2. Observe for persistent bleeding: steady, continuous drainage of blood; hypotension; low CVP; tachycardia. Prepare to administer blood products, IV solutions.
3. Observe for cardiac tamponade: hypotension; rising PAWP, PAD, left atrial pressure, or CVP; muffled heart sounds; weak, thready pulse; jugular vein distention; decreasing urinary output. Check for diminished amount of blood in chest drainage collection system. Prepare for pericardiocentesis. Assess for pulsus paradoxus.
4. Observe for cardiac failure: hypotension, rising PAWP, PAD, CVP, and left atrial pressure, tachycardia, restlessness, agitation, cyanosis, venous distention, dyspnea, moist crackles, ascites. Prepare to administer diuretics and digoxin.
5. Observe for myocardial infarction: ST-segment elevations, T-wave changes, decreased cardiac output in the presence of normal circulating volume and filling pressures. Obtain serial ECGs and iso-enzymes. Differentiate myocardial pain from incisional pain.

#### Rationale

2. Bleeding can result from cardiac incision, tissue fragility, trauma to tissues, clotting defects.
3. Cardiac tamponade results from bleeding into the pericardial sac or accumulation of fluid in the sac, which compresses the heart and prevents adequate filling of the ventricles. Decrease in chest drainage may indicate fluid is accumulating in the pericardial sac.
4. Cardiac failure results from decreased pumping action of the heart; can cause deficient blood perfusion to vital organs.
5. Symptoms may be masked by the patient's level of consciousness and pain medication.

#### Expected Outcomes

- Less than 200 mL/hr of drainage through chest tubes during first 4 to 6 hours
- Vital signs stable
- Chest tube drainage expected amount
- CVP and left atrial pressures within normal limits
- Urinary output within normal limits
- Skin color normal
- Respirations unlabored, clear breath sounds
- Pain limited to incision
- ECG and isoenzymes negative for ischemic changes

**Nursing Diagnosis:** Impaired gas exchange related to trauma of extensive chest surgery

**Goal:** Adequate gas exchange

1. Maintain mechanical ventilation until the patient is able to breathe independently.
2. Monitor arterial blood gases, tidal volumes, peak inspiratory pressures, and extubation parameters.
3. Auscultate chest for breath sounds.
4. Sedate patient adequately, as prescribed, and monitor respiratory rate and depth if ventilations are not "controlled."
5. Promote deep breathing, forced expiratory technique (FET, coughing), and turning. Encourage use of the incentive spirometer and compliance with breathing treatments. Teach incisional splinting with a "cough pillow" to decrease discomfort during deep breathing and FET (coughing).
6. Suction tracheobronchial secretions as needed, using strict aseptic technique.
7. Assist in weaning and endotracheal tube removal.

1. Ventilatory support may be used to decrease work of the heart, to maintain effective ventilation, and to provide an airway in the event of cardiac arrest.
2. ABGs and tidal volume indicate effectiveness of ventilator and changes that need to be made to improve gas exchange.
3. Crackles indicate pulmonary congestion; decreased or absent breath sounds may indicate pneumothorax or hemothorax.
4. Sedation helps the patient to tolerate the endotracheal tube and to cope with ventilatory sensations; sedatives can depress respiratory rate and depth.
5. Aids in keeping airway patent, preventing atelectasis, and facilitating lung expansion.
6. Retention of secretions leads to hypoxia and possible cardiac arrest; retained secretions promote infection.
7. Decreased risk of pulmonary infections and enhanced ability of patient to communicate without an endotracheal tube.

- Airway patent
- ABGs within normal range
- Endotracheal tube correctly placed, as evidenced by x-ray
- Breath sounds clear
- Ventilator synchronous with respirations
- Breath sounds clear after suctioning/FET
- Nailbeds and mucous membranes pink
- Mental acuity consistent with amount of sedatives and analgesics received
- Oriented to person; able to respond yes and no appropriately

(continued)

## Plan of Nursing Care

### Care of the Patient After Cardiac Surgery (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Risk for deficient fluid volume and electrolyte imbalance related to alterations in blood volume

**Goal:** Fluid and electrolyte balance

- |  |   |   |
|--|---|---|
| <p>1. Maintain fluid and electrolyte balance.</p> <p>a. Keep intake and output flow sheets; record urine volume every ½ hour to 4 hours while in critical care unit; then every 8 to 12 hours while hospitalized.</p> <p>b. Assess the following parameters: pulmonary artery pressures, left atrial pressures, blood pressure, CVP, PAWP, weight, electrolyte levels, hematocrit, jugular venous pressure, tissue turgor, liver size, breath sounds, urinary output, and nasogastric tube drainage.</p> <p>c. Measure postoperative chest drainage (should not exceed 200 mL/hr for first 4 to 6 hours); cessation of drainage may indicate kinked or blocked chest tube. Ensure patency and integrity of the drainage system. Maintain auto-transfusion system if in use.</p> <p>d. Weigh daily once patient is ambulatory.</p> <p>2. Be alert to changes in serum electrolyte levels.</p> <p>a. Hypokalemia (low potassium) <i>Effects:</i> dysrhythmias, digitalis toxicity, metabolic alkalosis, weakened myocardium, cardiac arrest<br/>Observe for specific ECG changes. Administer IV potassium replacement as directed.</p> <p>b. Hyperkalemia (high potassium)<br/><i>Effects:</i> mental confusion, restlessness, nausea, weakness, paresthesias of extremities<br/>Be prepared to administer an ion-exchange resin (sodium polystyrene sulfonate [Kayexalate]); IV sodium bicarbonate, or IV insulin and glucose.</p> <p>c. Hypomagnesemia (low magnesium)<br/><i>Effects:</i> paresthesias, carpopedal spasm, muscle cramps, tetany, irritability, tremors, hyperexcitability, hyperreflexia, disorientation, depression, seizures, hypotension, dysrhythmias, prolonged PR and QT intervals, broad flat T waves.</p> | <p>1. Adequate circulating blood volume is necessary for optimal cellular activity; metabolic acidosis and electrolyte imbalance can occur after use of cardiopulmonary bypass.</p> <p>a. Provides a method to determine positive or negative fluid balance and fluid requirements.</p> <p>b. Provides information about state of hydration.</p> <p>c. Excessive blood loss from chest cavity can cause hypovolemia.</p> <p>d. Indicator of fluid balance.</p> <p>2. A specific concentration of electrolytes is necessary in both extracellular and intracellular body fluids to sustain life.</p> <p>a. <i>Causes:</i> inadequate intake, diuretics, vomiting, excessive nasogastric drainage, stress from surgery</p> <p>b. <i>Causes:</i> increased intake, hemolysis from cardiopulmonary bypass/mechanical assist devices, acidosis, renal insufficiency, tissue necrosis, adrenal cortical insufficiency.<br/>The resin binds potassium and promotes intestinal excretion of it.<br/>IV sodium bicarbonate drives potassium into the cells from extracellular fluid.<br/>Insulin assists the cells with glucose absorption. The glucose provides the energy to activate the sodium–potassium pumps, which pull potassium into the cell while pumping sodium out.</p> <p>c. <i>Causes:</i> decreased intake (chronic alcoholism, malnutrition, starvation), impaired absorption (malabsorption syndromes, excess intake of calcium) and increased excretion normal for 24 hours after major surgery, diuretic loss of intestinal fluids, diabetic ketoacidosis, primary aldosteronism, primary hyperparathyroidism.</p> | <ul style="list-style-type: none"> <li>• Fluid intake and output balanced</li> <li>• Hemodynamic assessment parameters negative for fluid overload and dehydration</li> <li>• Normal blood pressure with position changes</li> <li>• Absence of dysrhythmia</li> <li>• Stable weight</li> <li>• Notify physician if weight gain of 2 lb or more in 1 day or 5 lb or more in 1 week.</li> <li>• Blood pH 7.35 to 7.45</li> <li>• Serum potassium 3.5 to 5.0 mEq/L (3.5 to 5.0 mmol/L)</li> <li>• Serum magnesium 1.5 to 2.5 mEq/L (0.75 to 1.25 mmol/L)</li> <li>• Serum sodium 135 to 145 mEq/L (135 to 145 mmol/L)</li> <li>• Serum calcium 8.8 to 10.3 mg/100 mL (2.20 to 2.58 mmol/L)</li> </ul> |

## Plan of Nursing Care

### Care of the Patient After Cardiac Surgery (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Deficient knowledge about self-care activities

**Goal:** Ability to perform self-care activities

<ol style="list-style-type: none"> <li>Develop teaching plan for patient and family. Provide specific instructions for the following:               <ul style="list-style-type: none"> <li>Diet and daily weights</li> <li>Activity progression</li> <li>Exercise</li> <li>Deep breathing, FET (coughing), lung expansion exercises</li> <li>Temperature monitoring</li> <li>Medication regimen</li> <li>Pulse taking</li> <li>CPR, if appropriate for the family to learn</li> <li>Entry to the emergency medical system</li> <li>Need for MedicAlert identification</li> </ul> </li> <li>Provide verbal and written instructions; provide several teaching sessions for reinforcement and answering questions.</li> <li>Involve family in all teaching sessions.</li> <li>Provide information regarding follow-up phone call to surgeon, cardiologist, or liaison nurse; follow-up visit with surgeon.</li> <li>Make appropriate referrals: home care agency, cardiac rehabilitation program, community support groups, Mended Hearts Club.</li> </ol>	<ol style="list-style-type: none"> <li>Each patient will have unique learning needs.</li> <li>Repetition promotes learning by allowing for clarification of misinformation. After cardiac surgery, patients have short-term memory difficulty; information written in the patient's primary language is essential because it can be used as a resource after discharge. The less familiar or greater the amount of the content the patient and family need to learn, the more time it will take to learn.</li> <li>Family member responsible for home care is usually anxious and requires adequate time for learning.</li> <li>Arrangements for phone contacts with health care personnel help to allay anxieties.</li> <li>Learning and lifestyle changes continue after discharge from the hospital.</li> </ol>	<ul style="list-style-type: none"> <li>Patient and family members explain and comply with all therapeutic regimen</li> <li>Patient and family members identify lifestyle changes necessitated by therapeutic regimen</li> <li>Has copy of discharge instructions (in the patient's primary language)</li> <li>Makes follow-up phone calls</li> <li>Keeps follow-up appointments</li> </ul>
--	--	--

significant others will affect the patient's postoperative course and rehabilitation. Discharge plans are influenced by the lifestyle demands of the home situation and the physical environment of the home.

#### HEALTH HISTORY

The preoperative history and health assessment should be thorough and well documented because they provide a basis for postoperative comparison. A systematic assessment of all systems is performed, with emphasis on cardiovascular functioning.

Functional status of the cardiovascular system is determined by reviewing the patient's symptoms, including past and present experiences with chest pain, hypertension, palpitations, cyanosis, breathing difficulty (dyspnea), leg pain that occurs with walking (intermittent claudication), orthopnea, paroxysmal nocturnal dyspnea, and peripheral edema. Because alterations in cardiac output can affect renal, respiratory, gastrointestinal, integumentary, hematologic, and neurologic functioning, a history of

these systems is also reviewed. The patient's history of major illnesses, previous surgeries, medication therapies, and use of drugs, alcohol, and tobacco is also obtained.

#### PHYSICAL ASSESSMENT

A complete physical examination is performed, with special emphasis on the following:

- General appearance and behavior
- Vital signs
- Nutritional and fluid status, weight, and height
- Inspection and palpation of the heart, noting the point of maximal impulse, abnormal pulsations, and thrills
- Auscultation of the heart, noting pulse rate, rhythm, and quality; S<sub>3</sub> and S<sub>4</sub>, snaps, clicks, murmurs, and friction rub
- Jugular venous pressure
- Peripheral pulses
- Peripheral edema

## PSYCHOSOCIAL ASSESSMENT

The psychosocial assessment and the assessment of the patient's and family's learning needs are as important as the physical examination. Anticipation of cardiac surgery is a source of great stress to the patient and family. They will be anxious and fearful and often have many unanswered questions. Their anxiety usually increases with the patient's admission to the hospital and the immediacy of surgery. An assessment of the level of anxiety is important. If it is low, it may indicate denial. If it is extremely high, it may interfere with the use of effective coping mechanisms and with preoperative teaching. Questions may be asked to obtain the following information:

- Meaning of the surgery to the patient and family
- Coping mechanisms that are being used
- Measures used in the past to deal with stress
- Anticipated changes in lifestyle
- Support systems in effect
- Fears regarding the present and the future
- Knowledge and understanding of the surgical procedure, postoperative course, and long-term rehabilitation

The nurse allows adequate time for the patient and family to express their fears. The fears most often expressed are fear of the unknown, fear of pain, fear of body image change, and fear of dying. During the assessment, the nurse determines how much the patient and family know about the impending surgery and the expected postoperative events. They are encouraged to ask questions and to indicate how much information they wish to receive. Some patients prefer not to have detailed information, whereas others want to know as much as possible. Patients are approached as unique individuals with their own specific learning needs, learning styles, and levels of understanding.

Patients requiring emergency heart surgery may have cardiac catheterization and surgery within several hours of admission. The nurse will have little opportunity to assess and meet their emotional and learning needs before surgery. As a result, patients will need extra help after surgery to adjust to the situation.

## Diagnosis

### NURSING DIAGNOSES

The nursing diagnoses for patients awaiting cardiac surgery vary according to each patient's cardiac disease and symptoms. Most patients have a nursing diagnosis of decreased cardiac output (see Cardiac Failure in Chap. 30). Preoperative nursing diagnoses for most patients may include:

- Fear related to the surgical procedure, its uncertain outcome, and the threat to well-being
- Deficient knowledge regarding the surgical procedure and the postoperative course

### COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

The stress of impending cardiac surgery may precipitate complications that require collaborative management with the physician. Based on the assessment data, potential complications that may develop include:

- Angina or anginal pain equivalent
- Severe anxiety requiring an anxiolytic (anxiety-reducing) medication
- Cardiac arrest

## Planning and Goals

The major goals of the patient may include reducing fear, learning about the surgical procedure and postoperative course, and avoiding complications.

## Nursing Interventions

During the preoperative phase of cardiac surgery, the nurse develops a plan of care that includes emotional support and teaching for the patient and family. Establishing rapport, answering questions, listening to fears and concerns, clarifying misconceptions, and providing information about what to expect are interventions the nurse uses to prepare the patient and family emotionally for the surgery and for the postoperative events.

### REDUCING FEAR

The patient and family are provided time and opportunities to express their fears. If there is fear of the unknown, other surgical experiences that the patient has had can be compared with the impending surgery. It is often helpful to describe to the patient the sensations that are expected. If the patient has already had a cardiac catheterization, the similarities and differences between that procedure and the surgery may be compared. The patient is encouraged to talk about any concerns related to previous experiences.

A discussion of the patient's fears about pain is initiated. A comparison is made between the pain experienced with cardiac surgery and other pain experiences. The preoperative sedation, the anesthetic, and the postoperative pain medications are described. The nurse reassures the patient that the fear of pain is normal, that some pain will be experienced, that medication to relieve pain will be provided, and that the patient will be closely observed. The patient is encouraged to take pain medication before the pain becomes severe. Positioning and relaxation will make the pain more tolerable. Patients who have a fear of scarring from surgery are encouraged to discuss this concern, and misconceptions are corrected. It may be helpful to indicate that the health care team members will keep the patient informed about the healing process.

The patient and family are encouraged to talk about their fear of the patient dying. They should be reassured that this fear is normal. For those who only hint about this concern despite efforts to encourage them to talk about their fear, coaching may be helpful (eg, "Are you worrying about not making it through surgery? Most people who have heart surgery at least think about the possibility of dying."). After the fear is expressed, the patient and family can be helped to explore their feelings.

By alleviating undue anxiety and fear, preparing the patient emotionally for surgery decreases the chance of preoperative problems, promotes smooth anesthesia induction, and enhances the patient's involvement in care and recovery after surgery. Preparing the family for the events to come helps them to cope, be supportive to the patient, and participate in postoperative and rehabilitative care (Chart 28-9).

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Angina may occur because of increased stress and anxiety related to the forthcoming surgery. The patient who develops angina usually responds to normal angina therapy, most commonly nitroglycerin. Some patients require oxygen and intravenous nitroglycerin drips (see the Angina Pectoris section).

### Chart 28-9 • Ethics and Related Issues

#### When Is Withholding or Withdrawing Life Support Discussed with Patients and Families?

##### Situation

Life support includes the use of intraaortic balloon pumps and ventricular assist devices, ventilators, vasoactive infusions, cardiopulmonary resuscitation, and antibiotics. Patients who receive these treatments include those who are acutely, chronically, and terminally ill. When dependent on life support, a patient may be unable to make decisions about his or her own care, and the patient's family may be asked to participate in decision making for the patient. At what point is the sensitive issue of withholding or withdrawing life support discussed?

##### Dilemma

A patient is unresponsive and utilizing life support in the critical care unit. The consulting cardiologist has written a progress note stating, "Patient is terminal. Further treatment is futile." The patient does not have a living will or a durable power of attorney for health care. The oldest child does not want the patient to suffer but states, "If there is any hope, I want everything done." The other child states that the patient "would not want to live like this."

Does the statement by the second child support the principle of autonomy? Does the statement by the oldest child provide precedence for the principles of sanctity of life, beneficence, or non-maleficence? If you determined that the statement by the second child supported the principle of autonomy, should sanctity of life, beneficence, or nonmaleficence be used in decision making in this situation?

##### Discussion

What arguments would you offer to support the view that discussions about the extent of life-supporting treatments desired should occur before an individual experiences a life-threatening event?

What arguments would you offer to support the view that discussions about the extent of life-supporting treatment should occur only when certain circumstances arise?

For patients with extreme anxiety or fear and for whom emotional support and education are not successful, medication therapy may be helpful. The anxiolytic agents most commonly used before cardiac surgery are lorazepam (Ativan) and diazepam (Valium).

If cardiac arrest occurs in the preoperative period, advanced cardiac life support is provided (see Chap. 27).

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

Patient and family teaching is based on assessed learning needs. Teaching usually includes information about hospitalization, surgery (eg, preoperative and postoperative care, length of surgery, pain and discomfort that can be expected, visiting hours, and procedures in the critical care unit), the recovery phase (eg, length of hospitalization, what to expect from home care and rehabilitation, when normal activities such as housework, shopping, and work can be resumed), and ongoing lifestyle habits. Any changes made in medical therapy and preoperative preparations need to be explained and reinforced.

The patient is informed that physical preparation usually involves several showers or scrubs with an antiseptic solution. A sedative may be prescribed the night before and the morning of

surgery. Most cardiac surgical teams use prophylactic antibiotic therapy, and the antibiotic therapy is initiated before surgery.

If no preadmission teaching has been done and the preoperative hospitalization period is very short, teaching the patient and family together may be most effective. Anxiety often increases with the admission process and impending surgery. Teaching the patient and family together capitalizes on their established support relationship. Teaching in this phase should be directed primarily by the patient's and family's questions. Too much detail may only increase anxiety.

The patient may be offered a tour of the critical care unit, the postanesthesia care unit, or both. (In some hospitals, the patient initially goes to the postanesthesia care unit.) The patient recovering from anesthesia may be reassured by having already seen the surroundings and having met someone from the unit. The patient and family are informed about the equipment, tubes, and lines that will be present after surgery and their purposes. They should know to expect monitors, several intravenous lines, chest tubes, and a urinary catheter. Explaining the purpose and the approximate time that these devices will be in place helps to reassure the patient. Most patients will remain intubated and on mechanical ventilation for 2 to 24 hours after surgery. They need to be aware that this prevents them from talking, and they should be reassured that the staff will be able to assist them with other means of communication.

The nurse takes care to answer the patient's questions about postoperative care and procedures. Deep breathing and huffing (or coughing), use of the incentive spirometer, and foot exercises are explained and practiced by the patient before surgery. The family's questions at this time usually focus on the length of the surgery, who will discuss the results of the procedure with them after surgery and when this may occur, where to wait during the surgery, the visiting procedures for the critical care unit, and how they can support the patient before surgery and in the critical care unit.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Demonstrates reduced fear
  - a. Identifies fears
  - b. Discusses fears with family
  - c. Uses past experiences as a focus for comparison
  - d. Expresses positive attitude about outcome of surgery
  - e. Expresses confidence in measures to be used to relieve pain
2. Learns about the surgical procedure and postoperative course
  - a. Identifies the purposes of the preoperative preparation procedure
  - b. Tours the critical care unit, if desired
  - c. Identifies limitations expected after surgery
  - d. Discusses expected immediate postoperative environment (eg, tubes, machines, nursing surveillance)
  - e. Demonstrates expected activities after surgery (eg, deep breathing, huffing [coughing], foot exercises)
3. Shows no evidence of complications
  - a. Reports anginal pain is relieved with medications and rest
  - b. Takes medications as prescribed

## INTRAOPERATIVE NURSING MANAGEMENT

The perioperative nurse performs an assessment and prepares the patient for the operating room and recovery experience. Any changes in the patient's status and the need for changes in therapy are identified. Procedures are explained before they are performed, such as the application of electrodes and use of continuous monitoring, indwelling catheters, and an SpO<sub>2</sub> probe. Intravenous lines are inserted to administer fluids, medications, and blood products. The patient will receive general anesthesia, be intubated, and placed on mechanical ventilation. In addition to assisting with the surgical procedures, perioperative nurses are responsible for the comfort and safety of the patient. Some of the areas of intervention include positioning, skin care, wound care, and emotional support of the patient and family.

Before the chest incision is closed, chest tubes are positioned to evacuate air and drainage from the mediastinum and the thorax. Epicardial pacemaker electrodes are implanted on the surface of the right atrium and the right ventricle. These epicardial electrodes can be used to pace the heart and to monitor it for dysrhythmias through the atrial leads.

Possible intraoperative complications include dysrhythmias, hemorrhage, MI, CVA (stroke, brain attack), embolization, and organ failure from shock, embolus, or adverse drug reactions. Astute intraoperative patient assessment is critical in preventing these complications and for detecting symptoms and initiating prompt therapy.

## NURSING PROCESS: THE PATIENT WHO HAS HAD CARDIAC SURGERY

Initial postoperative care focuses on achieving or maintaining hemodynamic stability and recovery from general anesthesia. Care may be provided in the postanesthesia care unit or intensive care unit. After hemodynamic stability and recovery from general anesthesia have been achieved, the patient is transferred to a surgical stepdown unit with telemetry. Care focuses on wound care, progressive activity, and nutrition. Education about medications and risk factor modification is emphasized (see Plan of Nursing Care: Care of the Patient After Cardiac Surgery). Discharge from the hospital usually occurs 3 to 5 days after CABG or 1 to 3 days after MIDCAB. Patients can expect fewer symptoms from CAD and an improved quality of life. CABG has been shown to increase the life span of high-risk patients—those with left main artery blockages, left ventricular dysfunction with multivessel blockages, three-vessel blockages with one being the left anterior descending artery, and diabetes (Eagle et al., 1999).

The immediate postoperative period for the patient who has undergone cardiac surgery presents many challenges to the health care team. All efforts are made to facilitate the transition from the operating room to the critical care unit or PACU with minimal risk. Specific information about the operation and important factors about postoperative management are communicated by the surgical team and anesthesia personnel to the critical care nurse, who then assumes responsibility for the patient's care. Figure 28-10 presents a graphic overview of the many aspects of postoperative care for the cardiac surgical patient.

### Assessment

When the patient is admitted to the critical care unit or PACU and for at least every 12 hours thereafter, a complete assessment of all systems is performed to determine the postoperative status

of the patient compared with the preoperative baseline and to identify anticipated changes since surgery. The following parameters are assessed:

*Neurologic status:* level of responsiveness, pupil size and reaction to light, reflexes, facial symmetry, movement of extremities, and hand grip strength

*Cardiac status:* heart rate and rhythm, heart sounds, arterial blood pressure, central venous pressure (CVP), pulmonary artery pressure, pulmonary artery wedge pressure (PAWP), left atrial pressure, waveforms from the invasive blood pressure lines, cardiac output or index, systemic and pulmonary vascular resistance, pulmonary artery oxygen saturation (SvO<sub>2</sub>) if available, mediastinal chest tube drainage, and pacemaker status and function

*Respiratory status:* chest movement, breath sounds, ventilator settings (eg, rate, tidal volume, oxygen concentration, mode such as synchronized intermittent mandatory ventilation, positive end-expiratory pressure, pressure support), respiratory rate, ventilatory pressure, arterial oxygen saturation (SaO<sub>2</sub>), percutaneous oxygen saturation (SpO<sub>2</sub>), end-tidal CO<sub>2</sub>, pleural chest tube drainage, arterial blood gases

*Peripheral vascular status:* peripheral pulses; color of skin, nailbeds, mucosa, lips, and earlobes; skin temperature; edema; condition of dressings and invasive lines

*Renal function:* urinary output; urine specific gravity and osmolality may be assessed

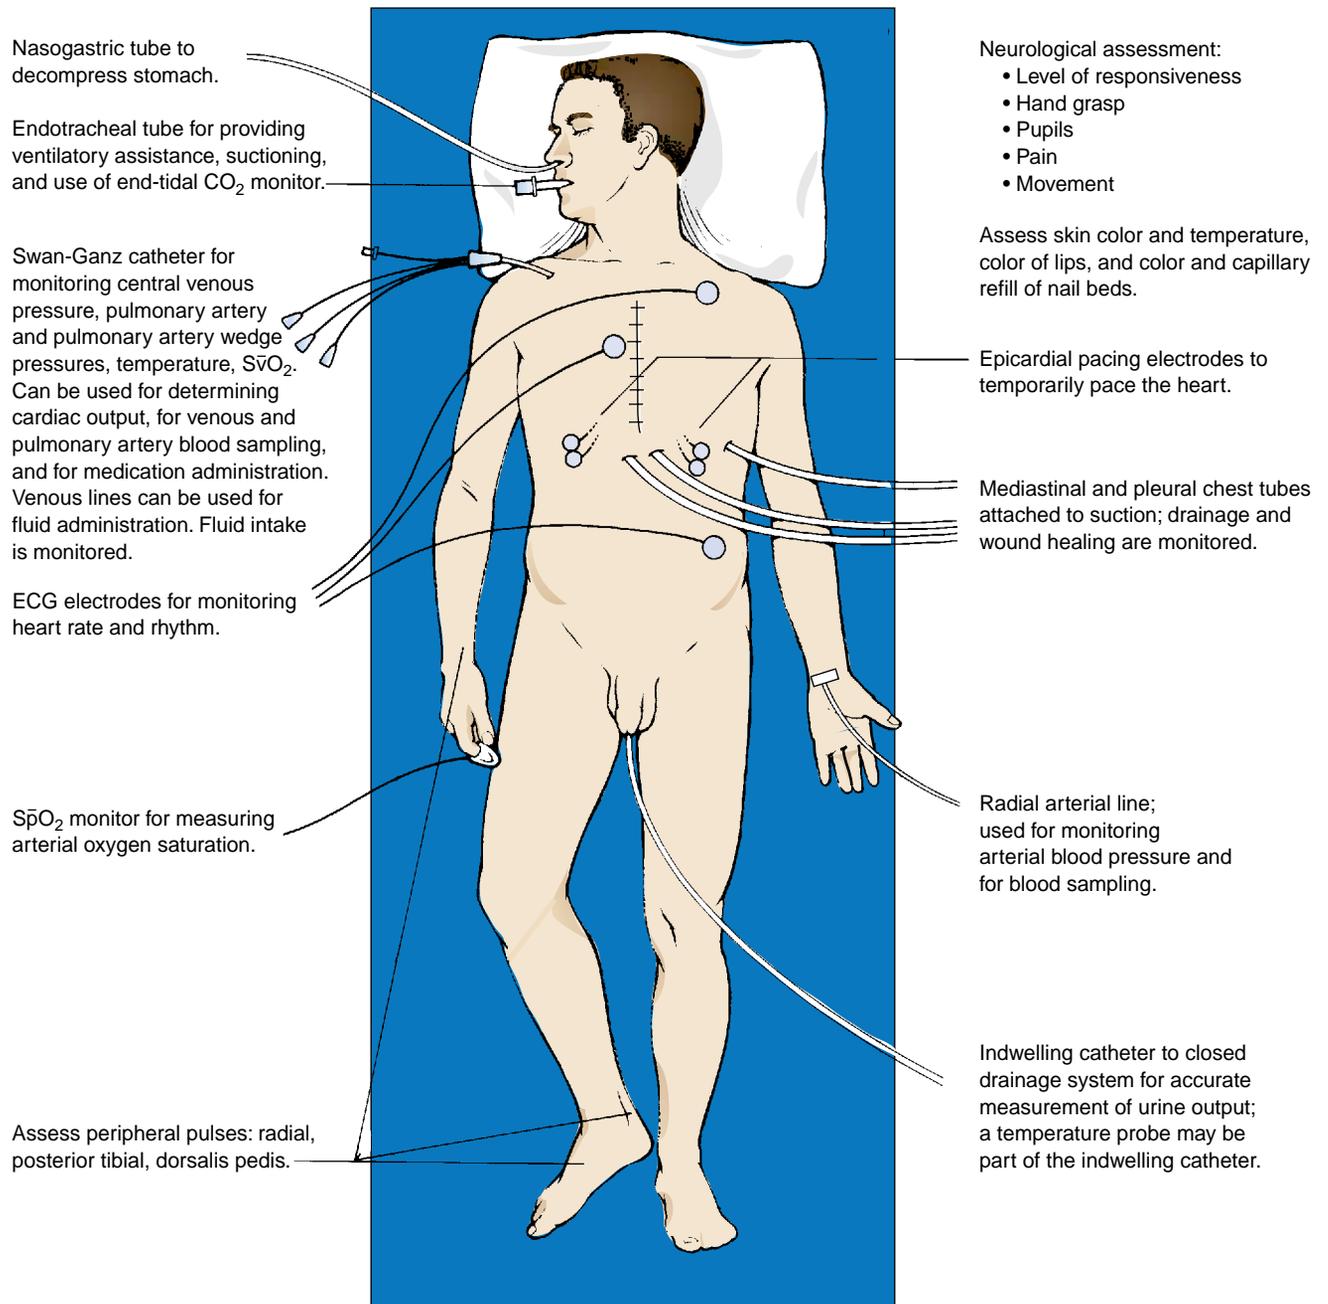

*Fluid and electrolyte status:* intake, output from all drainage tubes, all cardiac output parameters, and the following indications of electrolyte imbalance:

- *Hypokalemia:* digitalis toxicity, dysrhythmias, ECG changes (U wave, atrioventricular block, flat or inverted T waves)
- *Hyperkalemia:* mental confusion, restlessness, nausea, weakness, paresthesias of extremities, dysrhythmias, ECG changes (tall, peaked T waves; increased amplitude, widening QRS complex; prolonged QT interval)
- *Hypomagnesemia:* paresthesias, carpopedal spasm, muscle cramps, tetany, irritability, tremors, hyperexcitability, hyperreflexia, cardiac dysrhythmias, ECG changes (prolonged PR and QT intervals; broad, flat T waves), disorientation, depression, hypotension, seizures
- *Hypermagnesemia:* vasodilation, hypotension, hyporeflexia, slow gastrointestinal motility (hypoactive bowel sounds), lethargy, respiratory depression, coma, apnea, cardiac arrest
- *Hyponatremia:* weakness, fatigue, confusion, seizures, coma
- *Hypocalcemia:* paresthesias, carpopedal spasm, muscle cramps, tetany
- *Hypercalcemia:* digitalis toxicity, asystole

*Pain:* nature, type, location, duration (incisional pain must be differentiated from anginal pain); apprehension; response to analgesics

Some patients who have had a MIDCAB using a midsternal incision or an internal mammary artery CABG experience ulnar nerve paresthesia on the same side of the body as the graft. The paresthesia may be temporary or permanent. Patients who have had CABG using the gastroepiploic artery may experience an ileus for a longer period after surgery and have abdominal pain at the site of the incision and pain at the site of the chest incision.

Assessment also includes observing all equipment and tubes to determine whether they are functioning properly: endotracheal tube, ventilator, end-tidal CO<sub>2</sub> monitor, SpO<sub>2</sub> monitor, pul-

**FIGURE 28-10** Postoperative care of the cardiac surgical patient requires the nurse to be proficient in interpreting hemodynamics, correlating physical assessments with laboratory results, sequencing interventions, and evaluating progress toward desired outcomes.

monary artery catheter, SvO<sub>2</sub> monitor, arterial and intravenous lines, intravenous infusion devices and tubing, cardiac monitor, pacemaker, chest tubes, and urinary drainage system.

As the patient regains consciousness and progresses through the postoperative period, the nurse expands the assessment to include parameters indicative of psychological and emotional status. The patient may exhibit behavior that reflects denial or depression or may experience postcardiotomy psychosis. Characteristic signs of psychosis include transient perceptual illusions, visual and auditory hallucinations, disorientation, and paranoid delusions.

The family's needs also should be assessed. The nurse ascertains how they are coping with the situation; determines their psychological, emotional, and spiritual needs; and finds out whether they are receiving adequate information about the patient's condition.

#### ASSESSING FOR COMPLICATIONS

The patient is continuously assessed for indications of impending complications (Table 28-8). The nurse and the surgeon function collaboratively to identify early signs and symptoms of complications and to institute measures to reverse their progression.

*(text continues on page 754)*

Table 28-8 • Potential Complications of Cardiac Surgery

COMPLICATION	DESCRIPTION	ASSESSMENT AND MANAGEMENT
<b>Cardiac Complications</b> (The patient may require interventions for more than one complication at a time. Collaboration among nurses, physicians, pharmacists, respiratory therapists, and dietitians is necessary to achieve the desired patient outcomes.)		
<b>Decreased Cardiac Output</b>		
<i>Preload Alterations</i> (the amount of myocardial muscle fiber stretch at the end of diastole)		
Hypovolemia (most common cause of decreased cardiac output after cardiac surgery)	<ul style="list-style-type: none"> <li>• Blood loss (although some blood may be replaced to provide sufficient hemoglobin to carry oxygen to the tissues)</li> <li>• Surgical hypothermia (As the reduced body temperature rises after surgery, blood vessels dilate, and more volume is needed to fill the vessels.)</li> <li>• Intravenous fluid loss to the interstitial spaces because cardiopulmonary bypass makes capillary beds more permeable</li> <li>• Arterial hypotension with low pulmonary artery wedge pressure (PAWP) and low central venous pressures (CVP) often are seen with an increased heart rate.</li> </ul>	<ul style="list-style-type: none"> <li>• Fluid replacement may be prescribed. Replacement fluids include: colloid (albumin or protein), starch (hetastarch), packed red blood cells, or crystalloid solution (normal saline, lactated Ringer's solution).</li> </ul>
Persistent bleeding	<ul style="list-style-type: none"> <li>• Cardiopulmonary bypass procedure, which may cause platelet malfunction (blood clots abnormally) and hypothermia, which alters clotting mechanisms</li> <li>• Surgical trauma causing tissues and blood vessels to ooze bloody drainage</li> <li>• Anticoagulant (heparin) therapy</li> </ul>	<ul style="list-style-type: none"> <li>• Accurate measurement of wound bleeding and drainage tube blood is essential. Bloody drainage should not exceed 200 mL/h for the first 4 to 6 hours. Drainage should decrease and stop within a few days, while progressing from sanguineous to serosanguineous and serous drainage.</li> <li>• Protamine sulfate may be administered to neutralize unfractionated heparin; vitamin K and blood products may be used to treat hematologic deficiencies.</li> <li>• If bleeding persists, the patient may return to the operating room for corrective surgery.</li> </ul>
Cardiac tamponade (may decrease preload to the heart by preventing available blood from entering the heart)	<ul style="list-style-type: none"> <li>• Fluid accumulates in the pericardial sac, which compresses the heart, preventing blood from filling the ventricles.</li> <li>• Signs and symptoms include arterial hypotension, tachycardia, muffled heart sounds, decreasing urine output and equalizing of the PAWP, CVP, and pulmonary artery diastolic pressures. Additional signs and symptoms: arterial and pulmonary artery pressure waveforms demonstrating a pulsus paradoxus (decrease of more than 10 mm Hg during inspiration) and decreased chest tube drainage (suggesting that the drainage is trapped or clotted in the mediastinum).</li> </ul>	<ul style="list-style-type: none"> <li>• Equipment is checked to eliminate possible kinks or obstructions in the tubing.</li> <li>• Drainage system patency may be reestablished by milking the tubing (taking care not to strip the tubing, creating massive negative pressure within the chest, which may harm the surgical repair or trigger a dysrhythmia).</li> <li>• Chest x-ray may show a widening mediastinum.</li> <li>• Emergency medical management is required; may include pericardiocentesis or return to surgery.</li> </ul>
Fluid overload	<ul style="list-style-type: none"> <li>• High PAWP, CVP, and pulmonary artery diastolic pressures as well as crackles indicate fluid overload.</li> </ul>	<ul style="list-style-type: none"> <li>• Diuretics are usually prescribed and the rate of IV fluid administration is reduced.</li> <li>• Fluid restriction may be prescribed. Alternative treatments include continuous renal replacement therapy, dialysis, and phlebotomy.</li> </ul>
<i>Afterload Alterations</i> (The force that the ventricle must overcome to move blood forward. Vascular resistance may be calculated to assess afterload and the effects of any vasoactive treatments. Alteration in the patient's body temperature is the most common cause of alterations in afterload after cardiac surgery.)		
Hypothermia	<ul style="list-style-type: none"> <li>• Blood vessel constriction, which increases afterload. (Blood vessel dilation from fever or other hyperthermic condition decreases afterload.)</li> </ul>	<ul style="list-style-type: none"> <li>• Patient is rewarmed gradually, although vasodilators may be required if the resistance is too great to wait for rewarming. The patient may require volume support or vasopressors during a fever or severe vasodilation.</li> </ul>
Hypertension	<ul style="list-style-type: none"> <li>• Various causes. Some patients have a history of this condition and the nurse can anticipate the need for treatment postoperatively. Other patients experience transient hypertension.</li> </ul>	<ul style="list-style-type: none"> <li>• Vasodilators (nitroglycerin [Nitro-Bid], nitroprusside [Nipride, Nitropress]) may be used to treat hypertension. If patient had hypertension before surgery, the preoperative management regimen resumes as soon as possible.</li> </ul>

(continued)

**Table 28-8 • Potential Complications of Cardiac Surgery (Continued)**

COMPLICATION	DESCRIPTION	ASSESSMENT AND MANAGEMENT
<i>Heart Rate Alterations</i> Tachydysrhythmias	<ul style="list-style-type: none"> <li>• May or may not result from preload or afterload alterations</li> </ul>	<ul style="list-style-type: none"> <li>• Rhythms are assessed to establish that they are not the result of preload or afterload alterations.</li> <li>• If a tachydysrhythmia is the primary symptom, the heart rhythm is assessed and medications (eg, adenosine [Adenocard, Adenoscan], digoxin [Lanoxin], diltiazem [Cardizem], esmolol [Brevibloc], lidocaine [Xylocaine], procainamide [Procanbid, Pronestyl], propranolol [Inderal], quinidine [Cardioquin, Quinaglute, Quinidex], verapamil [Calan, Corvera, Isoptin, Verelan]) are prescribed. (Patients may be prescribed antiarrhythmics before CABG to minimize the risk of postoperative tachydysrhythmias.)</li> <li>• Carotid massage may be performed by a physician to assist with diagnosing or treating the dysrhythmia.</li> <li>• Cardioversion and defibrillation are alternatives for symptomatic tachydysrhythmias.</li> </ul>
Bradycardias	<ul style="list-style-type: none"> <li>• Decreased heart rate</li> </ul>	<ul style="list-style-type: none"> <li>• Many postoperative patients will have temporary pacer wires that can be attached to a pulse generator (pacemaker) to stimulate the heart to beat faster. Less commonly, atropine, epinephrine or isoproterenol may be used to increase heart rate.</li> </ul>
Dysrhythmias (may or may not affect cardiac output)	<ul style="list-style-type: none"> <li>• Abnormal heart rates</li> </ul>	<ul style="list-style-type: none"> <li>• Treatment may include medication (Table 27-1), pacemakers (antibradycardiac, antitachycardiac), carotid massage, cardioversion, or defibrillation. Goal of treatment is to return the heart to a normal sinus rhythm.</li> <li>• For patients who cannot attain normal sinus rhythm, an alternate goal may be to establish a stable rhythm that produces a sufficient cardiac output.</li> </ul>
<i>Contractility Alterations</i> Cardiac failure	<ul style="list-style-type: none"> <li>• Possible when the heart fails as a pump and the chambers cannot adequately empty</li> </ul>	<ul style="list-style-type: none"> <li>• The nurse observes for and reports falling mean arterial pressure; rising PAWP, pulmonary artery diastolic pressure, and CVP; increasing tachycardia; restlessness and agitation; peripheral cyanosis; venous distention; labored respirations; and edema.</li> <li>• Medical management includes diuretics and digoxin.</li> </ul>
Myocardial infarction (may occur intraoperatively or postoperatively)	<ul style="list-style-type: none"> <li>• Portion of the cardiac muscle dies, therefore contractility decreases. Until the infarcted area becomes edematous, the ventricular wall moves paradoxically during contractions, further decreasing cardiac output. Symptoms may be masked by the postoperative surgical discomfort or the anesthesia–analgesia regimen.</li> </ul>	<ul style="list-style-type: none"> <li>• Careful assessment to determine the type of pain the patient is experiencing; MI suspected if the mean blood pressure is low with normal preload. The systemic vascular resistance (afterload) and heart rate may be elevated to compensate for poor contractility.</li> <li>• Serial ECGs and cardiac enzymes assist in making the diagnosis (alterations may be due to the surgical intervention). Analgesics are prescribed in small amounts while the patient's blood pressure and respiratory rate are monitored (because vasodilation secondary to analgesics or decreasing pain may occur and compound the hypotension).</li> <li>• Activity progression depends on the patient's activity tolerance.</li> </ul>
<i>Pulmonary Complications</i> Impaired gas exchange	<ul style="list-style-type: none"> <li>• During and after anesthesia, patients require mechanical assistance to breathe.</li> <li>• Potential for postoperative atelectasis.</li> <li>• Endotracheal tubes stimulate production of mucus and chest incision pain may decrease the effectiveness of the forced expiratory technique (FET, cough).</li> </ul>	<ul style="list-style-type: none"> <li>• Pulmonary complications are often detected during assessment of breath sounds, oxygen saturation levels, and end-tidal CO<sub>2</sub> levels, and when monitoring peak pressure and exhaled tidal volumes on the ventilator. Arterial blood gas results and mixed venous saturations also are monitored when available.</li> </ul>

Table 28-8 • Potential Complications of Cardiac Surgery (Continued)

COMPLICATION	DESCRIPTION	ASSESSMENT AND MANAGEMENT
<b>Fluid Volume Complications</b>		
Hemorrhage	<ul style="list-style-type: none"> <li>• Untoward and excessive bleeding may be life-threatening.</li> </ul>	<ul style="list-style-type: none"> <li>• Extended periods of mechanical ventilation are often required while the complications are treated and until they are resolved.</li> <li>• In patients with hypoxia, ventricular stroke work index may be calculated to assist with assessment of contractility.</li> <li>• Hemorrhage usually requires surgical intervention, and blood products are often administered.</li> <li>• Compression of a bleeding vessel is another treatment of hemorrhage. Lungs may be used to compress bleeding mediastinal blood vessels; lung volume and pressure are increased by adding PEEP to the ventilator settings of an intubated patient. The lungs slow or stop the bleeding by pushing in on the mediastinum and creating pressure on the bleeding vessels of the pericardium, coronary arteries, and bypass grafts.</li> </ul>
<b>Neurologic Complications</b>		
Cerebrovascular accident (brain attack, stroke)	<ul style="list-style-type: none"> <li>• Inability to follow simple command within 6 hours of recovery from anesthetic; different capabilities on right or left side of body</li> </ul>	<ul style="list-style-type: none"> <li>• Neurologically, most patients begin to recover from anesthesia in the operating room.</li> <li>• Patients who are elderly or who have renal or hepatic failure may take longer to recover.</li> <li>• Patient should be evaluated for CVA (brain attack, stroke) or air embolism.</li> </ul>
<b>Pain (see Chapter 13)</b>		
<b>Renal Failure and Electrolyte Imbalance</b>		
Renal failure	<ul style="list-style-type: none"> <li>• Usually acute and resolves within 3 months, but may become chronic and require ongoing dialysis</li> </ul>	<ul style="list-style-type: none"> <li>• May respond to diuretics or may require continuous renal replacement therapy (CRRT) or dialysis</li> </ul>
Acute tubular necrosis	<ul style="list-style-type: none"> <li>• Often results from hypoperfusion of the kidneys or from injury to the renal tubules by medications in the filtrate or from exacerbation of a pre-existing condition</li> </ul>	<ul style="list-style-type: none"> <li>• Fluids, electrolytes, and urine output are monitored frequently.</li> </ul>
Hypokalemia (low potassium level; normal level is 3.5 to 5.0 mEq/L [3.5 to 5.0 mmol/L])	<ul style="list-style-type: none"> <li>• May be caused by inadequate intake, diuretics, vomiting, diarrhea, excessive nasogastric drainage without potassium replacement, and stress due to surgery (increased aldosterone secretion produces decreased potassium and increased sodium retention).</li> <li>• Signs and symptoms: digitalis toxicity, dysrhythmias, metabolic alkalosis, a weakened myocardium, and cardiac arrest</li> <li>• One specific ECG change is a U wave (a positive deflection after the T wave) that is more than 1 mm high. Additional signs are atrioventricular block, flat or inverted T waves, and low voltage.</li> </ul>	<ul style="list-style-type: none"> <li>• Must be detected and treated immediately</li> <li>• Patient must be observed carefully when serum potassium rises or falls outside the normal level</li> <li>• Some cardiac surgeons strive to maintain potassium level at 4.0 mEq/L (4.0 mmol/L) or higher to avoid dysrhythmias in the postoperative period.</li> <li>• When necessary, IV potassium replacement is prescribed.</li> </ul>
Hyperkalemia (high potassium level)	<ul style="list-style-type: none"> <li>• Hyperkalemia may be caused by increased intake, red blood cell hemolysis caused by cardiopulmonary bypass or mechanical assist devices, acidosis, renal insufficiency, tissue necrosis, and adrenal cortical insufficiency.</li> <li>• Signs and symptoms: mental confusion, restlessness, nausea, weakness, and paresthesias of the extremities.</li> <li>• ECG changes specific for hyperkalemia are tall peaked T waves, increased amplitude and widening of the QRS complex, and a prolonged QT interval.</li> </ul>	<ul style="list-style-type: none"> <li>• An ion exchange resin, sodium polystyrene sulfonate (Kayexalate), may be prescribed to bind the potassium in the gastrointestinal tract and decrease serum potassium.</li> <li>• Alternative treatments include IV sodium bicarbonate, IV insulin, and glucose to temporarily drive the potassium back into the cells from the extracellular fluid.</li> <li>• Hemodialysis or peritoneal dialysis may be used to reduce the potassium level.</li> </ul>

Table 28-8 • Potential Complications of Cardiac Surgery (Continued)

COMPLICATION	DESCRIPTION	ASSESSMENT AND MANAGEMENT
Hypomagnesemia (low magnesium level, <1.5 mEq/L (0.75 mmol/L), although symptoms usually develop with <1.0 mEq/L). Normal magnesium level ranges from 1.5–2.5 mEq/L (0.75–1.25 mmol/L)	<ul style="list-style-type: none"> <li>• Can be caused by decreased intake, impaired absorption or increased excretion, and surgery, which causes the kidneys to excrete higher amounts of magnesium for 24 hours. Other causes may be decreased intake due to chronic alcoholism, malnutrition or starvation. Impaired absorption may be related to malabsorption syndromes (such as sprue, steatorrhea, or bowel resections) and excess intake of calcium. Increased excretion may result from diuretic use, loss of intestinal fluids (especially fistulas), diabetic ketoacidosis, primary aldosteronism, and primary hyperparathyroidism. Magnesium is important for the function of the neuromuscular system, so the signs and symptoms most often seen are neuromuscular.</li> <li>• Signs and symptoms: paresthesias, carpopedal spasm, muscle cramps, tetany, irritability, tremors, hyperexcitability, hyperreflexia, disorientation, depression, and seizures. Also, hypotension, dysrhythmias (atrial and ventricular), prolonged PR and QT intervals and broad flat T waves.</li> </ul>	<ul style="list-style-type: none"> <li>• Treatment is to correct the cause. If necessary, magnesium supplements may be given. The oral route is preferred to intramuscular injections, which are painful, and the IV route, which carries a significant risk for respiratory depression and hypotension. If the IV route is chosen for magnesium supplements, the nurse needs to assess the patient at least every 15 min for respiratory rate less than 16, hypotension, flushing, and diaphoresis. Loss of the patellar reflex may occur. If symptoms occur, the nurse slows or stops the infusion and notifies the physician.</li> </ul>
Hypermagnesemia (high serum magnesium level, usually >3.0 Eq/L)	<ul style="list-style-type: none"> <li>• Possibly caused by renal failure or intake of large amounts of medications with magnesium, such as some antacids and cathartics.</li> <li>• Signs and symptoms: vasodilation resulting in flushing, feeling warm, and hypotension. As the levels continue to rise, loss of reflexes, slowing bowel function, drowsiness, respiratory depression, coma, apnea and cardiac arrest may occur.</li> </ul>	<ul style="list-style-type: none"> <li>• Dialysis can be used to remove some magnesium but is not usually effective alone. Calcium gluconate is a temporary treatment until the cause can be identified and corrected.</li> </ul>
Hypernatremia (high sodium level). and hyponatremia (low sodium level). Normal level is 135–145 mEq/L (135–145 mmol/L).	<ul style="list-style-type: none"> <li>• Both may occur after cardiac surgery, but hyponatremia is more common.</li> <li>• Hyponatremia may result from reduced total body sodium or from increased water intake, which causes a dilution of body sodium.</li> <li>• Signs and symptoms of hyponatremia: weakness, fatigue, confusion, convulsions, and coma</li> </ul>	<ul style="list-style-type: none"> <li>• The patient must be observed for sodium values that vary from the normal ranges</li> <li>• When there is a true loss of sodium from the body, sodium replacement may be necessary.</li> <li>• Diuretics are prescribed when reduction in sodium is due to increased water intake.</li> </ul>
Hypocalcemia (low calcium level). Normal level is 8.8–10.3 mg/100 mL (2.20–2.58 mmol/L).	<ul style="list-style-type: none"> <li>• May result from alkalosis, which reduces the amount of calcium in the extracellular fluid, or from transfusions of large amounts of citrated blood products—packed red blood cells or whole blood. Citrate binds with calcium, reducing the amount of circulating ionized calcium. After 5–6 units of packed cells or whole blood from the blood bank, calcium binding may become a concern.</li> <li>• Signs and symptoms: numbness and tingling in the fingertips, toes, ears, and nose; carpopedal spasm; and muscle cramps and tetany</li> </ul>	<ul style="list-style-type: none"> <li>• Calcium level is monitored to determine if it is within normal limits.</li> <li>• Any symptoms of hypocalcemia are reported promptly so that calcium replacement can be instituted.</li> </ul>
Hypercalcemia (high calcium level)	<ul style="list-style-type: none"> <li>• Signs and symptoms: dysrhythmias that imitate those caused by digitalis toxicity (calcium can potentiate, or enhance, the action of digitalis)</li> </ul>	<ul style="list-style-type: none"> <li>• The nurse assesses the patient for signs of digitalis toxicity and reports these immediately so that the physician can institute treatment to prevent asystole and death.</li> </ul>

(continued)

**Table 28-8 • Potential Complications of Cardiac Surgery (Continued)**

COMPLICATION	DESCRIPTION	ASSESSMENT AND MANAGEMENT
<b>Other Complications</b>		
Hepatic failure	<ul style="list-style-type: none"> <li>• Most common in patients with cirrhosis, hepatitis, or prolonged right-sided heart failure</li> </ul>	<ul style="list-style-type: none"> <li>• Use of medications metabolized by the liver must be minimized. If hepatic failure cannot be reversed, death is inevitable.</li> <li>• Bilirubin, albumin, and amylase levels are monitored, and nutritional support must be provided.</li> </ul>
Coagulopathies	<ul style="list-style-type: none"> <li>• Result of hypothermia, blood component depletion, anticoagulation, or liver dysfunction</li> </ul>	<ul style="list-style-type: none"> <li>• Each patient must be carefully evaluated to determine the cause. Appropriate therapy is then provided.</li> </ul>
Infection	<ul style="list-style-type: none"> <li>• Cardiopulmonary bypass and anesthesia alter the patient's immune system. Many invasive devices are used to monitor and support the patient's recovery and may serve as a source of infection.</li> </ul>	<ul style="list-style-type: none"> <li>• The following must be monitored to detect signs of possible infection: body temperature, white blood cell counts and differential counts, incision and puncture sites, cardiac output and systemic vascular resistance, urine (clarity, color, and odor), bilateral breath sounds, sputum (color, odor, amount), as well as nasogastric secretions.</li> <li>• Antibiotic therapy may be expanded or modified as necessary.</li> <li>• Invasive devices must be discontinued as soon as they are no longer required. Institutional protocols for maintaining and replacing invasive lines and devices must be followed to minimize the patient's risk for infection.</li> </ul>

### Decreased Cardiac Output

A decrease in cardiac output is always a threat to the patient who has had cardiac surgery. It can have a variety of causes:

*Preload alterations:* too little or too much blood volume returning to the heart because of hypovolemia, persistent bleeding, cardiac tamponade, or fluid overload

*Afterload alteration:* hypertension and arterioles that are too constricted or too dilated because of alterations in body temperature or use of **vasoconstrictors** and **vasodilators**

*Heart rate alterations:* too fast, too slow, or dysrhythmias

*Contractility alterations:* cardiac failure, MI, electrolyte imbalances, hypoxia

### Fluid Volume and Electrolyte Imbalance

The risk for fluid and electrolyte imbalance may occur after cardiac surgery. Nursing assessment for these complications includes monitoring of intake and output, weight, PAWP, left atrial pressure and CVP readings, hematocrit levels, distention of neck veins, edema, liver size, breath sounds (eg, fine crackles, wheezing), and electrolyte levels. Changes in serum electrolytes are reported promptly so that treatment can be instituted. Especially important are dangerously high or dangerously low levels of potassium, magnesium, sodium, and calcium.

### Impaired Gas Exchange

Impaired gas exchange is another possible complication after cardiac surgery. All body tissues require an adequate supply of oxygen and nutrients for survival. To achieve this after surgery, an endotracheal tube with ventilator assistance may be used for 24 or more hours. The assisted ventilation is continued until the patient's blood gas measurements are acceptable and the patient demonstrates the ability to breathe independently. Patients who are stable after surgery may be extubated as early as 2 to 4 hours

after surgery, which reduces their anxiety regarding their limited ability to communicate.

The patient is continuously assessed for signs of impaired gas exchange: restlessness, anxiety, cyanosis of mucous membranes and peripheral tissues, tachycardia, and fighting the ventilator. Breath sounds are assessed often to detect fluid in the lungs and monitor lung expansion. Arterial blood gas values are monitored. Arterial blood gases, SpO<sub>2</sub>, SaO<sub>2</sub>, and end-tidal CO<sub>2</sub> are assessed for decreased oxygen and increased carbon dioxide.

### Impaired Cerebral Circulation

Brain function depends on a continuous supply of oxygenated blood. The brain does not have the capacity to store oxygen and must rely on adequate continuous perfusion by the heart. It is important to observe the patient for any symptoms of hypoxia: restlessness, headache, confusion, dyspnea, hypotension, and cyanosis. An assessment of the patient's neurologic status includes level of consciousness, response to verbal commands and painful stimuli, pupil size and reaction to light, facial symmetry, movement of extremities, hand grip strength, presence of pedal and popliteal pulses, and temperature and color of extremities. Any indication of a changing status is documented, and abnormal findings are reported to the surgeon because they may signal the beginning of a complication. Hypoperfusion or microemboli may produce central nervous system injury after cardiac surgery.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data and the type of surgical procedure performed, major nursing diagnoses of the patient may include:

- Decreased cardiac output related to blood loss, compromised myocardial function, and dysrhythmias

- Impaired gas exchange related to trauma of extensive chest surgery
- Risk for deficient fluid volume (and electrolyte imbalance) related to alteration in circulating blood volume
- Disturbed sensory perception (visual or auditory) related to excessive environmental stimuli (critical care environment, surgical experience), insufficient sleep, psychological stress, altered sensory integration, and electrolyte imbalances
- Acute pain related to surgical trauma and pleural irritation caused by chest tubes
- Ineffective tissue perfusion (renal, cerebral, cardiopulmonary, gastrointestinal, peripheral) related to decreased cardiac output, hemolysis, vasopressor drug therapy, venous stasis, embolization, underlying atherosclerotic disease, effects of vasopressors, or coagulation problems
- Ineffective thermoregulation related to infection or post-pericardiotomy syndrome
- Deficient knowledge about self-care activities

### COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include:

- Cardiac complications: heart failure, MI, stunned myocardium, dysrhythmias, tamponade, cardiac arrest
- Pulmonary complications: pulmonary edema, pulmonary emboli, pleural effusions, pneumothorax or hemothorax, respiratory failure, acute respiratory distress syndrome
- Hemorrhage
- Neurologic complications: CVA (brain attack, stroke), air emboli
- Renal failure, acute or chronic
- Electrolyte imbalances
- Hepatic failure
- Coagulopathies
- Infection, sepsis

### Planning and Goals

The major goals for the patient include restoration of cardiac output, adequate gas exchange, maintenance of fluid and electrolyte balance, reduction of symptoms of sensory-perception alterations, relief of pain, maintenance of adequate tissue perfusion, maintenance of normal body temperature, learning self-care activities, and absence of complications.

### Nursing Interventions

#### RESTORING CARDIAC OUTPUT

Nursing management of the patient involves continuously observing the patient's cardiac status and notifying the surgeon of any changes that indicate decreased cardiac output. The nurse and the surgeon then work collaboratively to correct the problem.

In evaluating the patient's cardiac status, the nurse primarily determines the effectiveness of cardiac output through clinical observations and routine measurements: serial readings of blood pressure, heart rate, CVP, arterial pressure, and left atrial or pulmonary artery pressure.

Renal function is related to cardiac function, as blood pressure and heart rate drive glomerular filtration; therefore, urinary output is measured and recorded. Urine output of less than 25 mL/hr may indicate a decrease in cardiac output. Urine specific gravity may also be assessed (normal: 1.010 to 1.025), as may urine osmolality. Inadequate fluid volume may be manifested by low urinary out-

put and high specific gravity, whereas overhydration is manifested by high urine output with low specific gravity.

The growth and function of body cells depend on adequate cardiac output to provide a continuous supply of oxygenated blood to meet the changing demands of the organs and body systems. Because the buccal mucosa, nailbeds, lips, and earlobes are sites with rich capillary beds, they should be observed for cyanosis or duskiens as possible signs of reduced heart action. Moist or dry skin may indicate vasodilation or vasoconstriction, respectively. Distention of the neck veins or of the dorsal surface of the hand raised to heart level may signal a changing demand or diminishing capacity of the heart. If cardiac output has fallen, the skin becomes cool, moist, and cyanotic or mottled.

Dysrhythmias, which may arise when poor perfusion of the heart exists, also serve as important indicators of cardiac function. The most common dysrhythmias encountered during the post-operative period are atrial fibrillation, bradycardias, tachycardias, and ectopic beats. Continuous observation of the cardiac monitor for various dysrhythmias is an essential part of patient care and management.

Any indications of decreased cardiac output are reported promptly to the physician. These assessment data and results of diagnostic tests are used by the physician to determine the cause of the problem. After a diagnosis has been made, the physician and the nurse work collaboratively to restore cardiac output and prevent further complications. When indicated, the physician prescribes blood components, fluids, digitalis or other antidysrhythmics, diuretics, vasodilators, or vasopressors. When additional surgery is necessary, the patient and family are prepared for the procedure.

#### PROMOTING ADEQUATE GAS EXCHANGE

To ensure adequate gas exchange, the nurse assesses and maintains the patency of the endotracheal tube. The patient is suctioned when wheezes, coarse crackles, or rhonchi are present. Suctioning may be performed with an in-line suction catheter; the nurse and respiratory therapist determine if the ventilator's fractional inspired oxygen (FiO<sub>2</sub>) should be increased for three or more breaths before the patient is suctioned. Alternatively, 100% oxygen is delivered to the patient by a manual resuscitation bag (eg, Ambu-Bag) before and after suctioning to minimize the risk of hypoxia that can result from the suctioning procedure. Arterial blood gas determinations are compared with baseline data, and changes are reported to the physician promptly.

Because a patent airway is essential for oxygen and carbon dioxide exchange, the endotracheal tube must be secured to prevent it from slipping into the right mainstem bronchus and occluding the left bronchus. When the patient's condition stabilizes, body position is changed every 1 to 2 hours. Frequent changes of patient position provide for optimal pulmonary ventilation and perfusion by allowing the lungs to expand more fully. The nurse assesses breath sounds to detect crackles, wheezes, and fluid in the lungs.

The patient is usually weaned from the ventilator and extubated within 24 hours of CABG. Physical assessment and arterial blood gas results guide the process. Before being extubated, the patient should have cough and gag reflexes and stable vital signs; be able to lift the head off the bed or give firm hand grasps; have adequate vital capacity, negative inspiratory force, and minute volume appropriate for body size; and have acceptable arterial blood gas levels while breathing warmed humidified oxygen without the assistance of the ventilator.

Extubation has been performed within these parameters without any adverse effects on the patient's condition or prognosis.

During this time, the nurse assists with the weaning process and eventually with removal of the endotracheal tube. Deep breathing and forced expiration technique (FET, huffing) or coughing are encouraged at least every 1 to 2 hours after extubation to open the alveolar sacs and provide for increased perfusion. FET is the rapid exhalation of a deep breath using the diaphragm and abdominal muscles to force air out through an open mouth and glottis (the glottis is not held closed then suddenly opened, as in a cough). Patients may experience less pain with FET than coughing, which may increase the frequency with which a patient performs the exercises. The patient should be taught and assisted to splint the chest incision before and during FET or coughing to minimize discomfort.

### MAINTAINING FLUID AND ELECTROLYTE BALANCE

To promote fluid and electrolyte balance, the nurse carefully assesses intake and output. Flow sheets are used to determine positive or negative fluid balance. All fluid intake is recorded, including intravenous, nasogastric tube, and oral fluids. All output is recorded, including urine, nasogastric drainage, and chest drainage.

Hemodynamic parameters (ie, blood pressure, pulmonary wedge and left atrial pressures, and CVP) are correlated with intake, output, and weight to determine the adequacy of hydration and cardiac output. Serum electrolytes are monitored, and the patient is observed for signs of potassium, magnesium, sodium, or calcium imbalance (ie, hypokalemia, hyperkalemia, hypomagnesemia, hyponatremia, or hypocalcemia).

Any indications of dehydration, fluid overload, or electrolyte imbalance are reported promptly, and the physician and nurse work collaboratively to restore fluid and electrolyte balance. The patient's response is monitored.

### MINIMIZING SENSORY-PERCEPTION IMBALANCE

A large number of patients experience abnormal behaviors that occur with varying intensity and duration. In the early years of cardiac surgery, this phenomenon occurred more frequently than it does today. At that time, it was attributed to inadequate cerebral perfusion during surgery, microemboli, and the length of time that the patient remained on the CPB machine. Advances in surgical techniques have significantly decreased these factors. Today, when it occurs, it is thought to be caused by anxiety, sleep deprivation, increased sensory input, and disorientation to night and day when the patient loses track of time (Arrowsmith et al., 1999; Braunwald et al., 2001; Fuster et al., 2001). An important finding is that patients who do not or cannot express anxiety before surgery and those who are not able to sleep postoperatively are more prone to develop psychosis in the postoperative period. Psychosis may appear after a 2- to 5-day lucid interval.

Basic comfort measures used in conjunction with prescribed analgesics potentiate the effects of the analgesics and promote rest. The patient is assisted in changing positions every 1 to 2 hours and is positioned in such a way to avoid strain on incisions and chest tubes. Nursing care is scheduled as much as possible to provide undisturbed periods of rest. As the patient's condition stabilizes and the patient is disturbed less frequently for monitoring and therapeutic procedures, rest periods can be extended. As much uninterrupted sleep as possible is provided, especially during the patient's normal hours of sleep.

The nurse monitors the patient for signs of denial and provides an opportunity for emotional expression during the preoperative period. Careful explanations of all procedures and of the need for cooperation help to keep the patient oriented throughout the postoperative course. Continuity of care is desirable; a familiar face

and a nursing staff with a consistent approach promote the delivery of quality nursing care. A well-designed and individualized plan of nursing care can assist the nursing team in coordinating their efforts for the emotional well-being of the patient.

### RELIEVING PAIN

Deep pain may not be reflected in the immediate area of injury but occur in a broader, more diffuse area. Patients who have had cardiac surgery experience pain caused by the interruption of intercostal nerves along the incision route and irritation of the pleura by the chest catheters. Incisional pain may also be experienced from peripheral vein or artery graft harvest sites.

It is essential to observe and listen to the patient for verbal and nonverbal clues about pain. The nurse accurately records the nature, type, location, and duration of the pain. (Chest incisional pain must be differentiated from anginal pain.) The patient is encouraged to use patient-controlled analgesia or accept medication as often as it is prescribed to reduce the amount of pain. Physical support of the incision during deep breathing and FET (or coughing) also helps to minimize pain. The patient should then be able to participate in respiratory exercises and to increase self-care progressively.

Pain produces tension, which may stimulate the central nervous system to release adrenaline, which results in constriction of the arterioles and increased heart rate. This can cause increased afterload and decreased cardiac output. Opioids alleviate anxiety and pain and induce sleep, which reduces the metabolic rate and oxygen demands. After the administration of opioids, any observations indicating relief of apprehension and pain are documented in the patient's record. The patient is observed for any respiratory depressant effects of the analgesic. If respiratory depression occurs, an opioid antagonist (eg, naloxone [Narcan]) is used to counteract the effect.

### MAINTAINING ADEQUATE TISSUE PERFUSION

Peripheral pulses (eg, pedal, tibial, popliteal, femoral, radial, brachial) are routinely palpated to assess for arterial obstruction. If a pulse is absent in any extremity, the cause may be prior catheterization of that extremity. The newly identified absence of any pulse is immediately reported to the physician.

Thrombus formation and resulting embolus formation also can result from injury to the intima of the blood vessels, dislodging a clot from a damaged valve, loosening of mural thrombi, and coagulation problems. Air embolism may occur as a result of CPB or central venous cannulation. Symptoms of embolization vary according to site. The usual embolic sites are the lungs, coronary arteries, mesentery, spleen, extremities, kidneys, and brain. The patient is observed for:

- Chest pain and respiratory distress with pulmonary embolus or MI
- Midabdominal or midback pain
- Pain, cessation of pulses, blanching, numbness, or coldness in an extremity
- Decreased urine output
- One-sided weakness and pupillary changes, as occur in CVAs (brain attacks, strokes)

All such symptoms are promptly reported to the physician.

After surgery, the following measures are taken to prevent venous stasis, which can cause thrombus formation and subsequent embolization:

- Applying elastic compression stockings or elastic bandage wrap and pneumatic antiembolic stockings

- Discouraging crossing of legs
- Avoiding use of the knee gatch on the bed
- Omitting pillows in the popliteal space
- Instituting passive exercises followed by active exercises to promote circulation and prevent loss of muscle tone (patients need to ambulate as early as possible)

Inadequate renal perfusion can occur as a complication of cardiac surgery. One possible cause is low cardiac output. Trauma to blood cells during CPB can cause hemolysis of red blood cells, which then occlude the renal glomeruli. Use of vasopressor agents to increase blood pressure may constrict the renal arterioles and reduce blood flow to the kidneys.

Nursing management includes accurate measurement of urine output. An output of less than 25 mL/hr may indicate hypovolemia. Urine specific gravity can be monitored to determine the kidneys' ability to concentrate urine in the renal tubules. Rapid-acting diuretics or inotropic medications (eg, digoxin [Lanoxin], isoproterenol [Isuprel]) may be prescribed to increase cardiac output and renal blood flow. The nurse should be aware of the patient's blood urea nitrogen, serum creatinine, and urine and serum electrolyte levels. Abnormal levels are reported promptly because it may be necessary to adjust fluids and the dose or type of medication administered. If efforts to maintain renal perfusion are not effective, the patient may require dialysis or continuous renal replacement therapy (see Chap. 44).

### MAINTAINING NORMAL BODY TEMPERATURE

Patients are usually hypothermic when admitted to the critical care unit from the cardiac surgical procedure. The patient must be gradually warmed to a normal temperature. This is accomplished partially by the patient's own basal metabolic processes and often with the assistance of warmed ventilator air, warm air or warm cotton blankets, or heat lamps. While the patient is hypothermic, the clotting process is less efficient, the heart is prone to dysrhythmias, and oxygen does not readily transfer from the hemoglobin to the tissues. Because anesthesia and hypothermia suppress the basal metabolism, oxygen supply usually meets the cellular demand.

After cardiac surgery, the patient is at risk for developing elevated body temperature caused by infection or postpericardiotomy syndrome. The resultant increase in metabolic rate increases tissue oxygen demands and increases cardiac workload. Measures are taken to prevent this sequence of events or to halt it as soon as it is recognized.

Sites of infection include the lungs, urinary tract, incisions, and intravascular catheters. Meticulous care is used to prevent contamination at the sites of catheter and tube insertions. Aseptic technique is used when changing dressings and when providing endotracheal tube and catheter care. Clearance of pulmonary secretions is accomplished by frequent repositioning of the patient, suctioning, and chest physical therapy, as well as teaching and encouraging the patient to breathe deeply and use FET (or cough). Closed systems are used to maintain all intravenous and arterial lines. All invasive equipment is discontinued as soon as possible after surgery.

Postpericardiotomy syndrome occurs in approximately 10% to 40% of patients who undergo cardiac surgery. Although the precise cause is unknown, a common factor appears to be trauma, with residual blood in the pericardial sac after surgery. The syndrome is characterized by fever, pericardial pain, pleural pain, dyspnea, pericardial effusion, pericardial friction rub, and arthralgia. There may be a combination of these signs and symptoms.

Leukocytosis occurs, along with elevation of the erythrocyte sedimentation rate. These symptoms frequently appear after the patient is discharged from the hospital.

The syndrome must be differentiated from other postoperative complications (eg, infection, incisional pain, MI, pulmonary embolus, bacterial endocarditis, pneumonia, atelectasis). Treatment depends on the severity of the symptoms. Bed rest and anti-inflammatory agents, such as salicylates and corticosteroids, produce a dramatic improvement in symptoms.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

Depending on the type of surgery and postoperative progress, the patient may be discharged from the hospital as early as 1 day after MIDCAB and 3 days after other surgery. Although the patient may be anxious to return home, the patient and family usually have apprehensions about this transition. The family members often express the fear that they are not capable of caring for the patient at home. They often are concerned that complications will occur that they are unprepared to handle.

The nurse helps the patient and family to set realistic, achievable goals. A teaching plan that meets the patient's individual needs is developed with the patient and family. This is done before admission and reviewed each shift through the hospitalization or with each home care and rehabilitation contact. Specific instructions are provided about incision care; signs and symptoms of infection; diet; activity progression and exercise; deep breathing, FET (or coughing), incentive spirometry; and smoking cessation; weight and temperature monitoring; the medication regimen; and follow-up visits with home care nurses, the rehabilitation personnel, the surgeon, and the cardiologist or internist.

Some patients may have difficulty learning and retaining information after cardiac surgery. Studies have documented that many patients have difficulties in cognitive function after cardiac surgery that do not occur after other types of major surgery (Arrowsmith et al., 1999; Roach et al., 1996). The patient may experience recent memory loss, short attention span, difficulty with simple math, poor handwriting, and visual disturbances. Patients with these difficulties often become frustrated when they try to resume normal activities and learn how to care for themselves at home. The patient and family are reassured that the difficulty is temporary and will subside, usually in 6 to 8 weeks. In the meantime, instructions are given to the patient at a much slower pace than normal, and a family member assumes responsibility for making sure that the prescribed regimen is followed. All information is provided in writing in the patient's primary language.

### Continuing Care

Arrangements are made for a home care nurse to provide care when appropriate. Since the length of time that the patient remains in the hospital is relatively short, it is particularly important for the nurse to assess the patient's and family's ability to manage care in the home. The education plan is continued by the home care nurse. Vital signs and incisions are monitored, the patient is assessed for signs and symptoms of complications, and support for the patient and family is provided. Additional interventions may include dressing changes, intravenous antibiotic administration, diet counseling, and tobacco use cessation strategies. Patients and families need to know that cardiac surgery did not cure the patient's underlying heart disease. Lifestyle changes for risk factor reduction must be made, and medications taken preoperatively may be prescribed postoperatively.

## NURSING RESEARCH PROFILE 28-1

### Cardiac Surgery Patients' Transition From Hospital To Home

Weaver, L. A., & Doran, K. A. (2001). Telephone follow-up after cardiac surgery. *American Journal of Nursing*, 101(5), 2400–2404.

#### Purpose

Hospital length of stay (LOS) for patients after cardiac surgery may be 3 or 4 days. Formal patient/family education programs describing how to care for the patient at home are often provided during the hospitalization. These researchers identified that no health care professionals were contacting or seeing patients for 2 to 4 weeks after discharge from the hospital. The researchers implemented a telephone follow-up program. The purpose of the study was to evaluate the telephone follow-up program for patients who had undergone cardiac surgery.

#### Study Sample and Design

A convenience sample of heart surgery patients was selected, 46 of whom received usual care (control patients) and 44 of whom received usual care and postdischarge follow-up telephone calls (intervention patients). Patients in the intervention group were called by a cardiovascular step-down unit registered nurse within 2 days after discharge, and then once a week for 1 month. At the end of this period, each participant was mailed a questionnaire to measure patient satisfaction, depression, recidivism, and complications. Patient satisfaction was measured with a modified four-question survey, the Continuity and Transition Dimensions, Picker Institute Survey. Depression was measured with a modified 15-question survey, the Geriatric Depression Scale. Recidivism was measured by the number of emergency department visits and hospital admissions during the 30 days after discharge from the hospital for cardiac surgery. Complications were self-reported by the participants.

#### Findings

Patient satisfaction in the intervention group was at least 10% higher than in the control group for three of four variables, but the

results were not statistically significant. Twenty-two percent of the control group and 18% of the intervention group were readmitted or made emergency department visits during the first 30 days after discharge (recidivism); this difference in incidence was not statistically significant. There were no differences in the rate of depression or complications between the groups. The nurses who conducted the follow-up telephone program reported that they provided reassurance and support in each phone call. They provided reinforcement and clarification of postoperative education regarding leg swelling (31%), pain medication (23%), weight-taking and knowing when to call a health care provider (16%), and medication teaching (100%). The nurses also made referrals (to physicians, cardiac rehabilitation programs, dietitians, tobacco intervention programs [7%]) and coached patients with questions they wanted to ask their physicians (12%).

#### Nursing Implications

Telephone calls by step-down unit registered nurses to cardiac surgery patients after hospital discharge increase patient satisfaction (although not to statistical significance) and provide opportunities for reassurance and patient education. Development and use of scripts (algorithms, decision tree standards) may be helpful to the nurse making the telephone calls and facilitate consistency in the information provided to the patient. Script topics suggested by this study include incision care, leg swelling, fever, weight measurements and when to call a health care provider, pain management, medications (especially warfarin [Coumadin]), dysrhythmias, fluid status, constipation, nutrition, sleep, and depression.

Patient teaching does not end at the time of discharge from home health. The patient is encouraged to maintain telephone contact with the surgeon, cardiologist, and nurses. This provides the patient and family with reassurance that questions can be answered and problems can be resolved if they arise. Many hospitals provide family support sessions that help family members cope with their own stress related to the patient's home health care management. The patient is expected to have a follow-up visit with the surgeon.

Many patients and families benefit from supportive programs such as the postcardiac surgery rehabilitation programs offered by many medical centers. These programs provide exercise monitoring; instructions about diet and stress reduction; information about resuming exercise, work, driving, and sexual activity; assistance with tobacco use cessation; and support groups for patients and families. The American Heart Association sponsors the Mended Hearts Club, which provides information as well as an opportunity for families to share experiences.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Maintains adequate cardiac output
2. Maintains adequate gas exchange
3. Maintains fluid (and electrolyte) balance
4. Experiences decreased symptoms of sensory-perception disturbances

5. Experiences relief of pain
6. Maintains adequate tissue perfusion
7. Maintains normal body temperature
8. Performs self-care activities

A typical plan of postoperative nursing care and more-detailed expected outcomes for the cardiac surgery patient are presented in the Plan of Nursing Care, on pages 740–745.

## Critical Thinking Exercises

1. You are caring for a patient who has undergone a PTCA with stent placement. The patient suddenly develops chest discomfort. In addition to the characteristics of the chest discomfort, identify the key factors that need to be assessed. Describe the actions that you would take and state why.
2. You are caring for a patient who is scheduled to have MIDCAB surgery. He appears quite anxious and states that he is afraid he will need to have traditional CABG surgery as discussed in obtaining informed consent. He states he does not want to have his "whole sternum cut open." His wife tends to minimize the significance of his concerns, commenting that, as the surgeon explained it, the possibility of having a traditional CABG is very small. How would you respond to

this patient and his wife? How might your response differ if the wife shares her husband's concerns?

**3.** You are caring for a patient who underwent traditional CABG surgery 2 days ago and is progressing well. After ambulating in the corridor with his daughter, he returns to his room and notices that the dressing on his saphenous vein site is stained with bright red blood. His daughter is visibly upset. Explain what your first action will be and why. If your initial actions do not achieve the desired outcome, how would you proceed? How would you explain the episode to the daughter to help her understand the bleeding?

**4.** You are caring for two patients, both of whom were hospitalized for acute MI. One patient lives in his home with a supportive family, the other patient is homeless and living on the street. How does your plan of care and patient teaching differ for these patients?

# ● Management of Patients With Structural, Infectious, and Inflammatory Cardiac Disorders

## **LEARNING OBJECTIVES** ●

*On completion of this chapter, the learner will be able to:*

1. Define valvular disorders of the heart and describe the pathophysiology, clinical manifestations, and management of patients with mitral and aortic disorders.
2. Describe types of cardiac valve repair and replacement procedures used to treat valvular problems and the care needed by patients who undergo these procedures.
3. Describe the pathophysiology, clinical manifestations, and management of patients with cardiomyopathies.
4. Describe the pathophysiology, clinical manifestations, and management of patients with infections of the heart.
5. Describe the rationale for prophylactic antibiotic therapy for patients with mitral valve prolapse, valvular heart disease, rheumatic endocarditis, infective endocarditis, and myocarditis.

Structural disorders of the heart present many challenges for the patient, family, and health care team, as do the conduction and vascular disorders discussed in Chapters 27 and 28. Problems with the heart valves, holes in the intracardiac septum, cardiomyopathies, and infectious diseases of the heart muscle alter cardiac output. Treatments for these diagnoses may be noninvasive, such as medication therapy and activity and dietary modification. Invasive treatments, such as valve repair or replacement, septal repair, ventricular assist devices, total artificial hearts, cardiac transplantation, and other procedures may also be used. Nurses have an integral role in the care of patients with structural, infectious, and inflammatory cardiac conditions.

## Acquired Valvular Disorders

The valves of the heart control the flow of blood through the heart into the pulmonary artery and aorta by opening and closing in response to the blood pressure changes as the heart contracts and relaxes through the cardiac cycle.

The atrioventricular valves separate the atria from the ventricles and include the **tricuspid valve**, which separates the right atrium from the right ventricle, and the **mitral valve**, which separates the left atrium from the left ventricle. The tricuspid valve has three leaflets; the mitral valve has two. Both valves have chordae tendineae that anchor the valve leaflets to the papillary muscles and ventricular wall.

The semilunar valves are located between the ventricles and their corresponding arteries. The **pulmonic valve** lies between the right ventricle and the pulmonary artery; the **aortic valve** lies between the left ventricle and the aorta. Figure 29-1 shows valves in the closed position.

When any of the heart valves do not close or open properly, blood flow is affected. When valves do not close completely, blood flows backward through the valve in a process called **regurgitation**. When valves do not open completely, a condition called **stenosis**, the flow of blood through the valve is reduced.

Disorders of the mitral valve fall into the following categories: mitral valve **prolapse** (ie, stretching of the valve leaflet into the

atrium during systole), mitral regurgitation, and mitral stenosis. Disorders of the aortic valve are categorized as aortic regurgitation and aortic stenosis. These valvular disorders lead to various symptoms that, depending on their severity, may require surgical repair or replacement of the valve to correct the problem (Fig. 29-2). Tricuspid and pulmonic valve disorders also occur, usually with fewer symptoms and complications. Regurgitation and stenosis may occur at the same time in the same or different valves.

## MITRAL VALVE PROLAPSE

Mitral valve prolapse, formerly known as mitral prolapse syndrome, is a deformity that usually produces no symptoms. Rarely, it progresses and can result in sudden death. Mitral valve prolapse occurs more frequently in women than in men. In recent years, this disorder has been diagnosed more frequently, probably as a result of improved diagnostic methods.

## Pathophysiology

In mitral valve prolapse, a portion of a mitral valve leaflet balloons back into the atrium during systole. Rarely, the ballooning stretches the leaflet to the point that the valve does not remain closed during systole (ie, ventricular contraction). Blood then regurgitates from the left ventricle back into the left atrium (Braunwald et al., 2001).

## Clinical Manifestations

Many people have a ballooned leaflet but no symptoms. Others have symptoms of fatigue, shortness of breath, light-headedness, dizziness, syncope, palpitations, chest pain, and anxiety (Braunwald et al., 2001; Freed et al., 1999; Fuster et al., 2001).

Fatigue may occur regardless of the person's activity level and amount of rest or sleep. Shortness of breath is not correlated with activity levels or pulmonary function. Atrial or ventricular dysrhythmias may produce the sensation of palpitations, but palpi-

## Glossary

**allograft:** heart valve replacement made from a human heart valve (synonym: homograft)

**annuloplasty:** repair of a cardiac valve's outer ring

**aortic valve:** semilunar valve located between the left ventricle and the aorta

**autograft:** heart valve replacement made from the patient's own heart valve (ie, the pulmonic valve is excised and used as an aortic valve)

**cardiomyopathy:** disease of the heart muscle

**chordoplasty:** repair of the stringy, tendinous fibers that connect the free edges of the atrioventricular valve leaflets to the papillary muscles

**commissurotomy:** splitting or separating fused cardiac valve leaflets

**heterograft:** heart valve replacement made of tissue from an animal heart valve (synonym: xenograft)

**heterotopic transplantation:** procedure in which the recipient's heart remains in place and a donor heart is grafted to the right and anterior of it; the patient has two hearts

**homograft:** heart valve replacement made from a human heart valve (synonym: allograft)

**leaflet repair:** repair of a cardiac valve's movable "flaps" (leaflets)

**mitral valve:** atrioventricular valve located between the left atrium and left ventricle

**orthotopic transplantation:** the recipient's heart is removed, and a donor heart is grafted into the same site; the patient has one heart

**prolapse (of a valve):** stretching of an atrioventricular heart valve leaflet into the atrium during systole

**pulmonic valve:** semilunar valve located between the right ventricle and the pulmonary artery

**regurgitation:** backward flow of blood through a heart valve

**stenosis:** narrowing or obstruction of a cardiac valve's orifice

**total artificial heart:** mechanical device used to aid a failing heart, assisting the right and left ventricles

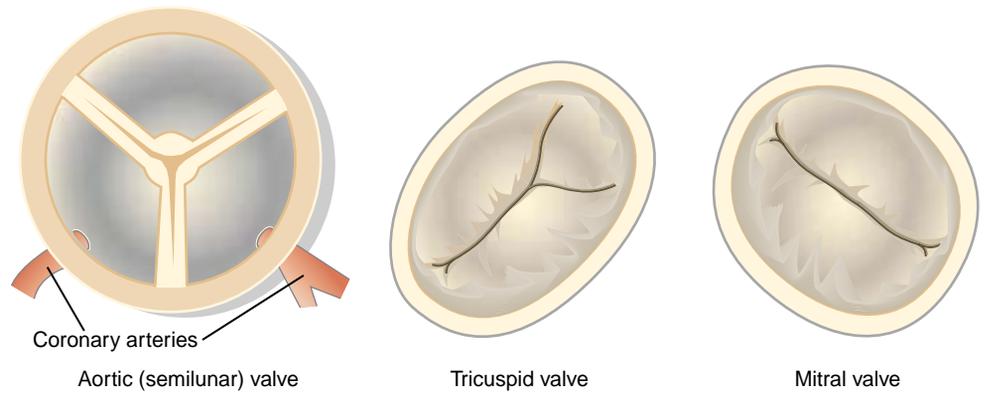

**tricuspid valve:** atrioventricular valve located between the right atrium and right ventricle

**valve replacement:** insertion of a device at the site of a malfunctioning heart valve to restore blood flow in one direction through the heart

**valvuloplasty:** repair of a stenosed or regurgitant cardiac valve by commissurotomy, annuloplasty, leaflet repair, or chordoplasty (or a combination of procedures)

**ventricular assist device:** mechanical device used to aid a failing right or left ventricle

**xenograft:** heart valve replacement made of tissue from an animal heart valve (synonym: heterograft)

**FIGURE 29-1** The valves of the heart (aortic or semilunar, tricuspid, and mitral) in closed position.

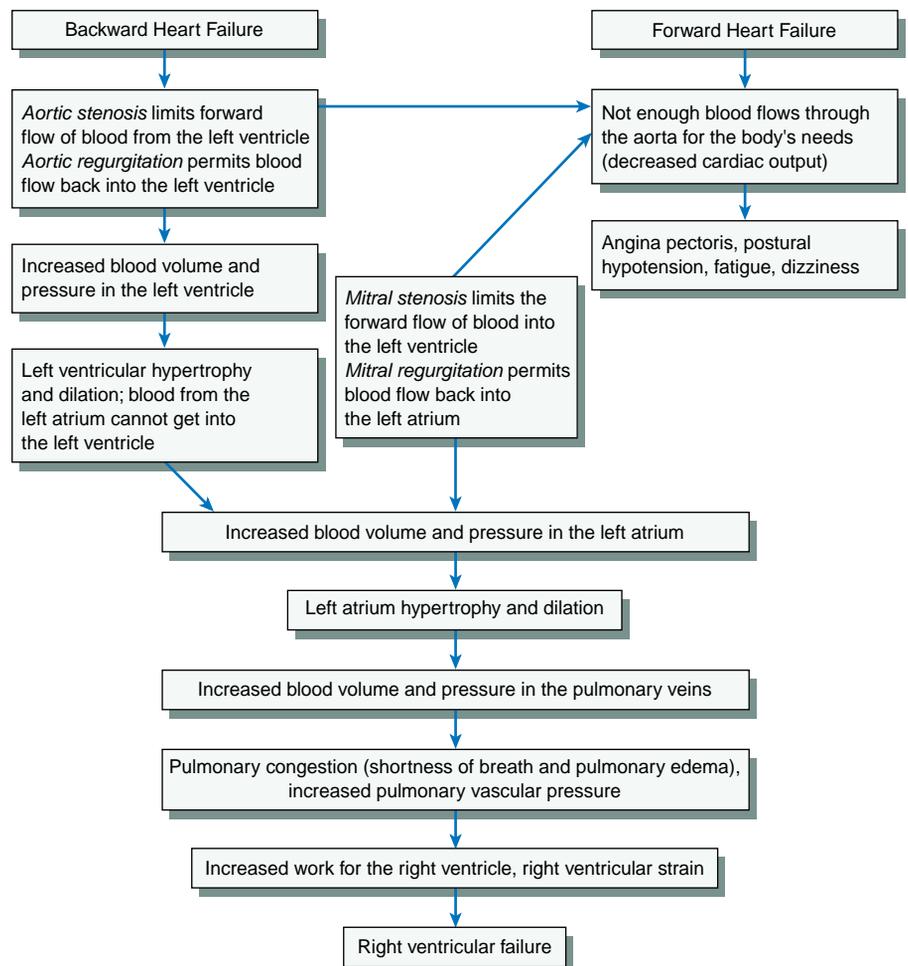

tations have been reported while the heart has been beating normally. Another puzzling symptom is chest pain, which is often localized to the chest and may last for days.

Anxiety may be a response to the symptoms experienced by the patient; however, some patients report anxiety as the only

symptom. Some clinicians speculate that the symptoms may be explained by dysautonomia, a dysfunction of the autonomic nervous system, although no consensus exists about the cause of the symptoms experienced by some patients with mitral valve prolapse.

### Physiology/Pathophysiology

**FIGURE 29-2** Pathophysiology: Left heart failure as a result of aortic and mitral valvular heart disease and the development of right ventricular failure.

## Assessment and Diagnostic Findings

Often, the first and only sign of mitral valve prolapse is identified when a physical examination of the heart discloses an extra heart sound, referred to as a mitral click. The systolic click is an early sign that a valve leaflet is ballooning into the left atrium. In addition to the mitral click, a murmur of mitral regurgitation may be heard if progressive valve leaflet stretching and regurgitation have occurred. A small number of patients experience signs and symptoms of heart failure if mitral regurgitation exists.

## Medical Management

Medical management is directed at controlling symptoms. If dysrhythmias are documented and cause symptoms, the patient is advised to eliminate caffeine and alcohol from the diet and to stop smoking; antiarrhythmic medications may be prescribed.

Chest pain that does not respond to nitrates may respond to calcium channel blockers or beta-blockers. Heart failure is treated the same as it would be for any other patient with heart failure (see Chap. 30). In advanced stages of disease, mitral valve repair or replacement may be necessary.

## Nursing Management

The nurse educates patients about the diagnosis and the possibility that the condition is hereditary. Because most patients with mitral valve prolapse are asymptomatic, the nurse explains the need to inform the health care provider about any symptoms that may develop. The nurse also instructs patients about the need for prophylactic antibiotic therapy before undergoing invasive procedures (eg, dental work, genitourinary or gastrointestinal procedures) that may introduce infectious agents systemically. This therapy is prescribed for symptomatic patients and for asymptomatic patients who have both a systolic click and murmur or mitral regurgitation. If in doubt about risk factors and the need for antibiotics, patients should consult their physicians.

To minimize symptoms, the nurse teaches patients to avoid caffeine and alcohol. The nurse encourages patients to read product labels, particularly in over-the-counter products such as cough medicine, because these products may contain alcohol, caffeine, ephedrine, and epinephrine, which may produce dysrhythmias and other symptoms. Dysrhythmias, chest pain, heart failure, or other complications of mitral valve prolapse are treated as described in Chapter 30. The nurse also explores with patients possible diet, activity, sleep, and other lifestyle factors that may correlate with symptoms experienced.

## MITRAL REGURGITATION

Mitral regurgitation involves blood flowing back from the left ventricle into the left atrium during systole. Often, the margins of the mitral valve cannot close during systole.

## Pathophysiology

Mitral regurgitation may be caused by problems with one or more of the leaflets, the chordae tendineae, the annulus, or the papillary muscles. A mitral valve leaflet may shorten or tear. The chordae tendineae may elongate, shorten, or tear. The annulus may be stretched by heart enlargement or deformed by calcification. The papillary muscle may rupture, stretch, or be pulled out of position by changes in the ventricular wall (eg, scar from a

### NURSING RESEARCH PROFILE 29-1

#### Mitral Valve Prolapse Support Group

Scordo, K. A. B. (2001). Factors associated with participating in a mitral valve prolapse support group. *Heart Lung, 30*(2), 128–137.

#### Purpose

The purpose of this study was to identify factors that influence a patient's attendance at mitral valve prolapse support groups.

#### Study Sample and Design

Questionnaires were used for this descriptive study of mitral valve support group leaders, current and former support group participants, and nonparticipants, all of whom had a diagnosis of mitral valve prolapse. A total of 376 questionnaires were analyzed.

#### Findings

People with mitral valve prolapse were more likely to participate in support groups if they were older than 50 years of age and participated in other self-help groups. The reason for attending was to obtain more information about mitral valve prolapse, information not usually available from family, friends, and physicians. No relationship was found between participation in a support group and patient gender, education level, marital status, age when first diagnosed, age when symptoms were first experienced, perceived social support, any symptoms experienced, or travel time or distance required to participate in the support group.

#### Nursing Implications

Nurses need to be aware that patients with mitral valve prolapse desire information about the condition, and not just at the time of diagnosis or development of symptoms. Nurses can provide education and facilitate support groups. Patients older than 50 years of age and those who participate in other self-help groups may be particularly interested in mitral valve prolapse support groups.

myocardial infarction or ventricular dilation). The papillary muscle may be unable to contract because of ischemia. Regardless of the cause, blood regurgitates back into the atrium during systole.

With each beat of the left ventricle, some of the blood is forced back into the left atrium. Because this blood is added to the blood that is beginning to flow in from the lungs, the left atrium must stretch. It eventually hypertrophies and dilates. The backward flow of blood from the ventricle diminishes the volume of blood flowing into the atrium from the lungs. As a result, the lungs become congested, eventually adding extra strain on the right ventricle. Mitral regurgitation ultimately involves the lungs and the right ventricle.

## Clinical Manifestations

Chronic mitral regurgitation is often asymptomatic, but acute mitral regurgitation (eg, that resulting from a myocardial infarction) usually manifests as severe congestive heart failure. Dyspnea, fatigue, and weakness are the most common symptoms. Palpitations, shortness of breath on exertion, and cough from pulmonary congestion also occur.

## Assessment and Diagnostic Findings

A systolic murmur is heard as a high-pitched, blowing sound at the apex. The pulse may be regular and of good volume, or it may be irregular as a result of extrasystolic beats or atrial fibrillation.

Echocardiography is used to diagnose and monitor the progression of mitral regurgitation.

### Medical Management

Management of mitral regurgitation is the same as that for congestive heart failure. Surgical intervention consists of mitral valve replacement or valvuloplasty (ie, surgical repair of the heart valve).

### MITRAL STENOSIS

Mitral stenosis is an obstruction of blood flowing from the left atrium into the left ventricle. It is most often caused by rheumatic endocarditis, which progressively thickens the mitral valve leaflets and chordae tendineae. The leaflets often fuse together. Eventually, the mitral valve orifice narrows and progressively obstructs blood flow into the ventricle.

### Pathophysiology

Normally, the mitral valve opening is as wide as the diameter of three fingers. In cases of marked stenosis, the opening narrows to the width of a pencil. The left atrium has great difficulty moving blood into the ventricle because of the increased resistance of the narrowed orifice; it dilates (stretches) and hypertrophies (thickens) because of the increased blood volume it holds. Because there is no valve to protect the pulmonary veins from the backward flow of blood from the atrium, the pulmonary circulation becomes congested. As a result, the right ventricle must contract against an abnormally high pulmonary arterial pressure and is subjected to excessive strain. Eventually, the right ventricle fails.

### Clinical Manifestations

The first symptom of mitral stenosis is often breathing difficulty (ie, dyspnea) on exertion as a result of pulmonary venous hypertension. Patients with mitral stenosis are likely to show progressive fatigue as a result of low cardiac output. They may expectorate blood (ie, hemoptysis), cough, and experience repeated respiratory infections.

### Assessment and Diagnostic Findings

The pulse is weak and often irregular because of atrial fibrillation (caused by the strain on the atrium). A low-pitched, rumbling, diastolic murmur is heard at the apex. As a result of the increased blood volume and pressure, the atrium dilates, hypertrophies, and becomes electrically unstable, and the patient experiences atrial dysrhythmias. Echocardiography is used to diagnose mitral stenosis. Electrocardiography (ECG) and cardiac catheterization with angiography are used to determine the severity of the mitral stenosis.

### Medical Management

Antibiotic prophylaxis therapy is instituted to prevent recurrence of infections. Congestive heart failure is treated as described in Chapter 30. Patients with mitral stenosis may benefit from anticoagulants to decrease the risk for developing atrial thrombus. They may also require treatment for anemia.

Surgical intervention consists of valvuloplasty, usually a commissurotomy to open or rupture the fused commissures of the mitral valve. Percutaneous transluminal valvuloplasty or mitral valve replacement may be performed.

### AORTIC REGURGITATION

Aortic regurgitation is the flow of blood back into the left ventricle from the aorta during diastole. It may be caused by inflammatory lesions that deform the leaflets of the aortic valve, preventing them from completely closing the aortic valve orifice. This valvular defect also may result from endocarditis, congenital abnormalities, diseases such as syphilis, a dissecting aneurysm that causes dilation or tearing of the ascending aorta, or deterioration of an aortic valve replacement.

### Pathophysiology

In aortic regurgitation, blood from the aorta returns to the left ventricle during diastole in addition to the blood normally delivered by the left atrium. The left ventricle dilates, trying to accommodate the increased volume of blood. It also hypertrophies, trying to increase muscle strength to expel more blood with above-normal force—raising systolic blood pressure. The arteries attempt to compensate for the higher pressures by reflex vasodilation; the peripheral arterioles relax, reducing peripheral resistance and diastolic blood pressure.

### Clinical Manifestations

Aortic insufficiency develops without symptoms in most patients. Some patients are aware of a forceful heartbeat, especially in the head or neck. There may be marked arterial pulsations that are visible or palpable at the carotid or temporal arteries. This is a result of the increased force and volume of the blood ejected from the hypertrophied left ventricle. Exertional dyspnea and fatigue follow. Progressive signs and symptoms of left ventricular failure include breathing difficulties (eg, orthopnea, paroxysmal nocturnal dyspnea), especially at night.

### Assessment and Diagnostic Findings

A diastolic murmur is heard as a high-pitched, blowing sound at the third or fourth intercostal space at the left sternal border. The pulse pressure (ie, difference between systolic and diastolic pressures) is considerably widened in patients with aortic regurgitation. One characteristic sign of the disease is the water-hammer pulse, in which the pulse strikes the palpating finger with a quick, sharp stroke and then suddenly collapses. Diagnosis may be confirmed by echocardiogram, radionuclide imaging, ECG, magnetic resonance imaging, and cardiac catheterization.

### Medical Management

Before the patient undergoes invasive or dental procedures, antibiotic prophylaxis is needed to prevent endocarditis. Heart failure and dysrhythmias are treated as described in Chapters 27 and 30. Aortic valvuloplasty or valve replacement is the treatment of choice, preferably performed before left ventricular failure. Surgery is recommended for any patient with left ventricular hypertrophy, regardless of the presence or absence of symptoms.

### AORTIC STENOSIS

Aortic valve stenosis is narrowing of the orifice between the left ventricle and the aorta. In adults, the stenosis may involve congenital leaflet malformations or an abnormal number of leaflets (ie, one or two rather than three), or it may result from rheumatic

endocarditis or cusp calcification of unknown cause. The leaflets of the aortic valve may fuse.

## Pathophysiology

There is progressive narrowing of the valve orifice, usually over a period of several years to several decades. The left ventricle overcomes the obstruction to circulation by contracting more slowly but with greater energy than normal, forcibly squeezing the blood through the very small orifice. The obstruction to left ventricular outflow increases pressure on the left ventricle, which results in thickening of the muscle wall. The heart muscle hypertrophies. When these compensatory mechanisms of the heart begin to fail, clinical signs and symptoms develop.

## Clinical Manifestations

Many patients with aortic stenosis are asymptomatic. After symptoms develop, patients usually first have exertional dyspnea, caused by left ventricular failure. Other signs are dizziness and syncope because of reduced blood flow to the brain. Angina pectoris is a frequent symptom that results from the increased oxygen demands of the hypertrophied left ventricle, the decreased time in diastole for myocardial perfusion, and the decreased blood flow into the coronary arteries. Blood pressure can be low but is usually normal; there may be a low pulse pressure (30 mm Hg or less) because of diminished blood flow.

## Assessment and Diagnostic Findings

On physical examination, a loud, rough systolic murmur may be heard over the aortic area. The sound to listen for is a systolic crescendo-decrescendo murmur, which may radiate into the carotid arteries and to the apex of the left ventricle. The murmur is low-pitched, rough, rasping, and vibrating. If the examiner rests a hand over the base of the heart, a vibration may be felt. The vibration is caused by turbulent blood flow across the narrowed valve orifice. Evidence of left ventricular hypertrophy may be seen on a 12-lead ECG and echocardiogram.

Echocardiography is used to diagnose and monitor the progression of aortic stenosis. After the stenosis progresses to the point that surgical intervention is considered, left-sided heart catheterization is necessary to measure the severity of the valvular abnormality and evaluate the coronary arteries. Pressure tracings are taken from the left ventricle and the base of the aorta. The systolic pressure in the left ventricle is considerably higher than that in the aorta during systole.

## Medical Management

Antibiotic prophylaxis to prevent endocarditis is essential for anyone with aortic stenosis. After left ventricular failure or dysrhythmias occur, medications are prescribed. Definitive treatment for aortic stenosis is surgical replacement of the aortic valve. Patients who are symptomatic and are not surgical candidates may benefit from one- or two-balloon percutaneous valvuloplasty procedures.

## VALVULAR HEART DISORDERS: NURSING MANAGEMENT

The nurse teaches all patients with valvular heart disease about the diagnosis, the progressive nature of valvular heart disease, and the treatment plan. The patient is taught to report any new symp-

toms or changes in symptoms to the health care provider. The nurse emphasizes the need for prophylactic antibiotic therapy before any invasive procedure (eg, dental work, genitourinary or gastrointestinal procedure) that may introduce infectious agents to the patient's bloodstream. The patient is taught that the infectious agent, usually a bacterium, is able to adhere to the diseased heart valve more readily than to a normal valve. Once attached to the valve, the infectious agent multiplies, resulting in endocarditis and further damage to the valve.

The patient's heart rate, blood pressure, and respiratory rate are measured and compared with previous data for any changes. Heart and lung sounds are auscultated and peripheral pulses palpated. The nurse assesses patients with valvular heart disease for signs and symptoms of heart failure: fatigue, dyspnea with exertion, an increase in coughing, hemoptysis, multiple respiratory infections, orthopnea, or paroxysmal nocturnal dyspnea (see Chap. 30). The nurse assesses for dysrhythmias by palpating the patient's pulse for strength and rhythm (ie, regular or irregular) and asks if the patient has experienced palpitations or felt forceful heartbeats (see Chap. 27). The nurse also assesses for dizziness, syncope, increased weakness, or angina pectoris (see Chap. 28).

The nurse collaborates with the patient to develop a medication schedule and teaches about the name, dosage, actions, side effects, and any drug-drug or drug-food interactions of the prescribed medications for heart failure, dysrhythmias, angina pectoris, or other symptoms. The nurse teaches the patient to weigh daily and report the gain of 2 pounds in 1 day or 5 pounds in 1 week to the health care provider. The nurse may assist the patient with planning activity and rest periods to achieve a lifestyle acceptable to the patient. If the patient is to have surgical valve replacement or valvuloplasty, the nurse teaches the patient about the procedure and anticipated recovery.

## Valve Repair and Replacement Procedures

### VALVULOPLASTY

The repair, rather than replacement, of a cardiac valve is referred to as **valvuloplasty**. The type of valvuloplasty depends on the cause and type of valve dysfunction. Repair may be made to the commissures between the leaflets in a procedure known as **commissurotomy**, to the annulus of the valve by annuloplasty, to the leaflets, or to the chordae by chordoplasty.

Most valvuloplasty procedures require general anesthesia and often require cardiopulmonary bypass. Some procedures, however, can be performed in the cardiac catheterization laboratory; these procedures do not always require general anesthesia or cardiopulmonary bypass. Percutaneous partial cardiopulmonary bypass is used in some cardiac catheterization laboratories. The cardiopulmonary bypass is achieved by inserting a large catheter (ie, cannula) into two peripheral blood vessels, usually a femoral vein and an artery. Blood is diverted from the body through the venous catheter to the cardiopulmonary bypass machine (see Chap. 28) and returned to the patient through the arterial catheter.

The patient is usually managed in a critical care unit for the first 24 to 72 hours after surgery. Care focuses on hemodynamic stabilization and recovery from anesthesia. Vital signs are assessed every 5 to 15 minutes and as needed until the patient recovers from anesthesia or sedation and then every 2 to 4 hours and as needed. Intravenous medications to increase or decrease blood pressure and to treat dysrhythmias or altered heart rates are administered, and their effects are monitored. The intravenous medications are gradually decreased until they are no longer re-

quired or the patient takes needed medication by another route (eg, oral, topical). Patient assessments are conducted every 1 to 4 hours and as needed, with particular attention to neurologic, respiratory, and cardiovascular assessments.

After the patient has recovered from anesthesia and sedation, is hemodynamically stable without intravenous medications, and assessments are stable, the patient is usually transferred to a telemetry or surgical unit for continued postsurgical care and teaching. The nurse provides wound care and patient teaching regarding diet, activity, medications, and self-care. Patients are discharged from the hospital in 1 to 7 days. In general, valves that have undergone valvuloplasty function longer than replacement valves, and the patients do not require continuous anticoagulation.

## Commissurotomy

The most common valvuloplasty procedure is commissurotomy. Each valve has leaflets; the site where the leaflets meet is called the *commissure*. The leaflets may adhere to one another and close the commissure (ie, stenosis). Less commonly, the leaflets fuse in such a way that, in addition to stenosis, the leaflets are also prevented from closing completely, resulting in a backward flow of blood (ie, regurgitation). A commissurotomy is the procedure performed to separate the fused leaflets.

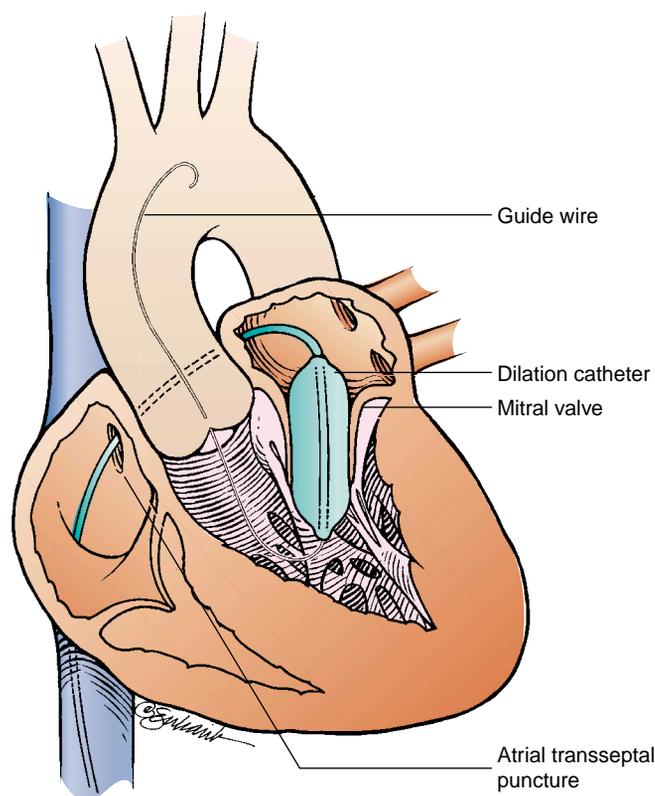

### CLOSED COMMISSUROTOMY

Closed commissurotomies do not require cardiopulmonary bypass. The valve is not directly visualized. The patient receives a general anesthetic, a midsternal incision is made, a small hole is cut into the heart, and the surgeon's finger or a dilator is used to break open the commissure. This type of commissurotomy has been performed for mitral, aortic, tricuspid, and pulmonary valve disease.

**Balloon Valvuloplasty.** Balloon valvuloplasty (Fig. 29-3) is another type of closed commissurotomy beneficial for mitral valve stenosis in younger patients, for aortic valve stenosis in elderly patients, and for patients with complex medical conditions that place them at high risk for the complications of more extensive surgical procedures. Most commonly used for mitral and aortic valve stenosis, balloon valvuloplasty also has been used for tricuspid and pulmonic valve stenosis. The procedure is performed in the cardiac catheterization laboratory, and the patient may receive a local anesthetic. Patients remain in the hospital 24 to 48 hours after the procedure.

Mitral valvuloplasty is contraindicated for patients with left atrial or ventricular thrombus, severe aortic root dilation, significant mitral valve regurgitation, thoracolumbar scoliosis, rotation of the great vessels, and other cardiac conditions that require open heart surgery.

Mitral balloon valvuloplasty involves advancing one or two catheters into the right atrium, through the atrial septum into the left atrium, across the mitral valve into the left ventricle, and out into the aorta. A guide wire is placed through each catheter, and the original catheter is removed. A large balloon catheter is then placed over the guide wire and positioned with the balloon across the mitral valve. The balloon is then inflated with a dilute angiographic solution. When two balloons are used, they are inflated simultaneously. The advantage of two balloons is that they are each smaller than the one large balloon often used, making smaller atrial septal defects. As the balloons are inflated, they usually do not completely occlude the mitral valve, thereby permitting some forward flow of blood during the inflation period.

**FIGURE 29-3** Balloon valvuloplasty: cross-section of heart illustrating guide wire and dilation catheter placed through an atrial transseptal puncture and across the mitral valve. The guide wire is extended out from the aortic valve into the aorta for catheter support.

All patients have some degree of mitral regurgitation after the procedure. Other possible complications include bleeding from the catheter insertion sites, emboli resulting in complications such as strokes, and rarely, left-to-right atrial shunts through an atrial septal defect caused by the procedure.

Aortic balloon valvuloplasty also may be performed by passing the balloon or balloons through the atrial septum, but it is performed more commonly by introducing a catheter through the aorta, across the aortic valve, and into the left ventricle. The one-balloon or the two-balloon technique can be used for treating aortic stenosis. The aortic procedure is not as effective as the procedure for the mitral valve, and the rate of restenosis is nearly 50% in the first 12 to 15 months after the procedure (Braunwald et al., 2001). Possible complications include aortic regurgitation, emboli, ventricular perforation, rupture of the aortic valve annulus, ventricular dysrhythmias, mitral valve damage, and bleeding from the catheter insertion sites.

### OPEN COMMISSUROTOMY

Open commissurotomies are performed with direct visualization of the valve. The patient is under general anesthesia, and a median sternotomy or left thoracic incision is made. Cardiopulmonary bypass is initiated, and an incision is made into the heart. A finger, scalpel, balloon, or dilator may be used to open the commissures. An added advantage of direct visualization of the valve is that thrombus may be identified and removed, calcifications can be seen, and if the valve has chordae or papillary muscles, they may be surgically repaired (chordoplasty is discussed later in this chapter).

## Annuloplasty

**Annuloplasty** is the repair of the valve annulus (ie, junction of the valve leaflets and the muscular heart wall). General anesthesia and cardiopulmonary bypass are required for all annuloplasties. The procedure narrows the diameter of the valve's orifice and is useful for the treatment of valvular regurgitation.

There are two annuloplasty techniques. One technique uses an annuloplasty ring (Fig. 29-4). The leaflets of the valve are sutured to a ring, creating an annulus of the desired size. When the ring is in place, the tension created by the moving blood and contracting heart is borne by the ring rather than by the valve or a suture line, and progressive regurgitation is prevented by the repair. The other technique involves tacking the valve leaflets to the atrium with sutures or taking tucks to tighten the annulus. Because the valve's leaflets and the suture lines are subjected to the direct forces of the blood and heart muscle movement, the repair may degenerate more quickly than with the annuloplasty ring technique.

## Leaflet Repair

Damage to cardiac valve leaflets may result from stretching, shortening, or tearing. **Leaflet repair** for elongated, ballooning, or other excess tissue leaflets is removal of the extra tissue. The elongated tissue may be folded over onto itself (ie, tucked) and sutured (ie, leaflet plication). A wedge of tissue may be cut from the middle of the leaflet and the gap sutured closed (ie., leaflet resection) (Fig. 29-5). Short leaflets are most often repaired by chordoplasty. After the short chordae are released, the leaflets often unfurl and can resume their normal function of closing the valve during systole. A piece of pericardium may also be sutured to extend the leaflet. A pericardial patch may be used to repair holes in the leaflets.

## Chordoplasty

**Chordoplasty** is the repair of the chordae tendineae. The mitral valve is involved with chordoplasty (because it has the chordae tendineae); seldom is chordoplasty required for the tricuspid valve.

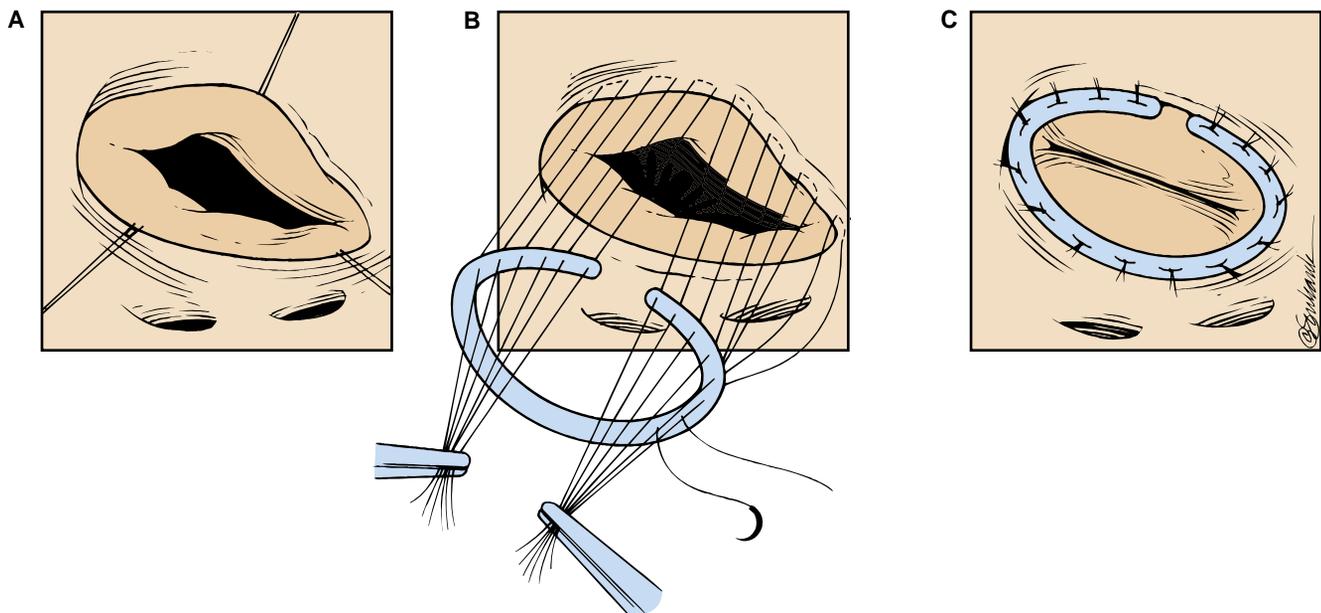

Regurgitation may be caused by stretched, torn, or shortened chordae tendineae. Stretched chordae tendineae can be shortened, torn ones can be reattached to the leaflet, and shortened ones can be elongated. Regurgitation may also be caused by stretched papillary muscles, which can be shortened.

## VALVE REPLACEMENT

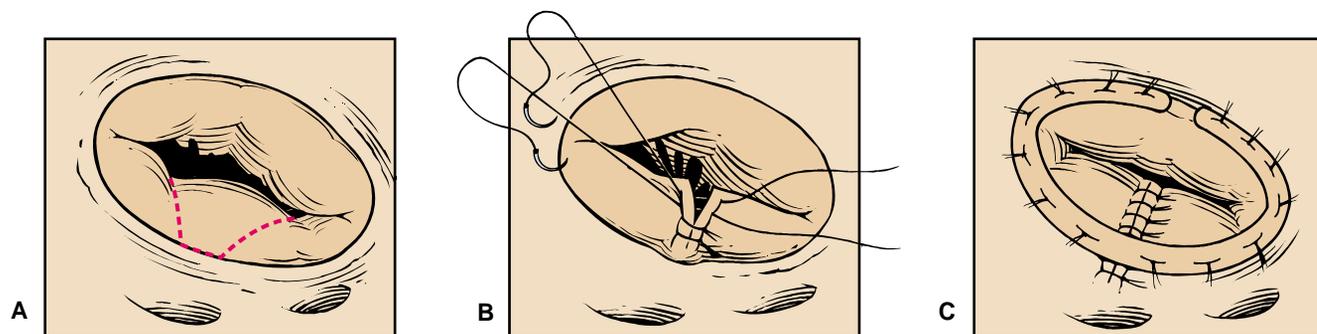

Prosthetic **valve replacement** began in the 1960s. When valvuloplasty or valve repair is not a viable alternative, such as when the annulus or leaflets of the valve are immobilized by calcifications, valve replacement is performed. General anesthesia and cardiopulmonary bypass are used for all valve replacements. Most procedures are performed through a median sternotomy (ie, incision through the sternum), although the mitral valve may be approached through a right thoracotomy incision.

After the valve is visualized, the leaflets and other valve structures, such as the chordae and papillary muscles, are removed. Some surgeons leave the posterior mitral valve leaflet, its chordae, and papillary muscles in place to help maintain the shape and function of the left ventricle after mitral valve replacement. Sutures are placed around the annulus and then into the valve prosthesis. The replacement valve is slid down the suture into position and tied into place (Fig. 29-6). The incision is closed, and the surgeon evaluates the function of the heart and the quality of the prosthetic repair. The patient is weaned from cardiopulmonary bypass, and surgery is completed.

Before surgery, the heart gradually adjusted to the pathology, but the surgery abruptly "corrects" the way blood flows through the heart. Complications unique to valve replacement are related to the sudden changes in intracardiac blood pressures. All prosthetic valve replacements create a degree of stenosis when they are implanted in the heart. Usually, the stenosis is mild and does not effect heart function. If valve replacement was for a stenotic valve, blood flow through the heart is often improved. The signs and symptoms of the backward heart failure resolve in a few hours or days. If valve replacement was for a regurgitant valve, it may take months for the chamber into which blood had been regurgitat-

**FIGURE 29-4** Annuloplasty ring insertion. (A) Mitral valve regurgitation; leaflets do not close. (B) Insertion of an annuloplasty ring. (C) Completed valvuloplasty; leaflets close.

ing to achieve its optimal postoperative function. The signs and symptoms of heart failure resolve gradually as the heart function improves. The patient is at risk for many postoperative complications, such as bleeding, thromboembolism, infection, congestive heart failure, hypertension, dysrhythmias, hemolysis, and mechanical obstruction of the valve.

### Types of Valve Prostheses

Two types of valve prostheses may be used: mechanical and tissue (ie, biologic) valves. Figure 29-7 shows mechanical and tissue valves.

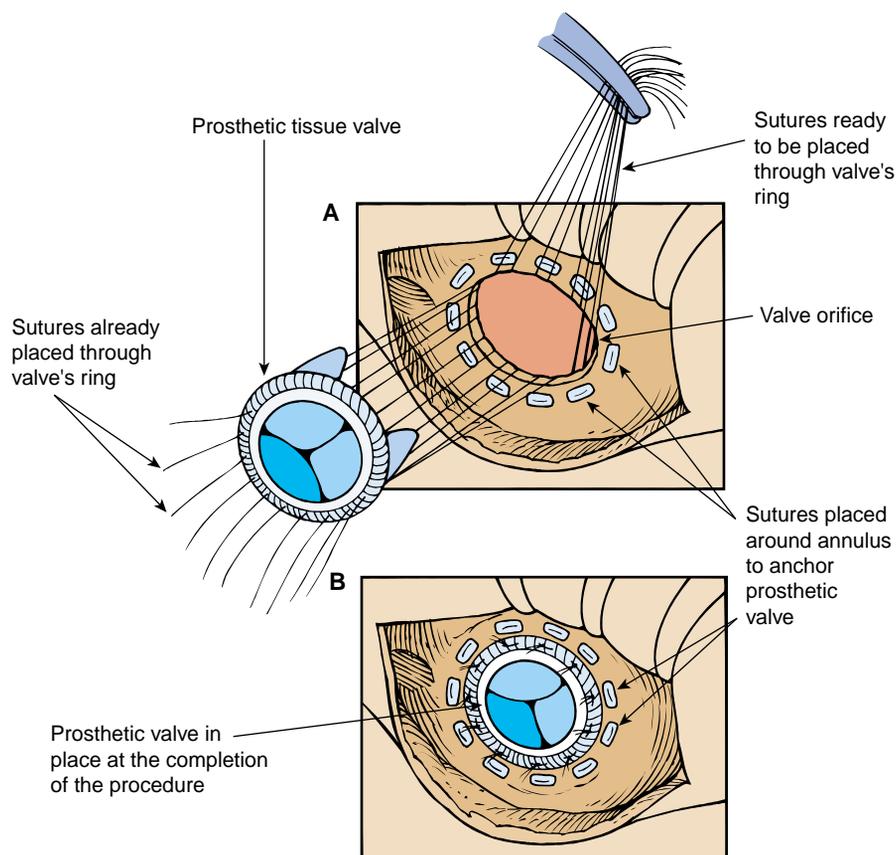

#### MECHANICAL VALVES

The mechanical valves are of the ball-and-cage or disk design. Mechanical valves are thought to be more durable than tissue

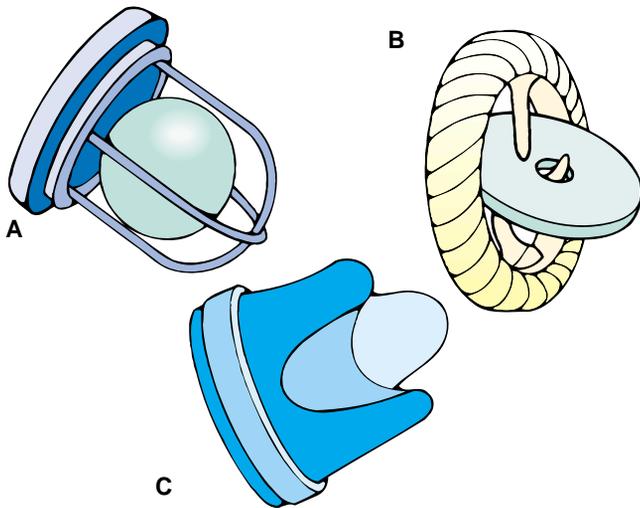

prosthetic valves and often are used for younger patients. Mechanical valves are used if the patient has renal failure, hypercalcemia, endocarditis, or sepsis and requires valve replacement. The mechanical valves do not deteriorate or become infected as easily as the tissue valves used for patients with these conditions. Thromboemboli are significant complications associated with mechanical valves, and long-term anticoagulation with warfarin is required.

#### TISSUE OR BIOLOGIC VALVES

Tissue (ie, biologic) valves are of three types: xenografts, homografts, and autografts. Tissue valves are less likely to generate thromboemboli, and long-term anticoagulation is not required. Tissue valves are not as durable as mechanical valves and require replacement more frequently.

**FIGURE 29-6** Valve replacement. (A) The native valve is excised and the prosthetic valve is sutured in place. (B) Once all sutures are placed through the ring, the surgeon slides the prosthetic valve down the sutures and into the natural orifice. The sutures are then tied off and trimmed.

**FIGURE 29-7** Common mechanical and tissue valve replacements. (A) Caged ball valve (Starr-Edwards, mechanical). (B) Tilting-disk valve (Medtronic-Hall, mechanical). (C) Porcine heterograft valve (Carpenter-Edwards, tissue).

**Xenografts.** Xenografts are tissue valves (eg, bioprostheses, **heterografts**); most are from pigs (porcine), but valves from cows (bovine) may also be used. Their viability is 7 to 10 years. They do not generate thrombi, thereby eliminating the need for long-term anticoagulation. They are used for women of childbearing age because the potential complications of long-term anticoagulation associated with menses, placental transfer to a fetus, and delivery of a child do not exist. Xenografts also are used for patients older than 70 years of age, patients with a history of peptic ulcer disease, and others who cannot tolerate long-term anticoagulation. Xenografts are used for all tricuspid valve replacements.

**Homografts.** Homografts, or **allografts** (ie, human valves), are obtained from cadaver tissue donations. The aortic valve and a portion of the aorta or the pulmonic valve and a portion of the pulmonary artery are harvested and stored cryogenically. Homografts are not always available and are very expensive. Homografts last for about 10 to 15 years, somewhat longer than xenografts. Homografts are not thrombogenic and are resistant to subacute bacterial endocarditis. They are used for aortic and pulmonic valve replacement.

**Autografts.** Autografts (ie, autologous valves) are obtained by excising the patient's own pulmonic valve and a portion of the pulmonary artery for use as the aortic valve. Anticoagulation is unnecessary because the valve is the patient's own tissue and is not thrombogenic. The autograft is an alternative for children (it may grow as the child grows), women of childbearing age, young adults, patients with a history of peptic ulcer disease, and those who cannot tolerate anticoagulation. Aortic valve autografts have remained viable for more than 20 years.

Most aortic valve autograft procedures are double valve-replacement procedures, because a homograft also is performed for pulmonic valve replacement. If pulmonary vascular pressures are normal, some surgeons elect not to replace the pulmonic valve. The patient can recover without a valve between the right ventricle and the pulmonary artery.

## VALVULOPLASTY AND REPLACEMENT: NURSING MANAGEMENT

Patients who have had valvuloplasty or valve replacements are admitted to the intensive care unit; care focuses on recovery from anesthesia and hemodynamic stability. Vital signs are assessed every 5 to 15 minutes and as needed until the patient recovers from anesthesia or sedation and then assessed every 2 to 4 hours and as needed. Intravenous medications to increase or decrease blood pressure and to treat dysrhythmias or altered heart rates are administered and their effects monitored. The intravenous medications are gradually decreased until they are no longer required or the patient takes needed medication by another route (eg, oral, topical). Patient assessments are conducted every 1 to 4 hours and as needed, with particular attention to neurologic, respiratory, and cardiovascular systems. (See Plan of Nursing Care 28-2: Care of the Patient After Cardiac Surgery, in Chap. 28).

After the patient has recovered from anesthesia and sedation, is hemodynamically stable without intravenous medications, and assessment values are stable, the patient is usually transferred to a telemetry unit, typically within 24 to 72 hours after surgery. Nursing care continues as for most postoperative patients, including wound care and patient teaching regarding diet, activity, medications, and self-care.

The nurse educates the patient about long-term anticoagulant therapy, explaining the need for frequent follow-up appointments and blood laboratory studies, and provides teaching about any prescribed medication: the name of the medication, dosage, its actions, prescribed schedule, potential side effects, and any drug-drug or drug-food interactions. Patients with a mechanical valve prosthesis require education to prevent bacterial endocarditis with antibiotic prophylaxis, which is prescribed before all dental and surgical interventions. Patients are discharged from the hospital in 3 to 7 days. Home care and office or clinic nurses reinforce all new information and self-care instructions with the patient and family for 4 to 8 weeks after the procedure.

## Septal Repair

The atrial or ventricular septum may have an abnormal opening between the right and left sides of the heart (ie, septal defect). Although most septal defects are congenital and are repaired during infancy or childhood, adults may not have undergone early repair or may develop septal defects as a result of myocardial infarctions or diagnostic and treatment procedures.

Repair of septal defects requires general anesthesia and cardiopulmonary bypass. The heart is opened, and a pericardial or synthetic (usually polyester or Dacron) patch is used to close the opening. Atrial septal defect repairs have low morbidity and mortality rates. When the mitral or tricuspid valve is involved, however, the procedure is more complicated because valve repair or replacement may be required and the heart failure may be more severe. Generally, ventricular septal repairs are uncomplicated, but the proximity of the defect to the intraventricular conduction system and the valves may make this repair more complex. (See Chapter 28, Plan of Nursing Care: Care of the Patient After Cardiac Surgery.)

## Cardiomyopathies

**Cardiomyopathy** is a heart muscle disease associated with cardiac dysfunction. It is classified according to the structural and functional abnormalities of the heart muscle: dilated cardiomyopathy

(DCM), hypertrophic cardiomyopathy (HCM), restrictive or constrictive cardiomyopathy, arrhythmogenic right ventricular cardiomyopathy (ARVC), and unclassified cardiomyopathy (Richardson et al., 1996). *Ischemic cardiomyopathy* is a term frequently used to describe an enlarged heart caused by coronary artery disease, which is usually accompanied by heart failure (see Chap. 30). Regardless of the category and the cause, cardiomyopathy may lead to severe heart failure, lethal dysrhythmias, and death. Cardiomyopathy causes more than 27,000 deaths each year in the United States (American Heart Association, 2001). The mortality rate is highest for African Americans and the elderly (American Heart Association, 2001).

## Pathophysiology

The pathophysiology of all cardiomyopathies is a series of progressive events that culminate in impaired cardiac output. Decreased stroke volume stimulates the sympathetic nervous system and the renin-angiotensin-aldosterone response, resulting in increased systemic vascular resistance and increased sodium and fluid retention, which places an increased workload on the heart. These alterations can lead to heart failure (see Chap. 30).

### DILATED CARDIOMYOPATHY

DCM is the most common form of cardiomyopathy, with an incidence of 5 to 8 cases per 100,000 people per year and increasing (Braunwald et al., 2001). DCM occurs more often in men and African Americans, who also experience higher mortality rates (Braunwald et al., 2001). DCM is distinguished by significant dilation of the ventricles (Fig. 29-8) without significant concomitant hypertrophy (ie, increased muscle wall thickness) and systolic dysfunction. DCM was formerly named *congestive cardiomyopathy*, but DCM may exist without signs and symptoms of congestion.

Microscopic examination of the muscle tissue shows diminished contractile elements of the muscle fibers and diffuse necrosis of myocardial cells. The result is poor systolic function. These structural changes decrease the amount of blood ejected from the ventricle with systole, increasing the amount of blood remaining in the ventricle after contraction. Less blood is then able to enter the ventricle during diastole, increasing end-diastolic pressure and eventually increasing pulmonary pressures. Altered valve function can result from the enlarged stretched ventricle, usually resulting in regurgitation. Embolic events caused by ventricular and atrial thrombi as a result of the poor blood flow through the ventricle may also occur. More than 75 conditions and diseases may cause DCM, including pregnancy, heavy alcohol intake, and viral infection (eg, influenza). When the causative factor cannot be identified, the term used is *idiopathic DCM*. Idiopathic DCM accounts for approximately 25% of all heart failure cases (Braunwald et al., 2001). Early diagnosis and treatment can prevent or delay significant symptoms and sudden death from DCM. Echocardiography and ECG are used to diagnose DCM and should be conducted for all first-degree relatives (eg, parents, siblings, children) of patients with DCM (Braunwald et al., 2001).

### HYPERTROPHIC CARDIOMYOPATHY

In HCM, the heart muscle increases in size and mass, especially along the septum (see Fig. 29-8). The increased thickness of the heart muscle reduces the size of the ventricular cavities and causes the ventricles to take a longer time to relax, making it more difficult for the ventricles to fill with blood during the first part of diastole and making them more dependent on atrial contraction for

**FIGURE 29-8** Cardiomyopathies that lead to congestive heart failure. A<sub>O</sub>, aorta; LA, left atrium; LV, left ventricle. With permission from Braunwald, E., et al. (Eds.) (2001). *Heart disease: A textbook of cardiovascular medicine* (6th ed.). Philadelphia: W. B. Saunders.

filling. The increased septal size may misalign the papillary muscles so that the septum and mitral valve obstruct the flow of blood from the left ventricle into the aorta during ventricular contraction. Hence, HCM may be obstructive or nonobstructive. Because of the structural changes, HCM had also been called idiopathic hypertrophic subaortic stenosis (IHSS) or asymmetric septal hypertrophy (ASH). Structural changes may also result in a smaller than normal ventricular cavity and a higher velocity flow of blood out of the left ventricle into the aorta, which may be detected by echocardiography (Braunwald et al., 2001). HCM may cause significant diastolic dysfunction, but systolic function can be normal or high, resulting in a higher than normal ejection fraction.

Because HCM is a genetic disease, family members are observed closely for signs and symptoms indicating development of the disease (Fuster et al., 2001). HCM is rare, occurring in men, women, and children (often detected after puberty) (Oakley, 1997) with an estimated prevalence rate of 0.05% to 0.2% (Berul & Zevitz, 2002). It may also be idiopathic (ie, no cause can be found).

### RESTRICTIVE CARDIOMYOPATHY

Restrictive cardiomyopathy (RCM) is characterized by diastolic dysfunction caused by rigid ventricular walls that impair ventricular stretch and diastolic filling (see Fig. 29-8). Systolic function is usually normal. Because RCM is the least common cardiomyopathy, representing approximately 5% of pediatric cardiomyopathies, its pathogenesis is the least understood (Shaddy, 2001). Restrictive cardiomyopathy can be associated with amyloidosis (in which amyloid, a protein substance, is deposited within the

cells) and other such infiltrative diseases. However, the cause is unknown in most cases (ie, idiopathic).

### ARRHYTHMOGENIC RIGHT VENTRICULAR CARDIOMYOPATHY

ARVC occurs when the myocardium of the right ventricle is progressively infiltrated and replaced by fibrous scar and adipose tissue. Initially, only localized areas of the right ventricle are affected, but as the disease progresses, the entire heart is affected. Eventually, the right ventricle dilates and develops poor contractility, right ventricular wall abnormalities, and dysrhythmias. The prevalence of ARVC is unknown because many cases are not recognized. ARVC should be suspected in patients with ventricular tachycardia originating in the right ventricle (ie, a left bundle branch block configuration on ECG) or sudden death, especially among previously symptom-free athletes (McRae et al., 2001). The disease may be genetic (ie, autosomal dominant) (Richardson et al., 1996). Family members should be screened for the disease with a 12-lead ECG, Holter monitor, and echocardiography.

### UNCLASSIFIED CARDIOMYOPATHIES

Unclassified cardiomyopathies are different from or have characteristics of more than one of the previously described cardiomyopathies. Examples of unclassified cardiomyopathies include fibroelastosis, noncompacted myocardium, systolic dysfunction with minimal dilation, and mitochondrial involvement (Richardson et al., 1996).

### Clinical Manifestations

The patient may have cardiomyopathy but remain stable and without symptoms for many years. As the disease progresses, so do symptoms. Frequently, dilated and restrictive cardiomyopathy are first diagnosed when the patient presents with signs and symptoms of heart failure (eg, dyspnea on exertion, fatigue). Patients with cardiomyopathy may also report paroxysmal nocturnal dyspnea, cough (especially with exertion), and orthopnea, which may lead to a misdiagnosis of bronchitis or pneumonia. Other symptoms include fluid retention, peripheral edema, and nausea, which is caused by poor perfusion of the gastrointestinal system. The patient may experience chest pain, palpitations, dizziness, nausea, and syncope with exertion. However, with HCM, cardiac arrest (ie, sudden cardiac death) may be the initial manifestation in young people, including athletes (Spirito et al., 2000).

### Assessment and Diagnostic Findings

Physical examination in the early stage may reveal tachycardia and extra heart sounds. With disease progression, examination also reveals signs and symptoms of heart failure (eg, crackles on pulmonary auscultation, jugular vein distention, pitting edema of dependent body parts, enlarged liver).

Diagnosis is usually made from findings disclosed by the patient history and by ruling out other causes of heart failure, such as myocardial infarction. The echocardiogram is one of the most helpful diagnostic tools because the structure and function of the ventricles can be observed easily. ECG demonstrates dysrhythmias and changes consistent with left ventricular hypertrophy. The chest x-ray film reveals heart enlargement and possibly pulmonary congestion. Cardiac catheterization is sometimes used to rule out coronary artery disease as a causative factor. An endomyocardial biopsy may be performed to analyze myocardial tissue cells.

### Medical Management

Medical management is directed toward determining and managing possible underlying or precipitating causes; correcting the heart failure with medications, a low-sodium diet, and an exercise regimen (see Chap. 30); and controlling dysrhythmias with antiarrhythmic medications and possibly with an implanted electronic device, such as an implantable cardioverter-defibrillator (see Chap. 27). If patients exhibit signs and symptoms of congestion, their fluid intake may be limited to 2 liters each day. The person with HCM may also have to limit physical activity to avoid a life-threatening dysrhythmia. A pacemaker may be implanted to alter the electrical stimulation of the muscle and prevent the forceful hyperdynamic contractions that occur with HCM.

### SURGICAL MANAGEMENT

When heart failure progresses and medical treatment is no longer effective, surgical intervention, including heart transplantation, is considered. However, because of the limited number of organ donors, many patients die waiting for transplantation. In some cases, a left ventricular assist device (LVAD) is implanted to support the failing heart until a suitable donor heart becomes available (mechanical assist devices and total artificial hearts are discussed later in this chapter).

**Left Ventricular Outflow Tract Surgery.** When a patient with HCM becomes symptomatic despite medical therapy and a difference in pressure of 50 mm Hg or more exists between the left ventricle and the aorta, surgery is considered. The most common procedure is a myectomy (sometimes referred to as a myotomy-myectomy), in which some of the heart tissue is excised. Septal tissue approximately 1 cm wide and deep is cut from the enlarged septum below the aortic valve. The length of septum removed depends on the degree of obstruction caused by the hypertrophied muscle.

Instead of a septal myectomy, the surgeon may open the left ventricular outflow tract to the aortic valve by removing the mitral valve, chordae, and papillary muscles. The mitral valve then is replaced with a low-profile disk valve. The space taken up by the mitral valve is substantially reduced by the prosthetic valve compared with the patient's own valve, chordae, and papillary muscles, allowing blood to move around the enlarged septum to the aortic valve in the area that the mitral valve once occupied. The primary complication of both procedures is dysrhythmia; additional complications are postoperative surgical complications such as pain, ineffective airway clearance, deep vein thrombosis, risk for infection, and delayed surgical recovery.

**Heart Transplantation.** The first human-to-human heart transplant was performed in 1967. Since then, transplant procedures, equipment, and medications have continued to improve. Since 1983, when cyclosporine became available, heart transplantation has become a therapeutic option for patients with end-stage heart disease. Cyclosporine (Neoral, Sandimmune, SangCya) is an immunosuppressant that greatly decreases the body's rejection of foreign proteins, such as transplanted organs. Unfortunately, cyclosporine also decreases the body's ability to resist infections, and a satisfactory balance must be achieved between suppressing rejection and avoiding infection.

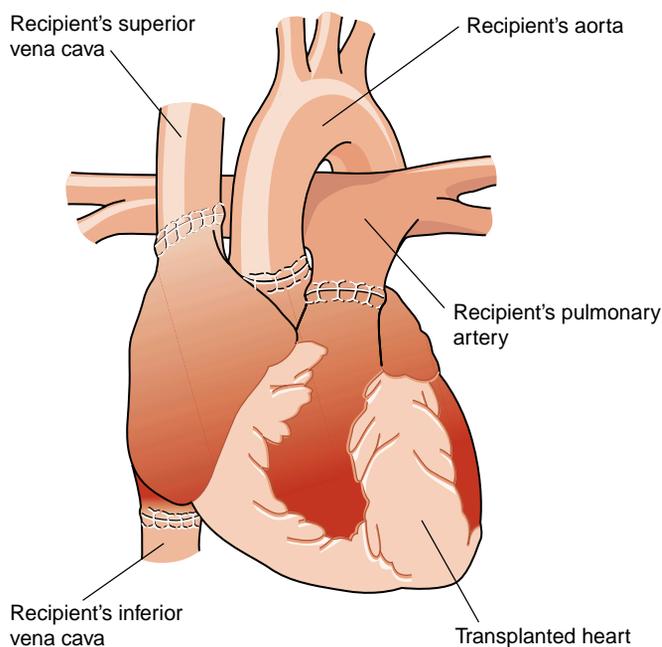

Cardiomyopathy, ischemic heart disease, valvular disease, rejection of previously transplanted hearts, and congenital heart disease are the most common indications for transplantation (Becker & Petlin, 1999; Rourke et al., 1999). A typical candidate

has severe symptoms uncontrolled by medical therapy, no other surgical options, and a prognosis of less than 12 months to live. A multidisciplinary team screens the candidate before recommending the transplantation procedure. The person's age, pulmonary status, other chronic health conditions, psychosocial status, family support, infections, history of other transplantations, compliance, and current health status are considered in the screening.

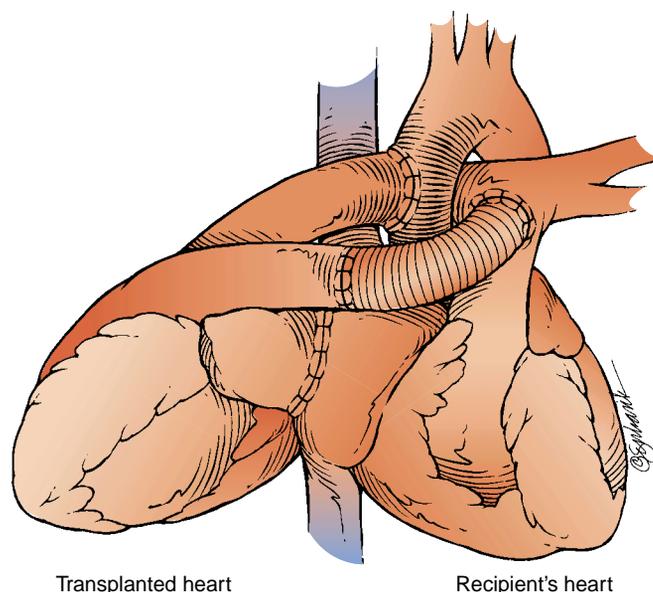

When a donor heart becomes available, a computer generates a list of potential recipients on the basis of ABO blood group compatibility, the sizes of the donor and the potential recipient, and the geographic locations of the donor and potential recipient; distance is a variable because postoperative function depends on the heart being implanted within 6 hours of harvest from the donor. Some patients are candidates for more than one organ transplant: heart-lung, heart-pancreas, heart-kidney, heart-liver.

**Transplantation Techniques.** **Orthotopic transplantation** is the most common surgical procedure for cardiac transplantation (Fig. 29-9). The recipient's heart is removed, and the donor heart is implanted at the vena cava and pulmonary veins. Some surgeons still prefer to remove the recipient's heart leaving a portion of the recipient's atria (with the vena cava and pulmonary veins) in place. The donor heart, which usually has been preserved in ice, is prepared for implant by cutting away a small section of the atria that corresponds with the sections of the recipient's heart that were left in place. The donor heart is implanted by suturing the donor atria to the residual atrial tissue of the recipient's heart. Both techniques then connect the recipient's pulmonary artery and aorta to those of the donor heart.

**Heterotopic transplantation** is less commonly performed (Fig. 29-10). The donor heart is placed to the right and slightly anterior to the recipient's heart; the recipient's heart is not removed. Initially, it was thought that the original heart might provide some protection for the patient in the event that the transplanted heart was rejected. Although the protective effect has not been proved, other reasons for retaining the original heart have been identified: a small donor heart or pulmonary hypertension (Becker & Petlin, 1999; Kadner et al., 2000).

**FIGURE 29-9** Orthotopic method of heart transplantation.

**FIGURE 29-10** Heterotopic method of heart transplantation.

The transplanted heart has no nerve connections with the recipient's body (ie, denervated heart), and the sympathetic and vagus nerves do not affect the transplanted heart. The resting rate of the transplanted heart is approximately 70 to 90 beats per minute, but it increases gradually if catecholamines are in the circulation. Patients must gradually increase and decrease their exercise (ie, extended warm-up and cool-down periods), because 20 to 30 minutes may be required to achieve the desired heart rate. Atropine does not increase the heart rate of these patients.

**Postoperative Course.** Heart transplant patients are constantly balancing the risk of rejection with the risk of infection. They must comply with a complex regimen of diet, medications, activity, follow-up laboratory studies, biopsies (to diagnose rejection), and clinic visits. Most commonly, patients receive cyclosporine or tacrolimus (FK506, Prograf), azathioprine (Imuran) or mycophenolate mofetil (CellCept), and corticosteroids (ie, prednisone) to minimize rejection.

In addition to rejection and infection, complications may include accelerated atherosclerosis of the coronary arteries (ie, cardiac allograft vasculopathy [CAV] or accelerated graft atherosclerosis [AGA]). Although the cause is unknown, the disease is believed to be immunologically mediated (Augustine, 2000; Rourke et al., 1999). Hypertension may be experienced by patients taking cyclosporine or tacrolimus; the cause has not been identified. Osteoporosis frequently occurs as a side effect of the anti-rejection medications and pretransplantation dietary insufficiency and medications. Posttransplantation lymphoproliferative disease and cancer of the skin and lips are the most common malignancies after transplantation, possibly caused by immunosuppression. Weight gain, obesity, diabetes, dyslipidemia (eg, hypercholesterolemia), hypotension, renal failure, and central nervous system, respiratory, and gastrointestinal disturbances may be caused by the corticosteroids or other immunosuppressants. Other complications are immunosuppressant medication toxicities and responses to the psychosocial stresses imposed by organ transplantation. Patients may experience guilt that someone died for them to live, have anxiety about the new heart, experience depression or fear when rejection is identified, or have difficulty with family role changes before and after transplantation (Augustine, 2000; Becker &

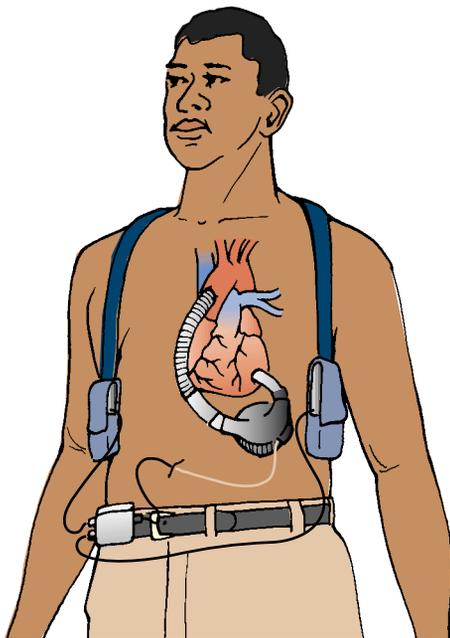

Petlin, 1999; Braunwald et al., 2001; Fuster et al., 2001; Rourke et al., 1999).

The 1-year survival rate for patients with transplanted hearts is approximately 80% to 90%; the 5-year survival rate is approximately 60% to 70% (Augustine, 2000; Becker & Petlin, 1999; Braunwald et al., 2001; Fuster et al., 2001; Rourke et al., 1999).

**Mechanical Assist Devices and Total Artificial Hearts.** The use of cardiopulmonary bypass for cardiovascular surgery and the possibility of performing heart transplantation for end-stage cardiac disease have increased the need for mechanical assist devices. Patients who cannot be weaned from cardiopulmonary bypass or patients in cardiogenic shock may benefit from a period of mechanical heart assistance. The most commonly used device is the intra-aortic balloon pump (see Chap. 30). This pump decreases the work of the heart during contraction but does not perform the actual work of the heart.

**Ventricular Assist Devices.** More complex devices that actually perform some or all of the pumping function for the heart also are being used. These more sophisticated **ventricular assist devices** (VADs) (Fig. 29-11) can circulate as much blood per minute as the patient's heart, if not more. Each ventricular assist device is used to support one ventricle. Some ventricular assist devices can be combined with an oxygenator; the combination is called extracorporeal membrane oxygenation (ECMO). The oxygenator–ventricular assist device combination is used for the patient whose heart cannot pump adequate blood through the lungs or the body.

There are three basic types of devices: centrifugal, pneumatic, and electric or electromagnetic. Centrifugal VADs are external, nonpulsatile, cone-shaped devices with internal mechanisms that spin rapidly, creating a vortex (tornado-like action) that pulls blood from a large vein into the pump and then pushes it back into a large artery. Pneumatic VADs are external or implanted pulsatile devices with a flexible reservoir housed in a rigid exte-

**FIGURE 29-11** Left ventricular assist device.

rior. The reservoir usually fills with blood drained from the patient's atrium or ventricle. The VAD then forces pressurized air into the rigid housing, compressing the reservoir and returning the blood to the patient's circulation, usually into the aorta. Electric or electromagnetic VADs are similar to the pneumatic VADs, but instead of pressurized air, one or more flat metal plates are pushed against the reservoir to return the blood to the patient's circulation.

**Total Artificial Hearts.** **Total artificial hearts** are designed to replace both ventricles. Some require the removal of the patient's heart to implant the total artificial heart; others do not. All of these devices are experimental. Although there has been some short-term success, the long-term results have been disappointing. Researchers hope to develop a device that can be permanently implanted and that will eliminate the need for donated human heart transplantation for the treatment of end-stage cardiac disease (Braunwald et al., 2001; Chillcott et al., 1998; Fuster et al., 2001; Rose et al., 1999; Schakenbach, 2001).

Most VADs and total artificial hearts are temporary treatments while the patient's own heart recovers or until a donor heart becomes available for transplantation (ie, "bridge to transplant"). Some devices are being investigated for permanent use. Bleeding disorders, hemorrhage, thrombus, emboli, hemolysis, infection, renal failure, right heart failure, multisystem failure, and mechanical failure are some of the complications of VADs and total artificial hearts (Braunwald et al., 2001; Duke & Perna, 1999; Schakenbach, 2001; Scherr et al., 1999). The nursing care for these patients focuses on assessing for and minimizing these complications and involves providing emotional support and education about the mechanical assist device.

## NURSING PROCESS: THE PATIENT WITH CARDIOMYOPATHY

### Assessment

Nursing assessment for the patient with cardiomyopathy begins with a detailed history of the presenting signs and symptoms. The nurse identifies possible etiologic factors, such as heavy alcohol intake, recent illness or pregnancy, or history of the disease in immediate family members. If the patient complains of chest pain, a thorough review of the pain, including its precipitating factors, should be performed. The review of systems includes the presence of orthopnea, paroxysmal nocturnal dyspnea, and syncope or dyspnea with exertion. The number of pillows that are needed to sleep, usual weight, any weight change, and limitation to activities of daily living also are assessed. The New York Heart Association Classification for heart failure is determined. The patient's usual diet is evaluated to determine if alterations are needed to reduce sodium intake.

Because of the chronicity of cardiomyopathy, the nurse compiles a careful psychosocial history exploring the impact of the disease on the patient's role within the family and community. Identification of all perceived stressors helps the patient and the health care team to implement activities to relieve anxiety related to changes in health status. Very early on, the patient's support systems are identified, and members are involved in the patient's care and therapeutic regimen. The assessment addresses the effect the diagnosis has had on the patient and members of his or her support system and the patient's emotional status. Depression is not uncommon in patients with cardiomyopathy who have developed heart failure.

The physical assessment focuses on signs and symptoms of congestive heart failure. The baseline assessment includes such key components as:

- Vital signs
- Calculation of pulse pressure and identification of pulsus paradoxus
- Current weight; determination of weight gain or loss
- Detection by palpation of the point of maximal impulse, often shifted to the left
- Cardiac auscultation for a systolic murmur and third and fourth heart sounds
- Pulmonary auscultation for crackles
- Measurement of jugular vein distention
- Identification of presence and severity of edema

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses for the patient may include:

- Decreased cardiac output related to structural disorders caused by cardiomyopathy or to dysrhythmia from the disease process and medical treatments
- Ineffective cardiopulmonary, cerebral, peripheral, and renal tissue perfusion related to decreased peripheral blood flow (resulting from decreased cardiac output)
- Impaired gas exchange related to pulmonary congestion caused by myocardial failure (decreased cardiac output)
- Activity intolerance related to decreased cardiac output or excessive fluid volume, or both
- Anxiety related to the change in health status and in role functioning
- Powerlessness related to disease process
- Noncompliance with medication and diet therapies

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications include:

- Congestive heart failure
- Ventricular dysrhythmias
- Atrial dysrhythmias
- Cardiac conduction defects
- Pulmonary or cerebral embolism
- Valvular dysfunction

These complications are discussed earlier in this chapter and in Chapters 27 and 30.

## Planning and Goals

The major goals for the patient include improved or maintained cardiac output, increased activity tolerance, reduction of anxiety, adherence to the self-care program, increased sense of power with decision making, and absence of complications.

## Nursing Interventions

### IMPROVING CARDIAC OUTPUT

During a symptomatic episode, rest is indicated. Many patients with DCM find that sitting up with their legs down is more comfortable than lying down in a bed. This position is helpful in pooling venous blood in the periphery and reducing preload. As-

sessing the patient's oxygen saturation at rest and during activity may assist with determining a need for supplemental oxygen. Oxygen is usually given through nasal cannula when indicated.

Ensuring that medications are taken as prescribed is important to preserving adequate cardiac output. It is important to ensure that patients with HCM avoid diuretics and that patients with DCM avoid verapamil (Calan, Isoptin) to maintain contractility. The nurse may assist the patient with planning a schedule for taking medications and identifying methods to remember to follow it, such as associating the time to take a medication with an activity (eg, eating a meal, brushing teeth). Ensuring that the patient receives or chooses food selections that are appropriate for the low-sodium diet is also important. Determining the patient's weight every day and identifying any significant change is one way to monitor the patient's response to treatment. Assessing if the patient experiences shortness of breath after more or less activity than before treatment is another indication of the effect of treatment. Patients with low cardiac output may need assistance keeping warm and frequently changing position to stimulate circulation and reduce the possibility of skin breakdown.

### INCREASING ACTIVITY TOLERANCE

The nurse plans the patient's activities so that they occur in cycles, alternating rest with activity periods. This benefits the patient's physiologic status, and it helps to teach the patient about the need for planned cycles of rest and activity. For example, after taking a bath or shower, the patient should plan to sit and read the paper or pay bills. Suggesting that patients sit while chopping vegetables, drying their hair, or shaving helps them to identify methods to balance rest with activity. The nurse can also make sure that the patient recognizes the symptoms that indicate the need for rest and the actions to take when the symptoms occur. Patients with HCM need to avoid strenuous activity and sports.

### REDUCING ANXIETY

Spiritual, psychological, and emotional support may be indicated for the patient, family, and significant others. Interventions are directed toward eradicating or alleviating perceived stressors. The patient is provided with appropriate information about cardiomyopathy and self-management activities. An atmosphere in which the patient feels free to verbalize concerns is provided, as is assurance that these concerns are legitimate. If the patient is facing death or awaiting transplantation, time must be provided to discuss these issues. Providing the patient with realistic hope helps to reduce anxiety while the patient awaits a donor heart. Nurses help the patient, family, and significant others with anticipatory grieving. Accomplishing a goal, no matter how small, also promotes the patient's sense of well-being.

### DECREASING THE SENSE OF POWERLESSNESS

Patients need to recognize that they go through a grieving process when given a diagnosis of cardiomyopathy. They are assisted in identifying the things in their life that they have lost (eg, foods that they have enjoyed eating but are high in sodium, ability to engage in constant active lifestyle, ability to play sports, ability to lift grandchildren). They also are assisted in identifying their emotional responses to the loss (eg, anger, depression). The nurse then assists patients in identifying the amount of control that they have in their lives, such as making food choices, managing their medications, and working with their provider to achieve the best possible outcomes. The use of patient tools that track behaviors with the resulting symptoms may be helpful. For example, a diary in which the patient records his or her food selections and

weight may assist the patient with understanding the relationship between sodium intake and weight gain. Some patients are able to manage a self-titrating diuretic regimen, in which the patient is able to adjust the dose of diuretic to his or her symptoms.

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** Teaching patients about the medication regimen, symptom monitoring, and symptom management is a key part of the plan of nursing care. The nurse is integral to the learning process as patients learn to balance their lifestyle and work while accomplishing their therapeutic activities. Helping patients cope with their disease status assists them in adjusting their lifestyles and implementing a self-care program at home.

**Continuing Care.** The nurse reinforces previous teaching and performs ongoing assessment of the patient's symptoms and progress. The nurse also assists the patient and family to adjust to lifestyle changes. Teaching patients to read nutritional labels, to maintain a record of daily weights and symptoms, and to organize daily activities to increase activity tolerance can be helpful. The patient's responses to diet and fluid restrictions and to the medication regimen are assessed, and explanations about symptoms that should be reported to the physician are emphasized. Because of the risk of dysrhythmia, the patient's family may be taught cardiopulmonary resuscitation. Women are often advised to avoid pregnancy; each case is assessed individually. The nurse assesses the psychosocial needs of the patient and family on an ongoing basis. There may be concerns and fears about the prognosis, changes in lifestyle, effects of medications, and the possibility of others in the family having the same condition that increase the patient's anxiety and interfere with effective coping strategies. Establishing trust is vital to the relationship with these chronically ill patients and their families. This is particularly significant when the nurse is involved with the patient and family in discussions about end-of-life decisions. Patients who have significant symptoms of heart failure or other complications of cardiomyopathy may need a home care referral.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Maintains or improves cardiac function
  - a. Exhibits heart and respiratory rates within normal limits
  - b. Reports decreased dyspnea and increased comfort; maintains or improves gas exchange
  - c. Reports no weight gain
  - d. Maintains or improves peripheral blood flow
2. Maintains or increases activity tolerance
  - a. Carries out activities of daily living (eg, brushes teeth, feeds self)
  - b. Reports increased tolerance to activity
3. Is less anxious
  - a. Discusses prognosis freely
  - b. Verbalizes fears and concerns
  - c. Participates in support groups if appropriate
4. Decreases sense of powerlessness
  - a. Identifies emotional response to diagnosis
  - b. Discusses the control he or she has in life
5. Adheres to the self-care program
  - a. Takes medications according to prescribed schedule

- b. Modifies diet to accommodate sodium and fluid restrictions
- c. Modifies lifestyle to accommodate recommended activity and rest behaviors
- d. Identifies signs and symptoms to be reported to the health care professional

## Cardiac Tumor and Trauma Surgery

### TUMOR EXCISION

Tumors of the heart are rare; most (75% to 88%) are benign (Braunwald et al., 2001; Kamiya et al., 2001). Primary tumors occur in less than 1% of the population; metastatic tumors have been reported in 1.5% to 35% of oncology patients (Braunwald et al., 2001; Reynan, 1996; Shapiro, 2001). Tumors may be sites for thrombus formation and therefore create a risk of embolism. Dysrhythmias may occur as the myocardium or conduction system is affected.

Surgical excision is performed to prevent obstruction of a chamber or valve. Cardiopulmonary bypass is used, except for epicardial tumors, which can be excised without entering the heart and without stopping the heart from beating. The tumor location may necessitate valve replacement, myocardial patching, or pacemaker implantation. The nursing care is the same as that for patients undergoing other forms of cardiac surgery (see Chap. 28).

### TRAUMA REPAIR

Patients who have sustained nonpenetrating (ie, blunt force) injury or penetrating injury (eg, gunshot wound, stabbing) causing cardiac trauma often do not survive to treatment (Flynn & Bonini, 1999; Thourani et al., 1999). Patients who do survive to treatment often require surgical treatment (Thourani et al., 1999; Wall et al., 1997). The repairs are typically to the valves or septum in blunt force injuries and to the ventricular and atrial walls in penetrating injuries. The wound is débrided and closed surgically when possible, but valve repair and replacement or patch grafts of the septum and atrial or ventricular walls may be required. The surgery is usually an emergency procedure, and the risk of complications from the injury and surgery is high. The nursing care is the same as that for patients undergoing other forms of cardiac surgery (See Chap. 28).

## Infectious Diseases of the Heart

Among the most common infections of the heart are infective endocarditis, myocarditis, and pericarditis. The ideal management is prevention.

### RHEUMATIC ENDOCARDITIS

Acute rheumatic fever, which occurs most often in school-age children, follows 0.3% to 3% of cases of group A beta-hemolytic streptococcal pharyngitis (Chin, 2001). Prompt treatment of strep throat with antibiotics can prevent the development of rheumatic fever (Chart 29-1). The *Streptococcus* is spread by direct contact with oral or respiratory secretions. Although the bacteria are the causative agents, malnutrition, overcrowding, and lower socioeconomic status may predispose individuals to rheumatic fever (Beers et al., 1999). The incidence of rheumatic fever in the United States and other developed countries is believed to have steadily decreased, but the exact incidence is difficult to deter-

### Chart 29-1 • ASSESSMENT

#### Recognizing and Preventing Rheumatic Fever

Rheumatic fever is a preventable disease. Eradicating rheumatic fever would eliminate rheumatic heart disease. Penicillin therapy in patients with streptococcal infections can prevent almost all primary attacks of rheumatic fever. A throat culture is the only method by which an accurate diagnosis can be determined.

The signs and symptoms of streptococcal pharyngitis are the following:

- Fever (38.9° to 40°C [101° to 104°F])
- Chills
- Sore throat (sudden in onset)
- Diffuse redness of throat with exudate on oropharynx (may not appear until after the first day)
- Enlarged and tender lymph nodes
- Abdominal pain (more common in children)
- Acute sinusitis and acute otitis media (if due to streptococci)

mine because the infection may go unrecognized and patients may not seek treatment (Braunwald et al., 2001; Beers et al., 1999). As many as 39% of patients with rheumatic fever develop various degrees of rheumatic heart disease associated with valvular insufficiency, heart failure, and death (Chin, 2001). The disease also affects all bony joints, producing polyarthritides. The prevalence of rheumatic heart disease is difficult to determine because clinical diagnostic criteria are not standardized and autopsies are not routinely performed. Except for rare outbreaks, the prevalence of rheumatic heart disease in the United States is believed to be less than 0.05 cases per 1000 people (Chin, 2001). The number of U.S. citizens who die from rheumatic heart disease declined from approximately 15,000 in 1950 to about 4,000 in 2001 (AHA, 2001).

### Pathophysiology

The heart damage and the joint lesions of rheumatic endocarditis are not infectious in the sense that these tissues are not invaded and directly damaged by destructive organisms; rather, they represent a sensitivity phenomenon or reaction occurring in response to hemolytic streptococci. Leukocytes accumulate in the affected tissues and form nodules, which eventually are replaced by scar tissue. The myocardium is certain to be involved in this inflammatory process; rheumatic myocarditis develops, which temporarily weakens the contractile power of the heart. The pericardium also is affected, and rheumatic pericarditis occurs during the acute illness. These myocardial and pericardial complications usually occur without serious sequelae. Rheumatic endocarditis, however, results in permanent and often crippling side effects.

### Clinical Manifestations

Rheumatic endocarditis anatomically manifests first by tiny translucent vegetations or growths, which resemble pinhead-sized beads arranged in a row along the free margins of the valve flaps. These tiny beads look harmless enough and may disappear without injuring the valve leaflets. More often, however, they have serious effects. They are the starting point of a process that gradually thickens the leaflets, rendering them shorter and thicker than normal and preventing them from closing completely. The

result is leakage, a condition called *valvular regurgitation*. The most common site of valvular regurgitation is the mitral valve. In some patients, the inflamed margins of the valve leaflets become adherent, resulting in valvular stenosis, a narrowed or stenotic valvular orifice. Regurgitation and stenosis may occur in the same valve.

A few patients with rheumatic fever become critically ill with intractable heart failure, serious dysrhythmias, and pneumonia. These patients are treated in an intensive care unit. Most patients recover quickly. However, although the patient is free of symptoms, certain permanent residual effects remain that often lead to progressive valvular deformities. The extent of cardiac damage, or even its existence, might not have been apparent in clinical examinations during the acute phase of the disease. Eventually, however, the heart murmurs that are characteristic of valvular stenosis, regurgitation, or both become audible on auscultation and, in some patients, even detectable as thrills on palpation. Usually, the myocardium can compensate for these valvular defects very well for a time. As long as the myocardium can compensate, the patient remains in apparently good health. With continued valvular alterations, the myocardium is unable to compensate (see Fig. 29-2), as evidenced by signs and symptoms of heart failure, as described in Chapter 30.

### Assessment and Diagnostic Findings

During assessment, the nurse should keep in mind that the symptoms depend on which side of the heart is involved. The mitral valve is most often affected, producing symptoms of left-sided heart failure: shortness of breath with crackles and wheezes in the lungs (see Chap. 30 for a discussion of left-sided versus right-sided failure). The severity of the symptoms depends on the size and location of the lesion. The systemic symptoms that are present are proportionate to the virulence of the invading organism. When a new murmur is detected in a patient with a systemic infection, infectious endocarditis should be suspected. The patient is also at risk for embolic phenomena of the lung (eg, recurrent pneumonia, pulmonary abscesses), kidney (eg, hematuria, renal failure), spleen (eg, left upper quadrant pain), heart (eg, myocardial infarction), brain (eg, stroke), or peripheral vessels.

### Prevention

Rheumatic endocarditis is prevented through early and adequate treatment of streptococcal infections. A first-line approach in preventing initial attacks of rheumatic endocarditis is to recognize streptococcal infections, treat them adequately, and control epidemics in the community. Every nurse should be familiar with the signs and symptoms of streptococcal pharyngitis: high fever (38.9°C to 40°C [101°F to 104°F]), chills, sore throat, redness of the throat with exudate, enlarged lymph nodes, abdominal pain, and acute rhinitis.

**NURSING ALERT** A throat culture is the only method by which an accurate diagnosis of streptococcal infection of the throat can be made.

### Medical Management

The objectives of medical management are to eradicate the causative organism and prevent additional complications, such as a thromboembolic event. Long-term antibiotic therapy is the

recommended treatment, and penicillin administered parenterally remains the medication of choice.

The patient who has rheumatic endocarditis and whose valvular dysfunction is mild may require no further treatment. Nevertheless, the danger exists for recurrent attacks of acute rheumatic fever, bacterial endocarditis, embolism from vegetations or mural thrombi in the heart, and eventual cardiac failure.

## Nursing Management

A key nursing role in rheumatic endocarditis is teaching patients about the disease, its treatment, and the preventive steps needed to avoid potential complications. After acute treatment with antibiotics, patients need to learn about the need to take prophylactic antibiotics before invasive procedures (see Prevention in the Infective Endocarditis section).

## INFECTIVE ENDOCARDITIS

Infective endocarditis is an infection of the valves and endothelial surface of the heart. Endocarditis usually develops in people with cardiac structural defects (eg, valve disorders). Infective endocarditis is more common in older people, probably because of decreased immunologic response to infection and the metabolic alterations associated with aging. There is a high incidence of staphylococcal endocarditis among IV/injection drug users who most commonly have infections of the right heart valves (Bayer et al., 1998; Braunwald, 2001).

The incidence of infective endocarditis remained steady at about 4.2 cases per 100,000 patients in the years from 1950 to the mid-1980s (Braunwald et al., 2001). The incidence then increased, partially attributed to increased IV/injection drug abuse (Braunwald et al., 2001). In 1998, a total of 2212 deaths were attributed to infective endocarditis (American Heart Association, 2001). Invasive procedures, particularly those involving mucosal surfaces, can cause a bacteremia. The bacteremia rarely lasts for more than 15 minutes (Dajani et al., 1997). If a person has some anatomic cardiac defect, bacteremia can cause bacterial endocarditis (Dajani et al., 1997). The combination of the invasive procedure, the particular bacteria introduced into the bloodstream, and the cardiac defect may result in infective endocarditis.

## Pathophysiology

Infective endocarditis is most often caused by direct invasion of the endocardium by a microbe (eg, streptococci, enterococci, pneumococci, staphylococci). The infection usually causes deformity of the valve leaflets, but it may affect other cardiac structures such as the chordae tendineae. Other causative microorganisms include fungi and rickettsiae. Patients at higher risk for infective endocarditis are those with prosthetic heart valves, a history of endocarditis, complex cyanotic congenital malformations, and systemic or pulmonary shunts or conduits that were surgically constructed (eg, saphenous vein grafts, internal mammary artery grafts). At high risk are patients with rheumatic heart disease or mitral valve prolapse and those who have prosthetic heart valves (Chart 29-2).

Hospital-acquired endocarditis occurs most often in patients with debilitating disease, those with indwelling catheters, and those receiving prolonged intravenous or antibiotic therapy. Patients receiving immunosuppressive medications or corticosteroids may develop fungal endocarditis.

Chart 29-2

### Risk Factors for Infective Endocarditis

#### High Risk

- Prosthetic cardiac valves
- History of bacterial endocarditis (even without heart disease)
- Complex cyanotic congenital malformations
- Surgically constructed systemic or pulmonary shunts or conduits

#### Moderate Risk

- Mitral valve prolapse with valvular regurgitation or thickened leaflets
- Hypertrophic cardiomyopathy
- Acquired valvular dysfunction
- Most congenital cardiac malformations (other than those listed above and surgical repair of atrial and ventricular septal defect, or patent ductus arteriosus)

A diagnosis of acute infective endocarditis is made when the onset of infection and resulting valvular destruction is rapid, occurring within days to weeks. The onset of infection may take 2 weeks to months, diagnosed as subacute infective endocarditis (Braunwald et al., 2001).

## Clinical Manifestations

Usually, the onset of infective endocarditis is insidious. The signs and symptoms develop from the toxic effect of the infection, from destruction of the heart valves, and from embolization of fragments of vegetative growths on the heart. The occurrence of peripheral emboli is not experienced by patients with right heart valve infective endocarditis (Bayer et al., 1998; Braunwald, 2001). The patient exhibits signs and symptoms similar to those described in rheumatic endocarditis (see previous discussion).

## Assessment and Diagnostic Findings

The general manifestations, which may be mistaken for influenza, include vague complaints of malaise, anorexia, weight loss, cough, and back and joint pain. Fever is intermittent and may be absent in patients who are receiving antibiotics or corticosteroids or in those who are elderly or have heart failure or renal failure. Splinter hemorrhages (ie, reddish-brown lines and streaks) may be seen under the fingernails and toenails, and petechiae may appear in the conjunctiva and mucous membranes. Small, painful nodules (Osler's nodes) may be present in the pads of fingers or toes. Hemorrhages with pale centers (Roth's spots) that may be seen in the fundi of the eyes are caused by emboli in the nerve fiber layer of the eye.

The cardiac manifestations include heart murmurs, which may be absent initially. Progressive changes in murmurs over time may be encountered and indicate valvular damage from vegetations or perforation of the valve or the chordae tendineae. Enlargement of the heart or evidence of heart failure is also found.

The central nervous system manifestations include headache, temporary or transient cerebral ischemia, and strokes, which may be caused by emboli to the cerebral arteries. Embolization may be a presenting symptom; it may occur at any time and may involve other organ systems. Embolic phenomena may occur, as discussed in the previous section on rheumatic endocarditis.

Although the described characteristics may indicate infective endocarditis, the signs and symptoms may indicate other diseases

as well. A definitive diagnosis is made when a microorganism is found in two separate blood cultures, in a vegetation, or in an abscess. Three sets of blood cultures (with each set including one aerobic and one anaerobic culture) should be obtained before administration of any antimicrobial agents. Negative blood cultures do not totally rule out the diagnosis of infective endocarditis. An echocardiogram may assist in the diagnosis by demonstrating a moving mass on the valve, prosthetic valve, or supporting structures and by identification of vegetations, abscesses, new prosthetic valve dehiscence, or new regurgitation (Braunwald et al., 2001). An echocardiogram may also demonstrate the development of heart failure.

## Prevention

Although rare, bacterial endocarditis may be life-threatening. A key strategy is primary prevention in high-risk patients (ie, those with rheumatic heart disease, mitral valve prolapse, or prosthetic heart valves). Antibiotic prophylaxis is recommended for high-risk patients immediately before and sometimes after the following procedures:

- Dental procedures that induce gingival or mucosal bleeding, including professional cleaning and placement of orthodontic bands (not brackets)
- Tonsillectomy or adenoidectomy
- Surgical procedures that involve intestinal or respiratory mucosa
- Bronchoscopy with a rigid bronchoscope
- Sclerotherapy for esophageal varices
- Esophageal dilation
- Gallbladder surgery
- Cystoscopy
- Urethral dilation
- Urethral catheterization if urinary tract infection is present
- Urinary tract surgery if urinary tract infection is present
- Prostatic surgery
- Incision and drainage of infected tissue
- Vaginal hysterectomy
- Vaginal delivery

The type of antibiotic used for prophylaxis varies with the type of procedure and the degree of risk. The patient is usually instructed to take 2 g of amoxicillin (Amoxil) 1 hour before dental, oral, respiratory, or esophageal procedures. If the patient is allergic to penicillin (eg, ampicillin [Omnipen, Polycillin], carbenicillin [Geocillin], cloxacillin [Cloxapen], methicillin [Staphcillin], nafcillin [Nafcil, Unipen], oxacillin [Prostaphlin, Bactocill], penicillin G [Bicillin, Permapen]), clindamycin (Cleocin), cephalexin (Keflex), cefadroxil (Duricef), azithromycin (Zithromax), or clarithromycin (Biaxin) may be used. Recommendations for gastrointestinal or genitourinary procedures are ampicillin and gentamicin (Garamycin) for high-risk patients, amoxicillin or ampicillin for moderate-risk patients, and substituting vancomycin (Vancocin) only for patients allergic to ampicillin or amoxicillin.

The severity of oral inflammation and infection is a significant factor in the incidence and degree of bacteremia. Poor dental hygiene can lead to bacteremia, particularly in the setting of a dental procedure. Regular personal and professional oral health care and rinsing with an antiseptic mouthwash for 30 seconds before dental procedures may assist in reducing the risk of bacteremia. Increased vigilance is also needed in patients with intravenous catheters. To minimize the risk of infection, nurses must ensure that meticulous hand hygiene, site preparation, and the use of

aseptic technique occur during the insertion and maintenance procedures (Schmid, 2000). All catheters are removed as soon as they are no longer needed or no longer function.

## Complications

Even if the patient responds to the therapy, endocarditis can be destructive to the heart and other organs. Heart failure and cerebral vascular complications, such as stroke, may occur before, during, or after therapy. The development of heart failure, which may result from perforation of a valve leaflet, rupture of chordae, blood flow obstruction due to vegetations, or intracardiac shunts from dehiscence of prosthetic valves, indicates a poor prognosis with medical therapy alone and a higher surgical risk (Braunwald et al., 2001). Valvular stenosis or regurgitation, myocardial damage, and mycotic (fungal) aneurysms are potential heart complications. Many other organ complications can result from septic or non-septic emboli, immunologic responses, abscess of the spleen, mycotic aneurysms, and hemodynamic deterioration.

## Medical Management

The causative organism may be identified by serial blood cultures. The objective of treatment is to eradicate the invading organism through adequate doses of an appropriate antimicrobial agent.

### PHARMACOLOGIC THERAPY

Antibiotic therapy is usually administered parenterally in a continuous intravenous infusion for 2 to 6 weeks. Parenteral therapy is administered in doses that achieve a high serum concentration and for a significant duration to ensure eradication of the dormant bacteria within the dense vegetations. This therapy is often delivered in the patient's home and is monitored by a home care nurse. Serum levels of the selected antibiotic are monitored. If the serum does not demonstrate bactericidal activity, increased dosages of the antibiotic are prescribed, or a different antibiotic is used. Numerous antimicrobial regimens are in use, but penicillin is usually the medication of choice. Blood cultures are taken periodically to monitor the effect of therapy. In fungal endocarditis, an antifungal agent, such as amphotericin B (Abelect, Amphocin, Fungizone), is the usual treatment.

The patient's temperature is monitored at regular intervals because the course of the fever is one indication of the effectiveness of treatment. However, febrile reactions also may occur as a result of medication. After adequate antimicrobial therapy is initiated, the infective organism usually disappears. The patient should begin to feel better, regain an appetite, and have less fatigue. During this time, patients require psychosocial support because, although they feel well, they may find themselves confined to the hospital or home with restrictive intravenous therapy.

### SURGICAL MANAGEMENT

After the patient recovers from the infectious process, seriously damaged valves may need to be replaced. Surgical valve replacement greatly improves the prognosis for patients with severe symptoms from damaged heart valves. Aortic or mitral valve excision and replacement are required for patients who develop congestive heart failure despite adequate medical treatment, patients who have more than one serious systemic embolic episode, and patients with uncontrolled infection, recurrent infection, or fungal endocarditis. Many patients who have prosthetic valve endocarditis (ie, infected prostheses) require valve replacement.

## Nursing Management

The nurse monitors the patient's temperature; the patient may have fever for weeks. Heart sounds are assessed; a new murmur may indicate involvement of the valve leaflets. The nurse monitors for signs and symptoms of systemic embolization, or for patients with right heart endocarditis, the nurse monitors for signs and symptoms of pulmonary infarction and infiltrates. The nurse assesses signs and symptoms of organ damage such as stroke (ie, cerebrovascular accident or brain attack), meningitis, heart failure, myocardial infarction, glomerulonephritis, and splenomegaly.

Patient care is directed toward management of infection. The patient is started on antibiotics as soon as blood cultures have been obtained. All invasive lines and wounds should be assessed daily for redness, tenderness, warmth, swelling, drainage, or other signs of infection. Patients and their families are instructed about any activity restrictions, medications, and signs and symptoms of infection. The nurse should instruct the patient and family about the need for prophylactic antibiotics before, and possibly after, dental, respiratory, gastrointestinal, or genitourinary procedures. Home care nurses supervise and monitor intravenous antibiotic therapy delivered in the home setting and educate the patient and family about prevention and health promotion. The nurse provides the patient and family with emotional support and facilitates coping strategies during the prolonged course of the infection and antibiotic treatment required. If the patient received surgical treatment, the nurse provides postoperative care and instruction.

## MYOCARDITIS

Myocarditis is an inflammatory process involving the myocardium. Myocarditis can cause heart dilation, thrombi on the heart wall (mural thrombi), infiltration of circulating blood cells around the coronary vessels and between the muscle fibers, and degeneration of the muscle fibers themselves. The incidence of myocarditis is estimated to be 1 to 10 cases per 100,000 persons. The rate may be higher because the variety of clinical presentations may cause underreporting (Tang, 2001). Mortality varies with the severity of symptoms. Most patients with mild symptoms recover completely. Other patients may develop cardiomyopathy and heart failure. Patients with symptomatic heart failure and an ejection fraction of less than 45% had a 1-year mortality rate of 20% and a 4-year mortality rate of 56% (Tang, 2001).

## Pathophysiology

Myocarditis usually results from a viral, bacterial, mycotic, parasitic, protozoal, or spirochetal infection. It also may occur in patients after acute systemic infections such as rheumatic fever, in those receiving immunosuppressive therapy, or in those with infective endocarditis. Myocarditis may result from an allergic reaction to pharmacologic agents used in the treatment of other diseases. It may begin in one small area and then spread throughout the myocardium. The degree of myocardial involvement determines the degree of hemodynamic effect and resulting signs and symptoms. It is theorized that dilated cardiomyopathy is a latent manifestation of myocarditis.

## Clinical Manifestations

The symptoms of acute myocarditis depend on the type of infection, the degree of myocardial damage, and the capacity of the myocardium to recover. The patient may be asymptomatic, and

the infection resolves on its own. The patient may develop mild to moderate symptoms and seek medical attention. The patient may also sustain sudden cardiac death or quickly develop severe congestive heart failure. The patient with mild to moderate symptoms often complains of fatigue and dyspnea, palpitations, and occasional discomfort in the chest and upper abdomen.

## Assessment and Diagnostic Findings

Assessment of the patient may reveal no abnormalities; as a result, the entire illness goes unrecognized. The patient may complain of chest pain (with a subsequent cardiac catheterization demonstrating normal coronary arteries). The patient without any abnormal heart structure (at least initially) may suddenly develop dysrhythmias. If the patient has developed structural abnormalities (eg, systolic dysfunction), the clinical assessment may disclose cardiac enlargement, faint heart sounds, gallop rhythm, and a systolic murmur.

## Prevention

Prevention of infectious diseases by means of appropriate immunizations (eg, influenza, hepatitis) and early treatment appears to be important in decreasing the incidence of myocarditis (Braunwald et al., 2001).

## Medical Management

The patient receives specific treatment for the underlying cause if it is known (eg, penicillin for hemolytic streptococci) and is placed on bed rest to decrease the cardiac workload. Bed rest also helps to decrease myocardial damage and the complications of myocarditis. Activities, especially sports in young patients with myocarditis, should be limited for a 6-month period or at least until heart size and function have returned to normal. Physical activity is increased slowly, and the patient is instructed to report any symptoms that occur with increasing activity, such as a rapidly beating heart. The use of corticosteroids in treating myocarditis remains controversial (Braunwald et al., 2001). Non-steroidal anti-inflammatory drugs (NSAIDs) such as aspirin and ibuprofen are not to be used during the acute phase or if the patient develops heart failure, because these medications can cause further myocardial damage. If the patient develops heart failure, management is essentially the same as for all causes of heart failure (see Chap. 30).

## Nursing Management

The nurse assesses the patient's temperature to determine whether the disease is subsiding. The cardiovascular assessment focuses on signs and symptoms of heart failure and dysrhythmia. The patient experiencing dysrhythmias should receive continuous cardiac monitoring with personnel and equipment readily available to treat life-threatening dysrhythmias.

**NURSING ALERT** Patients with myocarditis are sensitive to digitalis. They must be closely monitored for digitalis toxicity, which is evidenced by dysrhythmia, anorexia, nausea, vomiting, headache, and malaise (see Chap. 30).

Elastic compression stockings and passive and active exercises should be used, because embolization from venous thrombosis and mural thrombi can occur.

## PERICARDITIS

Pericarditis refers to an inflammation of the pericardium, the membranous sac enveloping the heart. It may be a primary illness, or it may develop in the course of a variety of medical and surgical disorders. The incidence of pericarditis varies with the cause. For example, pericarditis occurs after pericardectomy (opening of the pericardium) in 5% to 30% of patients after cardiac surgery (Beers et al., 1999). Pericarditis that occurs within 10 days to 2 months after acute myocardial infarction (Dressler's syndrome) causes 1% to 3% of all cases of pericarditis (Beers et al., 1999). Pericarditis may be acute or chronic. It may be classified by the layers of the pericardium becoming attached to each other (adhesive) or by what accumulates in the pericardial sac: serum (serous), pus (purulent), calcium deposits (calcific), clotting proteins (fibrinous), or blood (sanguinous).

### Pathophysiology

The following are some of the causes underlying or associated with pericarditis:

- Idiopathic or nonspecific causes
- Infection: usually viral (eg, Coxsackie, influenza); rarely bacterial (eg, streptococci, staphylococci, meningococci, gonococci); and mycotic (fungal)
- Disorders of connective tissue: systemic lupus erythematosus, rheumatic fever, rheumatoid arthritis, polyarteritis
- Hypersensitivity states: immune reactions, medication reactions, serum sickness
- Disorders of adjacent structures: myocardial infarction, dissecting aneurysm, pleural and pulmonary disease (pneumonia)
- Neoplastic disease: caused by metastasis from lung cancer or breast cancer, leukemia, and primary (mesothelioma) neoplasms
- Radiation therapy
- Trauma: chest injury, cardiac surgery, cardiac catheterization, pacemaker implantation
- Renal failure and uremia
- Tuberculosis

Pericarditis can lead to an accumulation of fluid in the pericardial sac (pericardial effusion) and increased pressure on the heart, leading to cardiac tamponade (see Chap. 30). Frequent or prolonged episodes of pericarditis may also lead to thickening and decreased elasticity that restrict the heart's ability to fill properly with blood (constrictive pericarditis). The pericardium may become calcified, further restricting ventricular expansion during ventricular filling (diastole). With less filling, the ventricles pump out less blood, leading to decreased cardiac output and signs and symptoms of heart failure. Restricted diastolic filling may result in increased systemic venous pressure, causing peripheral edema and hepatic failure.

### Clinical Manifestations

The most characteristic symptom of pericarditis is chest pain, although pain also may be located beneath the clavicle, in the neck, or in the left scapula region. The pain or discomfort usually remains fairly constant, but it may worsen with deep inspiration and when lying down or turning. It may be relieved with a forward-leaning or sitting position. The most characteristic sign of pericarditis is a friction rub. Other signs may include mild fever,

increased white blood cell count, and increased erythrocyte sedimentation rate (ESR). Dyspnea and other signs and symptoms of heart failure may occur as the result of pericardial compression due to constrictive pericarditis or cardiac tamponade.

### Assessment and Diagnostic Findings

Diagnosis is most often made on the basis of the patient's history, signs, and symptoms. An echocardiogram may detect inflammation and fluid build-up, as well as indications of heart failure, and help to confirm the diagnosis. Because the pericardial sac surrounds the heart, a 12-lead ECG detects ST changes in many, if not all, leads.

### Medical Management

The objectives of management are to determine the cause, administer therapy, and be alert for cardiac tamponade. When cardiac output is impaired, the patient is placed on bed rest until the fever, chest pain, and friction rub have subsided.

Analgesics and NSAIDs such as aspirin or ibuprofen may be prescribed for pain relief during the acute phase. They also hasten the reabsorption of fluid in the patient with rheumatic pericarditis. Corticosteroids (eg, prednisone) may be prescribed if the pericarditis is severe or if the patient does not respond to NSAIDs. Colchicine may also be used as an alternative medication.

Pericardiocentesis, a procedure in which some of the pericardial fluid is removed, may be performed to assist in the identification of the causative agent. It may also relieve symptoms, especially if there are signs and symptoms of heart failure. A pericardial window, a small opening made in the pericardium, may be performed to allow continuous drainage into the chest cavity. Surgical removal of the tough encasing pericardium (pericardiectomy) may be necessary to release both ventricles from the constrictive and restrictive inflammation.

### Nursing Management

The nurse caring for the patient with pericarditis must be alert to the possibility of cardiac tamponade.

**NURSING ALERT** Nursing assessment skills are key to anticipating and identifying the triad of symptoms of cardiac tamponade: falling arterial pressure, rising venous pressure, and distant heart sounds.

Patients with acute pericarditis require pain management with analgesics, positioning, and psychological support. Patients experiencing chest pain often benefit from education and reassurance that the pain is not a heart attack. To minimize complications, the nurse educates and assists the patient with activity restrictions until the pain and fever subside. As the patient's condition improves, the nurse encourages gradual increases of activity. If pain, fever, or friction rub reappear, however, activity restrictions must be resumed. The nurse educates the patient and family about a healthy lifestyle to enhance the patient's immune system.

The nurse monitors the patient for heart failure. A patient who is hemodynamically unstable or experiencing congestion is treated the same as a patient with acute heart failure (see Chap. 30).

## NURSING PROCESS: THE PATIENT WITH PERICARDITIS

### Assessment

The primary symptom of the patient with pericarditis is pain, which is assessed by observing and evaluating the patient in various positions. While observing the patient, the nurse tries to discover whether the pain is influenced by respiratory movements, with or without the actual passage of air; by flexion, extension, or rotation of the spine, including the neck; by movements of the shoulders and arms; by coughing; or by swallowing. Recognizing the events that precipitate or intensify pain may help establish a diagnosis and differentiate the pain of pericarditis from the pain of myocardial infarction.

A pericardial friction rub occurs when the pericardial surfaces lose their lubricating fluid because of inflammation. The rub is audible on auscultation and is synchronous with the heartbeat. However, it may be elusive and difficult to detect.

**NURSING ALERT** A pericardial friction rub is diagnostic of pericarditis. The nurse should search diligently for the rub by placing the diaphragm of the stethoscope tightly against the thorax and auscultating the left sternal edge in the fourth intercostal space, the site where the pericardium comes into contact with the left chest wall. A pericardial friction rub has a scratching or leathery sound. The rub is louder at the end of exhalation and may be heard best with the patient sitting and leaning forward.

If there is difficulty in distinguishing a pericardial friction rub from a pleural friction rub, patients are asked to hold their breath; a pericardial friction rub will continue.

The patient's temperature is monitored frequently. Pericarditis may cause an abrupt onset of fever in a patient who has been afebrile.

### Diagnosis

#### NURSING DIAGNOSES

Based on the assessment data, the major nursing diagnosis of the patient may include:

- Acute pain related to inflammation of the pericardium

#### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include:

- Pericardial effusion
- Cardiac tamponade

### Planning and Goals

The patient's major goals may include relief of pain and absence of complications.

### Nursing Interventions

#### RELIEVING PAIN

Relief of pain is achieved by having the patient rest. Because sitting upright and leaning forward is the posture that tends to relieve pain, chair rest may be more comfortable. It is important to instruct the patient to restrict activity until the pain subsides. As the chest pain and friction rub abate, activities of daily living may

resume gradually. If the patient is receiving medications such as analgesics, antibiotics, or corticosteroids for the pericarditis, his or her responses are monitored and recorded. If chest pain and friction rub recur, bed or chair rest resumes.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

**Pericardial Effusion.** If the patient does not respond to medical management, fluid may accumulate between the pericardial linings or in the sac. This condition is called *pericardial effusion* (see Chap. 30). Fluid in the pericardial sac can constrict the myocardium and interrupt its ability to pump. Cardiac output declines with each contraction. Failure to identify and treat this problem can lead to the development of cardiac tamponade and the possibility of sudden death.

**Cardiac Tamponade.** The signs and symptoms of cardiac tamponade begin with falling arterial pressure. Usually, the systolic pressure falls while the diastolic pressure remains stable; hence, the pulse pressure narrows. Heart sounds may progress from sounding distant to being imperceptible. Neck vein distention and other signs of rising central venous pressure are observed. These signs and symptoms occur because, as the fluid-filled pericardial sac compresses the myocardium, blood continues to return to the heart from the periphery but cannot flow into the heart to be pumped back into the circulation.

In such situations, the nurse notifies the physician immediately and prepares to assist with pericardiocentesis (see Chap. 30). The nurse stays with the patient and continues to assess and record signs and symptoms while intervening to decrease the patient's anxiety.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Is free of pain
  - a. Performs activities of daily living without pain, fatigue, or shortness of breath
  - b. Temperature returns to normal range
  - c. Exhibits no pericardial friction rub
2. Absence of complications
  - a. Sustains blood pressure in normal range
  - b. Has heart sounds that are strong and can be auscultated
  - c. Shows absence of neck vein distention

### Critical Thinking Exercises

1. One of your neighbors has been diagnosed with mitral regurgitation and does not understand why antibiotics need to be taken before undergoing any dental work, including routine checkups. How would you explain the rationale for these instructions?
2. Plans for discharge from the hospital are being made for a 26-year-old man with cardiomyopathy. His 24-year-old wife says she is prepared to care for him at home; she expects that he will be unable to participate extensively in his care. Based on your knowledge about developmental tasks of 24- to 26-year-olds, how would you explain the husband's emo-

tional and physical needs to the wife and the ways she can address these needs, as well as her own? The cardiologist has requested a consult with the transplant services; how will your plan of care change?

**3.** A patient recovering from heart transplantation has a short attention span, has a poor short-term memory, and cannot sleep well. The family reports the patient is speaking more rapidly than usual and is excessively excited and happy. The surgeon states the high doses of steroids are most likely the reason and expects the symptoms to diminish as the steroids are tapered. Another patient who has undergone the same surgical procedure cries frequently and has reported being overwhelmed by the variety and schedule of medications. The family has not been in to visit the patient for 2 days. How would you explain the different reactions, and how would your teaching strategies for these two patients differ?

**4.** You are caring for a man with pericarditis. His systolic blood pressure begins to fall, and heart sounds cannot be heard. Describe the actions you would take and why.

# ● Management of Patients With Complications From Heart Disease

## **LEARNING OBJECTIVES** ●

*On completion of this chapter, the learner will be able to:*

1. Describe the management of patients with chronic heart failure.
2. Use the nursing process as a framework for care of patients with heart failure.
3. Describe the management of patients with acute heart failure.
4. Develop teaching plans for patients with heart failure.
5. Describe the management of patients with cardiogenic shock.
6. Describe the management of patients with thromboembolic episodes, pericardial effusion and cardiac tamponade, and myocardial rupture.
7. Demonstrate the techniques of cardiopulmonary resuscitation.

Today, the patient with heart disease can be assisted to live longer and achieve a higher quality life than even a decade ago. Through advancements in diagnostic procedures that allow earlier and more accurate diagnoses, treatment can begin well before significant debilitation occurs. Newer treatments, technologies, and pharmacotherapies are being developed rapidly. However, heart disease remains a chronic condition, and complications may develop. This chapter presents the complications most often resulting from heart diseases and the treatments provided by the health care team for these complications.

## Cardiac Hemodynamics

The basic function of the heart is to pump blood. The heart's ability to pump is measured by **cardiac output (CO)**, the amount of blood pumped in 1 minute. CO is determined by measuring the heart rate (HR) and multiplying it by the **stroke volume (SV)**, which is the amount of blood pumped out of the ventricle with each contraction. CO usually is calculated using the equation  $CO = HR \times SV$ .

One of the factors controlling HR is the autonomic nervous system. When SV falls, the nervous system is stimulated to increase HR and thereby maintain adequate CO. SV depends on three factors: preload, afterload, and contractility.

**Preload** is the amount of myocardial stretch just before systole caused by the pressure created by the volume of blood within the ventricle. Like a rubber band, the ventricular muscle fibers need to be stretched (by the blood) to produce optimal ejection of blood. Too little or too much muscle fiber stretch decreases the volume of blood ejected. The major factor that determines preload is venous return, the volume of blood that enters the ventri-

cle during diastole. Another factor that determines preload is ventricular **compliance**, which is the elasticity or amount of "give" when blood enters the ventricle. Elasticity is decreased when the muscle thickens, as in hypertrophic cardiomyopathy (see Chap. 29) or when there is increased fibrotic tissue within the ventricle. Fibrotic tissue replaces dead cells, such as after a myocardial infarction (see Chap. 28). Fibrotic tissue has little compliance, making the ventricle stiff. Given the same volume of blood, a noncompliant ventricle has a higher intraventricular pressure than a compliant one. The higher pressure increases the workload of the heart and can lead to **heart failure (HF)**.

**Afterload** refers to the amount of resistance to the ejection of blood from the ventricle. To eject blood, the ventricle must overcome this resistance. Afterload is inversely related to SV. The major factors that determine afterload are the diameter and distensibility of the great vessels (aorta and pulmonary artery) and the opening and competence of the semilunar valves (pulmonic and aortic valves). The more open the valves, the lower the resistance. If the patient has significant vasoconstriction, hypertension, or a narrowed opening from a stenotic valve, resistance (afterload) increases. When afterload increases, the workload of the heart must increase to overcome the resistance and eject blood.

**Contractility**, which refers to the force of contraction, is related to the number and status of myocardial cells. Catecholamines, released by sympathetic stimulation such as exercise or from administration of positive inotropic medications, can increase contractility and stroke volume. MI causes necrosis of some myocardial cells, shifting the workload to the remaining cells. Significant loss of myocardial cells can decrease contractility and cause HF. Afterload must be reduced by stress reduction techniques or medications to match the lower contractility.

## Glossary

**afterload:** the amount of resistance to ejection of blood from a ventricle

**anuria:** urine output of less than 50 mL per 24 hours

**cardiac failure:** heart failure

**cardiac output (CO):** the amount of blood pumped out of the heart in 1 minute

**compliance:** the elasticity or amount of "give" when blood enters the ventricle

**congestive heart failure (CHF):** a fluid overload condition (congestion) that may or may not be caused by HF; often an acute presentation of HF with increased amount of fluid in the blood vessels

**contractility:** the force of ventricular contraction; related to the number and state of myocardial cells

**diastolic heart failure:** the inability of the heart to pump sufficiently because of an alteration in the ability of the heart to fill; current term used to describe a type of HF

**dyspnea on exertion (DOE):** shortness of breath that occurs with exertion

**ejection fraction (EF):** percent of blood volume in the ventricles at the end of diastole that is ejected during systole; a measurement of contractility

**heart failure (HF):** the inability of the heart to pump sufficient blood to meet the needs

of the tissues for oxygen and nutrients; signs and symptoms of pulmonary and systemic congestion may or may not be present

**left-sided heart failure (left ventricular failure):** inability of the left ventricle to fill or pump (empty) sufficient blood to meet the needs of the tissues for oxygen and nutrients; traditional term used to describe patient's HF symptoms

**oliguria:** diminished urine output; less than 400 mL per 24 hours

**orthopnea:** shortness of breath when lying flat

**paroxysmal nocturnal dyspnea (PND):** shortness of breath that occurs suddenly during sleep

**pericardiocentesis:** procedure that involves surgically opening the pericardial sac

**pericardiotomy:** surgically created opening of the pericardium

**preload:** the amount of myocardial stretch just before systole caused by the pressure created by the volume of blood within a ventricle

**pulmonary edema:** abnormal accumulation of fluid occurring in the interstitial spaces or in the alveoli of the lungs

**pulseless electrical activity (PEA):** condition in which electrical activity is present

but there is not an adequate pulse or blood pressure because of ineffective cardiac contraction or circulating blood volume

**pulsus paradoxus:** systolic blood pressure that is more than 10 mm Hg higher during exhalation than during inspiration; difference is normally less than 10 mm Hg

**right-sided heart failure (right ventricular failure):** inability of the right ventricle to fill or pump (empty) sufficient blood to the pulmonary circulation

**stroke volume (SV):** amount of blood pumped out of the ventricle with each contraction

**systolic heart failure:** inability of the heart to pump sufficiently because of an alteration in the ability of the heart to contract; current term used to describe a type of HF

**thermodilution:** method of determining cardiac output that involves injecting fluid into the pulmonary artery catheter. A thermistor measures the difference between the temperature of the fluid and the temperature of the blood ejected from the ventricle. Cardiac output is calculated from the change in temperature.

## NONINVASIVE ASSESSMENT OF CARDIAC HEMODYNAMICS

Several noninvasive assessment findings can indicate cardiac hemodynamic status, although the findings do not directly correlate to preload, afterload, or contractility. Right ventricular preload may be estimated by measuring jugular venous distention. Elevated left ventricular preload may be identified by a positive hepatojugular test. Mean arterial blood pressure is a rough indicator of left ventricular afterload. Activity tolerance may be used as an indicator of overall cardiac functioning. These assessments are described in more detail later in the chapter.

Impedance cardiography (ICG) is a noninvasive method for continuous calculation of SV, CO, systemic vascular resistance, ventricular contractility, and fluid status (Turner, 2000). Electrodes are placed on the patient's chest. The electrodes are connected to a device that transmits a very small amount of alternating electric current through the chest and measures the resistance ( $Z$ ) to the flow (conduction) of the current. Because the current seeks the path of least resistance and fluid is an excellent conductor, the current flows through the blood. ICG measures the volume of blood flow.

The cardiac cycle produces normal changes in blood flow volume; for example, there is more blood flow volume during systole and less blood flow volume during diastole. The changes in blood flow volume change the resistance to flow of the current, which is called electrical impedance ( $dZ$ ). During systole, the higher blood flow volume causes the red blood cells to be aligned in a more parallel pattern, which makes the flow of current faster and reduces impedance. During diastole, the lower blood flow volume causes the red blood cells to be more randomly arranged, which makes the flow of current slower and increases impedance. Stroke volume is determined by comparing  $dZ$  to the changes in time ( $dt$ ) (Von Rueden & Turner, 1999). The pre-ejection period (PEP) and ventricular ejection times (VET) can be measured, which further assists in understanding the hemodynamic status of the patient. For example, a dysfunctional left ventricle requires more time to generate pressure to overcome the resistance to ejection so that the aortic valve opens (increased PEP) and has less time during which blood is ejected into the aorta (decreased VET).

## INVASIVE ASSESSMENT OF CARDIAC HEMODYNAMICS

An important method for evaluating the components of SV in a hemodynamically unstable patient is the pulmonary artery (PA) catheter, which is used to obtain the hemodynamic data essential for diagnosis and treatment (see Chap. 26). Connected to a computerized transducer apparatus, the PA catheter serves as a fluid-filled conduit for detecting pressure changes within the heart. The pulsatile changes in pressure are converted into electrical signals, which are displayed as waveforms on a monitor (Fig. 30-1; Chart 30-1).

CO is measured most often by the **thermodilution** method with the thermistor port of the catheter. The port is connected to a computer that calculates CO and other cardiac parameters. In thermodilution, a specific volume of fluid that is colder than the patient's blood is injected into the proximal port (right atrium). The fluid enters the right ventricle and is then ejected into the PA. The thermistor records the temperature before and after the ejection of fluid. The change in temperature is inversely related to CO; the greater the CO, the faster the blood and fluid moves, the less time the fluid has to mix with the blood to cause a change

in temperature, and the less change in temperature detected by the thermistor.

Cardiac parameters for afterload and contractility are calculated at the same time as CO (Table 30-1). Measurements of the various pressures are made at intervals. Therapy, especially intravenous medication, is adjusted based on the assessment and diagnostic findings.

The patient with an invasive hemodynamic catheter is usually managed in an intensive care environment (see Chart 30-1) because of the need for frequent nursing assessments and interventions.

## Heart Failure

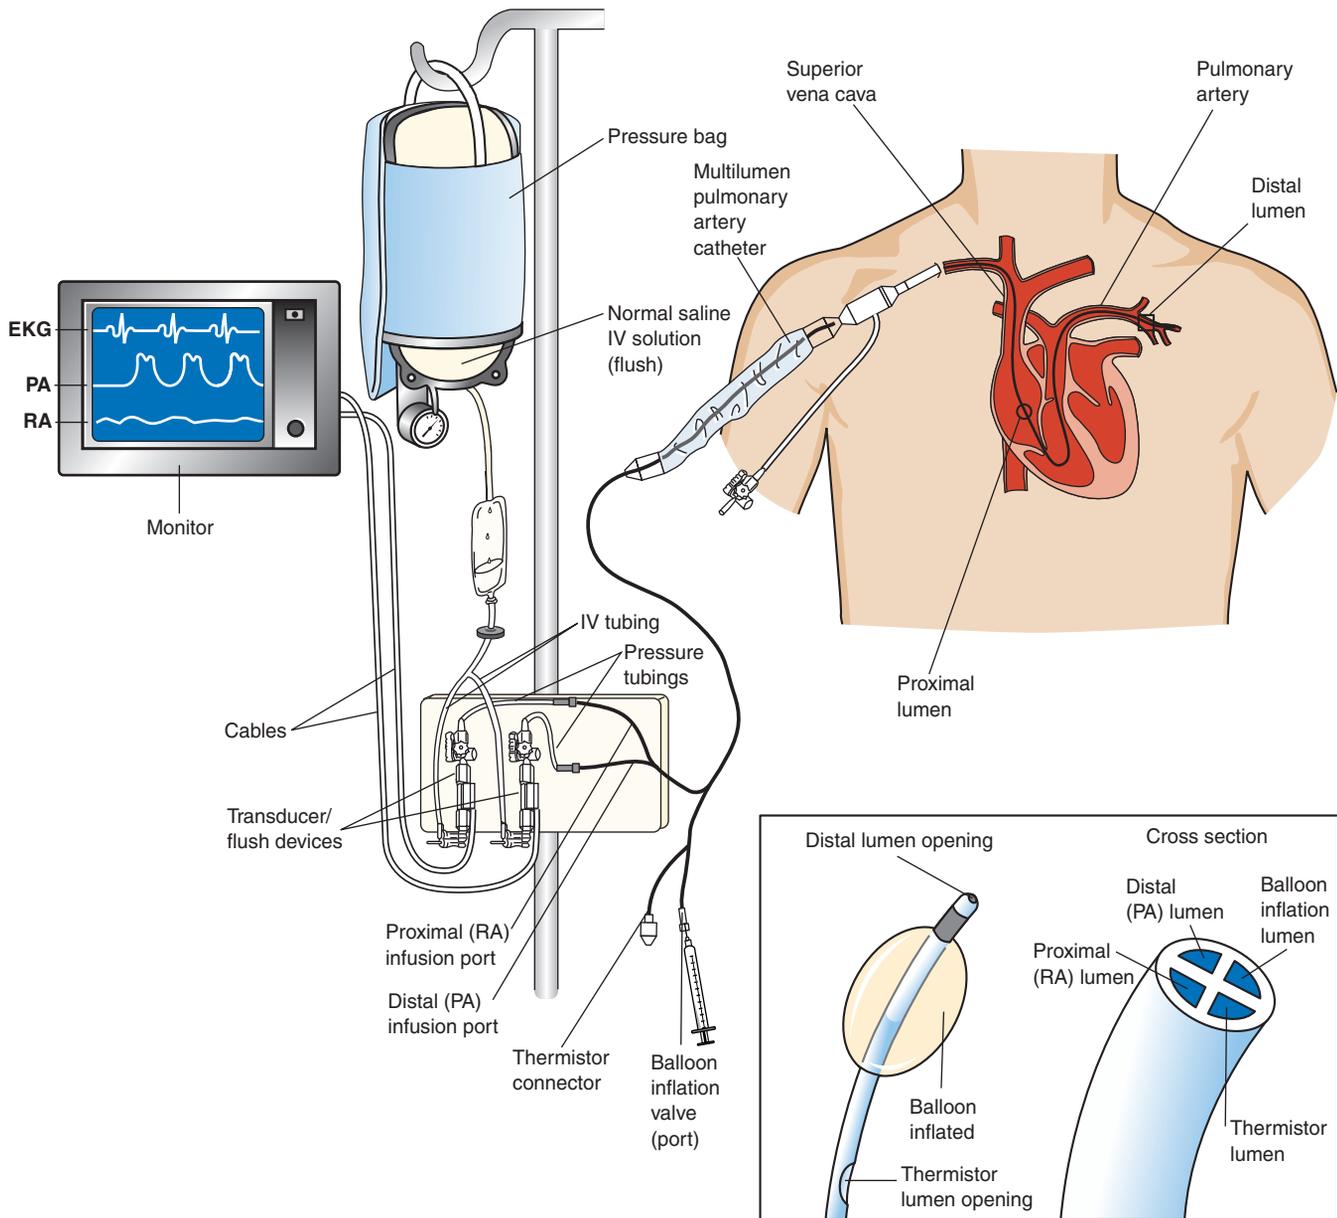

HF, often referred to as **congestive heart failure (CHF)**, is the inability of the heart to pump sufficient blood to meet the needs of the tissues for oxygen and nutrients. However, the term CHF is misleading, because it indicates that patients must experience pulmonary or peripheral congestion to have HF, and it implies that patients with congestion have HF. The Agency for Health Care Policy and Research (AHCPR) HF guidelines panel (1994) defined HF as a clinical syndrome characterized by signs and symptoms of fluid overload or of inadequate tissue perfusion. These signs and symptoms result when the heart is unable to generate a CO sufficient to meet the body's demands. The HF guideline panel used the term *heart failure* because many patients with HF do not manifest pulmonary or systemic congestion. The term HF is preferred and indicates myocardial heart disease in which there is a problem with contraction of the heart (systolic dysfunction) or filling of the heart (diastolic dysfunction) and which may or may not cause pulmonary or systemic congestion. Some cases of HF are reversible, depending on the cause. Most often, HF is a life-long diagnosis that is managed with lifestyle changes and medications to prevent acute congestive episodes. CHF is usually an acute presentation of HF.

## CHRONIC HEART FAILURE

As with coronary artery disease, the incidence of HF increases with age. However, the rate of coronary artery disease is decreasing and just the opposite is true for HF. Nearly 5 million people in the United States have HF, with more than one-half million new cases diagnosed each year (American Heart Association, 2001). The prevalence rate of HF among non-Hispanic whites 20 years of age or older is 2.3% for men and 1.5% for women; for non-Hispanic blacks, the rates are 3.5% and 3.1%, respectively (American Heart Association, 2001). HF is the most common reason for hospitalization of people older than age 65 and the second most common reason for visits to a physician's office. The rate of readmission to the hospital remains staggeringly high. The rise in the incidence of HF reflects the increased number of elderly and improvements in treatment of HF resulting in increased survival rates. However, the economic burden caused by HF is estimated to be more than 23 billion dollars in direct and indirect costs and is expected to increase (American Heart Association, 2001). Many hospitalizations could be prevented by improved and appropriate outpatient care. Prevention and early intervention to arrest the progression of HF are major health initiatives in the United States.

Medical management is based on the type, severity, and cause of HF. There are two types of HF, which are identified by assessment of left ventricular functioning: an alteration in ventricular filling (**diastolic heart failure**) and an alteration in ventricular contraction

(text continues on page 792)

**FIGURE 30-1** The pulmonary artery (PA) catheter system serves as a fluid-filled conduit for detecting pressure changes within the heart. (A) The PA catheter is inserted through a sheath into the superior vena cava, usually via the right internal jugular or subclavian vein. It is connected to pressure tubing (B) which is then connected to a transducer (C). The transducer detects pulsatile changes in pressure and converts them into electrical signals. These signals are converted into waveforms, which are shown on a monitor (D). The transducer also contains a flush device (E) that automatically infuses a small amount of flush fluid through the catheter to help maintain its patency. Because of the pressure that the heart generates, pressure is applied to the flush fluid to ensure that the fluid flows into the catheter and into the bloodstream and that blood does not flow back into the catheter. The PA catheter contains several lumens (F) with openings located at various intervals. These lumens allow for the measurement of hemodynamic pressures at different points. The proximal port is usually in the right atrium and is used to measure central venous pressure (CVP). The distal tip of the catheter rests in the pulmonary artery and measures the pulmonary artery systolic and diastolic pressures. When the balloon is inflated (G), the tip floats into smaller branches of the pulmonary artery until it can no longer pass, that is, until it is “wedged” in the vessel. The distal tip then records the pressure in front of it, called pulmonary artery wedge pressure (PAWP). Cardiac output is measured most often by the thermodilution method with the thermistor port. The port is connected to a computer that calculates cardiac output and other cardiac parameters.

Chart 30-1

## GUIDELINES FOR Hemodynamic Monitoring: Multilumen Pulmonary Artery Catheter

### ACTIONS

#### Preparatory Phase

1. Explain the procedure to the patient, family, and significant others.
2. Check vital signs and apply ECG electrodes.
3. Position the patient to allow the physician access to the insertion site, decrease the risk of complications, and promote patient comfort. To ensure consistency, the angle of elevation should be documented if the patient cannot lie flat.
4. Set up equipment according to manufacturer's directions.
  - a. The pulmonary artery (PA) catheter requires pressure tubing, a transducer, a flush system, and a pressure amplifier connected to a monitoring–recording system. In addition, an IV pole and a transducer holder are usually needed.
  - b. The pressure equipment is calibrated and flushed according to the manufacturer's directions.
  - c. The balloon is inflated with air to test for leakage.
5. Prepare the skin over the insertion site.

#### Performance Phase (Physician Responsibility)

1. The PA catheter is inserted through a sheath that has been placed in the internal jugular, subclavian, or any easily accessible, large-diameter vein by percutaneous puncture or venotomy. The sheath may be surrounded by a protective cover that maintains the sterility of the catheter.
2. The catheter is advanced while observing the monitor for pressure waveforms, which indicate the placement of the tip of the catheter within the heart. Occasionally fluoroscopy is used to verify proper placement of the PA catheter.
3. When the catheter is in the large vein, the balloon is inflated to its recommended volume.
4. The patient's blood flow will gently pull the inflated balloon at the tip of the catheter through the right atrium and tricuspid valve into the right ventricle and into the main pulmonary artery. The monitoring equipment displays specific pressure waveforms as the catheter advances through the various chambers of the heart. These initial waveforms and pressures are recorded.
5. The flowing blood will continue to direct the catheters more distally into the pulmonary arteries. When the catheter reaches a pulmonary vessel that is approximately the same size or slightly smaller in diameter than the inflated balloon, it will not advance any further. This is the wedge position from which pulmonary artery wedge pressure (PAWP) [pulmonary artery obstructive pressure (PAOP) or pulmonary capillary wedge pressure (PCWP)] is measured.
6. The pressure is recorded with the balloon wedged in the pulmonary vascular bed. A mean capillary wedge pressure between 8 and 12 mm Hg indicates normal left ventricular function.
7. The balloon is then deflated, causing the catheter to retract spontaneously into a larger pulmonary artery. The change in the catheter tip position causes a reappearance of the pulmonary artery waveform. The pulmonary artery systolic, diastolic, and mean pressures are recorded.

### RATIONALE/AMPLIFICATION

1. The information may assist in reducing the patient's anxiety, which may also help to limit the patient's movement during the procedure.
  2. An initial assessment provides a baseline for comparison.
  3. The patient is usually placed in a flat or Trendelenburg position to minimize the risk of air embolization and facilitate access.
  4. Monitoring systems and setups vary according to manufacturer.
    - a. The complexity of the setup requires an understanding of the equipment in use.
    - b. Flushing the catheter system ensures patency and eliminates air bubbles.
    - c. Testing for leakage ensures that the balloon is intact.
  5. Decreases risk of infection at insertion site
- 
1. The internal jugular vein insertion site has standard landmarks, establishes a straight route into the central venous system, and is associated with few complications. The subclavian insertion site allows the patient more mobility. It is also easier to secure the catheter from this site.
  2. Catheter placement is determined by characteristic waveforms and changes.
  3. The amount of air to be used is indicated on the catheter.
  4. Watching the ECG monitor for signs of ventricular irritability as the catheter enters the right ventricle allows dysrhythmias to be reported to the physician promptly. Subsequent pressure readings are taken from this baseline.
  5. With the catheter in the wedge position, the balloon blocks the flow of blood from the right side of the heart toward the lungs. The resulting artery wedge pressure (PAWP) correlates with the mean left ventricular end-diastolic pressure.
  6. Wedge pressure is a valuable measure of cardiac function. Lower-than-normal pressure readings indicate hypovolemia. Higher-than-normal pressure readings indicate hypervolemia and/or left ventricular failure.
  7. The normal pulmonary artery systolic pressure is 15 to 30 mm Hg, and the diastolic pressure range is 10 to 15 mm Hg. The normal mean pulmonary artery pressure (average pressure in pulmonary artery throughout the entire cardiac cycle) ranges from 10 to 20 mm Hg. Elevated pulmonary pressures can indicate several clinical problems, such as pulmonary disease, mitral valve disease, and ventricular failure.

Chart 30-1

## GUIDELINES FOR Hemodynamic Monitoring: Multilumen Pulmonary Artery Catheter (Continued)

### ACTIONS

- The protective cover is attached to the introducer and secured to the catheter. The catheter is sutured in place and a dry dressing placed over the insertion site.
- A chest x-ray to confirm catheter position and to serve as a baseline for future reference is obtained after catheter insertion.

#### To Obtain a Wedge Pressure Reading

- Inflate the balloon slowly until the pulmonary artery pressure waveform changes (indicating a wedge pressure waveform) and an increase in resistance to injection is detected. Once these changes occur, no more air is introduced. (The amount of air to cause these changes should be less than 1.5 mL.) Most cardiac monitors allow for freezing the wedge pressure waveform and its immediate printing.
- As soon as the wedge pressure is obtained, allow passive deflation of the balloon by releasing pressure on the syringe.  
To make sure that the syringe cannot be inflated accidentally, remove it, push the plunger to the bottom of the barrel so that it is totally empty of air, reattach it to the PA catheter, and lock it closed.

#### Follow-up Phase

- Inspect the insertion site daily. Observe for signs of infection, swelling, and bleeding.
- In accord with protocol, record date and time of dressing change and IV tubing change. If a peripheral vessel access site is used, assess the extremity for color, temperature, capillary filling, and sensation.
- Evaluate pulse.
- Assess for complications: pneumothorax, pulmonary ischemia or infarction (due to persistent balloon wedging from inflation or catheter migration), pulmonary artery rupture (due to overinflation of the balloon), dysrhythmias, heart block, damage to tricuspid valve, knotting of catheter within the heart or blood vessels, thromboembolus, infection, balloon rupture, hematoma at insertion site, and bleeding.

#### For Removal of the Catheter

- Explain the procedure to the patient, and make sure the balloon is not inflated.
- Place the patient in a supine position.
- Stop all IVs running through the PA catheter and turn stopcocks off.
- While the patient holds the breath or exhales, the catheter is withdrawn gently and continuously, without excessive force or traction; a sterile dressing is applied over the site.

### RATIONALE/AMPLIFICATION

- Maintaining catheter sterility in this manner allows for the advancement and repositioning of the catheter if needed. Apply sterile dressing.
- Accurate position will assure accurate readings and prevent complications.
- Do not allow the catheter to remain in the wedge position. The decrease in blood flow through the pulmonary artery that occurs when wedging the catheter may cause segmental pulmonary infarction.
- These are standard safety measures.
- Careful monitoring helps prevent complications. A foreign body (catheter) in the vascular system increases the risk of sepsis.
- Ischemia may occur from inadequate arterial flow.
- Absence of a pulse may indicate occlusion of the vessel.
- These are standard nursing practices.
- An informed patient is less fearful; a deflated balloon is less likely to injure the patient's heart or blood vessels during catheter removal.
- The supine position results in the least patient movement and is the best position for maintaining blood pressure and venous return.
- This prevents fluid from infusing into tissues as the catheter is removed; it also prevents air from entering the catheter.
- Positive intrathoracic pressure minimizes the chance of air entering the chest and vasculature through or around the catheter. Continuous gentle traction minimizes the risk of the catheter becoming kinked, knotted, or tangled. A sterile dressing minimizes the risk of infection from the skin wound.

(**systolic heart failure**). An assessment of the **ejection fraction (EF)** is performed to assist in determining the type of HF. EF is the percentage of the end-diastolic blood volume in the ventricle minus the end-systolic blood volume in the ventricle divided by the end-diastolic blood volume in the ventricle—an indication of the amount of blood that was ejected and the contractile ability of the ventricle. The EF is normal in diastolic HF, whereas the EF is less than 40% in systolic HF. The severity of HF is frequently classified according to the patient's symptoms. The New York Heart Association classification is described in Table 30-2, and the causes are explained in subsequent sections of this chapter.

## Pathophysiology

HF results from a variety of cardiovascular diseases but leads to some common heart abnormalities that result in decreased contraction (systole), decreased filling (diastole), or both. Significant myocardial dysfunction most often occurs before the patient experiences signs and symptoms of HF.

Systolic HF decreases the amount of blood ejected from the ventricle, which stimulates the sympathetic nervous system to release epinephrine and norepinephrine. The purpose of this initial response is to support the failing myocardium, but the continued

Table 30-1 • Hemodynamic Parameters

PARAMETER	RIGHT VENTRICLE	LEFT VENTRICLE
<b>Preload</b>		
Normal Values	CVP: 0–8 mm Hg	PAWP: 4–12 mm Hg
<b>Afterload</b>		
Normal Values	PVR: 20–120 dyne/sec/cm <sup>5</sup>	SVR: 800–1500 dyne/sec/cm <sup>5</sup>
Calculation	$\frac{\text{mean PAP} - \text{PAWP}}{\text{CO}} \times 80$	$\frac{\text{Mean arterial pressure} - \text{CVP}}{\text{CO}} \times 80$
<b>Contractility</b>		
Normal Values	Right ventricular stroke work index: 7–12 g/beat/m <sup>2</sup>	Left ventricular stroke work index: 35–85 g/beat/m <sup>2</sup>
Calculation	$\frac{(\text{PA systolic pressure} - \text{CVP}) \times \text{SV} \times 0.0136}{\text{Body Surface Area (height and weight)}}$	$\frac{(\text{Systolic BP} - \text{PAWP}) \times \text{SV} \times 0.0136}{\text{Body Surface Area (height and weight)}}$

BP, blood pressure; CO, cardiac output; CVP, central venous pressure; PA, pulmonary artery; PAP, pulmonary artery pressure; PAWP, pulmonary artery wedge pressure; PVR, pulmonary vascular resistance; SV, stroke volume; SVR, systemic vascular resistance.

response causes loss of beta<sub>1</sub>-adrenergic receptor sites (down-regulation) and further damage to the heart muscle cells. The sympathetic stimulation and the decrease in renal perfusion by the failing heart cause the release of renin by the kidney. Renin promotes the formation of angiotensin I, a benign, inactive substance. Angiotensin-converting enzyme (ACE) in the lumen of blood vessels converts angiotensin I to angiotensin II, a vasoconstrictor that also causes the release of aldosterone. Aldosterone promotes sodium and fluid retention and stimulates the thirst center. Aldosterone causes additional detrimental effects to the myocardium and exacerbates myocardial fibrosis (Pitt et al., 1999; Weber, 2001). Angiotensin, aldosterone, and other neurohormones (eg, atrial natriuretic factor, endothelin, and prostacyclin) lead to an increase in preload and afterload, which increases stress on the ventricular wall, causing an increase in the workload of the heart.

Table 30-2 • New York Heart Association (NYHA) Classification of Heart Failure

CLASSIFICATION	SYMPTOMS	PROGNOSIS
I	Ordinary physical activity does not cause undue fatigue, dyspnea, palpitations, or chest pain No pulmonary congestion or peripheral hypotension Patient is considered asymptomatic Usually no limitations of activities of daily living (ADLs)	Good
II	Slight limitation on ADLs Patient reports no symptoms at rest but increased physical activity will cause symptoms Basilar crackles and S <sub>3</sub> murmur may be detected	Good
III	Marked limitation on ADL Patient feels comfortable at rest but less than ordinary activity will cause symptoms	Fair
IV	Symptoms of cardiac insufficiency at rest	Poor

As the heart's workload increases, contractility of the myofibrils decreases. Decreased contractility results in an increase in end-diastolic blood volume in the ventricle, stretching the myofibers and increasing the size of the ventricle (ventricular dilation). The increased size of the ventricle further increases the stress on the ventricular wall, adding to the workload of the heart. One way the heart compensates for the increased workload is to increase the thickness of the heart muscle (ventricular hypertrophy). However, the hypertrophy is not accompanied by an adequate increase in capillary blood supply, resulting in myocardial ischemia. The sympathetic-induced coronary artery vasoconstriction, increased ventricular wall stress, and decreased mitochondrial energy production also lead to myocardial ischemia. Eventually, the myocardial ischemia causes myofibril death, even in patients without coronary artery disease. The compensatory mechanisms of HF have been called the "vicious cycle of HF" because the heart does not pump sufficient blood to the body, which causes the body to stimulate the heart to work harder; the heart is unable to respond and failure becomes worse.

Diastolic HF develops because of continued increased workload on the heart, which responds by increasing the number and size of myocardial cells (ie, ventricular hypertrophy and altered myocellular functioning). These responses cause resistance to ventricular filling, which increases ventricular filling pressures despite a normal or reduced blood volume. Less blood in the ventricles causes decreased CO. The low CO and high ventricular filling pressures cause the same neurohormonal responses as described for systolic HF.

## Etiology

Myocardial dysfunction is most often caused by coronary artery disease, cardiomyopathy, hypertension, or valvular disorders. Atherosclerosis of the coronary arteries is the primary cause of HF. Coronary artery disease is found in more than 60% of the patients with HF (Braunwald et al., 2001). Ischemia causes myocardial dysfunction because of resulting hypoxia and acidosis from the accumulation of lactic acid. Myocardial infarction causes focal heart muscle necrosis, the death of heart muscle cells, and a loss of contractility; the extent of the infarction correlates with the severity of HF. Revascularization of the coronary artery by a percutaneous coronary intervention or by coronary artery bypass surgery may correct the underlying cause so that HF is resolved.

Cardiomyopathy is a disease of the myocardium. There are three types: dilated, hypertrophic, and restrictive (see Chap. 29). Dilated cardiomyopathy, the most common type of cardiomyopathy, causes diffuse cellular necrosis, leading to decreased contractility (systolic failure). Dilated cardiomyopathy can be idiopathic (unknown cause), or it can result from an inflammatory process, such as myocarditis, from pregnancy, or from a cytotoxic agent, such as alcohol or adriamycin. Hypertrophic cardiomyopathy and restrictive cardiomyopathy lead to decreased distensibility and ventricular filling (diastolic failure). Usually, HF due to cardiomyopathy becomes chronic. However, cardiomyopathy and HF may resolve after the end of pregnancy or with the cessation of alcohol ingestion.

Systemic or pulmonary hypertension increases afterload (resistance to ejection), which increases the workload of the heart and leads to hypertrophy of myocardial muscle fibers; this can be considered a compensatory mechanism because it increases contractility. However, the hypertrophy may impair the heart's ability to fill properly during diastole.

Valvular heart disease is also a cause of HF. The valves ensure that blood flows in one direction. With valvular dysfunction, blood has increasing difficulty moving forward, increasing pressure within the heart and increasing cardiac workload, leading to diastolic HF. Chapter 29 discusses the effects of valvular heart disease.

Several systemic conditions contribute to the development and severity of HF, including increased metabolic rate (eg, fever, thyrotoxicosis), iron overload (eg, from hemochromatosis), hypoxia, and anemia (serum hematocrit less than 25%). All of these conditions require an increase in CO to satisfy the systemic oxygen demand. Hypoxia or anemia also may decrease the supply of oxygen to the myocardium. Cardiac dysrhythmias may cause HF, or they may be a result of HF; either way, the altered electrical stimulation impairs the myocardial contraction and decreases the overall efficiency of myocardial function. Other factors, such as acidosis (respiratory or metabolic), electrolyte abnormalities, and antiarrhythmic medications, can worsen the myocardial dysfunction.

## Clinical Manifestations

The clinical manifestations produced by the different types of HF (systolic, diastolic, or both) are similar (Chart 30-2) and therefore do not assist in differentiating the types of HF. The signs and symptoms of HF are most often described in terms of the effect on the ventricles. **Left-sided heart failure (left ventricular failure)** causes different manifestations than **right-sided heart failure (right ventricular failure)**. Chronic HF produces signs and symptoms of failure of both ventricles. Although dysrhythmias (especially tachycardias, ventricular ectopic beats, or atrioventricular [AV] and ventricular conduction defects) are common in HF, they may also be a result of treatments used in HF (eg, side effect of digitalis).

### LEFT-SIDED HEART FAILURE

Pulmonary congestion occurs when the left ventricle cannot pump the blood out of the ventricle to the body. The increased left ventricular end-diastolic blood volume increases the left ventricular end-diastolic pressure, which decreases blood flow from the left atrium into the left ventricle during diastole. The blood volume and pressure in the left atrium increases, which decreases blood flow from the pulmonary vessels. Pulmonary venous blood volume and pressure rise, forcing fluid from the pulmonary capillar-

## Chart 30-2 • ASSESSMENT

### Signs and Symptoms of Heart Failure

#### General

- Pale, cyanotic skin (with decreased perfusion to extremities)
- Dependent edema (with increased venous pressure)
- Decreased activity tolerance

#### Cardiovascular

- Apical impulse, enlarged and left lateral displacement (with cardiac enlargement)
- Third heart sound (S<sub>3</sub>)
- Murmurs (with valvular dysfunction)
- Tachycardia
- Increased jugular venous distention (JVD)

#### Cerebrovascular

- Lightheadness
- Dizziness
- Confusion

#### Gastrointestinal

- Nausea and anorexia
- Enlarged, pulsatile liver
- Ascites
- Hepatojugular test, increased (with increased right ventricular filling pressure)

#### Renal

- Decreased urinary frequency during the day
- Nocturia

#### Respiratory

- Dyspnea on exertion
- Orthopnea
- Paroxysmal nocturnal dyspnea
- Bilateral crackles that do not clear with cough

ies into the pulmonary tissues and alveoli, which impairs gas exchange. These effects of left ventricular failure have been referred to as *backward failure*. The clinical manifestations of pulmonary venous congestion include dyspnea, cough, pulmonary crackles, and lower-than-normal oxygen saturation levels. An extra heart sound, S<sub>3</sub>, may be detected on auscultation.

Dyspnea, or shortness of breath, may be precipitated by minimal to moderate activity (**dyspnea on exertion [DOE]**); dyspnea also can occur at rest. The patient may report **orthopnea**, difficulty in breathing when lying flat. Patients with orthopnea usually prefer not to lie flat. They may need pillows to prop themselves up in bed, or they may sit in a chair and even sleep sitting up. Some patients have sudden attacks of orthopnea at night, a condition known as **paroxysmal nocturnal dyspnea (PND)**. Fluid that accumulated in the dependent extremities during the day begins to be reabsorbed into the circulating blood volume when the person lies down. Because the impaired left ventricle cannot eject the increased circulating blood volume, the pressure in the pulmonary circulation increases, causing further shifting of fluid into the alveoli. The fluid-filled alveoli cannot exchange oxygen and carbon dioxide. Without sufficient oxygen, the patient experiences dyspnea and has difficulty getting an adequate amount of sleep.

The cough associated with left ventricular failure is initially dry and nonproductive. Most often, patients complain of a dry hacking cough that may be mislabeled as asthma or chronic obstructive pulmonary disease (COPD). The cough may become moist. Large quantities of frothy sputum, which is sometimes

pink (blood tinged), may be produced, usually indicating severe pulmonary congestion (pulmonary edema).

Adventitious breath sounds may be heard in various lobes of the lungs. Usually, bi-basilar crackles that do not clear with coughing are detected in the early phase of left ventricular failure. As the failure worsens and pulmonary congestion increases, crackles may be auscultated throughout all lung fields. At this point, a decrease in oxygen saturation may occur.

In addition to increased pulmonary pressures that cause decreased oxygenation, the amount of blood ejected from the left ventricle may decrease, sometimes called *forward failure*. The dominant feature in HF is inadequate tissue perfusion. The diminished CO has widespread manifestations because not enough blood reaches all the tissues and organs (low perfusion) to provide the necessary oxygen. The decrease in SV can also lead to stimulation of the sympathetic nervous system, which further impedes perfusion to many organs.

Blood flow to the kidneys decreases, causing decreased perfusion and reduced urine output (**oliguria**). Renal perfusion pressure falls, which results in the release of renin from the kidney. Release of renin leads to aldosterone secretion. Aldosterone secretion causes sodium and fluid retention, which further increases intravascular volume. However, when the patient is sleeping, the cardiac workload is decreased, improving renal perfusion, which then leads to frequent urination at night (nocturia).

Decreased CO causes other symptoms. Decreased gastrointestinal perfusion causes altered digestion. Decreased brain perfusion causes dizziness, lightheadedness, confusion, restlessness, and anxiety due to decreased oxygenation and blood flow. As anxiety increases, so does dyspnea, enhancing anxiety and creating a vicious cycle. Stimulation of the sympathetic system also causes the peripheral blood vessels to constrict, so the skin appears pale or ashen and feels cool and clammy.

The decrease in the ejected ventricular volume causes the sympathetic nervous system to increase the heart rate (tachycardia), often causing the patient to complain of palpitations. The pulses become weak and thready. Without adequate CO, the body cannot respond to increased energy demands, and the patient is easily fatigued and has decreased activity tolerance. Fatigue also results from the increased energy expended in breathing and the insomnia that results from respiratory distress, coughing, and nocturia.

### RIGHT-SIDED HEART FAILURE

When the right ventricle fails, congestion of the viscera and the peripheral tissues predominates. This occurs because the right side of the heart cannot eject blood and cannot accommodate all the blood that normally returns to it from the venous circulation. The increase in venous pressure leads to jugular vein distention (JVD).

The clinical manifestations that ensue include edema of the lower extremities (dependent edema), hepatomegaly (enlargement of the liver), distended jugular veins, ascites (accumulation of fluid in the peritoneal cavity), weakness, anorexia and nausea, and paradoxically, weight gain due to retention of fluid.

Edema usually affects the feet and ankles, worsening when the patient stands or dangles the legs. The swelling decreases when the patient elevates the legs. The edema can gradually progress up the legs and thighs and eventually into the external genitalia and lower trunk. Edema in the abdomen, as evidenced by increased abdominal girth, may be the only edema present. Sacral edema is not uncommon for patients who are on bed rest, because the sacral area is dependent. Pitting edema, in which

indentations in the skin remain after even slight compression with the fingertips (Fig. 30-2), is obvious only after retention of at least 4.5 kg (10 lb) of fluid (4.5 liters).

Hepatomegaly and tenderness in the right upper quadrant of the abdomen result from venous engorgement of the liver. The increased pressure may interfere with the liver's ability to perform (secondary liver dysfunction). As hepatic dysfunction progresses, pressure within the portal vessels may rise enough to force fluid into the abdominal cavity, a condition known as ascites. This collection of fluid in the abdominal cavity may increase pressure on the stomach and intestines and cause gastrointestinal distress. Hepatomegaly may also increase pressure on the diaphragm, causing respiratory distress.

Anorexia (loss of appetite) and nausea or abdominal pain results from the venous engorgement and venous stasis within the abdominal organs. The weakness that accompanies right-sided HF results from reduced CO, impaired circulation, and inadequate removal of catabolic waste products from the tissues.

### Assessment and Diagnostic Findings

HF may go undetected until the patient presents with signs and symptoms of pulmonary and peripheral edema (congestion), which can lead the physician to make a preliminary diagnosis of CHF. However, the physical signs that suggest HF may also occur with other diseases, such as renal failure, liver failure, oncologic conditions, and COPD. If further assessment and evaluation are

**FIGURE 30-2** Example of pitting edema. (A) The nurse applies finger pressure to an area near the ankle. (B) When the pressure is released, an indentation remains in the edematous tissue. Photographs © B. Proud.

not completed, these patients may be treated for HF inappropriately. The term *congestive heart failure* (CHF) means the patient has a fluid overload condition (congestion) that may or may not be caused by HF. CHF is caused by HF when ventricular dysfunction (systolic, diastolic, or both) has been identified. Assessment of ventricular function is an essential part of the initial diagnostic workup.

An echocardiogram is usually performed to confirm the diagnosis of HF, assist in the identification of the underlying cause, and determine the patient's ejection fraction, which assists in identification of the type and severity of HF. This information may also be obtained noninvasively by radionuclide ventriculography or invasively by ventriculogram as part of a cardiac catheterization procedure. A chest x-ray and an electrocardiogram (ECG) are obtained to assist in the diagnosis and to determine the underlying cause of HF. Laboratory studies usually completed in the initial workup include serum electrolytes, blood urea nitrogen (BUN), creatinine, B-type natriuretic peptide (BNP), thyroid-stimulating hormone (TSH), a complete blood cell count (CBC), and routine urinalysis. The results of these laboratory studies assist in determining the underlying cause and in establishing a baseline from which to measure effects of treatment. Exercise testing or cardiac catheterization may be performed to determine whether coronary artery disease and cardiac ischemia are causing the HF.

Ventricular function should be determined before discharge from a hospital of patients with acute myocardial infarction (MI) who are at risk for the development of HF. Patients who are at low risk for HF are those who meet all of the following criteria: no previous myocardial infarction, inferior myocardial infarction, small (less than two to four times normal) increase in cardiac enzymes, no Q waves on the ECG, and an uncomplicated clinical course (AHCPR, 1994). Evaluation of ventricular function may also be performed for patients whose initial assessment of HF suggested noncardiac causes but who failed to respond to treatment.

## Medical Management

A critical step in the management of HF is early identification and documentation of the type of HF. Medical management, especially the pharmacologic therapy, varies with the type of HF. The basic objectives in treating patients with HF are the following:

- Eliminate or reduce any etiologic contributory factors, especially those that may be reversible, such as atrial fibrillation or excessive alcohol ingestion.
- Reduce the workload on the heart by reducing afterload and preload.

Managing the patient with HF includes providing general counseling and education about sodium restriction, monitoring daily weights and other signs of fluid retention, encouraging regular exercise, and recommending avoidance of excessive fluid intake, alcohol, and smoking. Medications are prescribed based on the patient's type and severity of HF. Oxygen therapy is based on the degree of pulmonary congestion and resulting hypoxia. Some patients may need supplemental oxygen therapy only during activity. Others may require hospitalization and endotracheal intubation. If the patient has underlying coronary artery disease, coronary artery revascularization with percutaneous transluminal coronary angioplasty (PTCA) or bypass surgery (see Chap. 28) may be considered. If the patient's condition is unresponsive to advanced aggressive medical therapy, innovative therapies, including mechanical assist devices and transplantation, may be considered.

Cardiac resynchronization, involving the use of left ventricular and biventricular pacing, is a treatment for HF with electrical conduction defects. Left bundle branch block (LBBB) is frequently found in patients with systolic dysfunction. LBBB occurs when the electrical impulse, which normally depolarizes the right and left bundle branches at the same time, depolarizes the right bundle branch but not the left bundle branch. The dyssynchronous electrical stimulation of the ventricles causes the right ventricle to contract before the left ventricle, which can lead to further decreased ejection fraction (Gerber et al., 2001). Use of a pacing device (eg, Medtronic InSync), with leads placed on the inner wall of the right atrium and right ventricle and on the outer wall of the left ventricle, provides synchronized electrical stimulation to the heart. In one study, 63% of the patients who had received these devices showed improvement in clinical status, including NYHA functional class and global assessment, compared with 38% of placebo patients (Abraham, 2002).

## PHARMACOLOGIC THERAPY

Several medications are indicated for systolic HF. Medications for diastolic failure depend on the underlying condition, such as hypertension (see Chap. 32) or valvular dysfunction (see Chap. 29). If the patient is in mild systolic failure, an ACE inhibitor usually is prescribed. If the patient is unable to continue an ACE inhibitor (eg, because of development of renal impairment as evidenced by elevated serum creatinine or persistent serum potassium levels of 5.5 mEq/L or above), an angiotensin II receptor blocker (ARB) or hydralazine and isosorbide dinitrate are considered as part of the treatment plan. A diuretic is added if signs of fluid overload develop. Digitalis is added to ACE inhibitors if the symptoms continue. Although previously contraindicated in HF, specific beta-blockers decrease mortality and morbidity if added to the initial medications. Spironolactone, a weak diuretic may also be added for persistent symptoms.

**Angiotensin-Converting Enzyme Inhibitors.** ACE inhibitors (ACE-Is) have a pivotal role in the management of HF due to systolic dysfunction. They have been found to relieve the signs and symptoms of HF and significantly decrease mortality and morbidity (when used to treat a symptomatic patient) by inhibiting neurohormonal activation (CONSENSUS Trial Study Group, 1987; SOLVD Investigators, 1992). Available as oral and intravenous medications, ACE-Is promote vasodilation and diuresis by decreasing afterload and preload. By doing so, they decrease the workload of the heart. Vasodilation reduces resistance to left ventricular ejection of blood, diminishing the heart's workload and improving ventricular emptying. In promoting diuresis, ACE-Is decrease the secretion of aldosterone, a hormone that causes the kidneys to retain sodium. ACE-Is stimulate the kidneys to excrete sodium and fluid (while retaining potassium), thereby reducing left ventricular filling pressure and decreasing pulmonary congestion. ACE-Is may be the first medication prescribed for patients in mild failure—patients with fatigue or dyspnea on exertion but without signs of fluid overload and pulmonary congestion.

Results from studies (Clement et al., 2000; NETWORK Investigators, 1998) to identify the specific dose to achieve this effect are equivocal, although one large study showed significant reductions in death and hospitalization with higher doses (Packer et al., 1999). However, it is recommended to start at a low dose and increase every 2 weeks until the optimal dose is achieved and the patient is hemodynamically stable. The final maintenance dose depends on the patient's blood pressure, fluid status, renal status, and degree of **cardiac failure**.

Patients receiving ACE-I therapy are monitored for hypotension, hypovolemia, hyponatremia, and alterations in renal function, especially if they are also receiving diuretics. When to observe for these effects and for how long depends on the onset, peak, and duration of the medication. Table 30-3 identifies several types of ACE-Is and their pharmacokinetics. Hypotension is most likely to develop from ACE-I therapy in patients older than age 75 and in those with a systolic blood pressure of 100 mm Hg or less, a serum sodium level of less than 135 mEq/L, or severe cardiac failure. Adjusting the dose or type of diuretic in response to the patient's blood pressure and renal function may allow for continued increases in the dosage of ACE-Is.

Because ACE-Is cause the kidneys to retain potassium, the patient who is also receiving a diuretic may not need to take oral potassium supplements. However, patients receiving potassium-sparing diuretics (which do not cause potassium loss with diuresis) must be carefully monitored for hyperkalemia, an increased level of potassium in the blood. Before the initiation of the ACE-I, hyperkalemic and hypovolemic states must be corrected. ACE-Is may be discontinued if the potassium remains above 5.0 mEq/L or if the serum creatinine is 3.0 mg/dL and continues to increase. Other side effects of ACE-Is include a dry, persistent cough that may not respond to cough suppressants. However, the cough could also indicate a worsening of ventricular function and failure. Rarely, the cough indicates angioedema. If angioedema affects the oropharyngeal area and impairs breathing, the ACE-I must be stopped immediately.

**Angiotensin II Receptor Blockers (ARBs).** Although their action is different than that of ACE-Is, ARBs (eg, losartan [Cozaar]) have a similar hemodynamic effect as ACE-Is: lowered blood pressure and lowered systemic vascular resistance. Whereas ACE-Is block the conversion of angiotensin I to angiotensin II, ARBs block the effects of angiotensin II at the angiotensin II receptor. ACE-Is and ARBs also have similar side effects: hyperkalemia, hypotension, and renal dysfunction. ARBs are usually prescribed when patients are not able to tolerate ACE-Is.

**Hydralazine and Isosorbide Dinitrate.** A combination of hydralazine (Apresoline) and isosorbide dinitrate (Dilatrate-SR, Isordil, Sorbitrate) may be another alternative for patients who cannot take ACE-Is. Nitrates (eg, isosorbide dinitrate) cause ve-

nous dilation, which reduces the amount of blood return to the heart and lowers preload. Hydralazine lowers systemic vascular resistance and left ventricular afterload. It has also been shown to help avoid the development of nitrate tolerance. As with ARBs, this combination of medications is usually used when patients are not able to tolerate ACE-Is.

**Beta-Blockers.** When used with ACE-Is, beta-blockers, such as carvedilol (Coreg), metoprolol (Lopressor, Toprol), or bisoprolol (Zebeta), have been found to reduce mortality and morbidity in NYHA class II or III HF patients by reducing the cytotoxic effects from the constant stimulation of the sympathetic nervous system (Beta-Blocker Evaluation of Survival Trial [BEST] Investigators, 2001; CIBIS-II Investigators and Committees, 1999; MERIT, 1999; Packer et al., 1996; Packer et al., 2001). These agents have also been recommended for patients with asymptomatic systolic dysfunction, such as after acute myocardial infarction or revascularization to prevent the onset of symptoms of HF. However, beta-blockers may also produce many side effects, including exacerbation of HF. The side effects are most common in the initial few weeks of treatment. The most frequent side effects are dizziness, hypotension, and bradycardia. To minimize these side effects, staggering the administration of the beta-blocker with the ACE-I is recommended. Because of the side effects, beta-blockers are initiated only after stabilizing the patient and ensuring a euvolemic (normal volume) state. They are titrated slowly (every 2 weeks), with close monitoring at each increase in dose. If the patient develops symptoms during the titration phase, treatment options include increasing the diuretic, reducing the dose of ACE-I, or decreasing the dose of the beta-blocker.

An important nursing role during titration is educating the patient about the potential worsening of symptoms during the early phase of treatment, and that improvement may take several weeks. It is very important that nurses provide support to patients going through this symptom-provoking phase of treatment. Because beta-blockade can cause bronchiole constriction, a beta<sub>1</sub>-selective beta-blocker (ie, one that primarily blocks the beta-adrenergic receptor sites in the heart), such as metoprolol (Lopressor, Toprol), is recommended for patients with well-controlled, mild to moderate asthma. However, these patients need to be monitored closely for increased asthma symptoms. Any type of beta-blocker is contraindicated in patients with severe or uncontrolled asthma.

**Table 30-3 • Angiotensin-Converting Enzyme (ACE) Inhibitors**

ACE INHIBITOR	PHARMACOKINETICS			NURSING CONSIDERATIONS
	Onset	Peak (hr)	Duration (hr)	
benazepril (Lotensin)	within 1 hr	2–4	24	Monitor blood pressure, urine output, and electrolyte levels. Monitor serum creatinine and urine creatinine clearance. Monitor for development of cough that is resistant to cough suppressants. Teach patient to change positions gradually and to report signs of dizziness or lethargy. Instruct patient to weigh self daily and to report rapid weight gain and significant feet and hand swelling.
captopril (Capoten)	15–60 min	1–1.5	6–12*	
enalapril (Vasotec)	1 hr	4–6	24	
enalaprilat (Vasotec I.V.)	15 min	1–4	6	
fosinopril (Monopril)	within 1 hr	2–6	24	
lisinopril (Prinival, Zestril)	1 hr	6	24	
moexipril (Univasc)	1 hr	3–6	24	
quinapril (Accupril)	within 1 hr	2–4	up to 24*	
ramipril (Altace)	1–2 hr	4–6	24	
trandolapril (Mavik)	within 30 min	2–4	> 8 days	

\*Duration of effect is related to the dose.

**Diuretics.** Diuretics are medications used to increase the rate of urine production and the removal of excess extracellular fluid from the body. Of the types of diuretics prescribed for patients with edema from HF, three are most common: thiazide, loop, and potassium-sparing diuretics. These medications are classified according to their site of action in the kidney and their effects on renal electrolyte excretion and reabsorption. Thiazide diuretics, such as metolazone (Mykrox, Zaroxolyn), inhibit sodium and chloride reabsorption mainly in the early distal tubules. They also increase potassium and bicarbonate excretion. Loop diuretics, such as furosemide (Lasix), inhibit sodium and chloride reabsorption mainly in the ascending loop of Henle. Patients with signs and symptoms of fluid overload should be started on a diuretic, a thiazide for those with mild symptoms or a loop diuretic for patients with more severe symptoms or with renal insufficiency (Brater, 1998). Both types of diuretics may be used for those in severe HF

and unresponsive to a single diuretic. These medications may not be necessary if the patient responds to activity recommendations, avoidance of excessive fluid intake (<2 quarts/day), and a low-sodium diet (eg, <2 g/day).

Spirolactone (Aldactone) is a potassium-sparing diuretic that inhibits sodium reabsorption in the late distal tubule and collecting duct. It has been found to be effective in reducing mortality and morbidity in NYHA class III and IV HF patients when added to ACE-Is, loop diuretics, and digoxin. Serum creatinine and potassium levels are monitored frequently (eg, within the first week and then every 4 weeks) when this medication is first administered.

Side effects of diuretics include electrolyte imbalances, symptomatic hypotension (especially with overdiuresis), hyperuricemia (causing gout), and ototoxicity. Dosages depend on the indications, patient age, clinical signs and symptoms, and renal function. Table 30-4 lists commonly used diuretics, dosages, and pharma-

**Table 30-4 • Diuretic Medications Used to Treat Heart Failure**

DIURETIC	USUAL ADULT DOSE	ONSET (HR)	PEAK (HR)	DURATION (HR)
<b>Thiazide Diuretics</b>				
bendroflumethiazide (Naturetin)	2.5–20 mg in single or divided dose, once a day, once every other day, or once a day for 3–5 days per week	2	4	12–16
benzthiazide (Exna)	12.5–200 mg in single or divided dose	2	4–6	16–18
chlorothiazide (Diuril)	Oral: 0.25–2 g as single or divided dose; may be given on alternate days IV: 0.5–1 g in single or divided dose (note: avoid extravasation)	2 15 min	4 30 min	16–18
chlorthalidone (Hygroton)	12.5–200 mg once a day, once every other day, or once a day for 3 days per week	2	2–6	24–72
hydrochlorothiazide (HydroDIURIL, Esidrix, Oretic)	12.5–200 mg as single or divided dose once a day, once every other day, or once a day for 3–5 days per week	2	4–6	12–16
hydroflumethiazide (Diucardin, Saluron)	25–200 mg as single or divided dose once a day, once every other day, or once a day for 3–5 days per week	2	4	12–16
methylclothiazide (Enduron)	2.5–10 mg once a day	2	6	24
metolazone (Zaroxolyn, Mykrox)	Zaroxolyn: 2.5–20 mg once a day Mykrox: 0.5–1 mg once a day	1	2	12–24
polythiazide (Renese)	1–4 mg once a day, once every other day, or once a day for 3–5 days per week	2	6	24–28
quinethazone (Hydromox)	25–100 mg as single or divided dose; rarely, 200 mg once a day	2	6	18–24
trichlormethiazide (Metahydrin, Naqua)	1–4 mg once or twice a day	2	6	24
<b>Loop Diuretics</b>				
bumetanide (Bumex)	0.5–2 mg once, twice or three times a day; may be given on alternate days or once every 3 days	30–60 min	1–2	4–6
	0.5–1 mg over 2 min; repeat every 2–3 h; a continuous infusion may be given at a rate of 1 mg/h.	5–10 min	15–30 min	½–1
ethacrynic acid (Edecrin)	50–400 mg as single or divided dose	<30 min	2	6–8
	0.5–1 mg/kg (max 100 mg) over several min; may be repeated within 2–6 h; repeat every hour in emergencies	<5 min	15–30 min	2
furosemide (Lasix)	20–600 mg as single daily dose, divided daily dose, as a dose given every other day or given once a day for 2–4 days per week	<1	1–2	6–8
	20–200 mg (max 6 mg/kg) given at a rate of 4 mg/min; after response obtained, given once or twice a day	<5 min	30 min	2
toremide (Demadex)	5–200 mg as a daily single dose	<1	1–2	6–8
	IV and oral doses are equivalent. Give IV over 2 min.	<10 min	<1	6–8
<b>Potassium-Sparing Diuretics</b>				
amiloride (Midamor)	5–20 mg daily as single dose	2	6–10	24
spironolactone (Aldactone)	25–400 mg as single dose or divided up to 4 doses	24–48	48–72	48–72
triamterene (Dyrenium)	50–300 mg as single dose	2–4	6–8	12–16

cokinetic properties. Careful patient monitoring and dose adjustments are necessary to balance the effectiveness with the side effects of therapy. Diuretics greatly improve the patient's symptoms, but they do not prolong life.

**Digitalis.** The most commonly prescribed form of digitalis for patients with HF is digoxin (Lanoxin). The medication increases the force of myocardial contraction and slows conduction through the AV node. It improves contractility, increasing left ventricular output. The medication also enhances diuresis, which removes fluid and relieves edema. The effect of a given dose of medication depends on the state of the myocardium, electrolyte and fluid

balance, and renal and hepatic function. Although digitalis does not decrease the mortality rate, it is effective in decreasing the symptoms of systolic HF and in increasing the patient's ability to perform activities of daily living (Digitalis Investigation Group, 1997). It also has been shown to significantly decrease hospitalization rates and emergency room visits for NYHA class II and III HF patients (Uretsky et al., 1993).

A key concern associated with digitalis therapy is digitalis toxicity. Chart 30-3 summarizes the actions and uses of digitalis along with the nursing surveillance required when it is administered. The patient is observed for the effectiveness of digitalis therapy: lessening dyspnea and orthopnea, decrease in pulmonary

### Chart 30-3 • PHARMACOLOGY Digoxin Use and Toxicity in Heart Failure

Digoxin, a cardiac glycoside derived from digitalis, is used for patients with systolic HF, atrial fibrillation, and atrial flutter. Digoxin improves cardiac function as follows:

- Increases the force of myocardial contraction
- Slows cardiac conduction through the AV node and therefore slows the ventricular rate in instances of supraventricular dysrhythmias
- Increases cardiac output by enhancing the force of ventricular contraction
- Promotes diuresis by increasing cardiac output.

The therapeutic level is usually 0.5 to 2.0 ng/mL. Blood samples are usually obtained and analyzed to determine digitalis concentration at least 6 to 10 hours after the last dose. Toxicity may occur despite normal serum levels, and recommended dosages vary considerably.

#### Preparations

##### Digoxin

- Tablets: 0.125, 0.25, 0.5 mg (Lanoxin)
- Capsules: 0.05, 0.1, 0.2 mg (Lanoxicaps)
- Elixir: 0.05 mg/mL (Lanoxin Pediatric elixir)
- Injection: 0.25 mg/mL, 0.1 mg/mL (Lanoxin)

#### Digoxin Toxicity

A serious complication of digoxin therapy is toxicity. The incidence is high, and toxicity may occur even though the serum digoxin level remains within a normal range. Diagnosis of digoxin toxicity is based on the patient's clinical symptoms, which include the following:

- Fatigue, depression, malaise, anorexia, nausea, and vomiting (early effects of digitalis toxicity)
- Changes in heart rhythm: new onset of regular rhythm or new onset of irregular rhythm
- ECG changes indicating SA or AV block; new onset of irregular rhythm indicating ventricular dysrhythmias; and atrial tachycardia with block, junctional tachycardia, and ventricular tachycardia

#### Reversal of Toxicity

Digoxin toxicity is treated by holding the medication while monitoring the patient's symptoms and serum digoxin level. If the toxicity is severe, digoxin immune FAB (Digibind) may be prescribed. Digibind binds with digoxin and makes it unavailable for use. The Digibind dosage is based on the digoxin level and the patient's weight. Serum digoxin values are not accurate for several days after administration of Digibind because they do not differentiate between bound and unbound digoxin. Because Digibind quickly decreases the amount of available digoxin, an increase in ventricular rate due to atrial fibrillation and worsening of symptoms of HF may ensue shortly after its administration.

#### Nursing Considerations and Actions

1. Assess the patient's clinical response to digoxin therapy by evaluating relief of symptoms such as dyspnea, orthopnea, crackles, hepatomegaly, and peripheral edema.

2. Monitor serum potassium levels in patients receiving digoxin, especially those receiving both digoxin and diuretics. *An undetected, uncorrected potassium imbalance predisposes patients to digoxin toxicity and dysrhythmias.*

3. Assess for symptoms of electrolyte depletion: lassitude, apathy, mental confusion, anorexia, decreasing urinary output, azotemia.

4. Monitor the patient for factors that increase the risk of toxicity:

- Oral antibiotics, quinidine, amiodarone, calcium channel blocker therapy (See Table 27-1).
- Decreased potassium level (hypokalemia), which increases the action of digoxin and which may be caused by malnutrition, diarrhea, vomiting, or prolonged muscle wasting
- Impaired renal function, particularly in patients age 65 and older with decreased renal clearance.

5. Before administering digoxin, it is standard nursing practice to assess apical heart rate. When the patient's rhythm is atrial fibrillation and the heart rate is less than 60, or the rhythm becomes regular, the nurse may withhold the medication and notify the physician, because these signs indicate the development of AV conduction block. Although withholding digoxin is a common practice, the medication does not need to be withheld for a heart rate of less than 60 if the patient is in sinus rhythm because digoxin does not affect sinoatrial node automaticity. Measuring the PR interval for a patient with cardiac monitoring is more important than the apical pulse in determining whether digoxin should be held.

**Note:** If monitoring discloses that the patient is in sinus rhythm, the nurse monitors the patient's PR interval instead of the patient's heart rate. If the patient is in atrial fibrillation, the nurse monitors for the development of regular R-R intervals, indicating AV block.

6. Monitor for gastrointestinal side effects: anorexia, nausea, vomiting, abdominal pain and distention.

7. Monitor for neurologic side effects: headache, malaise, nightmares, forgetfulness, social withdrawal, depression, agitation, confusion, paranoia, hallucinations, decreased visual acuity, yellow or green halo around objects (especially lights), or "snowy" vision.

8. Observe for and anticipate potential drug interactions when other medications are added to the patient's regimen. This is an important step in preventing toxicity. For example, antiarrhythmic and antibiotic medications may increase the amount of digoxin available to the patient. Diuretics may decrease the amount of potassium and increase the availability of digoxin. In addition, because digoxin is eliminated by the kidneys, renal function (serum creatinine and urine creatinine clearance) are monitored carefully.

crackles on auscultation, relief of peripheral edema, weight loss, and increase in activity tolerance. The serum potassium level is measured at intervals because diuresis may have caused hypokalemia. The effect of digitalis is enhanced in the presence of hypokalemia, so digitalis toxicity may occur. Serum digoxin levels are obtained once each year or more frequently if there have been changes in the patient's medications, renal function, or symptoms.

**Calcium Channel Blockers.** First-generation calcium channel blockers, such as verapamil (Calan, Isoptin, Verelan), nifedipine (Adalat, Procardia), and diltiazem (Cardizem, Dilacor, Tiazac), are contraindicated in patients with systolic dysfunction, although they may be used in patients with diastolic dysfunction. Amlodipine (Norvasc) and felodipine (Plendil), dihydropyridine calcium channel blockers, cause vasodilation, reducing systemic vascular resistance. They may be used to improve symptoms especially in patients with nonischemic cardiomyopathy, although they have no effect on mortality.

**Other Medications.** Anticoagulants may be prescribed, especially if the patient has a history of an embolic event or atrial fibrillation or mural thrombus is present. Other medications such as anti-anginal medications may be given to treat the underlying cause of HF. Nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen (Aleve, Advil, Motrin) should be avoided (Page & Henry, 2000). They can increase systemic vascular resistance and decrease renal perfusion, especially in the elderly. For similar reasons, use of decongestants should be avoided.

### NUTRITIONAL THERAPY

A low-sodium ( $\leq 2$  to 3 g/day) diet and avoidance of excessive amounts of fluid are usually recommended. Although it has not been shown to affect the mortality rate, this recommendation reduces fluid retention and the symptoms of peripheral and pulmonary congestion. The purpose of sodium restriction is to decrease the amount of circulating volume, which would decrease the need for the heart to pump that volume. A balance needs to be achieved between the ability of the patient to alter the diet and the amount of medications that are prescribed. Any change in diet needs to be done with consideration of good nutrition as well as the patient's likes, dislikes, and cultural food patterns.

**NURSING ALERT** The sources of sodium should be specified in describing the regimen, rather than simply saying “low-salt” or “salt-free,” and the quantity should be indicated in milligrams. Salt is not 100% sodium; there are 393 mg of sodium in 1 g (1000 mg) of salt.

### Nursing Management

The nurse is responsible for administering the medications and for assessing their beneficial and detrimental effects to the patient. It is the balance of these effects that determines the type and dosage of pharmacologic therapy. Nursing actions to evaluate therapeutic effectiveness include the following:

- Keeping an intake and output record to identify a negative balance (more output than input)
- Weighing the patient daily at the same time and on the same scale, usually in the morning after urination; monitoring for a 2- to 3-lb gain in a day or 5-lb gain in week
- Auscultating lung sounds at least daily to detect an increase or decrease in pulmonary crackles

- Determining the degree of JVD
- Identifying and evaluating the severity of dependent edema
- Monitoring pulse rate and blood pressure, as well as monitoring for postural hypotension and making sure that the patient does not become hypotensive from dehydration
- Examining skin turgor and mucous membranes for signs of dehydration
- Assessing symptoms of fluid overload (eg, orthopnea, paroxysmal nocturnal dyspnea, and dyspnea on exertion) and evaluating changes

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Profuse and repeated diuresis can lead to hypokalemia (ie, potassium depletion). Signs are weak pulse, faint heart sounds, hypotension, muscle flabbiness, diminished deep tendon reflexes, and generalized weakness. Hypokalemia poses new problems for the patient with HF because it markedly weakens cardiac contractions. In patients receiving digoxin, hypokalemia can lead to digitalis toxicity. Digitalis toxicity and hypokalemia increase the likelihood of dangerous dysrhythmias (see Chart 30-3). Low levels of potassium may also indicate a low level of magnesium, which can add to the risk for dysrhythmias. Hyperkalemia may also occur, especially with the use of ACE-Is or ARBs and spironolactone.

**NURSING ALERT** To reduce the risk for hypokalemia, the nurse advises patients to increase their dietary intake of potassium. Dried apricots, bananas, beets, figs, orange or tomato juice, peaches, and prunes (dried plums), potatoes, raisins, spinach, squash, and watermelon are good dietary sources of potassium. An oral potassium supplement (potassium chloride) may also be prescribed for patients receiving diuretic medications. If the patient is at risk for hyperkalemia, the nurse advises the patient to avoid the above products, including salt substitutes.

**NURSING ALERT** Grapefruit (fresh and juice) is a good dietary source of potassium but has serious drug–food interactions. Patients are advised to consult their physician or pharmacist before including grapefruit in their diet.

Prolonged diuretic therapy may also produce hyponatremia (deficiency of sodium in the blood), which results in apprehension, weakness, fatigue, malaise, muscle cramps and twitching, and a rapid, thready pulse.

**NURSING ALERT** Periodic assessment of the patient's electrolyte levels will alert health team members to hypokalemia, hypomagnesemia, and hyponatremia. Serum levels are assessed frequently when the patient starts diuretic therapy and then usually every 3 to 12 months. It is important to remember that serum potassium levels do not always indicate the total amount of potassium within the body.

Other problems associated with diuretic administration are hyperuricemia (excessive uric acid in the blood), volume depletion from excessive urination, and hyperglycemia.

### Gerontologic Considerations

Several normal changes that occur with aging increase the frequency of diastolic HF: increased systolic blood pressure, increased ventric-

ular wall thickness, increased atrial size, and increased myocardial fibrosis. Elderly people may present with atypical signs and symptoms: fatigue, weakness, and somnolence. Decreased renal function makes the elderly patient resistant to diuretics and more sensitive to changes in volume, especially with diastolic dysfunction. The administration of diuretics to elderly men requires nursing surveillance for bladder distention caused by urethral obstruction from an enlarged prostate gland. The bladder may be assessed with an ultrasound scanner, or the suprapubic area palpated for an oval mass and percussed for dullness, indicative of bladder fullness,

## NURSING PROCESS: THE PATIENT WITH HEART FAILURE

### Assessment

The nursing assessment for the patient with HF focuses on observing for effectiveness of therapy and for the patient's ability to understand and implement self-management strategies. Signs and symptoms of pulmonary and systemic fluid overload are recorded and reported immediately so that adjustments can be made in therapy. The nurse also explores the patient's emotional response to the diagnosis of HF, a chronic illness.

### HEALTH HISTORY

The nurse explores sleep disturbances, particularly sleep suddenly interrupted by shortness of breath. The nurse also asks about the number of pillows needed for sleep (an indication of orthopnea), activities of daily living, and the activities that cause shortness of breath. The nurse also explores the patient's understanding of HF, the self-management strategies, and the desire to adhere to those strategies. The nurse helps patients to identify things that they have lost because of the diagnosis, their emotional response to that loss, and successful coping skills that they have used previously. Family and significant others are often included in these discussions.

### PHYSICAL EXAMINATION

The lungs are auscultated to detect crackles and wheezes or their absence. Crackles, which are produced by the sudden opening of small airways and alveoli that have adhered together by edema and exudate, may be heard at the end of inspiration and are not cleared with coughing. They may also sound like gurgling that may clear with coughing or suctioning. The rate and depth of respirations are also documented.

The heart is auscultated for an  $S_3$  heart sound, a sign that the heart is beginning to fail and that increased blood volume remains in the ventricle with each beat. HR and rhythm are also documented. Rapid rates indicate that SV has decreased and that the ventricle has less time to fill, producing some blood stagnation in the atria and eventually in the pulmonary bed.

JVD is also assessed; distention greater than 3 cm above the sternal angle is considered abnormal. This is an estimate, not a precise measurement, of central venous pressure.

Sensorium and level of consciousness must be evaluated. As the volume of blood ejected by the heart decreases, so does the amount of oxygen transported to the brain.

The nurse makes sure that dependent parts of the patient's body are assessed for perfusion and edema. With significant decreases in SV, there is a decrease in perfusion to the periphery, causing the skin to feel cool and appear pale or cyanotic. If the patient is sitting upright, the feet and lower legs are examined for edema; if the patient is supine in bed, the sacrum and back are assessed for edema. Fingers and hands may also become edematous.

In extreme cases of HF, the patient may develop periorbital edema, in which the eyelids may swell shut.

The liver is assessed for hepatojugular reflux. The patient is asked to breathe normally while manual pressure is applied over the right upper quadrant of the abdomen for 30 to 60 seconds. If neck vein distention increases more than 1 cm, the test finding is positive for increased venous pressure.

If the patient is hospitalized, the nurse measures output carefully to establish a baseline against which to measure the effectiveness of diuretic therapy. Intake and output records are rigorously maintained. It is important to know whether the patient has ingested more fluid than he or she has excreted (positive fluid balance), which is then correlated with a gain in weight. The patient must be monitored for oliguria (diminished urine output, <400 mL/24 hours) or **anuria** (urine output <50 mL/24 hours).

The patient is weighed daily in the hospital or at home, at the same time of day, with the same type of clothing, and on the same scale. If there is a significant change in weight (ie, 2- to 3-lb increase in a day or 5-lb increase in a week), the patient is instructed to notify the physician or adjust the medications (eg, increase the diuretic dose).

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses for the patient with HF may include the following:

- Activity intolerance (or risk for activity intolerance) related to imbalance between oxygen supply and demand because of decreased CO
- Excess fluid volume related to excess fluid or sodium intake and retention of fluid because of HF and its medical therapy
- Anxiety related to breathlessness and restlessness from inadequate oxygenation
- Powerlessness related to inability to perform role responsibilities because of chronic illness and hospitalizations
- Noncompliance related to lack of knowledge

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include the following:

- Cardiogenic shock (see also Chap. 15)
- Dysrhythmias (see Chap. 27)
- Thromboembolism (see Chap. 31)
- Pericardial effusion and cardiac tamponade (see also Chap. 29)

## Planning and Goals

Major goals for the patient may include promoting activity and reducing fatigue, relieving fluid overload symptoms, decreasing the incidence of anxiety or increasing the patient's ability to manage anxiety, teaching the patient about the self-care program, and encouraging the patient to verbalize his or her ability to make decisions and influence outcomes.

## Nursing Interventions

### PROMOTING ACTIVITY TOLERANCE

Although prolonged bed rest and even short periods of recumbency promote diuresis by improving renal perfusion, they also promote

decreased activity tolerance. Prolonged bed rest, which may be self-imposed, should be avoided because of the deconditioning effects and hazards, such as pressure ulcers (especially in edematous patients), phlebotrombosis, and pulmonary embolism. An acute event that causes severe symptoms or that requires hospitalization indicates the need for initial bed rest. Otherwise, a total of 30 minutes of physical activity three to five times each week should be encouraged (Georgiou et al., 2001). The nurse and patient can collaborate to develop a schedule that promotes pacing and prioritization of activities. The schedule should alternate activities with periods of rest and avoid having two significant energy-consuming activities occur on the same day or in immediate succession.

Before undertaking physical activity, the patient should be given the following safety guidelines:

- Begin with a few minutes of warm-up activities.
- Avoid performing physical activities outside in extreme hot, cold, or humid weather.
- Ensure that you are able to talk during the physical activity; if you are unable to do so, decrease the intensity of activity.
- Wait 2 hours after eating a meal before performing the physical activity.
- Stop the activity if severe shortness of breath, pain, or dizziness develops.
- End with cool-down activities and a cool-down period.

Because some patients may be severely debilitated, they may need to perform physical activities only 3 to 5 minutes at a time, one to four times per day. The patient then should be advised to increase the duration of the activity, then the frequency, before increasing the intensity of the activity (Meyer, 2001).

Barriers to performing an activity are identified, and methods of adjusting an activity to ensure pacing but still accomplish the task are discussed. For example, objects that need to be taken upstairs can be put in a basket at the bottom of the stairs throughout the day. At the end of the day, the person can carry the objects up the stairs all at once. Likewise, the person can carry cleaning supplies around in a basket or backpack rather than walk back and forth to obtain the items. Vegetables can be chopped or peeled while sitting at the kitchen table rather than standing at the kitchen counter. Small, frequent meals decrease the amount of energy needed for digestion while providing adequate nutrition. The nurse helps the patient to identify peak and low periods of energy and plan energy-consuming activities for peak periods. For example, the person may prepare the meals for the entire day in the morning. Pacing and prioritizing activities help maintain the patient's energy to allow participation in regular physical activity (see Chap. 28).

The patient's response to activities needs to be monitored. If the patient is hospitalized, vital signs and oxygen saturation level are monitored before, during, and immediately after an activity to identify whether they are within the desired range. Heart rate should return to baseline within 3 minutes. If the patient is at home, the degree of fatigue felt after the activity can be used as assessment of the response. If the patient tolerates the activity, short-term and long-term goals can be developed to gradually increase the intensity, duration, and frequency of activity. Referral to a cardiac rehabilitation program may be needed, especially for HF patients with recent myocardial infarction, recent open-heart surgery, or increased anxiety. A supervised program may also benefit those who need the structured environment, significant educational support, regular encouragement, and interpersonal contact.

## MANAGING FLUID VOLUME

Patients with severe HF may receive intravenous diuretic therapy, but patients with less severe symptoms may receive oral diuretic medication (see Table 30-4 for a summary of common diuretics). Oral diuretics should be administered early in the morning so that diuresis does not interfere with the patient's nighttime rest. Discussing the timing of medication administration is especially important for patients, such as elderly people, who may have urinary urgency or incontinence. A single dose of a diuretic may cause the patient to excrete a large volume of fluid shortly after administration.

The nurse monitors the patient's fluid status closely—auscultating the lungs, monitoring daily body weights, and assisting the patient to adhere to a low-sodium diet by reading food labels and avoiding high-sodium foods such as canned, processed, and convenience foods (Chart 30-4). If the diet includes fluid restriction, the nurse can assist the patient to plan the fluid intake throughout the day while respecting the patient's dietary preferences. If the patient is receiving intravenous fluids, the

Chart  
30-4

### Facts About Dietary Sodium

Although the major source of sodium in the average American diet is salt, many types of natural foods contain varying amounts of sodium. Even if no salt is added in cooking and if salty foods are avoided, the daily diet may still contain between 1000 and 2000 mg of sodium.

#### Additives in Food

Added food substances (additives), such as sodium alginate, which improves food texture; sodium benzoate, which acts as a preservative; and disodium phosphate, which improves cooking quality in certain foods, increase the sodium intake when included in the daily diet. Therefore, patients on low-sodium diets should be advised to check labels carefully for such words as "salt" or "sodium," especially on canned foods. For example, without looking at the sodium content per serving found on the nutrition labels, when given a choice between a serving of salt and vinegar potato chips and a cup of canned cream of mushroom soup, most would think that soup is lower in sodium. However, when the labels are examined, the lower sodium choice is found to be the chips. Although potato chips are *not* recommended in a low sodium diet, this example illustrates that it is important to read food labels to determine both sodium content and serving size.

#### Nonfood Sodium Sources

Sodium is also contained in toothpaste and municipal water. Patients on sodium-restricted diets should be cautioned against using non-prescription medications such as antacids, cough syrups, laxatives, sedatives, or salt substitutes, because these products contain sodium or excessive amounts of potassium. Over-the-counter medications should not be used without first consulting the physician.

#### Promoting Dietary Adherence

If patients find food unpalatable because of the dietary sodium restrictions and/or the taste disturbances caused by the medications, they may refuse to eat or to comply with the dietary regimen. For this reason, severe sodium restrictions should be avoided and the amount of medication should be balanced with the patient's ability to restrict dietary sodium. A variety of flavorings, such as lemon juice, vinegar, and herbs, may be used to improve the taste of the food and increase acceptance of the diet. The patient's food preferences should be taken into account—diet counseling and educational handouts can be geared to individual and ethnic preferences. It is very important to involve the family in the dietary teaching.

amount of fluid needs to be monitored closely, and the physician or pharmacist can be consulted about the possibility of maximizing the amount of medication in the same amount of intravenous fluid (eg, double-concentrating to decrease the fluid volume administered).

The nurse positions the patient or teaches the patient how to assume a position that shifts fluid away from the heart. The number of pillows may be increased, the head of the bed may be elevated (20- to 30-cm [8- to 10-inch] blocks may be used), or the patient may sit in a comfortable armchair. In this position, the venous return to the heart (preload) is reduced, pulmonary congestion is alleviated, and impingement of the liver on the diaphragm is minimized. The lower arms are supported with pillows to eliminate the fatigue caused by the constant pull of their weight on the shoulder muscles.

The patient who can breathe only in the upright position may sit on the side of the bed with the feet supported on a chair, the head and arms resting on an overbed table, and the lumbosacral spine supported by a pillow. If pulmonary congestion is present, positioning the patient in an armchair is advantageous, because this position favors the shift of fluid away from the lungs.

Because decreased circulation in edematous areas increases the risk of skin injury, the nurse assesses for skin breakdown and institutes preventive measures. Frequent changes of position, positioning to avoid pressure, the use of elastic compression stockings, and leg exercises may help to prevent skin injury.

### CONTROLLING ANXIETY

Because patients in HF have difficulty maintaining adequate oxygenation, they are likely to be restless and anxious and feel overwhelmed by breathlessness. These symptoms tend to intensify at night. Emotional stress stimulates the sympathetic nervous system, which causes vasoconstriction, elevated arterial pressure, and increased heart rate. This sympathetic response increases the amount of work that the heart has to do. By decreasing anxiety, the patient's cardiac work also is decreased. Oxygen may be administered during an acute event to diminish the work of breathing and to increase the patient's comfort.

When the patient exhibits anxiety, the nurse takes steps to promote physical comfort and psychological support. In many cases, a family member's presence provides reassurance. To help decrease the patient's anxiety, the nurse should speak in a slow, calm, and confident manner and maintain eye contact. When necessary, the nurse should also state specific, brief directions for an activity.

After the patient is comfortable, the nurse can begin teaching ways to control anxiety and to avoid anxiety-provoking situations. The nurse explains how to use relaxation techniques and assists the patient to identify factors that contribute to anxiety. Lack of sleep may increase anxiety, which may prevent adequate rest. Other contributing factors may include misinformation, lack of information, or poor nutritional status. Promoting physical comfort, providing accurate information, and teaching the patient to perform relaxation techniques and to avoid anxiety-triggering situations may relax the patient.

In cases of confusion and anxiety reactions that affect the patient's safety, the use of restraints should be avoided. Restraints are likely to be resisted, and resistance inevitably increases the cardiac workload. The patient who insists on getting out of bed at night can be seated comfortably in an armchair. As cerebral and systemic circulation improves, the degree of anxiety decreases, and the quality of sleep improves.

### MINIMIZING POWERLESSNESS

Patients need to recognize that they are not helpless and that they can influence the direction of their lives and the outcomes of treatment. The nurse assesses for factors contributing to a sense of powerlessness and intervenes accordingly. Contributing factors may include lack of knowledge and lack of opportunities to make decisions, particularly if health care providers and family members behave in maternalistic or paternalistic ways. If the patient is hospitalized, hospital policies may promote standardization and limit the patient's ability to make decisions (eg, what time to have meals, take medications, prepare for bed).

Taking time to listen actively to patients often encourages them to express their concerns and ask questions. Other strategies include providing the patient with decision-making opportunities, such as when activities are to occur or where objects are to be placed, and increasing the frequency and significance of those opportunities over time; providing encouragement while identifying the patient's progress; and assisting the patient to differentiate between factors that can be controlled and those that cannot. In some cases, the nurse may want to review hospital policies and standards that tend to promote powerlessness and advocate for their elimination or change (eg, limited visiting hours, prohibition of food from home, required wearing of hospital gowns).

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

The nurse provides patient education and involves the patient in implementing the therapeutic regimen to promote understanding and adherence to the plan. When the patient understands or believes that the diagnosis of HF can be successfully managed with lifestyle changes and medications, recurrences of acute HF lessen, unnecessary hospitalizations decrease, and life expectancy increases. Patients and their families need to be taught to follow the medication regimen as prescribed, maintain a low-sodium diet, perform and record daily weights, engage in routine physical activity, and recognize symptoms that indicate worsening HF. Although noncompliance is not well understood, interventions that may promote adherence include teaching to ensure accurate understanding. A summary of teaching points for the patient with HF is presented in Chart 30-5.

The patient and family members are supported and encouraged to ask questions so that information can be clarified and understanding enhanced. The nurse should be aware of cultural factors and adapt the teaching plan accordingly. Patients and their families need to be informed that the progression of the disease is influenced in part by choices made about health care and the decisions about following the treatment plan. They also need to be informed that health care providers are there to assist them in reaching their health care goals. Patients and family members need to make the decisions about the treatment plan, but they also need to understand the possible outcomes of those decisions. The treatment plan then will be based on what the patient wants, not just what the physician or other health care team members think is needed. Ultimately, the nurse needs to convey that monitoring symptoms and daily weights, restricting sodium intake, avoiding

**NURSING ALERT** Cerebral hypoxia with superimposed carbon dioxide retention may be a problem in HF, causing the patient to react to sedative-hypnotic medications with confusion and increased anxiety. Hepatic congestion may slow the liver's metabolism of medication, leading to toxicity. Sedative-hypnotic medications must be administered with caution.

Chart 30-5

## Home Care Checklist • The Patient With Heart Failure

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Identify heart failure as a chronic disease that can be managed with medications and specific self-management behaviors.	✓	✓
• Take or administer medications daily, exactly as prescribed.	✓	✓
• Monitor effects of medication.	✓	✓
• Know signs and symptoms of orthostatic hypotension and how to prevent it.	✓	✓
• Weigh self daily. <ul style="list-style-type: none"> <li>– Obtain weight at the same time each day (eg, every morning after urination).</li> <li>– Keep a record and report weight gain of <math>\geq 2\text{--}3</math> lb (0.9–1.4 kg) in 1 day or 5 lb (2.3 kg) in 1 week.</li> </ul>	✓	
• Restrict sodium intake to 2–3 g daily: adapt diet by examining nutrition labels to check sodium content per serving; avoid canned or processed foods; eat fresh or frozen foods; consult the written diet plan and the list of permitted and restricted foods; avoid salt use; and avoid excesses in eating and drinking.	✓	✓
• Review activity program. <ul style="list-style-type: none"> <li>– Participate in a daily exercise program.</li> <li>– Increase walking and other activities gradually, provided they do not cause unusual fatigue or dyspnea.</li> <li>– Conserve energies by balancing activity with rest periods.</li> <li>– Avoid activity in extremes of heat and cold, which increase the work of the heart.</li> <li>– Recognize that air conditioning may be essential in a hot, humid environment.</li> </ul>	✓	
• Develop methods to manage stress.	✓	
• Keep regular appointments with physician or clinic.	✓	✓
• Be alert for symptoms that may indicate recurring heart failure. <ul style="list-style-type: none"> <li>– Recall the symptoms experienced when illness began.</li> </ul>	✓	✓
• Report immediately to the physician or clinic any of the following: <ul style="list-style-type: none"> <li>– Gain in weight of <math>\geq 2\text{--}3</math> lb (0.9–1.4 kg) in 1 day, or 5 lb (2.3 kg) in 1 week</li> <li>– Loss of appetite</li> <li>– Unusual shortness of breath with activity</li> <li>– Swelling of ankles, feet, or abdomen</li> <li>– Persistent cough</li> <li>– Development of restless sleep; increase in number of pillows needed to sleep</li> </ul>	✓	✓

excess fluids, preventing infection with influenza and pneumococcal immunizations, avoiding noxious agents (eg, alcohol, tobacco), and participating in regular exercise all aid in preventing exacerbations of HF.

### Continuing Care

Depending on the patient's physical status and the availability of family assistance, a home care referral may be indicated for a patient who has been hospitalized. Elderly patients and those who have long-standing heart disease with compromised physical stamina often require assistance with the transition to home after hospitalization for an acute episode of HF. It is important for the home care nurse to assess the physical environment of the home. Suggestions for adapting the home environment to meet the patient's activity limitations are important. If stairs are the concern, the patient can plan the day's activities so that stair climbing is minimized; for some patients, a temporary bedroom may be set up on the main level of the home. The home care nurse collaborates with the patient and family to maximize the benefits of these changes.

The home care nurse also reinforces and clarifies information about dietary changes and fluid restrictions, the need to monitor symptoms and daily body weights, and the importance of obtaining follow-up health care. Assistance may be given in scheduling and keeping appointments as well. The patient is encouraged to gradually increase his or her self-care and responsibility for accomplishing the therapeutic regimen.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Demonstrates tolerance for increased activity
  - a. Describes adaptive methods for usual activities
  - b. Stops any activity that causes symptoms of intolerance
  - c. Maintains vital signs (pulse, blood pressure, respiratory rate, and pulse oximetry) within the targeted range
  - d. Identifies factors that contribute to activity intolerance and takes actions to avoid them
  - e. Establishes priorities for activities
  - f. Schedules activities to conserve energy and to reduce fatigue and dyspnea
2. Maintains fluid balance
  - a. Exhibits decreased peripheral and sacral edema
  - b. Demonstrates methods for preventing edema
3. Is less anxious
  - a. Avoids situations that produce stress
  - b. Sleeps comfortably at night
  - c. Reports decreased stress and anxiety
4. Makes decisions regarding care and treatment
  - a. States ability to influence outcomes
5. Adheres to self-care regimen
  - a. Performs and records daily weights
  - b. Ensures dietary intake includes no more than 2 to 3 g of sodium per day

- c. Takes medications as prescribed
- d. Reports any unusual symptoms or side effects

## ACUTE HEART FAILURE (PULMONARY EDEMA)

**Pulmonary edema** is the abnormal accumulation of fluid in the lungs. The fluid may accumulate in the interstitial spaces or in the alveoli.

### Pathophysiology

Pulmonary edema is an acute event that results from HF. It can occur acutely, such as with myocardial infarction, or it can occur as an exacerbation of chronic HF. Myocardial scarring as a result of ischemia can limit the ventricular distensibility and render it vulnerable to a sudden increase in workload. With increased resistance to left ventricular filling, the blood backs up into the pulmonary circulation. The patient quickly develops pulmonary edema, sometimes called flash pulmonary edema, from the blood volume overload in the lungs. Pulmonary edema can also be caused by noncardiac disorders, such as renal failure, liver failure, and oncologic conditions that cause the body to retain fluid. The left ventricle cannot handle the resulting hypervolemia, preventing blood from easily flowing from the left atrium into the left ventricle. This causes the pressure to increase in the left atrium. The increase in atrial pressure may result in an increase in pulmonary venous pressure, which produces an increase in hydrostatic pressure that forces fluid out of the pulmonary capillaries into the interstitial spaces and alveoli.

Impaired lymphatic drainage also contributes to the accumulation of fluid in the lung tissues. The fluid within the alveoli mixes with air, creating “bubbles” that are expelled from the mouth and nose, producing the classic symptom of pulmonary edema, frothy pink (blood-tinged) sputum. Because of the fluid within the alveoli, air cannot enter, and gas exchange is impaired. The result is hypoxemia, which is often severe. The onset may be preceded by premonitory symptoms of pulmonary congestion, but it also may develop quickly in the patient with a ventricle that has little reserve to meet increased oxygen needs.

In pulmonary edema, as well as in HF, preload, contractility, and afterload may be altered, thereby impairing CO. Technological advances (eg, impedance cardiography) have made it easier to implement effective pharmacologic therapy in treating acute pulmonary edema.

### Clinical Manifestations

As a result of decreased cerebral oxygenation, the patient becomes increasingly restless and anxious. Along with a sudden onset of breathlessness and a sense of suffocation, the patient's hands become cold and moist, the nail beds become cyanotic (bluish), and the skin turns ashen (gray). The pulse is weak and rapid, and the neck veins are distended. Incessant coughing may occur, producing increasing quantities of mucoid sputum. As pulmonary edema progresses, the patient's anxiety and restlessness increase; the patient becomes confused, then stuporous. Breathing is rapid, noisy, and moist sounding. The patient's oxygen levels (saturation) are significantly decreased. The patient, nearly suffocated by the blood-tinged, frothy fluid filling the alveoli, is literally drowning in secretions. The situation demands immediate action.

## Assessment and Diagnostic Findings

The diagnosis is made by evaluating the clinical manifestations resulting from pulmonary congestion. Most often, a chest x-ray is obtained to confirm that the pulmonary veins are engorged. Abrupt onset of signs and symptoms of left-sided HF (eg, crackles on auscultation of the lungs, flash pulmonary edema) without evidence of right-sided HF (eg, no JVD, no dependent edema) may indicate diastolic failure due to ischemia.

### Prevention

Like most complications, pulmonary edema is easier to prevent than to treat. To recognize it in its early stages, the nurse auscultates the lung fields and heart sounds, measures JVD, and assesses the degree of peripheral edema and the severity of breathlessness. A dry, hacking cough; fatigue; weight gain; development or worsening of edema; and decreased activity tolerance may be early indicators of developing pulmonary edema.

In an early stage, the condition may be corrected by placing the patient in an upright position with the feet and legs dependent, eliminating overexertion, and minimizing emotional stress to reduce the left ventricular load. A re-examination of the patient's treatment regimen and the patient's understanding of and adherence to it are also needed. The long-range approach to preventing pulmonary edema must be directed at identifying its precipitating factors.

### Medical Management

Clinical management of a patient with acute pulmonary edema due to HF is directed toward improving ventricular function and increasing respiratory exchange. These goals are accomplished through a combination of oxygen, medication therapies, and nursing support.

#### PHARMACOLOGIC THERAPY

Various treatments and medications are prescribed for pulmonary edema, among them oxygen, morphine, diuretics, and various intravenous medications.

**Oxygen Therapy.** Oxygen is administered in concentrations adequate to relieve hypoxemia and dyspnea. Usually, a face mask or non-rebreathing mask is initially used. If respiratory failure is severe or persists despite optimal management, endotracheal intubation and mechanical ventilation are required. The use of positive end-expiratory pressure (PEEP) is effective in reducing venous return, decreasing fluid movement from the pulmonary capillaries to the alveoli, and improving oxygenation. Oxygenation is monitored with pulse oximetry and by measurement of arterial blood gases.

**Morphine.** Morphine is administered intravenously in small doses (2 to 5 mg) to reduce peripheral resistance and venous return so that blood can be redistributed from the pulmonary circulation to other parts of the body. This action decreases pressure in the pulmonary capillaries and decreases seepage of fluid into the lung tissue. The effect of morphine in decreasing anxiety is also beneficial.

**Diuretics.** Diuretics promote the excretion of sodium and water by the kidneys. Furosemide (Lasix), for example, is administered intravenously to produce a rapid diuretic effect. Furosemide also causes vasodilation and pooling of blood in peripheral blood

vessels, which reduces the amount of blood returned to the heart, even before the diuretic effect. Some physicians may prescribe bumetanide (Bumex) and metolazone (Mykrox, Zaroxolyn) in place of furosemide.

**Dobutamine.** Dobutamine (Dobutrex) is an intravenous medication given to patients with significant left ventricular dysfunction. A catecholamine, dobutamine stimulates the beta<sub>1</sub>-adrenergic receptors. Its major action is to increase cardiac contractility. However, at higher amounts, it also increases the heart rate and the incidence of ectopic beats and tachydysrhythmias. Because it also increases AV conduction, care must be taken in patients who have underlying atrial fibrillation. A medication that protects the AV node, such as digitalis, a beta-blocker, or a calcium channel blocker, may be indicated before dobutamine therapy is initiated to prevent increased ventricular response rate.

**Milrinone.** Milrinone (Primacor) is a phosphodiesterase inhibitor that delays the release of calcium from intracellular reservoirs and prevents the uptake of extracellular calcium by the cells. This promotes vasodilation, decreasing preload and afterload, reducing the workload of the heart. Milrinone is administered intravenously, usually to patients who have not responded to other therapies. It is not usually used to treat patients with renal failure. The major side effects are hypotension (usually asymptomatic), gastrointestinal dysfunction, increased ventricular dysrhythmias, and decreased platelet counts. The patient's blood pressure is monitored closely.

**Nesiritide.** Nesiritide (Natrecor) is an intravenous medication that is indicated for acutely decompensated HF. Natriuretic peptides are produced by the myocardium as a compensatory response to increased ventricular end-diastolic pressure and myocardial wall stress and to the increased release of neurohormones (eg, norepinephrine, renin, aldosterone) that occur with HF. Nesiritide is a human B-type natriuretic peptide (BNP) made from *Escherichia coli* using recombinant technology. Human BNP binds to vascular smooth muscle and endothelial cells, causing dilation of arteries and veins and suppression of the neurohormones. The result is improved stroke volume and reduced preload and afterload (Colucci et al., 2000). This medication causes rapid improvement in the symptoms of HF and may be used with other HF medications (eg, beta-blockers, digoxin). The most common side effect is dose-related hypotension.

## Nursing Management

### POSITIONING THE PATIENT TO PROMOTE CIRCULATION

Proper positioning can help reduce venous return to the heart. The patient is positioned upright, preferably with the legs dangling over the side of the bed. This has the immediate effect of decreasing venous return, lowering the output of the right ventricle, and decreasing lung congestion. If the patient is unable to sit with the lower extremities dependent, the patient may be placed in an upright position in bed.

### PROVIDING PSYCHOLOGICAL SUPPORT

As the ability to breathe decreases, the patient's sense of fear and anxiety rises proportionately, making the condition more severe. Reassuring the patient and providing skillful anticipatory nursing care are integral parts of the therapy. Because this patient feels a sense of impending doom and has an unstable condition, the nurse must remain with the patient. The nurse should give the pa-

tient simple, concise information in a reassuring voice about what is being done to treat the condition and the expected results. The nurse should also identify any anxiety-inducing factors (eg, a pet left alone at home, presence of an unwelcome family member at the bedside, a wallet full of money) and initiate strategies to eliminate the concern or reduce its effect.

### MONITORING MEDICATIONS

The patient receiving morphine is observed for respiratory depression, hypotension, and vomiting; a morphine antagonist, such as naloxone hydrochloride (Narcan), is kept available and given to the patient who exhibits these side effects.

The patient receiving diuretic therapy may excrete a large volume of urine within minutes after a potent diuretic is administered. A bedside commode may be used to decrease the energy required by the patient and to reduce the resultant increase in cardiac workload induced by getting on and off a bedpan. If necessary, an indwelling urinary catheter may be inserted.

**NURSING ALERT** Because of the resulting diuresis, the patient's electrolyte levels, especially potassium and sodium, need to be monitored closely. Fluid balance in some patients is very brittle; they easily become hypovolemic or hypervolemic with small changes in the amount of circulating fluid. Falling blood pressure, increasing heart rate, and decreasing urine output indicate that the circulatory system is not tolerating diuresis and that measures must be taken to reverse the fluid imbalance that has occurred. Serum creatinine is monitored to assess renal function. Men with prostatic hyperplasia must be observed for signs of urinary retention. Additional monitoring activities are discussed in Chart 30-6.

## Other Complications

### CARDIOGENIC SHOCK

Cardiogenic shock occurs when the heart cannot pump enough blood to supply the amount of oxygen needed by the tissues. This may occur because of one significant or multiple smaller infarctions in which more than 40% of the myocardium becomes necrotic, because of a ruptured ventricle, significant valvular dysfunction, trauma to the heart resulting in myocardial contusion, or as the end stage of HF. It also can occur with cardiac tamponade, pulmonary embolism, cardiomyopathy, and dysrhythmias.

### Pathophysiology

The signs and symptoms of cardiogenic shock reflect the circular nature of the pathophysiology of HF. The degree of shock is proportional to the extent of left ventricular dysfunction. The heart muscle loses its contractile power, resulting in a marked reduction in SV and CO, which is sometimes called forward failure. The damage to the myocardium results in a decrease in CO, which reduces arterial blood pressure and tissue perfusion in the vital organs (heart, brain, lung, kidneys). Flow to the coronary arteries is reduced, resulting in decreased oxygen supply to the myocardium, which increases ischemia and further reduces the heart's ability to pump. The inadequate emptying of the ventricle also leads to increased pulmonary pressures, pulmonary congestion, and pulmonary edema, exacerbating the hypoxia, causing ischemia of vital organs, and setting a vicious cycle in motion (Fig. 30-3).

### Chart 30-6 • PHARMACOLOGY Administering and Monitoring Diuretic Therapy

When nursing care involves diuretic therapy for conditions such as pulmonary edema or heart failure, the nurse needs to administer the medication and monitor the patient's response carefully, as follows:

- Administer the diuretic at a time conducive to the patient's lifestyle; for example, early in the day to avoid nocturia.
- Give supplementary potassium with thiazide and loop diuretics as prescribed to replace potassium lost.
- Check laboratory results for electrolyte depletion, especially potassium, magnesium, and sodium; and for electrolyte elevation, especially potassium with potassium-sparing agents and calcium with thiazides.
- Monitor urine output or daily weights to identify appropriate response: intake and output balance, serum BUN and creatinine; notify the health care provider if renal impairment is suspected.
- Assess lung sounds, jugular vein distention, daily weight, and peripheral, abdominal, or sacral edema to identify need to adjust dose.
- Monitor for adverse reactions, such as nausea and gastrointestinal distress, vomiting, diarrhea, weakness, headache, fatigue, anxiety or agitation, and cardiac dysrhythmias.
- Assess for signs of volume depletion, such as postural hypotension, dizziness, imbalance, and reduced jugular venous distention (JVD).
- Monitor for glucose intolerance in patients with and without diabetes mellitus who are receiving thiazide diuretics.
- Monitor for potential ototoxicity in patients, especially those with renal failure, who are receiving a loop diuretic.
- Advise patients to avoid prolonged exposure to the sun because of the risk of photosensitivity.
- Monitor for elevated serum uric acid levels and the development of gout.
- Implement nursing actions to facilitate effect of medication, such as positioning patient upright with legs dangling.

## Clinical Manifestations

The classic signs of cardiogenic shock are tissue hypoperfusion manifested as cerebral hypoxia (restlessness, confusion, agitation), low blood pressure, rapid and weak pulse, cold and clammy skin, increased respiratory crackles, hypoactive bowel sounds, and decreased urinary output. Initially, arterial blood gas analysis may show respiratory alkalosis. Dysrhythmias are common and result from a decrease in oxygen to the myocardium.

## Assessment and Diagnostic Findings

Use of a PA catheter to measure left ventricular pressures and CO is important in assessing the severity of the problem and planning management. The PA wedge pressure is elevated and the CO decreased as the left ventricle loses its ability to pump. The systemic vascular resistance is elevated because of the sympathetic nervous system stimulation that occurs as a compensatory response to the decrease in blood pressure. The decreased blood flow to the kidneys causes a hormonal response (ie, increased catecholamines and activation of the renin-angiotensin-aldosterone system) that causes fluid retention and further vasoconstriction. Increases in HR, circulating volume, and vasoconstriction occur to maintain circulation to the brain, heart, kidneys, and lungs, but at a cost: an increase in the workload of the heart.

The reduction in blood volume delivered to the tissues results in an increase in the amount of oxygen that is extracted from the blood that is delivered to the tissues (to try to meet the cellular demand for oxygen). The increased systemic oxygen extraction results in decreased venous (mixed and central) oxygen saturation. When the cellular oxygen needs cannot be met by the systemic oxygen delivery and the oxygen extraction, anaerobic metabolism and the resulting build up of lactic acid occur. Continuous central venous oximetry and measurement of blood lactic acid levels may assist in assessing the severity of the shock as well as the effectiveness of treatment.

Continued cellular hypoperfusion eventually results in organ failure. The patient becomes unresponsive, severe hypotension ensues, and the patient develops shallow respirations; cold, cyanotic or mottled skin; and absent bowel sounds. Arterial blood gas analysis shows metabolic acidosis, and all laboratory test results indicate organ dysfunction. Chapter 15 presents in more detail the pathophysiology and management of cardiogenic shock.

## Physiology/Pathophysiology

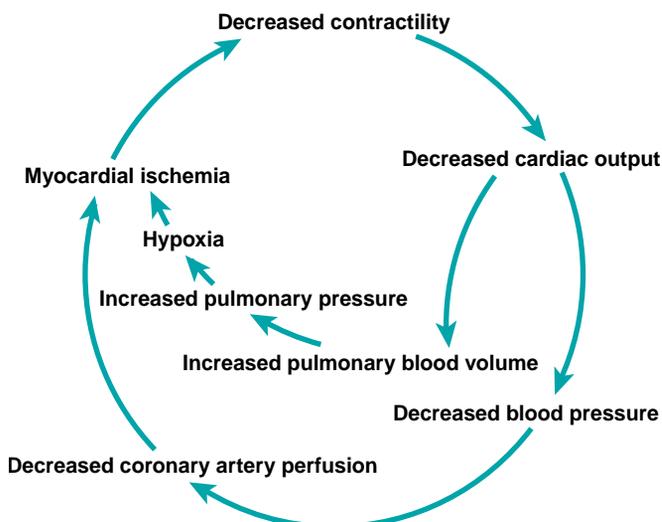

FIGURE 30-3 Pathophysiology of cardiogenic shock.

## Medical Management

The major approach to treating cardiogenic shock is to correct the underlying problems, reduce any further demand on the heart, improve oxygenation, and restore tissue perfusion. For example, if the ventricular failure is the result of an acute myocardial infarction, emergency percutaneous coronary intervention may be indicated (Webb et al., 2001). Ventricular assist devices may be implanted to support the pumping action of the heart (Barron et al., 2001) (see Chap. 29). Major dysrhythmias are corrected because they may have caused or contributed to the shock. If the patient has hypervolemia, diuresis is indicated. Diuretics, vasodilators, and mechanical devices, such as filtration (continuous renal replacement therapy [CRRT]) and dialysis, have been used to reduce the circulating blood volume. If hypovolemia or low intravascular volume is suspected or detected through pressure readings, the patient is given intravenous volume expanders (eg, normal saline solution, lactated Ringer's solution, albumin) to increase the amount of circulating fluid. The patient is placed on strict bedrest to conserve

energy. If the patient has hypoxemia, as detected by pulse oximetry or arterial blood gas analysis, oxygen administration is increased, often under positive pressure when regular flow is insufficient to meet tissue demands. Intubation and sedation may be necessary to maintain oxygenation. The settings for mechanical ventilation are adjusted according to the patient's oxygenation status and the need for conserving energy.

### PHARMACOLOGIC THERAPY

Medication therapy is selected and guided according to CO, other cardiac parameters, and mean arterial blood pressure. Because of the decreased perfusion to the gastrointestinal system and the need to adjust the dosage quickly, most medications are administered intravenously.

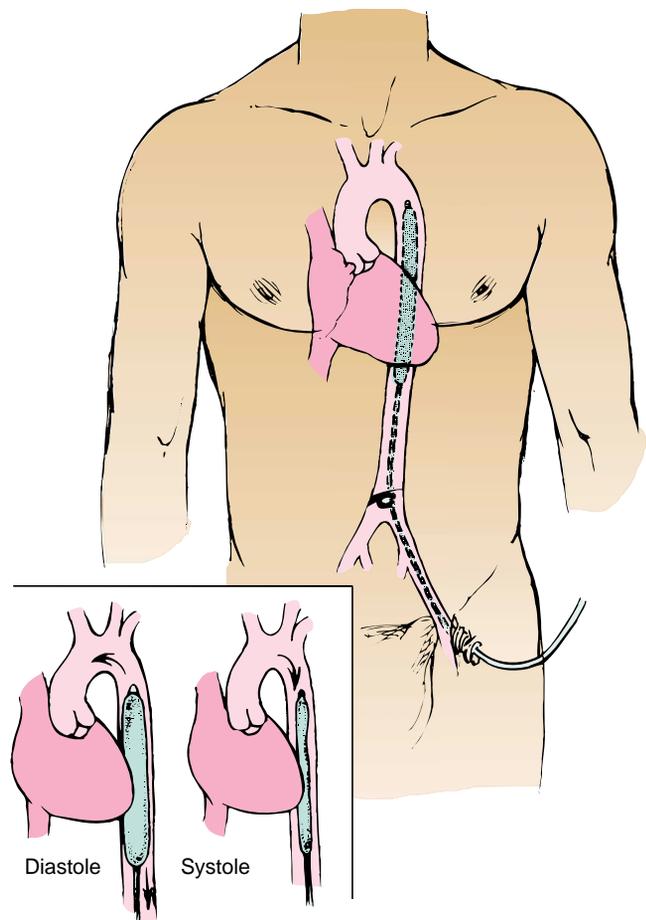

Vasopressors, or pressor agents, are medications used to raise blood pressure and increase CO. Many pressor medications are catecholamines, such as norepinephrine (Levophed) and high-dose (>10 µg/kg per minute) dopamine (Intropin). Their purpose is to promote perfusion to the heart and brain, but they compromise circulation to other organs (eg, kidney). Because they also tend to increase the workload of the heart by increasing oxygen demand, they are not administered early in the cardiogenic shock process.

Diuretics and vasodilators may be administered carefully to reduce the workload of the heart as long as they do not cause worsening of the tissue hypoperfusion. Agents such as amrinone (Inocor), milrinone (Primacor), sodium nitroprusside (Nipride), and nitroglycerin (Tridil) are effective vasoactive medications that lower the volume returning to the heart, decrease blood pressure, and decrease cardiac work. They cause the arteries and veins to dilate, thereby shunting much of the intravascular volume to the periphery and causing a reduction in preload and afterload.

Positive inotropic medications are given to increase myocardial contractility. Dopamine (Intropin, given at more than 2 µg/kg per minute), dobutamine (Dobutrex), and epinephrine (Adrenalin) are catecholamines that increase contractility. Each of these can cause tachydysrhythmias because they increase automaticity with increasing dosage. Monitoring baseline HR is therefore important. As the baseline HR increases, so does the risk of developing tachydysrhythmias.

### OTHER TREATMENTS

Other therapeutic modalities for cardiogenic shock include use of circulatory assist devices. The most frequently used mechanical support device is the intra-aortic balloon pump (IABP). The IABP is a catheter with an inflatable balloon at the end. The catheter is usually inserted through the femoral artery, and the balloon is positioned in the descending thoracic aorta (Fig. 30-4). IABP uses internal counterpulsation through the regular inflation and deflation of the balloon to augment the pumping action of the heart. The device inflates during diastole, increasing the pressure in the aorta during diastole and therefore increasing blood flow through the coronary and peripheral arteries. It deflates just before systole, lessening the pressure within the aorta before left ventricular contraction, decreasing the amount of resistance the heart has to overcome to eject blood and therefore decreasing the amount of work the heart must put forth to eject blood. The device is connected to a console that synchronizes the inflation and deflation of the balloon with the ECG or the arterial pressure (as indicators for systole and diastole). Hemodynamic monitoring is essential to determine the patient's response to the IABP. Other ventricular assist devices are described in Chapter 29.

**FIGURE 30-4** The intra-aortic balloon pump (IABP) inflates at the beginning of diastole, which results in increased perfusion of the coronary and peripheral arteries; it deflates just before systole, which results in a decrease in afterload (resistance to ejection) and in the left ventricular workload.

### Nursing Management

The patient in cardiogenic shock requires constant monitoring and intensive care. The critical care (intensive care) nurse must carefully assess the patient, observe the cardiac rhythm, monitor hemodynamic parameters, and record fluid intake and urinary output. The patient must be closely assessed for responses to the medical interventions and for the development of complications, which must be corrected immediately.

Because of the frequency of nursing interventions and the technology required for effective medical management, the patient is always treated in an intensive care environment. Critical care nurses are responsible for the nursing management, which includes frequent assessments and timely adjustments to medications and therapies based on the assessment data. More information about nursing management of the patient in cardiogenic shock can be found in Chapter 15.

### THROMBOEMBOLISM

The decreased mobility of the patient with cardiac disease and the impaired circulation that accompany these disorders contribute to the development of intracardiac and intravascular thrombosis. Intracardiac thrombus is especially common in patients with atrial fibrillation, because the atria do not contract forcefully

and blood flow slows through the atrium, increasing thrombus formation. Intracardiac thrombus is detected by an echocardiogram and treated with anticoagulants, such as heparin and warfarin (Coumadin). A part of the thrombus may become detached (embolus) and may be carried to the brain, kidneys, intestines, or lungs. The most common problem is pulmonary embolism. The symptoms of pulmonary embolism include chest pain, cyanosis, shortness of breath, rapid respirations, and hemoptysis (bloody sputum).

The pulmonary embolus may block the circulation to a part of the lung, producing an area of pulmonary infarction. Usually, there is a significant decrease in oxygenation measured by arterial blood gas analysis or pulse oximetry. Pain experienced is usually pleuritic; it increases with respiration and may subside when the patient holds the breath. Cardiac pain is usually continuous and does not vary with respirations. However, it may be difficult to differentiate by symptoms alone. The patient usually undergoes a ventilation-perfusion scan or a pulmonary arteriogram for definitive diagnosis. The treatment and care for patients with pulmonary embolism are discussed in Chapter 23.

Systemic embolism may manifest as cerebral, mesenteric, or renal infarction; an embolism can also compromise the blood supply to an extremity, which is discussed in more detail in Chapter 31. The nurse must be aware of such possible complications and be prepared to identify and report signs and symptoms.

## PERICARDIAL EFFUSION AND CARDIAC TAMPONADE

### Pathophysiology

Pericardial effusion refers to the accumulation of fluid in the pericardial sac. This occurrence may accompany pericarditis (see Chap. 29), advanced HF, metastatic carcinoma, cardiac surgery, trauma, or nontraumatic hemorrhage.

Normally, the pericardial sac contains less than 50 mL of fluid, which is needed to decrease friction for the beating heart. An increase in pericardial fluid raises the pressure within the pericardial sac and compresses the heart. This has the following effects:

- Increased right and left ventricular end-diastolic pressures
- Decreased venous return
- Inability of the ventricles to distend adequately and to fill

Pericardial fluid may accumulate slowly without causing noticeable symptoms. A rapidly developing effusion, however, can stretch the pericardium to its maximum size and, because of increased pericardial pressure, reduce venous return to the heart and decrease CO. The result is cardiac tamponade (compression of the heart).

### Clinical Manifestations

The patient may complain of a feeling of fullness within the chest or may have substantial or ill-defined pain. The feeling of pressure in the chest may result from stretching of the pericardial sac. Because of increased pressure within the pericardium, venous pressure tends to rise, as evidenced by engorged neck veins. Other signs include shortness of breath and a drop and fluctuation in blood pressure. Systolic blood pressure that is detected during exhalation but not heard with inhalation is called **pulsus paradoxus**. The difference in systolic pressure between the point that it is heard during exhalation and the point that it is heard during inhalation is measured. Pulsus paradoxus exceeding 10 mm Hg

is abnormal. The cardinal signs of cardiac tamponade are falling systolic blood pressure, narrowing pulse pressure, rising venous pressure (increased jugular venous distention), and distant (muffled) heart sounds (Chart 30-7).

**NURSING ALERT** Cardiac tamponade is a life-threatening situation, demanding immediate intervention.

## Assessment and Diagnostic Findings

Pericardial effusion is detected by percussing the chest and noticing an extension of flatness across the anterior aspect of the chest. An echocardiogram may be performed to confirm the diagnosis. The clinical signs and symptoms and chest x-ray findings are usually sufficient to diagnose pericardial effusion.

## Medical Management

### PERICARDIOCENTESIS

If cardiac function becomes seriously impaired, **pericardiocentesis** (puncture of the pericardial sac to aspirate pericardial fluid) is performed to remove fluid from the pericardial sac. The major

**Chart 30-7 • ASSESSMENT**

**Signs and Symptoms of Cardiac Tamponade**

Assessment findings in cardiac tamponade resulting from pericardial effusion include feelings of faintness, shortness of breath, anxiety, and pain from decreased cardiac output, cough from pressure created in the trachea from swelling of the pericardial sac, distended neck veins from rising venous pressure, paradoxical pulse, and muffled or distant heart sounds.

goal is to prevent cardiac tamponade, which restricts normal heart action.

During the procedure, the patient is monitored by ECG and hemodynamic pressure measurements. Emergency resuscitative equipment should be readily available. The head of the bed is elevated to 45 to 60 degrees, placing the heart in proximity to the chest wall so that the needle can be inserted into the pericardial sac more easily. If a peripheral intravenous device is not already in place, one is inserted, and a slow intravenous infusion is started in case it becomes necessary to administer emergency medications or blood products.

The pericardial aspiration needle is attached to a 50-mL syringe by a three-way stopcock. Several possible sites are used for pericardial aspiration. The needle may be inserted in the angle between the left costal margin and the xiphoid, near the cardiac apex; at the fifth or sixth intercostal space at the left sternal margin; or on the right sternal margin of the fourth intercostal space. The needle is advanced slowly until it has entered the epicardium and fluid is obtained. The ECG can help determine when the needle has contacted the epicardium. The cable of a precordial lead is attached to the aspirating needle with alligator clamps; contact with the epicardium is seen by ST segment elevation on the ECG. During the procedure, drainage fluid must be checked for clotting. Although not entirely accurate, the guideline is that pericardial blood does not clot readily, whereas blood obtained from inadvertent puncture of one of the heart chambers does clot.

A resulting fall in central venous pressure and an associated rise in blood pressure after withdrawal of pericardial fluid indicate that the cardiac tamponade has been relieved. The patient almost always feels immediate relief. If there is a substantial amount of pericardial fluid, a small catheter may be left in place to drain recurrent accumulation of blood or fluid. Pericardial fluid is sent to the laboratory for examination for tumor cells, bacterial culture, chemical and serologic analysis, and differential blood cell count.

Complications of pericardiocentesis include ventricular or coronary artery puncture, dysrhythmias, pleural laceration, gastric puncture, and myocardial trauma. After pericardiocentesis, the patient's heart rhythm, blood pressure, venous pressure, and heart sounds are monitored to detect any possible recurrence of cardiac tamponade. If it recurs, repeated aspiration is necessary. Cardiac tamponade may require treatment by open pericardial drainage (pericardiectomy). The patient is ideally in an intensive care unit.

### PERICARDIOTOMY

Recurrent pericardial effusions, usually associated with neoplastic diseases, may be treated by a **pericardiectomy** (pericardial window). The patient receives a general anesthetic, but cardiopulmonary bypass is seldom necessary. A portion of the pericardium is excised to permit the pericardial fluid to drain into the lymphatic system. Uncommonly, catheters are placed between the pericardium and abdominal cavity to drain the pericardial fluid. The nursing care is the same as that described for other cardiac surgery (see Chap. 28).

### MYOCARDIAL RUPTURE

Myocardial rupture is a rare event. However, it can occur when a myocardial infarction, infectious process, cardiac trauma, pericardial disease, or other myocardial dysfunction weakens the cardiac muscle (eg, ventricular aneurysm) substantially. Persistent elevation of the ST segment is an indication of ventricular aneurysm. In

many cases, the result of myocardial rupture is immediate death, even if the patient undergoes immediate cardiac surgery.

## CARDIAC ARREST

Cardiac arrest occurs when the heart ceases to produce an effective pulse and blood circulation. It may be caused by a cardiac electrical event, as when the HR is too fast (especially ventricular tachycardia or ventricular fibrillation) or too slow (bradycardia or AV block) or when there is no heart rate at all (asystole). Cardiac arrest may follow respiratory arrest; it may also occur when electrical activity is present but there is ineffective cardiac contraction or circulating volume, which is called **pulseless electrical activity (PEA)**. Formerly called electrical-mechanical dissociation (EMD), PEA can be caused by hypovolemia (eg, with excessive bleeding), cardiac tamponade, hypothermia, massive pulmonary embolism, medication overdoses (eg, tricyclic agents, digitalis, beta-blockers, calcium channel blockers), significant acidosis, and massive acute myocardial infarction.

### Clinical Manifestations

Consciousness, pulse, and blood pressure are lost immediately. Ineffective respiratory gasping may occur. The pupils of the eyes begin dilating within 45 seconds. Seizures may or may not occur.

The risk of irreversible brain damage and death increases with every minute from the time that circulation ceases. The interval varies with the age and underlying condition of the patient. During this period, the diagnosis of cardiac arrest must be made, and measures must be taken immediately to restore circulation.

**NURSING ALERT** The most reliable sign of cardiac arrest is the absence of a pulse. In the adult and the child, the carotid pulse is assessed. In an infant, the brachial pulse is assessed. Valuable time should not be wasted taking the blood pressure, listening for the heartbeat, or checking proper contact of electrodes.

### Emergency Management: Cardiopulmonary Resuscitation

The ABCDs of basic cardiopulmonary resuscitation (CPR) are *airway*, *breathing*, *circulation*, and *defibrillation* (Guidelines 2000 for Cardiopulmonary Resuscitation and Emergency Cardiovascular Care, 2000). Once loss of consciousness has been established, the resuscitation priority for the adult in most cases is placing a phone call to activate the code team or the emergency medical system (EMS). Exceptions to this include near drowning, drug or medication overdose, and respiratory arrest situations, for which 1 minute of CPR should be performed before activating the EMS. Because the underlying cause of arrest in an infant or child is usually respiratory, the priority is to begin CPR and then activate the EMS after 1 minute of CPR. Because the care of the pediatric patient is individualized, the following discussion on the care of a cardiac arrest patient applies only to adults.

Resuscitation consists of the following steps:

1. **Airway:** maintaining an open airway
2. **Breathing:** providing artificial ventilation by rescue breathing
3. **Circulation:** promoting artificial circulation by external cardiac compression
4. **Defibrillation:** restoring the heartbeat (see Chap. 27)

If the patient is monitored or is immediately placed on the monitor using the multifunction pads or the quick-look paddles (found on most defibrillators) and the ECG shows ventricular tachycardia or ventricular fibrillation, defibrillation rather than CPR is the treatment of choice. In this scenario, CPR is performed initially only if the defibrillator is not immediately available. The survival rate decreases by 10% for every minute that defibrillation is delayed (Guidelines, 2000). If the patient has not been defibrillated within 10 minutes, the chance of survival is close to zero. More information on defibrillation can be found in Chapter 27.

### MAINTAINING AIRWAY AND BREATHING

The first step in CPR is to obtain an open airway. Any obvious material in the mouth or throat should be removed. The chin is directed up and back, or the jaw (mandible) is lifted forward. The rescuer “looks, listens, and feels” for air movement. An oropharyngeal airway is inserted if available. Two rescue ventilations over 3 to 4 seconds are provided using a bag-mask or mouth-mask device (Fig. 30-5). An obstructed airway should be suspected when the rescuer cannot give the initial ventilations, and the Heimlich maneuver or abdominal thrusts should be administered to relieve the obstruction.

If the first rescue ventilations enter easily, the patient is ventilated with 12 breaths per minute, and the open airway is maintained. Endotracheal intubation is frequently performed by a physician, nurse anesthetist, or respiratory therapist during a resuscitation procedure (also called a code) to ensure an adequate airway and ventilation. The resuscitation bag device is then connected directly to the endotracheal tube.

Because of the risk of unrecognized esophageal intubation or dislodgement of the endotracheal tube (ET), tracheal intubation must be confirmed by one technique from each of two different methods: a primary method (visualization of the ET through the vocal cords, auscultation of breath sounds in five areas on the chest, or bilateral chest expansion) and a secondary method (an esophageal detector device [such as Ambu TubeChek] or an end-tidal CO<sub>2</sub> detector). The end-tidal CO<sub>2</sub> detectors available give qualitative (yes/no) or quantitative (measurable; ie, capnometry) results. Because delivery of CO<sub>2</sub> is low in patients in cardiopulmonary arrest, the qualitative devices are not as accurate in detecting incorrect placement as are esophageal detector devices (EDDs). There are two main types of EDD: a bulb type and a syringe type.

**FIGURE 30-5** The chin lift and bag-and-mask technique for ventilating patients who need cardiopulmonary resuscitation.

The bulb is collapsed or the plunger of the syringe compressed before its attachment to the ET; each creates a suction force at the end of the ET. If the ET is in the trachea, the presence of air in the lungs and the rigid walls of the trachea allow re-inflation of the bulb or aspiration of the syringe. If the ET is in the esophagus, the suction pulls on the unsupported walls of the esophagus, causing them to collapse and preventing the bulb from re-inflating or the syringe to aspirate. A chest x-ray, which is frequently obtained after ET placement, is helpful in determining whether the ET is too high, too low, or in a main bronchus. However, a chest x-ray cannot confirm placement of an ET. The ET may be in the esophagus or the trachea and result in the same appearance on the x-ray (Guidelines, 2000). Arterial blood gas levels are measured to guide oxygen therapy.

### RESTORING CIRCULATION

After performing ventilation, the carotid pulse is assessed and external cardiac compressions are provided when no pulse is detected. If a defibrillator is not yet available but a process has been put into place to obtain one, chest compressions are initiated. Compressions are performed with the patient on a firm surface, such as the floor, a cardiac board, or a meal tray. The rescuer (facing the patient's side) places the heel of one hand on the lower half of the sternum, two fingerwidths (3.8 cm [1.5 inches]) from the tip of the xiphoid and positions the other hand on top of the first hand (Fig. 30-6) (Guidelines, 2000). The fingers should not touch the chest wall.

Using the body weight while keeping the elbows straight, the rescuer presses quickly downward from the shoulder area to deliver a forceful compression to the victim's lower sternum about 3.8 to 5 cm (1.5 to 2 inches) toward the spine (Guidelines, 2000). The chest compression rate is 80 to 100 times per minute. If only one rescuer is available, the rate is two ventilations to every 15 cardiac compressions. When two rescuers are available, the first person performs the cardiac compressions, pausing after the fifth compression, when the second rescuer gives one ventilation over 1.5 to 2 seconds and at a tidal volume of less than 1 L.

**FIGURE 30-6** Chest compressions in cardiopulmonary resuscitation (CPR) are performed by placing the heel of one hand on the lower half of the sternum and the other hand on top of the first hand. Elbows are kept straight and body weight is used to apply quick, forceful compressions to the lower sternum. For the most effective hand placement and outcome, the patient's chest should be bare.

**Table 30-5 • Medications Used in Cardiopulmonary Resuscitation**

AGENT AND ACTION	INDICATIONS	NURSING CONSIDERATIONS
Oxygen—improves tissue oxygenation and corrects hypoxemia	Administered to all patients with acute cardiac ischemia or suspected hypoxemia, including those with COPD	<ul style="list-style-type: none"> <li>• Use 100% FiO<sub>2</sub> during resuscitation.</li> <li>• Recognize that no lung damage occurs when used for less than 24 hours.</li> <li>• Monitor dose by end-tidal CO<sub>2</sub> or pulse oximeter.</li> </ul>
Epinephrine (Adrenalin)—increases systemic vascular resistance and blood pressure; improves coronary and cerebral perfusion and myocardial contractility	Given to patients in cardiac arrest, especially caused by asystole or pulseless electrical activity; may be given if caused by ventricular tachycardia or ventricular fibrillation	<ul style="list-style-type: none"> <li>• Administer by IV push (IVP) or through the endotracheal (ET) tube.</li> <li>• Avoid adding to IV lines that contain alkaline solution (eg, bicarbonate).</li> </ul>
Atropine—blocks parasympathetic action; increases SA node automaticity and AV conduction	Given to patients with symptomatic bradycardia (hemodynamically unstable, frequent premature ventricular contractions and symptoms of ischemia)	<ul style="list-style-type: none"> <li>• Give rapidly as 2.0 to 2.5 mg IVP or through the ET tube.</li> <li>• Be aware that less than 0.5 mg in the adult can cause the heart rate to decrease to a worse bradycardia.</li> <li>• Monitor patient for reflexive tachycardia.</li> </ul>
Sodium bicarbonate (NaHCO <sub>3</sub> )—corrects metabolic acidosis	Given to correct metabolic acidosis that is refractory to standard advanced cardiac life support interventions (cardiopulmonary resuscitation, intubation, and respiratory management)	<ul style="list-style-type: none"> <li>• Administer initial dose of 1 mEq/kg IV; then administer the dose based on the base deficit calculated from arterial blood gas values.</li> <li>• Recognize that to prevent development of rebound metabolic alkalosis, complete correction of acidosis is not indicated</li> </ul>
Magnesium—promotes adequate functioning of the cellular sodium–potassium pump	Given to patients with torsades de pointes	<ul style="list-style-type: none"> <li>• May give diluted over 1–2 min or intravenous push.</li> <li>• Monitor for hypotension, asystole, bradycardia, respiratory paralysis.</li> </ul>
Vasopressin (Pitressin)—increases inotropic action (contraction) of the heart	An alternative to epinephrine when cardiac arrest is caused by ventricular tachycardia or ventricular fibrillation	<ul style="list-style-type: none"> <li>• Give 40 U IV one time only.</li> </ul>

When the code team or emergency medical personnel arrive, the patient is quickly assessed to determine cardiac rhythm and respiratory status, as well as possible causes for the arrest. The specific subsequent advanced life support interventions depend on the assessment results. For example, after the patient is placed on a cardiac monitor and ventricular fibrillation is detected, the patient will be defibrillated up to three times, and then CPR will be resumed. However, if asystole is detected on the monitor, CPR is resumed immediately while trying to identify the underlying cause, such as hypovolemia, hypothermia, or hypoxia. CPR may be stopped when the patient responds and begins to breathe, the rescuers are too exhausted or at risk (eg, the building is at risk of collapsing) to continue CPR, or signs of death are obvious. If the patient does not respond to therapies given during the arrest, the resuscitation effort may be stopped or “called” by the physician. The decision to terminate resuscitation is based on medical considerations and takes into account the underlying condition of the patient and the chances for survival.

### FOLLOW-UP MONITORING

Once successfully resuscitated, the patient is transferred to an intensive care unit for close monitoring. Continuous ECG monitoring and frequent blood pressure assessments are essential until hemodynamic stability is reestablished. Etiologic factors that precipitated the arrest, such as metabolic or rhythm abnormalities, must be identified and treated. Possible contributing factors, such as electrolyte or acid-base imbalances, need to be identified and corrected. Selected medications, as described in Table 30-5, may be used during and after resuscitation.

### Critical Thinking Exercises

**1.** Your patient is a 55-year-old man who was diagnosed last year with systolic HF (due to coronary artery disease) and was stabilized with lisinopril, Lasix, and metoprolol. He follows a low-sodium diet, with only an occasional indiscretion. He is complaining of a nagging cough. What are some of the possible causes for the cough? What would be key assessment factors that would help identify the cause? What medical treatments and nursing interventions would be appropriate for each of the possible causes?

**2.** A 77-year-old female patient was readmitted for HF for the third time in 2 months. Identify the factors that possibly contribute to her readmission and that would need to be assessed. What interventions could be implemented to prevent another readmission? Describe the interaction (ie, behaviors, words, and communication techniques) that would demonstrate the concept of partnering with the patient.

# ● Assessment and Management of Patients With Vascular Disorders and Problems of Peripheral Circulation

## **LEARNING OBJECTIVES** ●

*On completion of this chapter, the learner will be able to:*

1. Identify anatomic and physiologic factors that affect peripheral blood flow and tissue oxygenation.
2. Use appropriate parameters for assessment of peripheral circulation.
3. Use the nursing process as a framework of care for patients with circulatory insufficiency of the extremities.
4. Compare the various diseases of the arteries, their causes, pathologic and physiologic changes, clinical manifestations, management, and prevention.
5. Describe the prevention and management of venous thrombosis.
6. Compare the preventive management of venous insufficiency, leg ulcers, and varicose veins.
7. Use the nursing process as a framework of care for patients with leg ulcers.
8. Describe the relationship between lymphangitis and lymphedema.

Adequate perfusion oxygenates and nourishes body tissues and depends in part on a properly functioning cardiovascular system. Adequate blood flow depends on the efficient pumping action of the heart, patent and responsive blood vessels, and adequate circulating blood volume. Nervous system activity, blood viscosity, and the metabolic needs of tissues influence the rate and adequacy of blood flow.

## Anatomic and Physiologic Overview

The vascular system consists of two interdependent systems. The right side of the heart pumps blood through the lungs to the pulmonary circulation, and the left side of the heart pumps blood to all other body tissues through the systemic circulation. The blood vessels in both systems channel the blood from the heart to the tissues and back to the heart (Fig. 31-1). Contraction of the ventricles is the driving force that moves blood through the vascular systems.

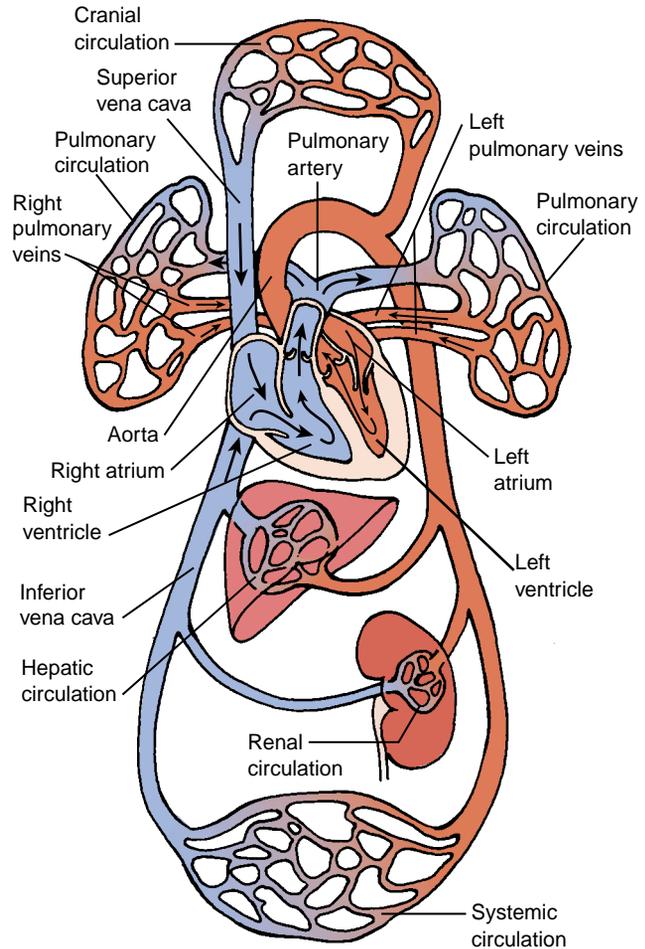

Arteries distribute oxygenated blood from the left side of the heart to the tissues, whereas the veins carry deoxygenated blood from the tissues to the right side of the heart. Capillary vessels, located within the tissues, connect the arterial and venous systems and are the site of exchange of nutrients and metabolic wastes between the circulatory system and the tissues. Arterioles and venules immediately adjacent to the capillaries, together with the capillaries, make up the microcirculation.

The lymphatic system complements the function of the circulatory system. Lymphatic vessels transport lymph (a fluid similar to plasma), and tissue fluids (containing smaller proteins, cells, and cellular debris) from the interstitial space to systemic veins.

## ANATOMY OF THE VASCULAR SYSTEM

### Arteries and Arterioles

Arteries are thick-walled structures that carry blood from the heart to the tissues. The aorta, which has a diameter of approximately 25 mm (1 inch), gives rise to numerous branches, which divide into smaller arteries that are about 4 mm (0.16 inch) in diameter by the time they reach the tissues. Within the tissues,

**FIGURE 31-1** Systemic and pulmonary circulation. Oxygen-rich blood from the pulmonary circulation is pumped from the left heart into the aorta and the systemic arteries to the capillaries, where the exchange of nutrients and waste products takes place. The deoxygenated blood returns to the right heart by way of the systemic veins and is pumped into the pulmonary circulation. From *Stedman's Medical Dictionary* (27th ed.). (2000). Philadelphia: Lippincott Williams & Wilkins.

## Glossary

**anastomosis:** surgical junction of two vessels

**aneurysm:** a localized sac or dilation of an artery formed at a weak point in the vessel wall

**ankle-brachial index (ABI) or ankle-arm index (AAI):** ratio of the ankle systolic pressure to the arm systolic pressure; an objective measurement of arterial disease that provides quantification of the degree of stenosis

**angioplasty:** an invasive procedure that uses a balloon-tipped catheter to dilate a stenotic area of a blood vessel

**arteriosclerosis:** diffuse process whereby the muscle fibers and the endothelial lining of the walls of small arteries and arterioles thicken

**atherosclerosis:** disease process involving the accumulation of lipids, calcium, blood components, carbohydrates, and fibrous tissue on the intimal layer of a large or medium-sized artery

**bruit:** sound produced by turbulent blood flow through an irregular, tortuous, stenotic, or dilated vessel

**dissection:** separation of the weakened elastic and fibromuscular elements in the medial layer of an artery

**duplex ultrasonography:** combines B-mode gray-scale imaging of tissue, organs, and blood vessels with capabilities of estimating velocity changes by use of a pulsed Doppler

**intermittent claudication:** a muscular, cramp-like pain in the extremities con-

sistently reproduced with the same degree of exercise or activity and relieved by rest

**international normalized ratio (INR):** method of measuring anticoagulation levels, such as warfarin (Coumadin); devised to bring a universal standard to monitoring of anticoagulation achieved by oral medications

**ischemia:** deficient blood supply

**rest pain:** persistent pain in the foot or digits when the patient is resting, indicating a severe degree of arterial insufficiency

**rubor:** reddish blue discoloration of the extremities; indicative of severe peripheral arterial damage in vessels that remain dilated and unable to constrict

**stenosis:** narrowing or constriction of a vessel

the vessels divide further, diminishing to approximately 30  $\mu\text{m}$  in diameter; these vessels are called arterioles.

The walls of the arteries and arterioles are composed of three layers: the intima, an inner endothelial cell layer; the media, a middle layer of smooth elastic tissue; and the adventitia, an outer layer of connective tissue. The intima, a very thin layer, provides a smooth surface for contact with the flowing blood. The media makes up most of the vessel wall in the aorta and other large arteries of the body. This layer is composed chiefly of elastic and connective tissue fibers that give the vessels considerable strength and allow them to constrict and dilate to accommodate the blood ejected from the heart (stroke volume) and maintain an even, steady flow of blood. The adventitia is a layer of connective tissue that anchors the vessel to its surroundings. There is much less elastic tissue in the smaller arteries and arterioles, and the media in these vessels is composed primarily of smooth muscle.

Smooth muscle controls the diameter of the vessels by contracting and relaxing. Chemical, hormonal, and nervous system factors influence the activity of smooth muscle. Because arterioles can alter their diameter, thereby offering resistance to blood flow, they are often referred to as *resistance vessels*. Arterioles regulate the volume and pressure in the arterial system and the rate of blood flow to the capillaries. Because of the large amount of muscle, the walls of the arteries are relatively thick, accounting for approximately 25% of the total diameter of the artery. The walls of the arterioles account for approximately 67% of the total diameter of arterioles.

The intima and the inner third of the smooth muscle layer are in such close contact with the blood that the blood vessel receives its nourishment by direct diffusion. The adventitia and the outer media layers have a limited vascular system for nourishment and require their own blood supply to meet metabolic needs.

## Capillaries

Capillary walls, which lack smooth muscle and adventitia, are composed of a single layer of endothelial cells. This thin-walled structure permits rapid and efficient transport of nutrients to the cells and removal of metabolic wastes. The diameter of capillaries ranges from 5 to 10  $\mu\text{m}$ ; this narrow channel requires red blood cells to alter their shape to pass through these vessels. Changes in a capillary's diameter are passive and are influenced by contractile changes in the blood vessels that carry blood to and from a capillary. The capillary's diameter also changes in response to chemical stimuli. In some tissues, a cuff of smooth muscle, called the precapillary sphincter, is located at the arteriolar end of the capillary and is responsible, along with the arteriole, for controlling capillary blood flow.

Some capillary beds, such as in the fingertips, contain arteriovenous anastomoses, through which blood passes directly from the arterial to the venous system. These vessels are believed to regulate heat exchange between the body and the external environment.

The distribution of capillaries varies with the type of tissue. For example, skeletal tissue, which is metabolically active, has a denser capillary network than does cartilage, which is less active.

## Veins and Venules

Capillaries join to form larger vessels called venules, which join to form veins. The venous system is therefore structurally analogous to the arterial system; venules correspond to arterioles, veins to arteries, and the vena cava to the aorta. Analogous types of ves-

sels in the arterial and venous systems have approximately the same diameters (see Fig. 31-1).

The walls of the veins, in contrast to those of the arteries, are thinner and considerably less muscular. The wall of the average vein amounts to only 10% of the vein diameter, in contrast to 25% in the artery. The walls of a vein, like those of arteries, are composed of three layers, although these layers are not as well defined.

The thin, less muscular structure of the vein wall allows these vessels to distend more than arteries. Greater distensibility and compliance permit large volumes of blood to be stored in the veins under low pressure. For this reason, veins are referred to as *capacitance vessels*. Approximately 75% of total blood volume is contained in the veins. The sympathetic nervous system, which innervates the vein musculature, can stimulate the veins to constrict (venoconstriction), thereby reducing venous volume and increasing the volume of blood in the general circulation. Contraction of skeletal muscles in the extremities creates the primary pumping action to facilitate venous blood flow back to the heart.

Some veins, unlike arteries, are equipped with valves. In general, veins that transport blood against the force of gravity, as in the lower extremities, have one-way bicuspid valves that interrupt the column of blood to prevent blood from seeping backward as it is propelled toward the heart. Valves are composed of endothelial leaflets, the competency of which depends on the integrity of the vein wall.

## Lymphatic Vessels

The lymphatic vessels are a complex network of thin-walled vessels similar to the blood capillaries. This network collects lymphatic fluid from tissues and organs and transports the fluid to the venous circulation. The lymphatic vessels converge into two main structures: the thoracic duct and the right lymphatic duct. These ducts empty into the junction of the subclavian and the internal jugular veins. The right lymphatic duct conveys lymph primarily from the right side of the head, neck, thorax, and upper arms. The thoracic duct conveys lymph from the remainder of the body. Peripheral lymphatic vessels join larger lymph vessels and pass through regional lymph nodes before entering the venous circulation. The lymph nodes play an important role in filtering foreign particles.

The lymphatic vessels are permeable to large molecules and provide the only means by which interstitial proteins can return to the venous system. With muscular contraction, lymph vessels become distorted to create spaces between the endothelial cells, allowing protein and particles to enter. Muscular contraction of the lymphatic walls and surrounding tissues aids in propelling the lymph toward the venous drainage points.

## FUNCTION OF THE VASCULAR SYSTEM

### Circulatory Needs of Tissues

The amount of blood flow needed by body tissues constantly changes. The percentage of blood flow received by individual organs or tissues is determined by the rate of tissue metabolism, the availability of oxygen, and the function of the tissues (Table 31-1). When metabolic requirements increase, blood vessels dilate to increase the flow of oxygen and nutrients to the tissues. When metabolic needs decrease, vessels constrict, and blood flow to the tissues decreases. Metabolic demands of tissues increase with physical activity or exercise, local heat application, fever, and infection. Reduced metabolic requirements of tissues accompany rest or decreased physical activity, local cold application, and

cooling of the body. If the blood vessels fail to dilate in response to the need for increased blood flow, tissue **ischemia** (ie, deficient blood supply to a body part) results. The mechanism by which blood vessels dilate and constrict to adjust for metabolic changes ensures that normal arterial pressure is maintained.

As blood passes through tissue capillaries, oxygen is removed, and carbon dioxide is added. The amount of oxygen extracted by each tissue differs. For example, the myocardium tends to extract about 50% of the oxygen from arterial blood in one pass through its capillary bed, whereas the kidneys extract only about 7% of the oxygen from the blood that passes through them. The average amount of oxygen removed collectively by all of the body tissues is about 25%. This means that the blood in the vena cavae contains about 25% less oxygen than aortic blood. This is known as the *systemic arteriovenous oxygen difference*. The value increases when the amount of oxygen delivered to the tissues is decreased relative to their metabolic needs (see Table 31-1).

## Blood Flow

Blood flow through the cardiovascular system always proceeds in the same direction: left side of the heart to the aorta, arteries, arterioles, capillaries, venules, veins, vena cavae, and right side of the heart. This unidirectional flow is caused by a pressure difference that exists between the arterial and venous systems. Because arterial pressure (approximately 100 mm Hg) is greater than venous pressure (approximately 4 mm Hg) and fluid always flows from an area of high pressure to an area of lower pressure, blood flows from the arterial to the venous system.

The pressure difference ( $\Delta P$ ) between the two ends of the vessel provides the impetus for the forward propulsion of blood. Impediments to blood flow offer the opposing force, which is known as resistance ( $R$ ). The rate of blood flow is determined by dividing the pressure difference by the resistance:

$$\text{Flow rate} = \Delta P/R$$

This equation clearly shows that, when resistance increases, a greater driving pressure is required to maintain the same degree of flow. In the body, an increase in driving pressure is accomplished by an increase in the force of contraction of the heart. If arterial resistance is chronically elevated, the myocardium hypertrophies (enlarges) to sustain the greater contractile force.

In most long smooth blood vessels, flow is laminar or streamlined, with blood in the center of the vessel moving slightly faster than the blood near the vessel walls. Laminar flow becomes turbulent when the blood flow rate increases, when blood viscosity increases, when the diameter of the vessel becomes greater than normal, or when segments of the vessel are narrowed or constricted. Turbulent blood flow creates a sound, called a **bruit**, that can be auscultated with a stethoscope.

## Blood Pressure

Chapters 26 and 32 provide more information on the physiology and measurement of blood pressure.

## Capillary Filtration and Reabsorption

Fluid exchange across the capillary wall is continuous. This fluid, which has the same composition as plasma without the proteins, forms the interstitial fluid. The equilibrium between hydrostatic and osmotic forces of the blood and interstitium, as well as capillary permeability, governs the amount and direction of fluid movement across the capillary. Hydrostatic force is a driving pressure that is generated by the blood pressure. Osmotic pressure is the pulling force created by plasma proteins. Normally, the hydrostatic pressure at the arterial end of the capillary is relatively high compared with that at the venous end. This high pressure at the arterial end of the capillaries tends to drive fluid out of the capillary and into the tissue space. Osmotic pressure tends to pull fluid back into the capillary from the tissue space, but this osmotic force cannot overcome the high hydrostatic pressure at the arterial end of the capillary. At the venous end of the capillary, however, the osmotic force predominates over the low hydrostatic pressure, and there is a net reabsorption of fluid from the tissue space back into the capillary.

Except for a very small amount, fluid that is filtered out at the arterial end of the capillary bed is reabsorbed at the venous end. The excess filtered fluid enters the lymphatic circulation. These processes of filtration, reabsorption, and lymph formation aid in maintaining tissue fluid volume and removing tissue waste and debris. Under normal conditions, capillary permeability remains constant.

Under certain abnormal conditions, the fluid filtered out of the capillaries may greatly exceed the amounts reabsorbed and car-

ried away by the lymphatic vessels. This imbalance can result from damage to capillary walls and subsequent increased permeability, obstruction of lymphatic drainage, elevation of venous pressure, or decrease in plasma protein osmotic force. The accumulation of fluid that results from these processes is known as *edema*.

## Hemodynamic Resistance

The most important factor that determines resistance in the vascular system is the vessel radius. Small changes in vessel radius lead to large changes in resistance. The predominant sites of change in the caliber or width of blood vessels, and therefore in resistance, are the arterioles and the precapillary sphincter. Peripheral vascular resistance is the opposition to blood flow provided by the blood vessels. Poiseuille's law provides the method by which resistance can be calculated:

$$R = 8\theta L/\pi r^4$$

where  $R$  = resistance,  $r$  = radius of the vessel,  $L$  = length of the vessel,  $\theta$  = viscosity of the blood, and  $8/\pi$  = a constant. This equation shows that the resistance is proportional to the viscosity or thickness of the blood and the length of the vessel but is inversely proportional to the fourth power of the vessel radius.

Under normal conditions, blood viscosity and vessel length do not change significantly, and these factors do not usually play an important role in blood flow. A large increase in hematocrit, however, may increase blood viscosity and reduce capillary blood flow.

## Peripheral Vascular Regulating Mechanisms

Because the metabolic needs of body tissues, even at rest, are continuously changing, an integrated and coordinated regulatory system is necessary so that blood flow to individual areas is maintained in proportion to the needs of that area. As might be expected, this regulatory mechanism is complex and consists of central nervous system influences, circulating hormones and chemicals, and independent activity of the arterial wall itself.

Sympathetic (adrenergic) nervous system activity, mediated by the hypothalamus, is the most important factor in regulating the caliber and therefore the blood flow of peripheral blood vessels. All vessels are innervated by the sympathetic nervous system except the capillary and precapillary sphincters. Stimulation of the sympathetic nervous system causes vasoconstriction. The neurotransmitter responsible for sympathetic vasoconstriction is norepinephrine. Sympathetic activation occurs in response to physiologic and psychological stressors. Diminution of sympathetic activity by medications or sympathectomy results in vasodilation.

Other hormonal substances affect peripheral vascular resistance. Epinephrine, released from the adrenal medulla, acts like norepinephrine in constricting peripheral blood vessels in most tissue beds. In low concentrations, however, epinephrine causes vasodilation in skeletal muscles, the heart, and the brain. Angiotensin, a potent substance formed from the interaction of renin (synthesized by the kidney) and a circulating serum protein, stimulates arterial constriction. Although the amount of angiotensin concentrated in the blood is usually small, its profound vasoconstrictor effects are important in certain abnormal states, such as heart failure and hypovolemia.

Alterations in local blood flow are influenced by various circulating substances that have vasoactive properties. Potent vasodilators include histamine, bradykinin, prostaglandin, and certain muscle metabolites. A reduction in available oxygen and nutrients

and changes in local pH also affect local blood flow. Serotonin, a substance liberated from platelets that aggregate at the site of vessel wall damage, constricts arterioles. The application of heat to parts of the body surface causes local vasodilation, whereas the application of cold causes vasoconstriction.

## PATHOPHYSIOLOGY OF THE VASCULAR SYSTEM

Reduced blood flow through peripheral blood vessels characterizes all peripheral vascular diseases. The physiologic effects of altered blood flow depend on the extent to which tissue demands exceed the supply of oxygen and nutrients available. If tissue needs are high, even modestly reduced blood flow may be inadequate to maintain tissue integrity. Tissues then fall prey to ischemia (deficient blood supply), become malnourished, and ultimately die if adequate blood flow is not restored.

## Pump Failure

Inadequate peripheral blood flow occurs when the heart's pumping action becomes inefficient. Left ventricular failure causes an accumulation of blood in the lungs and a reduction in forward flow or cardiac output, which results in inadequate arterial blood flow to the tissues. Right ventricular failure causes systemic venous congestion and a reduction in forward flow (see Chap. 30).

## Alterations in Blood and Lymphatic Vessels

Intact, patent, and responsive blood vessels are necessary to deliver adequate amounts of oxygen to tissues and to remove metabolic wastes. Arteries can become obstructed by atherosclerotic plaque, a thrombus, or an embolus. Arteries can become damaged or obstructed as a result of chemical or mechanical trauma, infections or inflammatory processes, vasospastic disorders, and congenital malformations. A sudden arterial occlusion causes profound and often irreversible tissue ischemia and tissue death. When arterial occlusions develop gradually, there is less risk for sudden tissue death because collateral circulation has an opportunity to develop and the body adapts to the decreased blood flow.

Venous blood flow can be reduced by a thrombus obstructing the vein, by incompetent venous valves, or by a reduction in the effectiveness of the pumping action of surrounding muscles. Decreased venous blood flow results in increased venous pressure, a subsequent rise in capillary hydrostatic pressure, net filtration of fluid out of the capillaries into the interstitial space, and subsequent edema. Edematous tissues cannot receive adequate nutrition from the blood and consequently are more susceptible to breakdown, injury, and infection. Obstruction of lymphatic vessels also results in edema. Lymphatic vessels can become obstructed by tumor or by damage resulting from mechanical trauma or inflammatory processes.

## Gerontologic Considerations

Aging produces changes in the walls of the blood vessels that affect the transport of oxygen and nutrients to the tissues. The intima thickens as a result of cellular proliferation and fibrosis. Elastin fibers of the media become calcified, thin, and fragmented, and collagen accumulates in the intima and the media. These changes cause the vessels to stiffen, which results in increased peripheral resistance, impaired blood flow, and increased left ventricular workload.

## Circulatory Insufficiency of the Extremities

Although many types of peripheral vascular diseases exist, most result in ischemia and produce some of the same symptoms: pain, skin changes, diminished pulse, and possible edema. The type and severity of symptoms depend in part on the type, stage, and extent of the disease process and on the speed with which the disorder develops. Table 31-2 highlights the distinguishing features of arterial and venous insufficiency. In this chapter, peripheral vascular disease is categorized as arterial, venous, or lymphatic disorders.

## Assessment

### HEALTH HISTORY AND CLINICAL MANIFESTATIONS

A description of the pain and any precipitating factors, the skin color and temperature, and the peripheral pulses are important for the diagnosis of arterial disorders.

### Intermittent Claudication

A muscular, cramp-type pain in the extremities consistently reproduced with the same degree of exercise or activity and relieved by rest is experienced by patients with peripheral arterial insufficiency. Referred to as **intermittent claudication**, this pain is caused by the inability of the arterial system to provide adequate blood flow to the tissues in the face of increased demands for nutrients during exercise. As the tissues are forced to complete the energy cycle without the nutrients, muscle metabolites and lactic acid are produced. Pain is experienced as the metabolites aggravate the nerve endings of the surrounding tissue. Usually, about 50% of the arterial lumen or 75% of the cross-sectional area must be obstructed before intermittent claudication is experienced. When the patient rests and thereby decreases the metabolic needs of the muscles, the pain subsides. The progression of the arterial disease can be monitored by documenting the amount of exercise or the distance a patient can walk before pain is produced. Persistent pain in the forefoot when the patient is resting indicates a severe degree of arterial insufficiency and a critical state of ischemia. Known as **rest pain**, this discomfort is often worse at

night and may interfere with sleep. This pain frequently requires that the extremity be lowered to a dependent position to improve perfusion pressure to the distal tissues.

The site of arterial disease can be deduced from the location of claudication, because pain occurs in muscle groups below the disease. As a general rule, the pain of intermittent claudication occurs one joint level below the disease process. Calf pain may accompany reduced blood flow through the superficial femoral or popliteal artery, whereas pain in the hip or buttock may result from reduced blood flow in the abdominal aorta or the common iliac or hypogastric arteries.

### Changes in Skin Appearance and Temperature

Adequate blood flow warms the extremities and gives them a rosy coloring. Inadequate blood flow results in cool and pale extremities. Further reduction of blood flow to these tissues, which occurs when the extremity is elevated, for example, results in an even whiter or more blanched appearance (pallor). **Rubor**, a reddish blue discoloration of the extremities, may be observed within 20 seconds to 2 minutes after the extremity is dependent. Rubor suggests severe peripheral arterial damage in which vessels that cannot constrict remain dilated. Even with rubor, the extremity begins to turn pale with elevation. Cyanosis, a bluish tint on the skin, is manifested when the amount of oxygenated hemoglobin contained in the blood is reduced.

Additional changes resulting from a chronically reduced nutrient supply include loss of hair, brittle nails, dry or scaling skin, atrophy, and ulcerations. Edema may be apparent bilaterally or unilaterally and is related to the affected extremity's chronically dependent position because of severe rest pain. Gangrenous changes appear after prolonged, severe ischemia and represent tissue necrosis. In elderly patients who are inactive, gangrene may be the first sign of disease. These patients may have adjusted their lifestyle to accommodate the limitations imposed by the disease, and may not walk enough to develop symptoms of claudication. Circulation is decreased, but this is not apparent to the patient until trauma occurs. At this point, gangrene develops when minimal arterial flow is impaired further by edema formation resulting from the traumatic event.

Table 31-2 • Characteristics of Arterial and Venous Insufficiency

CHARACTERISTIC	ARTERIAL	VENOUS
<b>Pain</b>	Intermittent claudication to sharp, unrelenting, constant	Aching, cramping
<b>Pulses</b>	Diminished or absent	Present, but may be difficult to palpate through edema
<b>Skin characteristics</b>	Dependent rubor—elevation pallor of foot, dry, shiny skin, cool-to-cold temperature, loss of hair over toes and dorsum of foot, nails thickened and ridged	Pigmentation in gaitor area (area of medial and lateral malleolus), skin thickened and tough, may be reddish blue, frequently with associated dermatitis
<b>Ulcer characteristics</b>		
Location	Tip of toes, toe webs, heel or other pressure areas if confined to bed	Medial malleolus; infrequently lateral malleolus or anterior tibial area
Pain	Very painful	Minimal pain if superficial or may be very painful
Depth of ulcer	Deep, often involving joint space	Superficial
Shape	Circular	Irregular border
Ulcer base	Pale to black and dry gangrene	Granulation tissue—beefy red to yellow fibrinous in chronic long-term ulcer
Leg edema	Minimal unless extremity kept in dependent position constantly to relieve pain	Moderate to severe

## Pulses

Determining the presence or absence, as well as the quality, of peripheral pulses is important in assessing the status of peripheral arterial circulation (Fig. 31-2). Absence of a pulse may indicate that the site of **stenosis** (narrowing or constriction) is proximal to that location. Occlusive arterial disease impairs blood flow and can reduce or obliterate palpable pulsations in the extremities. Pulses should be palpated bilaterally and simultaneously, comparing both sides for symmetry in rate, rhythm, and quality.

### Gerontologic Considerations

In elderly people, symptoms of peripheral arterial disease may be more pronounced than in younger people because of the condition's duration and coexisting chronic disease. Intermittent claudication may occur after walking only a few short blocks or after walking up a slight incline. Any prolonged pressure on the foot can cause pressure areas that become ulcerated, infected, and gangrenous. The outcomes of arterial insufficiency in the elderly person include reduced mobility and activity and a loss of independence.

## Diagnostic Evaluation

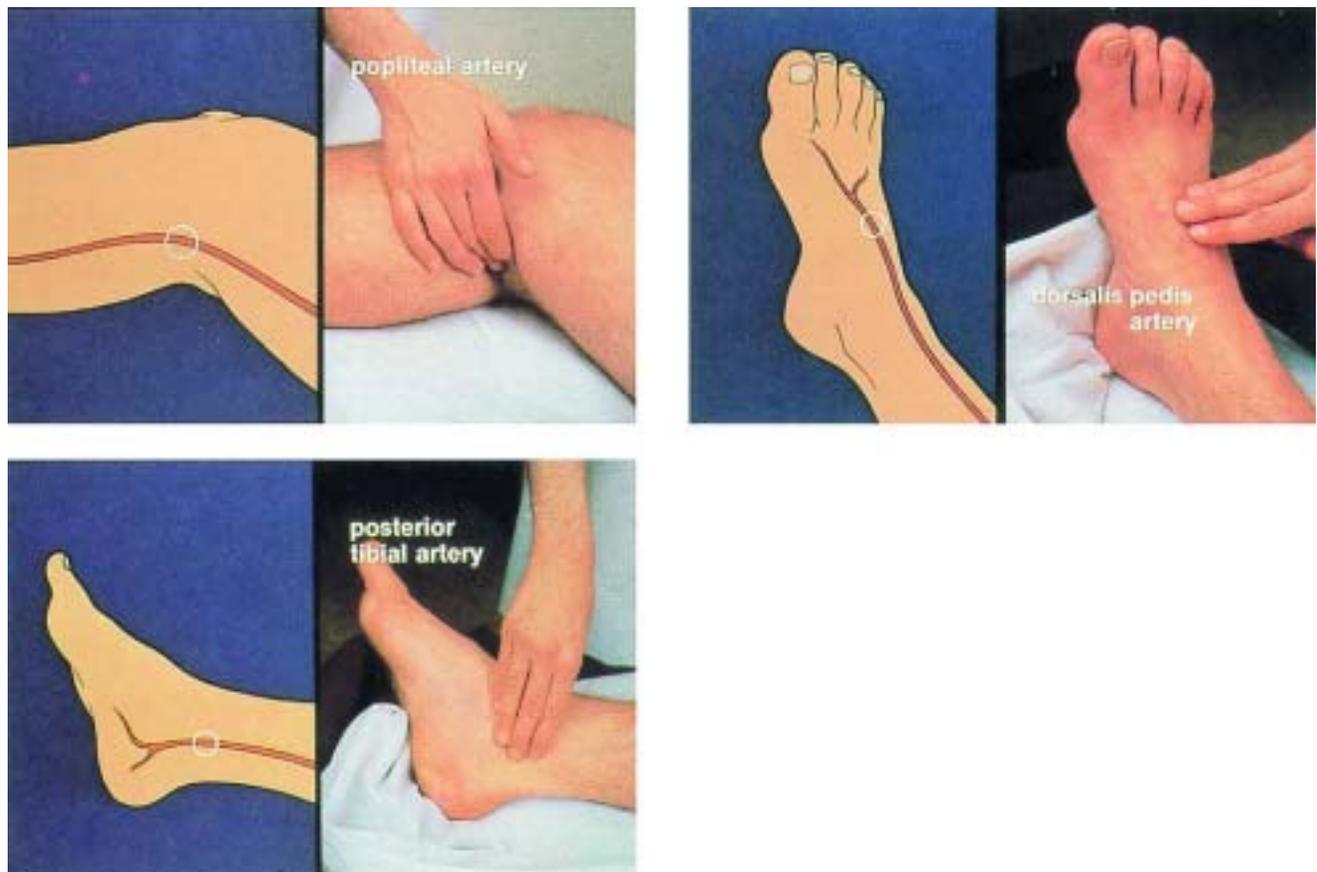

In identifying and diagnosing the various abnormalities affecting the vascular structures (arteries, veins, and lymphatics), various tests may be performed.

## DOPPLER ULTRASOUND FLOW STUDIES

Palpating pulses is subjective, and the examiner may mistake his or her own pulse for that of the patient. To prevent this, the examiner should use light touch and avoid using only the index finger for palpation, because this finger has the strongest arterial pulsation of all the fingers. The thumb should not be used for the same reason. When pulses cannot be reliably palpated, use of a microphone-like, hand-held Doppler ultrasound device, called a transducer or probe, may be helpful in detecting and assessing peripheral flow.

A continuous-wave (CW) Doppler ultrasound device may be used to hear (insonate) the blood flow in vessels when pulses cannot be palpated. This hand-held device emits a continuous signal through the patient's tissues. The signals are reflected by (echo off) the moving blood cells and are received by the device. The filtered-output Doppler signal is then transmitted to a loudspeaker or headphones, where it can be heard for interpretation. Because CW Doppler emits a continuous signal, all vascular structures in the path of the sound beam are insonated, and differentiating arterial from venous flow and detecting the site of a stenosis may be difficult. The depth at which blood flow can be detected by Doppler is determined by the frequency (in megahertz [MHz]) it generates. The lower the frequency, the deeper the tissue penetration; a 5- to 10-MHz probe may be used to evaluate the peripheral arteries.

To evaluate the lower extremities, the patient is placed in a supine position with the head of bed elevated 20 to 30 degrees; the legs are externally rotated, if possible, to permit adequate access to the medial malleolus. Acoustic gel is applied to the patient's skin

**FIGURE 31-2** Assessing peripheral pulses. (Left) Popliteal pulse. (Right) Dorsalis pedis pulse. (Bottom) Posterior tibial pulse.

to permit uniform transmission of the ultrasound wave (electrocardiogram gel is not used because it contains sodium, which may dissolve the epoxy that covers the transducer's tip). The tip of the Doppler transducer is positioned at a 45- to 60-degree angle over the expected location of the artery and angled slowly to identify arterial blood flow. Excessive pressure is avoided because severely diseased arteries can collapse with even minimal pressure.

Because the equipment can detect blood flow in advanced arterial disease states, especially if collateral circulation has developed, identifying a signal documents only the presence of blood flow. However, it is clinically relevant to notify the primary care provider of the absence of a signal if one had been detected during a previous examination.

CW Doppler (Fig. 31-3) is more useful as a clinical tool when combined with ankle blood pressures, which are used to determine the **ankle-brachial index (ABI)**, also called the **ankle-arm index (AAI)**. The ABI is the ratio of the ankle systolic blood pressure to the arm systolic blood pressure. It is an objective indicator of arterial disease that allows the examiner to quantify the degree of stenosis. With increasing degrees of arterial narrowing, there is a progressive decrease in systolic pressure distal to the involved sites.

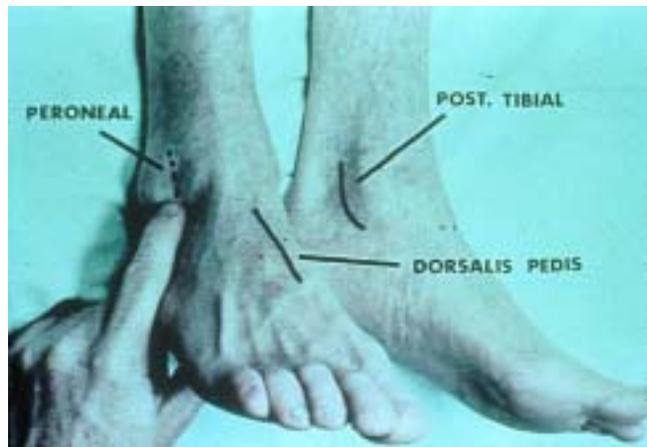

The first step in determining the ABI is to have the patient rest in a supine position (not seated) for at least 5 minutes. An appropriate-sized blood pressure cuff (typically, a 10-cm cuff) is applied to the patient's ankle above the malleolus. After identifying an arterial signal at the posterior tibial and dorsalis pedis arteries, the systolic ankle pressures are obtained in both feet. Diastolic pressures cannot be measured with a Doppler. If pressure in these arteries cannot be measured, pressure can be measured in the peroneal artery, which can also be assessed at the ankle (Fig. 31-4).

Doppler ultrasonography is used to measure brachial pressures in both arms. Both arms are evaluated because the patient may have an asymptomatic stenosis in the subclavian artery, causing brachial pressure on the affected side to be 20 mm Hg or more lower than systemic pressure. The abnormally low pressure should not be used for assessment.

To calculate ABI, the ankle systolic pressure for each foot is divided by the higher of the two brachial systolic pressures;

**FIGURE 31-3** Continuous-wave (CW) Doppler ultrasound detects blood flow in peripheral vessels. Combined with computation of ankle or arm pressures, this diagnostic technique helps health care providers characterize the nature of peripheral vascular disease. Photo reprinted with permission from Cantwell-Gab, K. (1996). Identifying chronic PAD. *American Journal of Nursing*, 96(7), 40–46.

**FIGURE 31-4** Location of peroneal artery; lateral malleolus. Photo reprinted with permission from Cantwell-Gab, K. (1996). Identifying chronic PAD. *American Journal of Nursing*, 96(7), 40–46.

Chart 31-1 offers more information. The ABI can be computed for a patient with the following systolic pressures:

*Right brachial:* 160 mm Hg  
*Left brachial:* 120 mm Hg  
*Right posterior tibial:* 80 mm Hg  
*Right dorsalis pedis:* 60 mm Hg  
*Left posterior tibial:* 100 mm Hg  
*Left dorsalis pedis:* 120 mm Hg

The highest systolic pressure for each ankle (80 mm Hg for the right, 120 mm Hg for the left) would be divided by the highest brachial pressure (160 mm Hg).

*Right:* 80/160 mm Hg = 0.50 ABI  
*Left:* 120/160 mm Hg = 0.75 ABI

In general, systolic pressure in the ankle of a healthy person is the same or slightly higher than the brachial systolic pressure, resulting in an ABI of about 1.0 (no arterial insufficiency). Patients with claudication usually have an ABI of 0.95 to 0.50 (mild to moderate insufficiency); patients with ischemic rest pain have an ABI of less than 0.50, and patients with severe ischemia or tissue loss have an ABI of 0.25 or less.

## EXERCISE TESTING

Exercise testing is used to determine how long a patient can walk and to measure the ankle systolic blood pressure in response to walking. The patient walks on a treadmill at 1.5 mph with a 10% incline for a maximum of 5 minutes. Most patients can complete the test unless they have severe cardiac, pulmonary, or orthopedic problems or are physically disabled. A normal response to the test is little or no drop in ankle systolic pressure after exercise. In a patient with true claudication, however, ankle pressure drops. Combining this hemodynamic information with the walking time helps the physician determine whether intervention is necessary.

## DUPLEX ULTRASONOGRAPHY

**Duplex ultrasonography** involves B-mode gray-scale imaging of the tissue, organs, and blood vessels (arterial and venous) and permits estimation of velocity changes by use of a pulsed Doppler

Chart  
31-1

### Avoiding Common Errors in Calculating Ankle-Brachial Index (ABI)

Take the following precautions to ensure an accurate ABI calculation:

- *Use the correctly sized blood pressure cuffs.* To obtain accurate blood pressure measurements, use a cuff with a bladder width at least 40% and length at least 80% of the limb circumference.
- *On the nursing plan of care, document the blood pressure cuff sizes used* (for example, “12-cm BP cuff used for brachial pressures; 10-cm BP cuff used for ankle pressures”). This minimizes the risk of shift-to-shift discrepancies in ABIs.
- *Use sufficient blood pressure cuff inflation.* To ensure complete closure of the artery and the most accurate measurements, inflate cuffs 20 to 30 mm Hg beyond the point at which the last arterial signal is detected.
- *Do not deflate blood pressure cuffs too rapidly.* Try to maintain a deflation rate of 2 to 4 mm Hg/second for patients without dysrhythmias and 2 mm Hg/second or slower for patients with dysrhythmias. Deflating the cuff more rapidly may miss the patient’s highest pressure and result in recording an erroneous (low) blood pressure measurement.
- *Be suspicious of arterial pressures recorded at less than 40 mm Hg.* This may mean the venous signal has been mistaken for the arterial signal. If the arterial pressure, which is normally 120 mm Hg, is measured at less than 40 mm Hg, ask a colleague to double-check the findings before recording this as an arterial pressure.
- *Suspect medial calcific sclerosis anytime an ABI is 1.3 or greater or ankle pressure is more than 300 mm Hg.* Medial calcific sclerosis is associated with diabetes mellitus, chronic renal failure, and hyperparathyroidism. It produces falsely elevated ankle pressures by hardening the medra of the arteries; making the vessels noncompressible.

(From Cantwell-Gab, K. [1996]. Identifying chronic PAD. *American Journal of Nursing*, 96[1] 40–46, with permission.)

(Fig. 31-5). Color flow techniques, which can identify vessels, may be used to shorten the examination time. The procedure helps determine the level and extent of disease and is universally employed to evaluate the venous system. The technique makes it possible to image and assess blood flow, evaluate the runoff status of the distal vessels, locate the disease (stenosis versus occlusion), and determine anatomic morphology and the hemodynamic significance of plaque causing stenosis. Duplex ultrasound findings help in planning therapy and monitoring its outcomes. Moreover, the test is noninvasive and usually requires no patient preparation. The equipment is portable, making it useful anywhere for initial diagnosis or follow-up evaluations.

## COMPUTED TOMOGRAPHY

Computed tomography (CT) provides cross-sectional images of soft tissue and can identify the area of volume changes to an extremity and the compartment where changes take place. CT of a lymphedematous arm or leg, for example, demonstrates a characteristic honeycomb pattern in the subcutaneous tissue.

In spiral (also called volumetric) CT, the scan head moves circumferentially around the patient as the patient passes through the scanner, creating a series of overlapping images that are connected to one another in a continuous spiral (Verta & Verta, 1998). Scan times are short; however, the patient is exposed to

**FIGURE 31-5** Color flow duplex image of popliteal artery with normal triphasic Doppler flow.

x-rays, and contrast agent usually must be injected to adequately visualize the blood vessels. Using computer software, the slicelike images are reconstructed into three-dimensional images that can be rotated and viewed from multiple angles.

## COMPUTED TOMOGRAPHIC ANGIOGRAPHY

In computed tomographic angiography (CTA), a spiral CT scanner and rapid intravenous infusion of contrast agent are used to image very thin (1-mm) sections of the target area; the results are configured in three dimensions so that the image closely resembles a regular angiogram (Verta & Verta, 1998). CTA shows the aorta and main visceral arteries better than it shows smaller branch vessels. Scan times are usually between 20 and 30 seconds. The large volume of contrast agent required for CTA limits the usefulness of this study in patients with allergy to the contrast agent or with significantly impaired renal function.

## MAGNETIC RESONANCE ANGIOGRAPHY

Magnetic resonance angiography is performed with a standard MRI scanner but with image-processing software specifically programmed to isolate the blood vessels. The images are reconstructed to resemble a standard angiogram, but because the images are reassembled in three dimensions, they can be rotated and viewed from multiple angles. Because no contrast agent is necessary, this study is useful in patients with poor renal function or allergy to contrast agent. Scan time is long, and motion artifacts are common, restricting the use of the test to relatively short segments of the vascular system (Verta & Verta, 1998).

## ANGIOGRAPHY

An arteriogram produced by angiography may be used to confirm the diagnosis of occlusive arterial disease when considering surgery or other interventions. The procedure involves injecting a radioopaque contrast agent directly into the vascular system to visualize the vessels. The location of a vascular obstruction or an **aneurysm** (abnormal dilation of a blood vessel) and the collateral circulation can be demonstrated. Usually, patients experience a temporary sensation of warmth as the contrast agent is injected, and local irritation may occur at the injection site. Infrequently, a patient

may have an immediate or delayed allergic reaction to the iodine contained in the contrast agent. Manifestations include dyspnea, nausea and vomiting, sweating, tachycardia, and numbness of the extremities. Any such reaction must be reported to the physician at once; treatment may include the administration of one or more of epinephrine (adrenaline), antihistamines, or corticosteroids. Additional risks include vessel injury, bleeding, and CVA (brain attack, stroke).

## AIR PLETHYSMOGRAPHY

Named for the standardized air chambers that fit around the lower leg and that are calibrated after being filled with a standard amount of air, air plethysmography quantifies venous reflux and calf muscle pump ejection. Changes in volume are measured with the patient's legs elevated, with the patient supine and standing, and after the patient performs toe-ups (patient extends ankle while standing; stands on tip-toes). Air plethysmography provides information about venous filling time, functional venous volume, ejected volume, and residual volume. It is useful in evaluating patients with suspected valvular incompetence or chronic venous insufficiency.

## CONTRAST PHLEBOGRAPHY

Also known as venography, contrast phlebography involves injecting radiographic contrast media into the venous system through a dorsal foot vein. If a thrombus exists, the x-ray image discloses an unfilled segment of vein in an otherwise completely filled vein. Injection of the contrast agent may cause a brief but painful inflammation of the vein. The test is generally performed if the patient is to undergo thrombolytic therapy, but duplex ultrasonography is now accepted as the gold standard for diagnosing venous thrombosis.

## LYMPHANGIOGRAPHY

Lymphangiography affords a means of detecting lymph node involvement that results from metastatic carcinoma, lymphoma, or infection in sites that are otherwise inaccessible to the examiner except by surgery. In this test, a lymphatic vessel in each foot (or hand) is injected with contrast agent. A series of x-rays are taken at the conclusion of the injection, 24 hours later, and periodically thereafter, as indicated. The failure to identify subcutaneous lymphatic collection of contrast agent and the persistence of contrast agent in the tissue for days afterward help to confirm a diagnosis of lymphedema.

## LYMPHOSCINTIGRAPHY

Lymphoscintigraphy is a reliable alternative to lymphangiography. A radioactively labeled colloid is injected subcutaneously in the second interdigital space. The extremity is then exercised to facilitate the uptake of the colloid by the lymphatic system, and serial images are obtained at preset intervals. No adverse reactions have been reported.

## Management of Arterial Disorders

### ARTERIOSCLEROSIS AND ATHEROSCLEROSIS

**Arteriosclerosis** is the most common disease of the arteries; the term means *hardening of the arteries*. It is a diffuse process whereby the muscle fibers and the endothelial lining of the walls of small

arteries and arterioles become thickened. **Atherosclerosis** involves a different process, affecting the intima of the large and medium-sized arteries. These changes consist of the accumulation of lipids, calcium, blood components, carbohydrates, and fibrous tissue on the intimal layer of the artery. These accumulations are referred to as atheromas or plaques.

Although the pathologic processes of arteriosclerosis and atherosclerosis differ, rarely does one occur without the other, and the terms are often used interchangeably. Because atherosclerosis is a generalized disease of the arteries, when it is present in the extremities, atherosclerosis is usually present elsewhere in the body.

## Pathophysiology

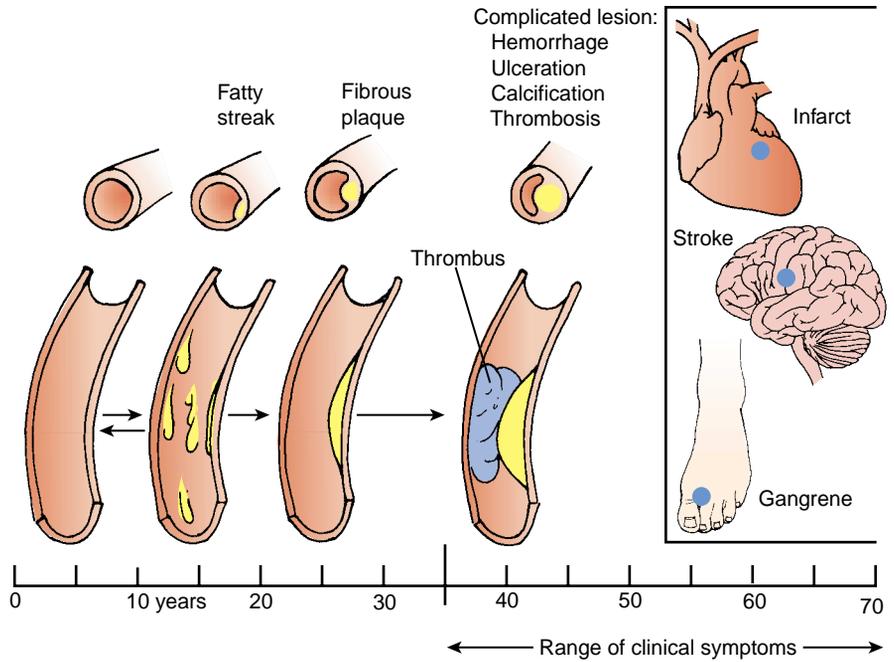

The most common direct results of atherosclerosis in arteries include narrowing (stenosis) of the lumen, obstruction by thrombosis, aneurysm, ulceration, and rupture. Its indirect results are malnutrition and the subsequent fibrosis of the organs that the sclerotic arteries supply with blood. All actively functioning tissue cells require an abundant supply of nutrients and oxygen and are sensitive to any reduction in the supply of these nutrients. If such reductions are severe and permanent, the cells undergo ischemic necrosis (death of cells due to deficient blood flow) and are replaced by fibrous tissue, which requires much less blood flow.

Atherosclerosis can develop at any point in the body, but certain sites are more vulnerable, typically bifurcation or branch areas. In the proximal lower extremity, these include the distal abdominal aorta, the common iliac arteries, the orifice of the superficial femoral and profunda femoris arteries, and the superficial femoral artery in the adductor canal. Distal to the knee, atherosclerosis occurs anywhere along the artery. There are no specific areas, such as arterial bifurcations, that are more vulnerable for atherosclerosis.

Although many theories exist about the development of atherosclerosis, no single theory fully explains the pathogenesis; however, parts of several theories have been combined into the reaction-to-injury theory. According to this theory, vascular endothelial cell injury results from prolonged hemodynamic forces, such as shearing stresses and turbulent flow, irradiation, chemical exposure, or chronic hyperlipidemia in the arterial system. Injury to the endothelium increases the aggregation of platelets and monocytes at the site of the injury. Smooth muscle cells migrate and proliferate, allowing a matrix of collagen and elastic fibers to form. It may be that there is no single cause or mechanism for the development of atherosclerosis; rather, multiple processes may be involved (Moore, 2002).

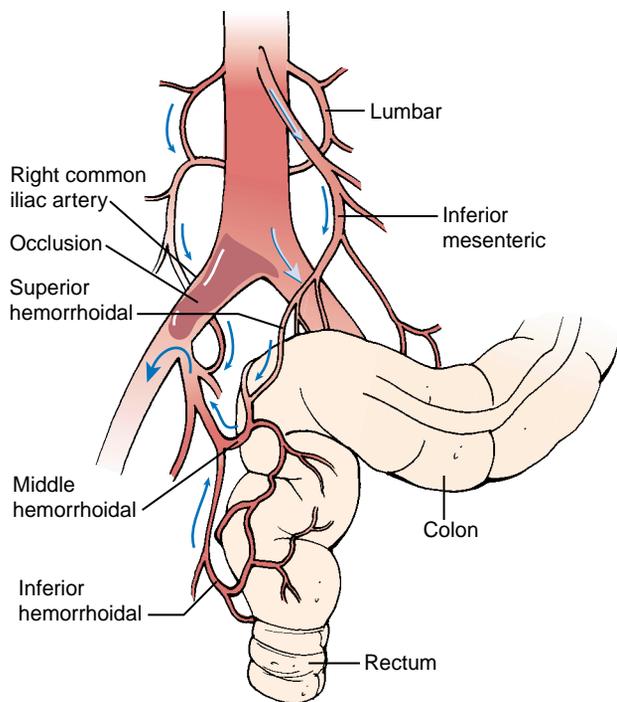

Morphologically, atherosclerotic lesions are of two types: fatty streaks and fibrous plaque. Fatty streaks are yellow and smooth, protrude slightly into the lumen of the artery, and are composed of lipids and elongated smooth muscle cells. These lesions have been found in the arteries of people of all age groups, including infants. It is not clear whether fatty streaks predispose the person to the formation of fibrous plaques or if they are reversible. They do not usually cause clinical symptoms.

The fibrous plaque characteristic of atherosclerosis is composed of smooth muscle cells, collagen fibers, plasma components, and lipids. It is white to whitish yellow and protrudes in various degrees into the arterial lumen, sometimes completely obstructing it. These plaques are found predominantly in the abdominal aorta and the coronary, popliteal, and internal carotid arteries. This plaque is believed to be an irreversible lesion (Fig. 31-6). Gradual narrowing of the arterial lumen as the disease process progresses stimulates the development of collateral circulation

**FIGURE 31-6** Schematic concept of the progression of atherosclerosis. Fatty streaks constitute one of the earliest lesions of atherosclerosis. Many fatty streaks regress, whereas others progress to fibrous plaques and eventually to atheroma, which may be complicated by hemorrhage, ulceration, calcification, or thrombosis and may produce myocardial infarction, stroke, or gangrene.

(Fig. 31-7). Collateral circulation consists of preexisting vessels that enlarge to reroute blood flow in the presence of a hemodynamically significant stenosis or occlusion. Collateral flow allows continued perfusion to the tissues beyond the arterial obstruction, but it is often inadequate to meet imposed metabolic demand, and ischemia results.

**FIGURE 31-7** Development of channels for collateral blood flow in response to occlusion of the right common iliac artery and the terminal aortic bifurcation.

### Risk Factors

Many risk factors are associated with atherosclerosis (Chart 31-2). Although it is not completely clear whether modification of these risk factors prevents the development of cardiovascular disease, evidence indicates that it may slow the disease process. Some risk factors, such as age or gender, cannot be modified. However, it is believed that genetic factors can be modified indirectly by altering other risk factors (Moore, 2002).

Tobacco use may be one of the strongest risk factors in the development of atherosclerotic lesions. Nicotine decreases blood flow to the extremities and increases heart rate and blood pressure by stimulating the sympathetic nervous system, causing vasoconstriction. It also increases the risk for clot formation by increasing the aggregation of platelets. Carbon monoxide, a toxin produced by burning tobacco, combines more readily with the hemoglobin than oxygen does, depriving the tissues of oxygen. The amount of tobacco use is directly related to the extent of the disease, and cessation of tobacco use reduces the risks. Many other factors

**Chart 31-2**  
**Risk Factors for Atherosclerosis**

**Modifiable**

- Nicotine use (ie, tobacco smoking, chewing)
- Diet (contributing to hyperlipidemia)
- Hypertension
- Diabetes (which speeds the atherosclerotic process by thickening the basement membranes of both large and small vessels)
- Stress
- Sedentary lifestyle

**Nonmodifiable**

- Age
- Gender

such as obesity, stress, and lack of exercise have been identified as contributing to the disease process.

## Prevention

Intermittent claudication is a sign of generalized atherosclerosis and may be a marker of occult coronary artery disease. Because a high-fat diet is suspected of contributing to atherosclerosis, it is reasonable to measure serum cholesterol and to begin prevention efforts. The American Heart Association recommends reducing the amount of fat ingested in a healthy diet, substituting unsaturated fats for saturated fats, and decreasing cholesterol intake to no more than 300 mg daily to reduce the risk of cardiovascular disease (Krauss et al., 2000).

Certain medications combined with dietary modification and exercise are being used to reduce blood lipid levels. There is limited evidence that these medications can alter the course of peripheral arterial disease, but they may reduce the mortality rate from cardiovascular disease. Several classes of medication are used to prevent atherosclerosis: bile acid sequestrants (cholestyramine [Questran, Prevalite] or colestipol [Colestid]), nicotinic acid (niacin, B<sub>3</sub>, Niacor; Niaspan), statins (atorvastatin [Lipitor], lovastatin [Mevacor], pravastatin [Pravachol], simvastatin [Zocor]), fibric acids (gemfibrozil [Lopid]), and lipophilic substances (probucol). Patients receiving long-term therapy with these medications require close medical supervision. Hypertension, which may accelerate the rate at which atherosclerotic lesions form in high-pressure vessels, can lead to cerebrovascular accident (CVA; brain attack, stroke), ischemic renal disease, severe peripheral arterial disease, or coronary artery disease. Results of large, randomized studies demonstrated dramatic reductions in myocardial infarction, stroke, and cardiovascular death when blood pressure was decreased to at least 140/90 mm Hg (Moser, 1999; McAlister et al., 2001).

Although no single risk factor has been identified as the primary contributor to the development of atherosclerotic cardiovascular disease, it is clear that the greater the number of risk factors, the greater the likelihood of developing the disease. Elimination of all controllable risk factors, particularly tobacco use, is strongly recommended.

## Clinical Manifestations

The clinical signs and symptoms resulting from atherosclerosis depend on the organ or tissue affected. Coronary atherosclerosis (heart disease), angina, and acute myocardial infarction are discussed in Chapter 28. Cerebrovascular diseases, including transient cerebral ischemic attacks and stroke, are discussed in Chapter 62. Atherosclerosis of the aorta, including aneurysm, and atherosclerotic lesions of the extremities are discussed later in this chapter. Renovascular disease (renal artery stenosis and end-stage renal disease), including hypertension, is discussed in Chapter 45.

## Medical Management

The traditional medical management of atherosclerosis involves modification of risk factors, a controlled exercise program to improve circulation and increase the functioning capacity of the circulation, medication, and interventional or surgical graft procedures.

## SURGICAL MANAGEMENT

Vascular surgical procedures are divided into two groups: inflow procedures, which provide blood supply from the aorta into the femoral artery, and outflow procedures, which provide blood sup-

ply to vessels below the femoral artery. Inflow surgical procedures are discussed with diseases of the aorta and outflow procedures with peripheral arterial occlusive disease.

## RADIOLOGIC INTERVENTIONS

Several interventional radiologic techniques are important adjunctive therapies to surgical procedures. If an isolated lesion or lesions are identified during the arteriogram, **angioplasty**, also called percutaneous transluminal angioplasty (PTA), may be performed. After the patient receives a local anesthetic, a balloon-tipped catheter is maneuvered across the area of stenosis. Exactly how PTA works is controversial. Some theorize that it improves blood flow by overstretching (and thereby dilating) the elastic fibers of the nondiseased arterial segment, but most clinicians believe that the procedure widens the arterial lumen by cracking and flattening the plaque against the vessel wall (see Chap. 28). Complications from PTA include hematoma formation, embolus, **dissection** (separation of the intima) of the vessel, and bleeding. To decrease the risk of reocclusion, stents (small, mesh tubes made of nitinol, titanium, or stainless steel) may be inserted to support the walls of blood vessels and prevent collapse immediately after balloon inflation (Fig. 31-8). A variety of covered wall stents and stent-grafts may be used for short-segment stenoses. Complications associated with stent or stent-graft use include distal embolization, intimal damage (dissection), and dislodgment. The advantage of angioplasty, stents, and stent-grafts is the decreased length of hospital stay required for the treatment; many of the procedures are performed on an outpatient basis.

## NURSING PROCESS: THE PATIENT WHO HAS PERIPHERAL ARTERIAL INSUFFICIENCY OF THE EXTREMITIES

### Assessment

The nursing assessment includes a complete health and medication history and identification of risk factors for peripheral artery disease. Signs and symptoms detected during the nursing assessment may include claudication pain; rest pain in the forefoot; pallor, rubor, or cyanosis; weak or absent peripheral pulses; and skin breakdown or ulcerations.

### Nursing Diagnosis

Based on assessment data, major nursing diagnoses for the patient may include the following:

- Ineffective peripheral tissue perfusion related to compromised circulation
- Chronic pain related to impaired ability of peripheral vessels to supply tissues with oxygen
- Risk for impaired skin integrity related to compromised circulation
- Deficient knowledge regarding self-care activities

### Planning and Goals

The major goals for the patient may include increased arterial blood supply to the extremities, promotion of vasodilation, prevention of vascular compression, relief of pain, attainment or maintenance of tissue integrity, and adherence to the self-care program.

Measures used by the patient and members of the health care team to accomplish a single goal must be evaluated in terms of

A

B

**FIGURE 31-8** (A) Flexible stent. Courtesy of Medtronic, Peripheral Division, Santa Rosa, California. (B) Representation of a common iliac artery with a Wallstent (Boston Scientific).

the positive and the negative effects these measures may have on the simultaneous achievement of other goals. An overview of the care of a patient with peripheral arterial problems is provided in the Plan of Nursing Care: The Patient With Peripheral Vascular Problems.

## Nursing Interventions

### IMPROVING PERIPHERAL ARTERIAL CIRCULATION

Arterial blood supply to a body part can be enhanced by positioning the part below the level of the heart. For the lower extremities, this is accomplished by elevating the head of the patient's bed on 15-cm (6-inch) blocks or by having the patient use a reclining chair or sit with the feet resting on the floor.

The nurse can assist the patient with walking or other moderate or graded isometric exercises that may be prescribed to promote blood flow and encourage the development of collateral circulation. The nurse instructs the patient to walk to the point of pain, rest until pain subsides, and then resume walking so that endurance can be increased as collateral circulation develops. Pain can serve as a guide in determining the amount of exercise appropriate for an individual. The onset of pain indicates that the tissues are not receiving adequate oxygen, signaling the patient to rest before continuing activity. However, a regular exercise program can result in increased walking distance before the onset of claudication. The amount of exercise a patient can tolerate before the onset of pain is determined to provide a baseline for evaluation.

Not all patients with peripheral vascular disease should exercise. Before recommending any exercise program, the primary health care provider should be consulted. Conditions that worsen with activity include leg ulcers, cellulitis, gangrene, or acute thrombotic occlusions.

### PROMOTING VASODILATION AND PREVENTING VASCULAR COMPRESSION

Arterial dilation promotes increased blood flow to the extremities and is therefore a desirable goal for patients with peripheral arterial disease. However, if the arteries are severely sclerosed, inelastic, or damaged, dilation is not possible. For this reason, measures to promote vasodilation, such as medications or surgery, may be only minimally effective.

Nursing interventions may involve applications of warmth to promote arterial flow and instructions to the patient to avoid exposure to cold temperatures, which causes vasoconstriction. Ad-

equate clothing and warm temperatures protect the patient from chilling. If chilling occurs, a warm bath or drink is helpful.

When heat is applied directly to ischemic extremities, the temperature of the heat source must not exceed body temperature. Even at lower temperatures, burn injuries can occur in ischemic extremities. Excess heat may increase the metabolic rate of the extremities and increase the need for oxygen beyond that provided by the reduced arterial flow through the diseased artery.

**NURSING ALERT** Patients are instructed to test the temperature of bath water and to avoid using hot-water bottles and heating pads on the extremities. Applying a heating pad to the abdomen can cause reflex vasodilation in the extremities and is safer than direct application of heat to affected extremities.

Nicotine causes vasospasm and can thereby dramatically reduce circulation to the extremities. Tobacco smoke also impairs transport and cellular use of oxygen and increases blood viscosity. Patients with arterial insufficiency who use tobacco (ie, smoke, chew) must be fully informed of the effects of nicotine on circulation and encouraged to stop using tobacco.

Emotional upsets stimulate the sympathetic nervous system, resulting in peripheral vasoconstriction. Although emotional stress is unavoidable, it can be minimized to some degree by avoiding stressful situations when possible or by consistently following a stress-management program. Counseling services or relaxation training may be indicated for people who cannot cope effectively with situational stressors.

Constrictive clothing and accessories such as tight socks, panty girdles, and shoelaces impede circulation to the extremities and promote venous stasis and therefore should be avoided. Crossing the legs should be discouraged because it compresses vessels in the legs.

### RELIEVING PAIN

Frequently, the pain associated with peripheral arterial insufficiency is chronic and continuous. It limits activities, affects work and responsibilities, disturbs sleep, and alters patients' sense of well-being. Patients are often depressed, irritable, and unable to exert the energy necessary to execute prescribed therapies, making pain relief even more difficult. Analgesics such as oxycodone plus acetylsalicylic acid (Percodan) or oxycodone plus acetamin-

## Plan of Nursing Care

### The Patient With Peripheral Vascular Problems

(continued)

## Plan of Nursing Care

### The Patient With Peripheral Vascular Problems (Continued)

#### Nursing Interventions

2. Encourage wearing protective shoes and padding for pressure areas.
3. Encourage meticulous hygiene; bathing with neutral soaps, applying lotions, carefully trimming nails.
4. Caution to avoid scratching or vigorous rubbing.
5. Promote good nutrition; adequate intake of vitamins A and C, protein, and zinc; control of obesity.

#### Rationale

2. Protective shoes and padding prevent foot injuries and blisters.
3. Neutral soaps and lotions prevent drying and cracking of skin.
4. Scratching and rubbing can cause skin abrasions and bacterial invasion.
5. Good nutrition promotes healing and prevents tissue breakdown.

#### Expected Outcomes

- Wears protective shoes
- Adheres to meticulous hygiene regimen
- Eats a healthy diet that contains adequate protein and vitamins A and C

**Nursing Diagnosis:** Deficient knowledge regarding self-care activities

**Goal:** Adherence to the self-care program

1. Include family/significant others in teaching program.
2. Provide written instructions about foot care, leg care, and exercise program.
3. Assist to obtain properly fitting clothing, shoes, stockings.
4. Refer to self-help groups as indicated, such as smoking cessation clinics, stress management, weight management, and exercise program.

1. Adherence to the self-care program is enhanced when the patient receives support from family and from appropriate self-help groups and agencies.
2. Written instructions serve as reminder and reinforcement of information.
3. Constrictive clothing and accessories impede circulation and promote venous stasis.
4. Reducing risk factors may reduce symptoms or slow disease progression.

- Practices frequent position changes as prescribed
- Practices postural exercises as prescribed
- Takes medications as prescribed
- Avoids vasoconstrictors
- Uses measures to prevent trauma
- Uses stress management program
- Accepts condition as chronic but amenable to therapies that will decrease symptoms

open (Percocet) may be helpful in reducing pain to the point where the patient can participate in the therapies that can increase circulation and ultimately relieve pain more effectively.

#### MAINTAINING TISSUE INTEGRITY

Poorly nourished tissues are susceptible to damage and infection. When lesions develop, healing may be delayed or inhibited because of the poor blood supply to the area. Infected, nonhealing ulcerations of the extremities can be debilitating and may require prolonged and often expensive treatments. Amputation of an ischemic limb may eventually be necessary. Measures to prevent these complications must be a high priority and vigorously implemented.

Trauma to the extremities must be avoided. Advising the patient to wear sturdy, well-fitting shoes or slippers to prevent foot injury and blisters may be helpful, as may be recommending neutral soaps and body lotions to prevent drying and cracking of skin. Scratching and vigorous rubbing can abrade skin and create a site for bacterial invasion; therefore, feet should be patted dry. Stockings should be clean and dry. Fingernails and toenails should be carefully trimmed straight across and sharp corners filed to follow the contour of the nail. If nails are thick and brittle and cannot be trimmed safely, a podiatrist must be consulted. Corns and calluses need to be removed by a health care professional. Special shoe inserts may be needed to prevent calluses from recurring. All signs of blisters, ingrown toenails, infection, or other problems should be

reported to health care professionals for treatment and follow-up. Patients with diminished vision may require assistance in periodically examining the lower extremities for trauma.

Good nutrition promotes healing and prevents tissue breakdown and is therefore included in the overall therapeutic program for patients with peripheral vascular disease. Eating a well-balanced diet that contains adequate protein and vitamins is necessary for patients with arterial insufficiency. Key nutrients play specific roles in wound healing. Vitamin C is essential for collagen synthesis and capillary development. Vitamin A enhances epithelialization. Zinc is necessary for cell mitosis and cell proliferation. Obesity strains the heart, increases venous congestion, and reduces circulation; therefore, a weight-reduction plan may be necessary for some patients. A diet low in lipids may be indicated for patients with atherosclerosis.

#### PROMOTING HOME AND COMMUNITY-BASED CARE

The self-care program is planned with the patient so that activities that promote arterial and venous circulation, relieve pain, and promote tissue integrity are acceptable. The patient and family are helped to understand the reasons for each aspect of the program and the possible consequences of nonadherence. Long-term care of the feet and legs is of prime importance in the prevention of trauma, ulceration, and gangrene. The Plan of Nursing Care describes nursing care for patients with peripheral vascular disease. Chart 31-3 provides detailed patient instructions for foot and leg care.

Chart 31-3

## Home Care Checklist • Foot and Leg Care in Peripheral Vascular Disease

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
<ul style="list-style-type: none"> <li>• Demonstrate daily foot bathing: Wash between toes with mild soap and lukewarm water, then rinse thoroughly and pat rather than rub dry.</li> </ul>	✓	✓
<ul style="list-style-type: none"> <li>• Recognize the dangers of thermal injury:               <ul style="list-style-type: none"> <li>– Wear clean, loose, soft cotton socks (they are comfortable, allow air to circulate, and will absorb moisture)</li> <li>– In cold weather, wear extra socks in extra-large shoes.</li> <li>– Avoid heating pads, whirlpools, and hot tubs.</li> <li>– Avoid sunburn.</li> </ul> </li> </ul>	✓	
<ul style="list-style-type: none"> <li>• Identify safety concerns:               <ul style="list-style-type: none"> <li>– Inspect feet daily with a mirror for redness, dryness, cuts, blisters, etc.</li> <li>– Always wear soft shoes or slippers when out of bed.</li> <li>– Trim nails straight across after showering.</li> <li>– Consult podiatrist to trim nails if vision is decreased; also for care of corns, blisters, ingrown nails.</li> <li>– Clear pathways in house to prevent injury.</li> <li>– Avoid wearing thong sandals.</li> <li>– Use lamb's wool between toes if they overlap or rub each other.</li> </ul> </li> </ul>	✓	✓
<ul style="list-style-type: none"> <li>• Demonstrate comfort measures:               <ul style="list-style-type: none"> <li>– Wear leather shoes with an extra-depth toebox. Synthetic shoes do not allow air to circulate.</li> <li>– If feet become dry and scaly, use cream with lanolin. Never put cream between toes.</li> <li>– If feet perspire, especially between toes, use powder daily and/or lamb's wool between toes to promote drying.</li> </ul> </li> </ul>	✓	
<ul style="list-style-type: none"> <li>• Demonstrate ability to decrease risk of constricting blood vessels:               <ul style="list-style-type: none"> <li>– Avoid promoting circular compression around feet or knees—for example, by applying knee-high stockings or tight socks.</li> <li>– Do not cross legs at knees.</li> <li>– Stop using nicotine (ie, tobacco smoking or chewing) because nicotine causes vasoconstriction and vasospasm.</li> <li>– Avoid applying tight, constricting bandages.</li> <li>– Participate in a regular walking exercise program to stimulate circulation.</li> </ul> </li> </ul>	✓	
<ul style="list-style-type: none"> <li>• Recognize when to seek medical attention:               <ul style="list-style-type: none"> <li>– Contact health care provider at the onset of skin breakdown such as abrasions, blisters, athlete's foot, or pain.</li> <li>– Do not use any medication on feet or legs unless prescribed.</li> <li>– Avoid using iodine, alcohol, corn/wart-removing compound, or adhesive products before checking with health care provider.</li> </ul> </li> </ul>	✓	✓

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Demonstrates an increase in arterial blood supply to extremities
  - a. Exhibits extremities warm to touch
  - b. Has improved color of extremities (ie, free of rubor or cyanosis)
  - c. Experiences decreased muscle pain with exercise
  - d. Demonstrates an increase in walking distance or duration
2. Promotes vasodilation; prevents vascular compression
  - a. Protects extremities from exposure to cold
  - b. Avoids use of tobacco
  - c. Uses stress management strategies to minimize emotional upset
  - d. Wears nonconstricting clothing
  - e. Avoids leg crossing
  - f. Takes medication as prescribed
3. Has decrease in severity and duration of pain
4. Attains or maintains tissue integrity
  - a. Avoids trauma and irritation to skin
  - b. Wears protective shoes
  - c. Adheres to meticulous hygienic regimen
  - d. Eats a healthy diet that contains adequate protein, vitamins A and C, and zinc
  - e. Performs self-care activities

## PERIPHERAL ARTERIAL OCCLUSIVE DISEASE

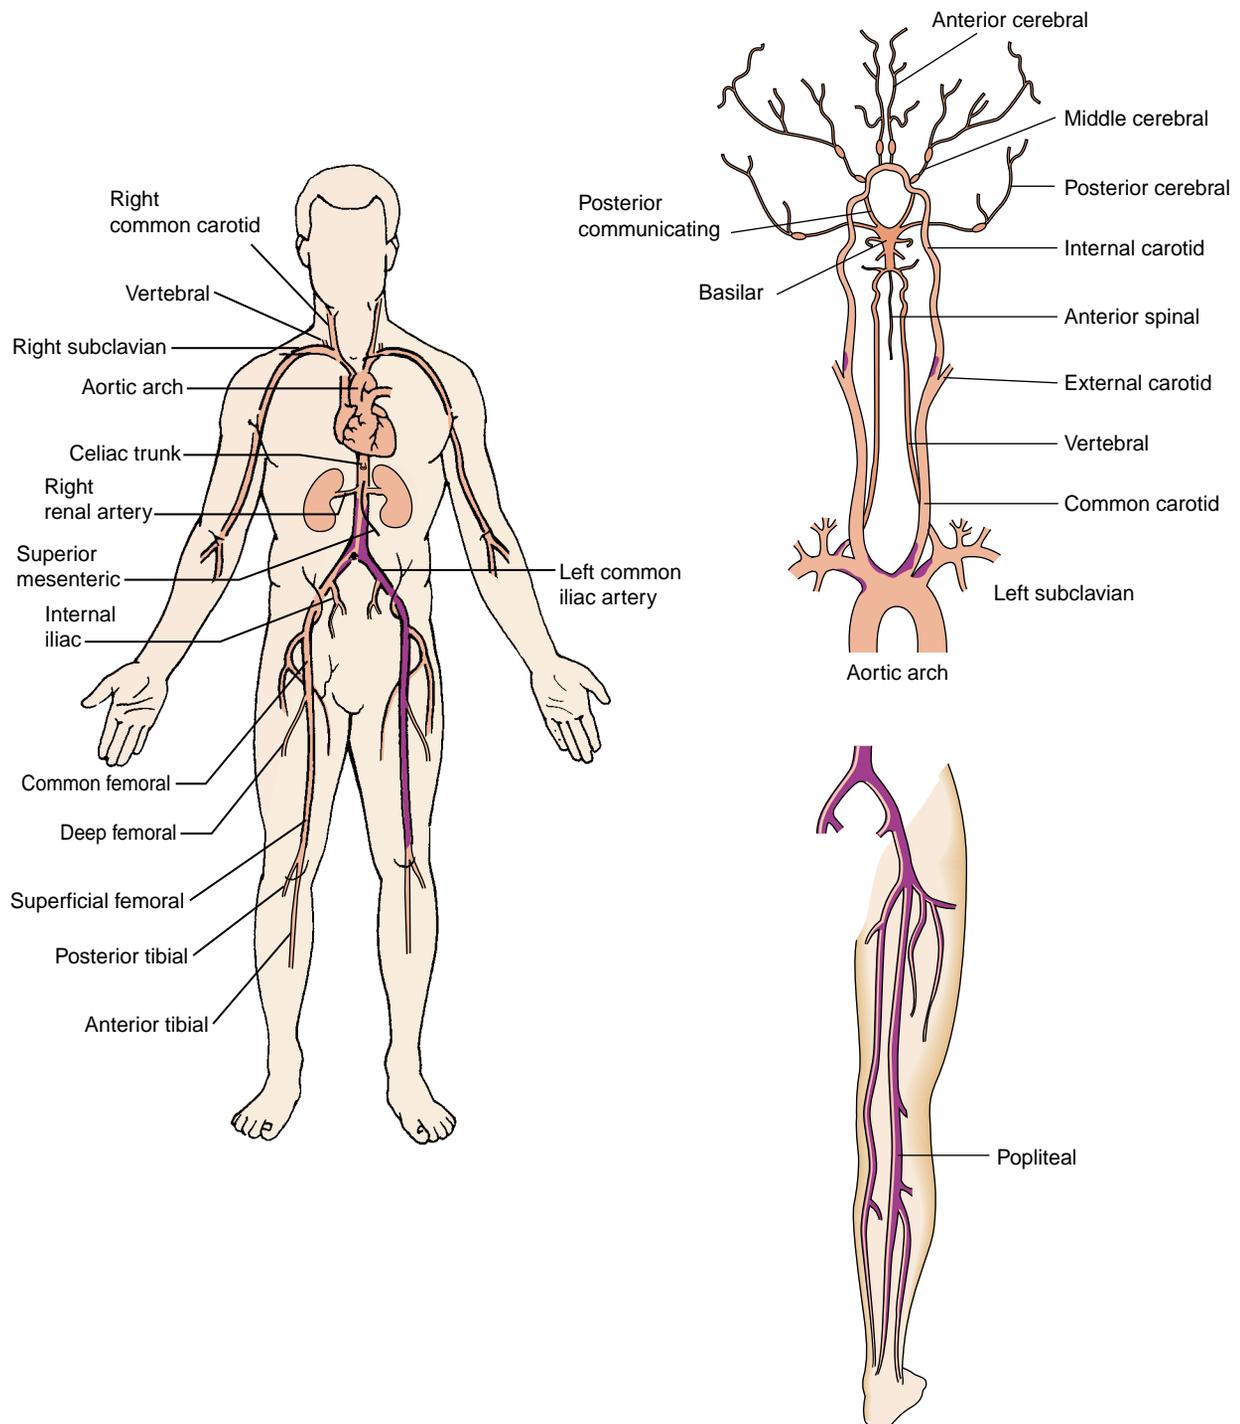

Arterial insufficiency of the extremities is usually found in individuals older than 50 years of age, most often in men. The legs are most frequently affected; however, the upper extremities may be involved. The age of onset and the severity are influenced by the type and number of atherosclerotic risk factors (Chart 31-4). In peripheral arterial disease, obstructive lesions are predominantly confined to segments of the arterial system extending from the aorta below the renal arteries to the popliteal artery (Fig. 31-9). However, distal occlusive disease is frequently seen in patients with diabetes mellitus and in elderly patients.

Chart 31-4

## Risk Factors for Peripheral Arterial Disease

<b>Nonmodifiable</b>	Hypertension
Age	Diet (contributing to hyperlipidemia)
Gender	Obesity
Familial predisposition	Sedentary lifestyle
<b>Modifiable</b>	Stress
Nicotine use (eg, tobacco smoking, chewing)	Diabetes mellitus

**FIGURE 31-9** Common sites of atherosclerotic obstruction in major arteries.

### Clinical Manifestations

The hallmark is intermittent claudication. This pain may be described as aching, cramping, fatigue, or weakness that is consistently reproduced with the same degree of exercise or activity and relieved with rest. The pain commonly occurs in muscle groups one joint level below the stenosis or occlusion. As the disease progresses, the patient may have a decreased ability to walk the same distance or may notice increased pain with ambulation. When the arterial insufficiency becomes severe, the

patient begins to have rest pain. This pain is associated with critical ischemia of the distal extremity and is persistent, aching, or boring; it may be so excruciating that it is unrelieved by opioids. Ischemic rest pain is usually worse at night and often wakes the patient. Elevating the extremity or placing it in a horizontal position increases the pain, whereas placing the extremity in a dependent position reduces the pain. In bed, some patients sleep with the affected leg hanging over the side of the bed. Some patients sleep in a reclining chair in an attempt to relieve the pain.

## Assessment and Diagnostic Findings

A sensation of coldness or numbness in the extremities may accompany intermittent claudication and is a result of the reduced arterial flow. When the extremity is examined, it may feel cool to the touch and look pale when elevated or ruddy and cyanotic when placed in a dependent position. Skin and nail changes, ulcerations, gangrene, and muscle atrophy may be evident. Bruits may be auscultated with a stethoscope; a bruit is the sound produced by turbulent blood flow through an irregular, tortuous, stenotic vessel or through a dilated segment of the vessel (aneurysm). Peripheral pulses may be diminished or absent.

Examining the peripheral pulses is an important part of assessing arterial occlusive disease. Unequal pulses between extremities or the absence of a normally palpable pulse is a sign of peripheral arterial disease. The femoral pulse in the groin and the posterior tibial pulse beside the medial malleolus are most easily palpated. The popliteal pulse is sometimes difficult to palpate; the location of the dorsalis pedis artery on the dorsum of the foot varies and is normally absent in about 7% of the population.

The presence, location, and extent of arterial occlusive disease are determined by a careful history of the symptoms and by physical examination. The color and temperature of the extremity are noted and the pulses palpated. The nails may be thickened and opaque, and the skin may be shiny, atrophic, and dry, with sparse hair growth. The assessment includes comparison of the right and left extremities.

The diagnosis of peripheral arterial occlusive disease may be made using CW Doppler and ankle-brachial indices (ABIs), treadmill testing for claudication, duplex ultrasonography, or other imaging studies previously described.

## Medical Management

Generally, patients feel better with some type of exercise program. If this program is combined with weight reduction and cessation of tobacco use, patients often can improve their activity tolerance. Patients should not be promised that their symptoms will be relieved if they stop tobacco use, because claudication may persist, and they may lose their motivation to stop using tobacco.

### PHARMACOLOGIC THERAPY

Various medications are prescribed to treat the symptoms of peripheral arterial disease. Pentoxifylline (Trental) increases erythrocyte flexibility and reduces blood viscosity, and it is therefore thought to improve the supply of oxygenated blood to the muscle. Cilostazol (Pletal) works by inhibiting platelet aggregation, inhibiting smooth muscle cell proliferation, and increasing vasodilation. Antiplatelet aggregating agents such as aspirin, ticlopidine (Ticlid), and clopidogrel (Plavix) are thought to improve circulation throughout diseased arteries or prevent intimal hyperplasia leading to stenosis.

### SURGICAL MANAGEMENT

In most patients, when intermittent claudication becomes severe and disabling or when the limb is at risk for amputation because of tissue loss, vascular grafting or endarterectomy is the treatment of choice. The choice of the surgical procedure depends on the degree and location of the stenosis or occlusion. Other important considerations are the overall health of the patient and the length of the procedure that can be tolerated. It is sometimes necessary to provide the palliative therapy of primary amputation rather than an arterial bypass. If endarterectomy is performed, an incision is made into the artery, and the atheromatous obstruction is

### NURSING RESEARCH PROFILE 31-1

#### Does Exercise Relieve Pain of Peripheral Arterial Claudication?

Braun, C. M., Colucci, A. M., & Patterson, R. B. (1999). Components of an optimal exercise program for the treatment of patients with claudication. *Journal of Vascular Nursing*, 17(2), 32–36.

#### Purpose

Because patients with peripheral arterial claudication increasingly limit activity because of pain, they become physically deconditioned. The patients and their families report decreased quality of life (QOL) because of the activity limitations. Traditional treatment for peripheral arterial claudication has been surgical bypass. Exercise programs are beginning to be offered as treatment for patients with peripheral arterial claudication. Little is known about the effectiveness of exercise in the treatment of this patient population. This study evaluated whether a supervised exercise and education program increased pain-free walking distance and improved total fitness of patients with peripheral arterial claudication.

#### Study Sample and Design

This study was a retrospective review of 96 patients who had experienced symptoms of peripheral arterial claudication for longer than 3 months. Patients participated in a cardiovascular conditioning and muscle training exercise program with education classes for 12 weeks. Twenty-two patients were monitored for 2 years; data were collected at 1 year and 2 years after the original 12-week program.

#### Findings

Patients' walking distances increased threefold after participation in the 12-week program. The average maximum distance patients were able to walk at the beginning of the program was 190 meters. After the 12-week program the average distance was 580 m. The 22 patients followed for two years had an average maximum walking distance of 882 m 1 year after the 12-week program and 731 m 2 years after the 12-week program. The researchers concluded that patients were able to maintain and continue exercising after completion of the 12-week program. Families reported improvement in general health and psychosocial behavior of the patients.

#### Nursing Implications

Patients with peripheral arterial claudication benefit from a supervised exercise program combined with education programs. Supervised exercise programs may enable patients with peripheral arterial claudication to increase the distance they can walk without symptoms, improve their quality of life, and avoid or delay surgical intervention.

removed. The artery is then sutured closed to restore vascular integrity (Fig. 31-10).

Bypass grafts are performed to reroute the blood flow around the stenosis or occlusion. Before bypass grafting, the surgeon determines where the distal **anastomosis** (site where the vessels are surgically joined) will be placed. The distal outflow vessel must be at least 50% patent for the graft to remain patent. A higher bypass graft patency rate is associated with keeping the length of the bypass as short as possible.

If the atherosclerotic occlusion is below the inguinal ligament in the superficial femoral artery, the surgical procedure of choice is the femoral-to-popliteal graft. This procedure is further classified as above-knee and below-knee grafts, referring to the location of the distal anastomosis.

Lower leg or ankle vessels with occlusions may also require grafts. Occasionally, the entire popliteal artery is occluded, and there is only collateral circulation. The distal anastomosis may be

**A** **B** **C** **D**

**FIGURE 31-10** In an aortoiliac endarterectomy, the vascular surgeon (A) identifies the diseased area, (B) clamps off the blood supply to the vessel, (C) removes the plaque, and (D) sutures the vessel shut, after which blood flow is restored. Adapted with permission from Rutherford, R. B. (1999). *Vascular surgery: Vol. 1 and 2* (5th ed.). Philadelphia: W. B. Saunders.

made onto any of the tibial arteries (posterior tibial, anterior tibial, or peroneal arteries) or the dorsalis pedis or plantar artery. The distal anastomosis site is determined by the ease of exposure of the vessel in surgery and by which vessel provides the best flow to the distal limb. These grafts require the use of native vein to ensure patency. Native vein is autologous vein (the patient's own vein). The greater or lesser saphenous vein or a combination of one of the saphenous veins and an upper extremity vein such as the cephalic vein are used to meet the required length.

How long the graft remains patent is determined by several factors, including the size of the graft, graft location, and development of intimal hyperplasia at anastomosis sites. Bypass grafts may be synthetic or autologous vein. Several synthetic materials are available for use as a peripheral bypass graft: woven or knitted Dacron, expanded polytetrafluoroethylene (ePTFE, such as Gore-Tex or Impra), collagen-impregnated, and umbilical vein. Infection is a problem that threatens survival of the graft and almost always requires removal of the graft.

If a vein graft is the surgical choice, care must be taken in the operating room not to damage the vein after harvesting (removing the vein from the patient's body). The vein is occluded at one end and inflated with a heparinized solution to check for leakage and competency. When this is done, the graft is placed in a heparinized solution to keep it from becoming dry and brittle.

## Nursing Management

### MAINTAINING CIRCULATION

The primary objective in the postoperative management of patients who have undergone vascular procedures is to maintain adequate circulation through the arterial repair. Pulses, Doppler assessment, color and temperature of the extremity, capillary refill, and sensory and motor function of the affected extremities are checked, compared with those of the other extremity, and recorded every hour for the first 8 hours and then every 2 hours for 24 hours. Doppler evaluation of the vessels distal to the bypass graft should be performed for all postoperative vascular patients, because it is more sensitive than palpation for pulses. The ABI is monitored at least once every 8 hours for the first 24 hours and then once each day until discharge (not usually assessed for pedal artery bypasses). An adequate circulating blood volume should be established and maintained. Disappearance of a pulse that was present may indicate thrombotic occlusion of the graft; the surgeon is immediately notified.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Continuous monitoring of urine output (more than 30 mL/hour), central venous pressure, mental status, and pulse rate and volume permit early recognition and treatment of fluid imbalances. Bleeding can result from the heparin administered during surgery or from an anastomotic leak. A hematoma may form as well.

Leg crossing and prolonged extremity dependency are avoided to prevent thrombosis. Edema is a normal postoperative finding; however, elevating the extremities and encouraging the patient to exercise the extremities while in bed reduces edema. Elastic compression stockings may be prescribed for some patients, but care must be taken to avoid compressing distal vessel bypass grafts. Severe edema of the extremity, pain, and decreased sensation of toes or fingers can be an indication of compartment syndrome.

### PROMOTING HOME AND COMMUNITY-BASED CARE

Discharge planning includes assessing the patient's ability to manage independently. The nurse determines if the patient has a network of family and friends to assist with activities of daily living. The patient may need to be encouraged to make the lifestyle changes necessary with a chronic disease, including pain management and modifications in diet, activity, and hygiene (skin care). The nurse ensures that the patient has the knowledge and ability to assess for any postoperative complications such as infection, occlusion of the artery or graft, and decreased blood flow. The nurse assists the patient in developing a plan to stop using tobacco. The Plan of Nursing Care describes nursing care for patients with peripheral vascular disease.

## UPPER EXTREMITY ARTERIAL OCCLUSIVE DISEASE

Arterial occlusions occur less frequently in the upper extremities (arms) than in the legs and cause less severe symptoms because the collateral circulation is significantly better in the arms. The arms also have less muscle mass and are not subjected to the workload of the legs.

### Clinical Manifestations

Stenosis and occlusions in the upper extremity result from atherosclerosis or trauma. The stenosis usually occurs at the origin of

the vessel proximal to the vertebral artery, setting up the vertebral artery as the major contributor of flow. The patient may develop a “subclavian steal” syndrome characterized by reverse flow in the vertebral and basilar artery to provide blood flow to the arm. This syndrome may cause vertebrobasilar (cerebral) symptoms. Most patients are asymptomatic; however, some report vertigo, ataxia, syncope, or bilateral visual changes.

The patient typically complains of arm fatigue and pain with exercise (forearm claudication) and inability to hold or grasp objects (eg, painting, combing hair, placing objects on shelves above the head). Some even notice difficulties driving.

### Assessment and Diagnostic Findings

Assessment findings include coolness and pallor of the affected extremity, decreased capillary refill, and a difference in arm blood pressures of more than 20 mm Hg. Noninvasive studies performed to evaluate for upper extremity arterial occlusions include upper and forearm blood pressure determinations and duplex ultrasonography to identify the anatomic location of the lesion and to evaluate the hemodynamics of the blood flow. Transcranial Doppler evaluation is performed to evaluate the intracranial circulation and to detect any siphoning of blood flow from the posterior circulation to provide blood flow to the affected arm. If a surgical or interventional procedure is planned, an arteriogram may be necessary.

### Medical Management

If a short, focal lesion is identified in an upper extremity artery, a PTA may be performed. If the lesion involves the subclavian artery with documented siphoning of blood flow from the intracranial circulation, several surgical procedures are available: carotid-to-subclavian artery bypass, axillary-to-axillary artery bypass, and autogenous reimplantation of the subclavian to the carotid artery.

### Nursing Management

Nursing assessment involves bilateral comparison of upper arm blood pressures (obtained by stethoscope and Doppler); radial, ulnar, and brachial pulses; motor and sensory function; temperature; color changes; and capillary refill every 2 hours. Disappearance of a pulse or Doppler flow that had been present may indicate an acute occlusion of the vessel, and the physician is notified immediately.

**NURSING ALERT** Before and for 24 hours after surgery, the patient's arm is kept at heart level and protected from cold, venipunctures or arterial sticks, tape, and constrictive dressings.

After surgery, the arm is kept at heart level or elevated, with the fingers at the highest level. Pulses are monitored with Doppler assessment of the arterial flow every hour for 8 hours and then every 2 hours for 24 hours. Blood pressure (obtained by stethoscope and Doppler) is also assessed every hour for 8 hours and then every 2 hours for 24 hours. Motor and sensory function, warmth, color, and capillary refill are monitored with each arterial flow (pulse) assessment.

Discharge planning includes assessing the patient's ability to manage independently. The nurse determines whether the patient has a network of family and friends to assist with activities of daily living. The patient may need to be encouraged to make the lifestyle changes necessary for a chronic disease, including pain management and modifications in diet, activity, and hygiene

(skin care). The nurse ensures that the patient has the knowledge and ability to assess for any postoperative complications such as infection, reocclusion of the artery or occlusion of the graft, and decreased blood flow. The patient is assisted in developing a plan to stop using tobacco. The Plan of Nursing Care describes nursing care for patients with peripheral vascular disease.

## THROMBOANGIITIS OBLITERANS (BUERGER'S DISEASE)

Buerger's disease is characterized by recurring inflammation of the intermediate and small arteries and veins of the lower and (in rare cases) upper extremities. It results in thrombus formation and occlusion of the vessels. It is differentiated from other vessel diseases by its microscopic appearance. In contrast to atherosclerosis, Buerger's disease is believed to be an autoimmune disease that results in occlusion of distal vessels.

The cause of Buerger's disease is unknown, but it is believed to be an autoimmune vasculitis. It occurs most often in men between the ages of 20 and 35 years, and it has been reported in all races and in many areas of the world. There is considerable evidence that heavy smoking or chewing of tobacco is a causative or an aggravating factor (Frost-Rude et al., 2000). Generally, the lower extremities are affected, but arteries in the upper extremities or viscera can also be involved. Buerger's disease is generally bilateral and symmetric with focal lesions. Superficial thrombophlebitis may be present.

### Gerontologic Considerations

Although this condition is different from atherosclerosis, Buerger's disease in older patients may also be followed by atherosclerosis of the larger vessels after involvement of the smaller vessels. The patient's ability to walk may be severely limited. Patients are at higher risk for nonhealing wounds because of impaired circulation.

### Clinical Manifestations

Pain is the outstanding symptom of Buerger's disease. The patient complains of foot cramps, especially of the arch (instep claudication), after exercise. The pain is relieved by rest; often, a burning pain is aggravated by emotional disturbances, nicotine, or chilling. Cold sensitivity of the Raynaud type is found in one half the patients and is frequently confined to the hands. Digital rest pain is constant, and the characteristics of the pain do not change between activity and rest.

Physical signs include intense rubor (reddish blue discoloration) of the foot and absence of the pedal pulse but with normal femoral and popliteal pulses. Radial and ulnar artery pulses are absent or diminished. Various types of paresthesia may develop.

As the disease progresses, definite redness or cyanosis of the part appears when the extremity is in a dependent position. Involvement is generally bilateral, but color changes may affect only one extremity or only certain digits. Color changes may progress to ulceration, and ulceration with gangrene eventually occurs.

### Assessment and Diagnostic Findings

Segmental limb blood pressures are taken to demonstrate the distal location of the lesions or occlusions. Duplex ultrasonography is used to document patency of the proximal vessels and to visualize the extent of distal disease. Contrast angiography is performed to demonstrate the diseased portion of the anatomy.

## Management

The treatment of Buerger's disease is essentially the same as that for atherosclerotic peripheral arterial disease. The main objectives are to improve circulation to the extremities, prevent the progression of the disease, and protect the extremities from trauma and infection. Treatment of ulceration and gangrene is directed toward minimizing infection and conservative débridement of necrotic tissue. Tobacco use is highly detrimental, and patients are strongly advised to stop using tobacco completely. Symptoms are often relieved by cessation of smoking and other uses of tobacco.

Vasodilators are rarely prescribed because these medications cause dilation of only healthy vessels; vasodilators may divert blood away from the partially occluded vessels, making the situation worse. A regional sympathetic block or ganglionectomy may be useful in some instances to produce vasodilation and increase blood flow.

### SURGICAL MANAGEMENT OF COMPLICATIONS

If gangrene of a toe develops as a result of arterial occlusive disease in the leg, it is unlikely that toe amputation or even transmetatarsal amputation will be sufficient; usually, a below-knee amputation or, occasionally, an above-knee amputation is necessary. The indications for amputation are worsening gangrene, especially if the infected area is moist, severe rest pain, or fulminating sepsis.

### NURSING MANAGEMENT OF COMPLICATIONS

If an amputation is performed, immediate postoperative care includes elevating the stump for the first 24 hours to promote venous return and minimize edema. The incision is monitored for signs of hematoma (unapproximated suture line, discoloration or ruddy color changes of the skin along the suture line, tenderness with palpation, or oozing of dark blood from the suture line). The nurse assesses the fit of the elastic bandages and ensures the integrity of the wrap and continued ability to fit two fingers between layers of the wrap. Distal skin color and warmth are assessed, if accessible, and recorded. Elastic bandages are removed and reapplied as prescribed by the surgeon (eg, every 6 hours using figure-of-eight turns).

The patient may experience grief, fear, or anxiety related to loss of the limb. The patient is encouraged to discuss his or her feelings. Spiritual advisors and other health care team members are consulted as appropriate. Recovery and rehabilitation require consultation among health care providers (eg, physicians, physical and occupational therapists, prosthetists, dietitians, nurses, discharge coordinators). The patient may decide to be fitted for and learn to use a prosthetic device. Rehabilitation facilities, home care, and outpatient therapy can assist the patient to adapt to the changes in lifestyle.

Discharge planning includes assessing the patient's ability to manage independently. The patient is assisted in developing a plan to stop using tobacco and to manage pain. The patient may need to be encouraged to make the lifestyle changes necessary with a chronic disease, including modifications in diet, activity, and hygiene (skin care). The nurse determines whether the patient has a network of family and friends to assist with activities of daily living. The nurse ensures that the patient has the knowledge and ability to assess for any postoperative complications such as infection and decreased blood flow. The Plan of Nursing Care describes nursing care for patients with peripheral vascular disease.

## AORTITIS

The aorta, which is the main trunk of the arterial system, is divided into the ascending aorta (5 cm [2 inches] in diameter, contained in the pericardium), the aortic arch (extending upward, backward, and downward), and the descending aorta. The thoracic aorta is above the diaphragm; the abdominal aorta is below the diaphragm. The abdominal aorta is further designated as suprarenal (above renal artery level), perirenal level (at renal artery level), and infrarenal (below renal artery level).

Aortitis is inflammation of the aorta, particularly of the aortic arch. Two types are known to occur: Takayasu's disease and syphilitic aortitis. Takayasu's disease, or occlusive thromboangiopathy, is uncommon; today, syphilitic aortitis is rare.

Takayasu's disease, a chronic inflammatory disease of the aortic arch and its branches, primarily affects young or middle-aged women and is more common in those of Asian descent. It is nonatherosclerotic; the exact pathologic mechanism is unknown but thought to be immune complex mediated. It progresses from a systemic inflammation with localized arteritis to end-organ ischemia because of large vessel stenosis or obstruction. Magnetic resonance angiography, CT, duplex ultrasonography, or arteriography is used to diagnose and evaluate the lesions, which are typically long, smooth areas of narrowing with or without aneurysms. In the early stages, the disease may respond to corticosteroids, and patients may benefit from the addition of cytotoxic immunosuppressive agents (Strider et al., 1996). Selective PTA and surgical revascularization may be performed after suppression of the systemic vascular inflammation.

## AORTOILIAC DISEASE

If collateral circulation has developed, patients with a stenosis or occlusion of the aortoiliac segment may be asymptomatic, or they may complain of buttock or low back discomfort associated with walking. Men may experience impotence. These patients may have decreased or absent femoral pulses.

### Medical Management

The treatment of aortoiliac disease is essentially the same as that for atherosclerotic peripheral arterial occlusive disease. The surgical procedure of choice is the aortobi iliac graft. If possible, the distal anastomosis is made to the iliac artery, and the entire surgical procedure can be performed within the abdomen. If the iliac vessels are diseased, the distal anastomosis is made to the femoral arteries (aortobifemoral graft). Bifurcated woven or knitted Dacron grafts are preferred for this surgical procedure.

### Nursing Management

Preoperative assessment, in addition to the standard parameters (see Chap. 18), includes evaluating the brachial, radial, ulnar, femoral, posterior tibial, and dorsalis pedis pulses to establish a baseline for follow-up after arterial lines are placed and postoperatively. Patient teaching includes an overview of the procedure to be performed, the preparation for surgery, and the anticipated postoperative plan of care. Sights, sounds, and sensations that the patient may experience are discussed.

Postoperative care includes monitoring for signs of thrombosis in arteries distal to the surgical site. The nurse assesses color and temperature of the extremity, capillary refill time, sensory and motor function, and pulses by palpation and Doppler every hour for the first 8 hours and then every 2 hours for the first

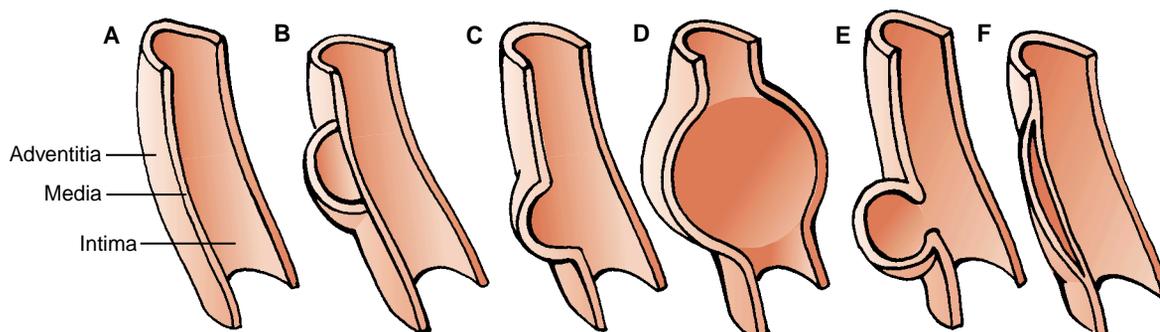

24 hours. Any dusky or bluish discoloration, coolness, capillary refill time greater than 3 seconds, decrease in sensory or motor function, or decrease in pulse quality are reported immediately to the physician.

Postoperative care also includes monitoring for urine output greater than or equal to 30 mL/hour. Renal function may be impaired as a result of hypoperfusion from hypotension, involvement of the renal arteries during the surgical procedure, hypovolemia, or embolization of the renal artery or renal parenchyma. Vital signs, pain, and intake and output are monitored with the pulse and extremity assessments. Results of laboratory tests are monitored and reported to the physician. Abdominal assessment for bowel sounds and paralytic ileus is performed at least every 8 hours. Bowel sounds may not return before the third postoperative day. The absence of bowel sounds, absence of flatus, and abdominal distention are indications of paralytic ileus. Manual manipulation of the bowel during surgery may have caused bruising, resulting in decreased peristalsis. Nasogastric suction may be necessary to decompress the bowel until peristalsis returns. A liquid bowel movement before the third postoperative day may indicate bowel ischemia, which may occur when the mesenteric blood supply (celiac, superior mesenteric, or inferior mesenteric arteries) is occluded. Ischemic bowel usually causes increased pain and an elevated white blood cell count (20,000 to 30,000 cells/mm<sup>3</sup>).

## AORTIC ANEURYSM

An aneurysm is a localized sac or dilation formed at a weak point in the wall of the aorta (Fig. 31-11). It may be classified by its shape or form. The most common forms of aneurysms are sacular or fusiform. A sacular aneurysm projects from one side of the vessel only. If an entire arterial segment becomes dilated, a fusiform aneurysm develops. Very small aneurysms due to localized infection are called mycotic aneurysms.

Historically, the cause of abdominal aortic aneurysm, the most common type of degenerative aneurysm, has been attributed to atherosclerotic changes in the aorta. Other causes of aneurysm formation are listed in Chart 31-5. Aneurysms are serious because they can rupture, leading to hemorrhage and death.

**FIGURE 31-11** Characteristics of arterial aneurysm. (A) Normal artery. (B) False aneurysm—actually a pulsating hematoma. The clot and connective tissue are outside the arterial wall. (C) True aneurysm. One, two, or all three layers of the artery may be involved. (D) Fusiform aneurysm—symmetric, spindle-shaped expansion of entire circumference of involved vessel. (E) Sacular aneurysm—a bulbous protrusion of one side of the arterial wall. (F) Dissecting aneurysm—this usually is a hematoma that splits the layers of the arterial wall.

Chart  
31-5

## Etiologic Classification of Arterial Aneurysms

**Congenital:** Primary connective tissue disorders (Marfan's syndrome, Ehlers-Danlos syndrome) and other diseases (focal medial agenesis, tuberous sclerosis, Turner's syndrome, Menkes' syndrome)

**Mechanical (hemodynamic):** Poststenotic and arteriovenous fistula and amputation-related

**Traumatic (pseudoaneurysms):** Penetrating arterial injuries, blunt arterial injuries, pseudoaneurysms

**Inflammatory (noninfectious):** Associated with arteritis (Takayasu's disease, giant cell arteritis, systemic lupus erythematosus, Behçet's syndrome, Kawasaki's disease) and periarterial inflammation (ie, pancreatitis)

**Infectious (mycotic):** Bacterial, fungal, spirochetal infections  
**Pregnancy-related degenerative:** Nonspecific, inflammatory variant

**Anastomotic (postarteriotomy) and graft aneurysms:** Infection, arterial wall failure, suture failure, graft failure

## THORACIC AORTIC ANEURYSM

Approximately 85% of all cases of thoracic aortic aneurysm are caused by atherosclerosis. They occur most frequently in men between the ages 40 and 70 years. The thoracic area is the most common site for a dissecting aneurysm. About one third of patients with thoracic aneurysms die of rupture of the aneurysm (Rutherford, 1999).

## Clinical Manifestations

Symptoms are variable and depend on how rapidly the aneurysm dilates and how the pulsating mass affects surrounding intrathoracic structures. Some patients are asymptomatic. In most cases, pain is the most prominent symptom. The pain is usually constant and boring but may occur only when the person is supine.

Other conspicuous symptoms are dyspnea, the result of pressure of the sac against the trachea, a main bronchus, or the lung itself; cough, frequently paroxysmal and with a brassy quality; hoarseness, stridor, or weakness or complete loss of the voice (aphonia), resulting from pressure against the left recurrent laryngeal nerve; and dysphagia (difficulty in swallowing) due to impingement on the esophagus by the aneurysm.

### Assessment and Diagnostic Findings

When large veins in the chest are compressed by the aneurysm, the superficial veins of the chest, neck, or arms become dilated, and edematous areas on the chest wall and cyanosis are often evident. Pressure against the cervical sympathetic chain can result in unequal pupils. Diagnosis of a thoracic aortic aneurysm is principally made by chest x-ray, transesophageal echocardiography, and CT.

### Medical Management

In most cases, an aneurysm is treated by surgical repair. General measures such as controlling blood pressure and correcting risk factors may be helpful. It is important to control blood pressure in patients with dissecting aneurysms. Systolic pressure is maintained at about 100 to 120 mm Hg with antihypertensive medications (eg, hydralazine hydrochloride [Hydralazine], esmolol hydrochloride [Brevibloc] or another beta-blocker such as atenolol [Tenormin] or timolol maleate [Timoptic]). Pulsatile flow is reduced by medications that reduce cardiac contractility (eg, pro-

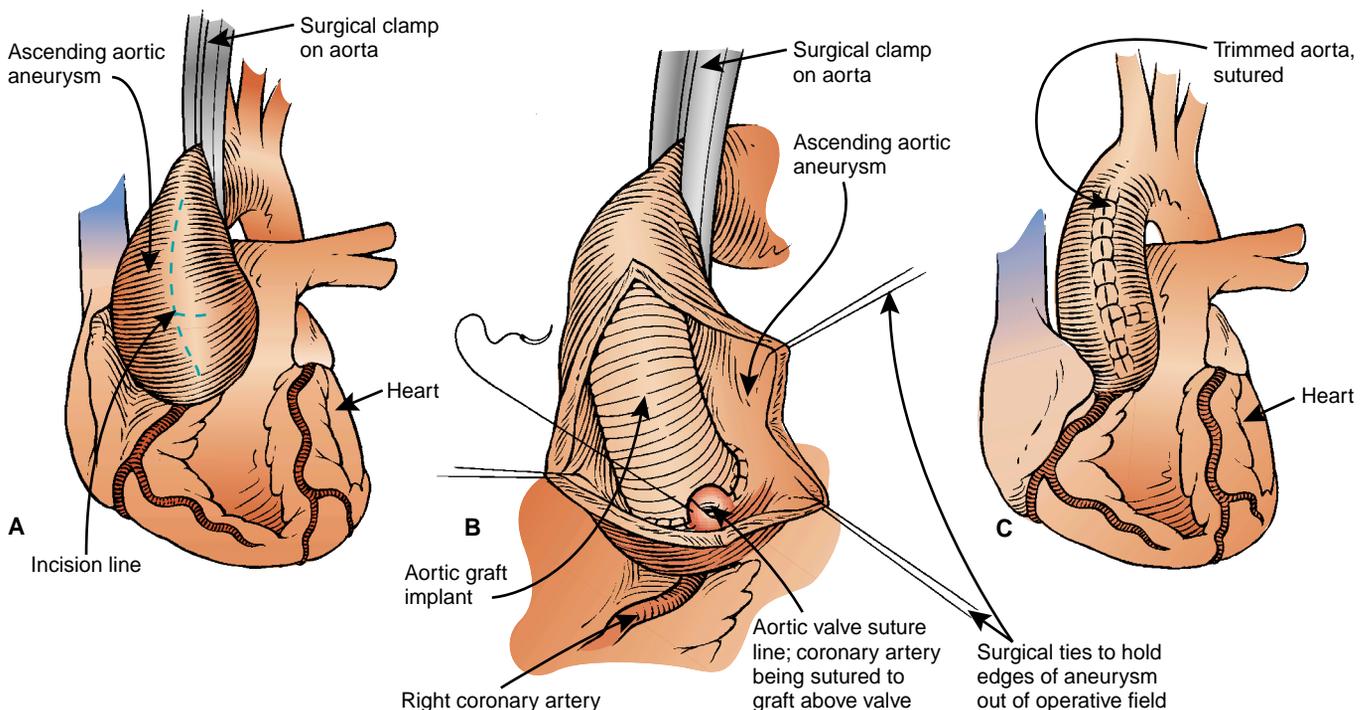

pranolol [Inderal]). The goal of surgery is to repair the aneurysm and restore vascular continuity with a vascular graft (Fig. 31-12). Intensive monitoring is usually required after this type of surgery, and the patient is cared for in the critical care unit. Repair of thoracic aneurysms using endovascular grafts implanted (deployed) percutaneously in an interventional laboratory (eg, cardiac catheterization laboratory) may decrease postoperative recovery time and decrease complications compared with traditional surgical techniques.

### ABDOMINAL AORTIC ANEURYSM

The most common cause of abdominal aortic aneurysm is atherosclerosis. The condition, which is more common among Caucasians, affects men four times more often than women and is most prevalent in elderly patients (Rutherford, 1999). Most of these aneurysms occur below the renal arteries (infrarenal aneurysms). Untreated, the eventual outcome may be rupture and death.

### Pathophysiology

All aneurysms involve a damaged media layer of the vessel. This may be caused by congenital weakness, trauma, or disease. After an aneurysm develops, it tends to enlarge. Risk factors include genetic predisposition, smoking (or other tobacco use), and hypertension; more than one half of patients with aneurysms have hypertension.

**FIGURE 31-12** Repair of an ascending aortic aneurysm and aortic valve replacement. (A) Incision into aortic aneurysm. (B) Aortic valve replacement with aortic graft implant to repair ascending aortic aneurysm. (C) Aortic aneurysm trimmed and closed over graft.

## Clinical Manifestations

About two fifths of patients with abdominal aortic aneurysms have symptoms; the remainder do not. Some patients complain that they can feel their heart beating in their abdomen when lying down, or they may say they feel an abdominal mass or abdominal throbbing. If the abdominal aortic aneurysm is associated with thrombus, a major vessel may be occluded or smaller distal occlusions may result from emboli. A small cholesterol, platelet, or fibrin emboli may lodge in the interosseous or digital arteries, causing blue toes.

## Assessment and Diagnostic Findings

The most important diagnostic indication of an abdominal aortic aneurysm is a pulsatile mass in the middle and upper abdomen. About 80% of these aneurysms can be palpated. A systolic bruit may be heard over the mass. Duplex ultrasonography or CT is used to determine the size, length, and location of the aneurysm (Fig. 31-13). When the aneurysm is small, ultrasonography is conducted at 6-month intervals until the aneurysm reaches a size at which surgery to prevent rupture is of more benefit than the possible complications of a surgical procedure. Some aneurysms remain stable over many years of observation.

### Gerontologic Considerations

Most abdominal aneurysms occur in patients between the ages of 60 and 90 years. Rupture is likely with coexisting hypertension and with aneurysms wider than 6 cm. In most cases at this point, the chances of rupture are greater than the chance of death during surgical repair. If the elderly patient is considered at moderate risk for complications related to surgery or anesthesia, the aneurysm is not repaired until it is at least 5 cm (2 inches) wide.

## Medical Management

An expanding or enlarging abdominal aneurysm is likely to rupture. Surgery is the treatment of choice for abdominal aneurysms wider than 5 cm (2 inches) wide or those that are enlarging.

### SURGICAL MANAGEMENT

The standard treatment for abdominal aortic aneurysm repair has been open surgical repair of the aneurysm by resecting the vessel

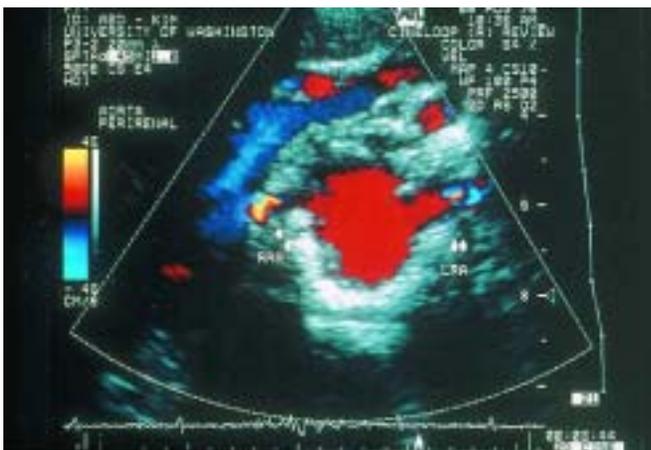

and sewing a bypass graft in place. The mortality rate associated with elective aneurysm repair, a major surgical procedure, is reported to be 1% to 4%. The prognosis for a patient with a ruptured aneurysm is poor, and surgery is performed immediately (Rutherford, 1999).

An alternative for treating an infrarenal abdominal aortic aneurysm is endovascular grafting. Endovascular grafting involves the transluminal placement and attachment of a sutureless aortic graft prosthesis across an aneurysm (Fig. 31-14). This procedure can be performed under local or regional anesthesia. Endovascular grafting of abdominal aortic aneurysms may be performed if the patient's abdominal aorta and iliac arteries are not extremely tortuous and if the aneurysm does not begin at the level of the renal arteries. Clinical trials are evaluating endograft treatment of abdominal aortic aneurysms at or above the level of the renal arteries and the thoracic aorta. Potential complications include bleeding, hematoma, or wound infection at the femoral insertion site; distal ischemia or embolization; dissection or perforation of the aorta; graft thrombosis; graft infection; break of the attachment system; graft migration; proximal or distal graft leaks; delayed rupture; and bowel ischemia.

## Nursing Management

Before surgery, nursing assessment is guided by anticipating a rupture and by recognizing that the patient may have cardiovascular, cerebral, pulmonary, and renal impairment from atherosclerosis. The functional capacity of all organ systems should be assessed. Medical therapies designed to stabilize physiologic function should be promptly implemented.

Signs of impending rupture include severe back pain or abdominal pain, which may be persistent or intermittent and is often

**FIGURE 31-13** Duplex ultrasonic image of abdominal aortic aneurysm at the perirenal level. Cross-sectional image documents the location of right and left renal arteries.

**FIGURE 31-14** Ancure Endograft repair of an abdominal aortic aneurysm.

localized in the middle or lower abdomen to the left of the midline. Low back pain may also be present because of pressure of the aneurysm on the lumbar nerves. This is a serious symptom, usually indicating that the aneurysm is expanding rapidly and is about to rupture. Indications of a rupturing abdominal aortic aneurysm include constant, intense back pain; falling blood pressure; and decreasing hematocrit. Rupture into the peritoneal cavity is rapidly fatal. A retroperitoneal rupture of an aneurysm may result in hematomas in the scrotum, perineum, flank, or penis. Signs of heart failure or a loud bruit may suggest a rupture into the vena cava. Rupture into the vena cava results in the higher-pressure arterial blood entering the lower-pressure venous system and causing turbulence, which is heard as a bruit. The high blood pressure and increased blood volume returning to the right heart from the vena cava may cause the right heart to fail. The overall surgical mortality rate associated with a ruptured aneurysm is 50% to 75%.

Postoperative care requires intense monitoring of pulmonary, cardiovascular, renal, and neurologic status. Possible complications of surgery include arterial occlusion, hemorrhage, infection, ischemic bowel, renal failure, and impotence.

## DISSECTING AORTA

Occasionally, in an aorta diseased by arteriosclerosis, a tear develops in the intima or the media degenerates, resulting in a dissection (see Fig. 31-11).

### Pathophysiology

Arterial dissections (separations) are commonly associated with poorly controlled hypertension; they are three times more common in men than in women and occur most commonly in the 50- to 70-year-old age group (Rutherford, 1999). Dissection is caused by rupture in the intimal layer. A rupture may occur through adventitia or into the lumen through the intima, allowing blood to reenter the main channel and resulting in chronic dissection or occlusion of branches of the aorta.

As the separation progresses, the arteries branching from the involved area of the aorta shear and occlude. The tear occurs most commonly in the region of the aortic arch, with the highest mortality rate associated with ascending aortic dissection. The dissection of the aorta may progress backward in the direction of the heart, obstructing the openings to the coronary arteries or producing hemopericardium (effusion of blood into the pericardial sac) or aortic insufficiency, or it may extend in the opposite direction, causing occlusion of the arteries supplying the gastrointestinal tract, kidneys, spinal cord, and legs.

### Clinical Manifestations

Onset of symptoms is usually sudden. Severe and persistent pain, described as tearing or ripping, may be reported. The pain is in the anterior chest or back and extends to shoulders, epigastric area, or abdomen. Aortic dissection may be mistaken for an acute myocardial infarction, which could confuse the clinical picture and initial treatment. Cardiovascular, neurologic, and gastrointestinal symptoms are responsible for other clinical manifestations, depending on the location and extent of the dissection. The patient may appear pale. Sweating and tachycardia may be detected. Blood pressure may be elevated or markedly different from one arm to the other if dissection involves the orifice of the subclavian artery on one side. Because of the variable clinical picture associated with this condition, early diagnosis is usually difficult.

## Assessment and Diagnostic Findings

Arteriography, CT, transesophageal echocardiography, duplex ultrasonography, and magnetic resonance imaging aid in the diagnosis.

## Medical Management

Medical or surgical treatment of a dissecting aneurysm depends on the type of dissection present and follows the general principles outlined for the treatment of thoracic aortic aneurysms.

## Nursing Management

A patient with a dissecting aorta requires the same nursing care as a patient with an aortic aneurysm requiring surgical intervention, as described earlier in this chapter. Interventions described in the Plan of Nursing Care are also appropriate.

## OTHER ANEURYSMS

Aneurysms may also arise in the peripheral vessels, most often as a result of atherosclerosis. These may involve such vessels as the subclavian artery, renal artery, femoral artery, or (most frequently) popliteal artery. Between 50% and 60% of popliteal aneurysms are bilateral and may be associated with abdominal aortic aneurysms.

The aneurysm produces a pulsating mass and disturbs peripheral circulation distal to it. Pain and swelling develop because of pressure on adjacent nerves and veins. Diagnosis is made by duplex ultrasonography and CT to determine the size, length, and extent of the aneurysm. Arteriography may be performed to evaluate the level of proximal and distal involvement.

Surgical repair is performed with replacement grafts or endovascular repair using a stent-graft or wall graft, which is a Dacron or PTFE (polytetrafluoroethylene) graft with external structures made from a variety of materials (nitinol, titanium, stainless steel) for additional support.

## Nursing Management

The patient who has had an endovascular repair must lie supine for 6 hours; the head of the bed may be elevated up to 45 degrees after 2 hours. The patient needs to use a bedpan or urinal while on bed rest, or a Foley catheter may be used. Vital signs and Doppler assessment of peripheral pulses are performed every 15 minutes for four times, then every 30 minutes for four times, then every hour for four times, and then as directed by the physician or unit standards. The catheterization site is assessed when vital signs and pulses are monitored. The nurse assesses for bleeding, swelling, pain, and hematoma formation. Any changes in vital signs, pulse quality, bleeding, swelling, pain, or hematoma are reported to the physician. The physician is also notified of persistent coughing, sneezing, vomiting, or systolic blood pressure above 180 mm Hg because of the increased risk for hemorrhage. Most patients are able to resume their preprocedure diet and are encouraged to drink fluids. An intravenous infusion may be continued until the patient is able to drink normally. Fluids are important to maintain blood flow through the arterial repair site and to assist the kidneys with excreting intravenous contrast agent and other medications used during the procedure. Six hours after the procedure, the patient may be able to roll side to side and may be able to ambulate with assistance to the bathroom. After the patient is able to

take adequate fluids orally, the intravenous infusion may be discontinued and the intravenous access converted to a saline lock.

## ARTERIAL EMBOLISM AND ARTERIAL THROMBOSIS

Acute vascular occlusion may be caused by an embolus or acute thrombosis. Acute arterial occlusions may result from iatrogenic injury, which can occur during insertion of invasive catheters such as those used for arteriography, PTA or stent placement, or an intra-aortic balloon pump. Other causes include trauma from a fracture, crush injury, and penetrating wounds that disrupt the arterial intima. The accurate diagnosis of an arterial occlusion as embolic or thrombotic in origin is necessary to initiate appropriate treatment.

### Pathophysiology

Arterial emboli arise most commonly from thrombi that develop in the chambers of the heart as a result of atrial fibrillation, myocardial infarction, infective endocarditis, or chronic heart failure. These thrombi become detached and are carried from the left side of the heart into the arterial system, where they lodge in and obstruct an artery that is smaller than the embolus. Emboli may also develop in advanced aortic atherosclerosis because the atheromatous plaques ulcerate or become rough. Acute thrombosis frequently occurs in patients with preexisting ischemic symptoms.

### Clinical Manifestations

The symptoms of arterial emboli depend primarily on the size of the embolus, the organ involved, and the state of the collateral vessels. The immediate effect is cessation of distal blood flow. The blockage can progress above and below the obstruction. Secondary vasospasm can contribute to the ischemia. The embolus can fragment or break apart, resulting in occlusion of distal vessels. Emboli tend to lodge at arterial bifurcations and areas narrowed by atherosclerosis. Cerebral, mesenteric, renal, and coronary arteries are often involved in addition to the large arteries of the extremities.

The symptoms of acute arterial embolism in extremities with poor collateral flow are acute, severe pain and a gradual loss of sensory and motor function. The six *P*s associated with acute arterial embolism are pain, pallor, pulselessness, paresthesia, poikilothermia (coldness), and paralysis. Eventually, superficial veins may collapse because of decreased blood flow to the extremity. The part of the extremity below the occlusion is markedly colder and paler than the part above the occlusion because of ischemia.

Arterial thrombosis can also acutely occlude an artery. A thrombosis is a slowly developing clot that usually occurs where the arterial wall has become damaged, generally as a result of atherosclerosis. Thrombi may also develop in an arterial aneurysm. The manifestations of an acute thrombotic arterial occlusion are similar to those described for embolic occlusion. However, treatment is more difficult with a thrombus because the arterial occlusion has occurred in a degenerated vessel and requires more extensive reconstructive surgery to restore flow than is required with an embolic event.

### Assessment and Diagnostic Findings

An arterial embolus is usually diagnosed on the basis of the sudden nature of the onset of symptoms and an apparent source for the embolus. Two-dimensional echocardiography or transesophageal

echocardiography, chest x-ray, and electrocardiography may reveal underlying cardiac disease. Noninvasive duplex and Doppler ultrasonography can determine the presence and extent of underlying atherosclerosis, and arteriography may be performed.

### Medical Management

Management of arterial thrombosis depends on its cause. Management of acute embolic occlusion usually requires surgery because time is of the essence. Because the onset of the event is acute, collateral circulation has not developed, and the patient quickly moves through the list of six *P*s to paralysis, which is the most advanced stage. Heparin therapy is initiated immediately to prevent further development of emboli and to hamper the extension of existing thrombi. Typically, an initial bolus of 5,000 to 10,000 units is administered intravenously, followed by a continuous infusion of 1,000 units per hour until the patient is able to undergo surgery.

### SURGICAL MANAGEMENT

Emergency embolectomy is the procedure of choice only if the involved extremity is viable (Fig. 31-15). Arterial emboli are usually treated by insertion of an embolectomy catheter. The catheter is passed through a groin incision into the affected artery and advanced past the occlusion. The balloon is inflated with sterile saline solution, and the thrombus is extracted as the catheter is withdrawn. This procedure involves incising the vessel and removing the clot.

### PHARMACOLOGIC THERAPY

When the patient has collateral circulation, treatment may include intravenous anticoagulation with heparin, which can prevent the thrombus from spreading and reduce muscle necrosis. The use of intra-arterial thrombolytic medications helps to dissolve the embolus. Fibrin-specific thrombolytic medications (eg, tissue plasminogen activator [t-PA, alteplase, Activase] and single-chain urokinase-type plasminogen activator [scu-PA, pro-urokinase]) avoid systemic depletion of circulating fibrinogen and plasminogen, which prevents the development of systemic fibrinolysis.

**FIGURE 31-15** Extraction of an embolus by balloon-tipped embolectomy catheter. The deflated balloon-tipped catheter is advanced past the embolus, inflated and then gently withdrawn, carrying the embolic material with it. Adapted with permission from Rutherford, R. B. (1999). *Vascular surgery: Vol. 1 and 2* (5th ed.). Philadelphia: W. B. Saunders.

Other thrombolytic medications are reteplase (r-PA, Retavase), tenecteplase (TNKase), and staphylokinase (Moore, 2002). Although these agents differ in their pharmacokinetics, they are administered in a similar manner. A catheter is advanced under x-ray visualization to the clot, and the thrombolytic agent is infused.

Thrombolytic therapy should not be used when there are known contraindications to therapy or when the extremity cannot tolerate the several additional hours of ischemia that it takes for the agent to lyse (disintegrate) the clot. Contraindications to thrombolytic therapy include active internal bleeding, CVA (brain attack, stroke), recent major surgery, uncontrolled hypertension, and pregnancy.

## Nursing Management

Before surgery, the patient remains on bed rest with the extremity level or slightly dependent (15 degrees). The affected part is kept at room temperature and protected from trauma. Heating and cooling pads are contraindicated because ischemic extremities are easily traumatized by alterations in temperature. If possible, tape and electrocardiogram electrodes should not be used on the extremity; sheepskin and foot cradles are used to protect the leg from mechanical trauma.

If the patient is treated with thrombolytic therapy, she or he is accurately weighed in kilograms, and the dose of thrombolytic therapy is determined based on the patient's weight. The patient is admitted to a critical care unit for continuous monitoring. Vital signs are taken every 15 minutes for 2 hours, then every 30 minutes for the next 6 hours, and then every hour for 16 hours. Bleeding is the most common side effect of thrombolytic therapy, and the patient is closely monitored for any signs of bleeding. The nurse also minimizes the number of punctures for inserting intravenous lines, avoids intramuscular injections, prevents any possible tissue trauma, and applies pressure at least twice as long as usual after any puncture that is performed. If t-PA is used for the treatment, heparin is usually administered to prevent another thrombus from forming at the site of the lesion. The t-PA activates plasminogen on the thrombus more than circulating plasminogen, but it does not decrease the clotting factors as much as other thrombolytic therapies, so patients receiving t-PA are able to make new thrombi more easily than with some of the other thrombolytics.

During the postoperative period, the nurse collaborates with the surgeon about the patient's appropriate activity level based on the patient's condition. Generally, every effort is made to encourage the patient to move the leg to stimulate circulation and prevent stasis. Anticoagulant therapy may be continued after surgery to prevent thrombosis of the affected artery and to diminish the development of subsequent thrombi at the initiating site. The nurse assesses for evidence of local and systemic hemorrhage, including mental status changes, which can occur when anticoagulants are administered. Pulses, Doppler signals, ABI, and motor and sensory function are assessed every hour for the first 24 hours, because significant changes may indicate reocclusion. Metabolic abnormalities, renal failure, and compartment syndrome may be complications after an acute arterial occlusion.

## RAYNAUD'S DISEASE

Raynaud's disease is a form of intermittent arteriolar vasoconstriction that results in coldness, pain, and pallor of the fingertips or toes. The cause is unknown, although many patients with the disease seem to have immunologic disorders. Symptoms may re-

sult from a defect in basal heat production that eventually decreases the ability of cutaneous vessels to dilate. Episodes may be triggered by emotional factors or by unusual sensitivity to cold. The disease is most common in women between 16 and 40 years of age, and it occurs more frequently in cold climates and during the winter.

The term *Raynaud's phenomenon* is used to refer to localized, intermittent episodes of vasoconstriction of small arteries of the feet and hands that cause color and temperature changes. Generally unilateral and affecting only one or two digits, the phenomenon is always associated with underlying systemic disease. It may occur with scleroderma, systemic lupus erythematosus, rheumatoid arthritis, obstructive arterial disease, or trauma.

The prognosis for Raynaud's disease varies; some patients slowly improve, some become progressively worse, and others show no change. Ulceration and gangrene are rare; however, chronic disease may cause atrophy of the skin and muscles. With appropriate patient teaching and lifestyle modifications, the disorder is generally benign and self-limiting.

## Clinical Manifestations

The classic clinical picture reveals pallor brought on by sudden vasoconstriction. The skin then becomes bluish (cyanotic) due to pooling of deoxygenated blood during vasospasm. As a result of exaggerated reflow (hyperemia) due to vasodilation, a red color is produced (rubor) when oxygenated blood returns to the digits after the vasospasm stops. The characteristic sequence of color change of Raynaud's phenomenon is described as white, blue, and red. Numbness, tingling, and burning pain occur as the color changes. The involvement tends to be bilateral and symmetric.

## Medical Management

Avoiding the particular stimuli (eg, cold, tobacco) that provoke vasoconstriction is a primary factor in controlling Raynaud's disease. Calcium channel blockers may be effective in relieving symptoms. Studies indicate that nifedipine (Procardia, Adalat) is an effective calcium channel blocker for treating an acute episode of vasospasm (Kaufman et al., 1996). Sympathectomy (interrupting the sympathetic nerves by removing the sympathetic ganglia or dividing their branches) may help some patients.

## Nursing Management

The nurse teaches patients to avoid situations that may be stressful or unsafe. Stress management classes may be helpful. Exposure to cold must be minimized, and in areas where the fall and winter months are cold, the patient should remain indoors as much as possible and wear layers of clothing when outdoors. Hats and mittens or gloves should be worn at all times when outside. Fabrics specially designed for cold climates (eg, Thinsulate) are recommended. Patients should warm up their vehicles before getting in so that they can avoid touching a cold steering wheel or door handle, which could elicit an attack. During summer, a sweater should be available when entering air-conditioned rooms.

Concerns about serious complications, such as gangrene and amputation, are common among patients. However, these consequences are uncommon. Patients should avoid all forms of nicotine; the nicotine gum or patches used to help people quit smoking may induce attacks.

Patients should be careful about safety. Sharp objects should be handled carefully to avoid injuring the fingers. Patients should be informed about the postural hypotension that may result

from medications, such as calcium channel blockers, used to treat Raynaud's disease. The nurse also discusses safety precautions related to alcohol, exercise, and hot weather.

## Management of Venous Disorders

### VENOUS THROMBOSIS, DEEP VEIN THROMBOSIS (DVT), THROMBOPHLEBITIS, AND PHLEBOTHROMBOSIS

Although the terms *venous thrombosis*, *deep vein thrombosis (DVT)*, *thrombophlebitis*, and *phlebothrombosis* do not necessarily reflect identical disease processes, for clinical purposes, they are often used interchangeably.

### Pathophysiology

Superficial veins, such as the greater saphenous, lesser saphenous, cephalic, basilic, and external jugular veins, are thick-walled muscular structures that lie just under the skin. Deep veins are thin walled and have less muscle in the media. They run parallel to arteries and bear the same names as the arteries. Deep and superficial veins have valves that permit unidirectional flow back to the heart. The valves lie at the base of a segment of the vein that is expanded into a sinus. This arrangement permits the valves to open without coming into contact with the wall of the vein, permitting rapid closure when the blood starts to flow backward. Other kinds of veins are known as perforating veins. These vessels have valves that allow one-way blood flow from the superficial system to the deep system.

Although the exact cause of venous thrombosis remains unclear, three factors, known as Virchow's triad, are believed to play a significant role in its development: stasis of blood (venous stasis), vessel wall injury, and altered blood coagulation (Chart 31-6). At least two of the factors seem to be necessary for thrombosis to occur. Venous stasis occurs when blood flow is reduced, as in heart failure or shock; when veins are dilated, as with some medication therapies; and when skeletal muscle contraction is reduced, as in immobility, paralysis of the extremities, or anesthesia. Moreover, bed rest reduces blood flow in the legs by at least 50%. Damage to the intimal lining of blood vessels creates a site for clot formation. Direct trauma to the vessels, as with fractures or dislocation, diseases of the veins, and chemical irritation of the vein from intravenous medications or solutions, can damage veins. Increased blood coagulability occurs most commonly in patients who have been abruptly withdrawn from anticoagulant medications. Oral contraceptive use and several blood dyscrasias (abnormalities) also can lead to hypercoagulability.

Formation of a thrombus frequently accompanies thrombophlebitis, which is an inflammation of the vein walls. When a thrombus develops initially in the veins as a result of stasis or hypercoagulability but without inflammation, the process is referred to as phlebothrombosis. Venous thrombosis can occur in any vein but occurs more in the veins of the lower extremities. The superficial and deep veins of the extremities may be affected.

Upper extremity venous thrombosis is not as common as lower extremity thrombosis. However, upper extremity venous thrombosis is more common in patients with intravenous catheters or in patients with an underlying disease that causes hypercoagulability. Internal trauma to the vessels may result from pacemaker leads, chemotherapy ports, dialysis catheters, or parenteral nutri-

Chart 31-6

### Risk Factors for Deep Vein Thrombosis (DVT) and Pulmonary Embolism

- Endothelial damage
  - Trauma
  - Surgery
  - Pacing wires
  - Central venous catheters
  - Dialysis access catheters
  - Local vein damage
  - Repetitive motion injury
- Venous stasis
  - Bed rest or immobilization
  - Obesity
  - History of varicosities
  - Spinal cord injury
  - Age (>65 yr)
- Coagulopathy
  - Cancer
  - Pregnancy
  - Oral contraceptive use
  - Presence of congenital proteins C and S
  - Presence of anticardiolipin antibody
  - Antithrombin III deficiency
  - Polycythemia
  - Septicemia

tion lines. The lumen of the vein may be decreased as a result of the catheter or from external compression, such as by neoplasms or an extra cervical rib. Effort thrombosis of the upper extremity is caused by repetitive motion, such as experienced by competitive swimmers, tennis players, and construction workers, that irritates the vessel wall, causing inflammation and subsequent thrombosis.

Venous thrombi are aggregates of platelets attached to the vein wall, along with a tail-like appendage containing fibrin, white blood cells, and many red blood cells. The "tail" can grow or can propagate in the direction of blood flow as successive layers of the thrombus form. A propagating venous thrombosis is dangerous because parts of the thrombus can break off and produce an embolic occlusion of the pulmonary blood vessels. Fragmentation of the thrombus can occur spontaneously as it dissolves naturally, or it can occur in association with an elevation in venous pressure, as occurs when a person stands suddenly or engages in muscular activity after prolonged inactivity. After an episode of acute deep vein thrombosis, recanalization of the lumen typically occurs. The time required for complete recanalization is an important determinant of venous valvular incompetence, which is one complication of venous thrombosis (Meissner et al., 2000). Other complications of venous thrombosis are listed in Chart 31-7.

### Clinical Manifestations

A major problem associated with recognizing deep vein thrombosis is that the signs and symptoms are nonspecific. The exception is phlegmasia cerulea dolens (massive iliofemoral venous thrombosis), in which the entire extremity becomes massively swollen, tense, painful, and cool to the touch. Despite this variability, clinical signs should always be investigated.

### DEEP VEINS

With obstruction of the deep veins comes edema and swelling of the extremity because the outflow of venous blood is inhibited.

Chart  
31-7

## Complications of Venous Thrombosis

**Chronic venous occlusion****Pulmonary emboli from dislodged thrombi****Valvular destruction**

- Chronic venous insufficiency
- Increased venous pressure
- Varicosities
- Venous ulcers

**Venous obstruction**

- Increased distal pressure
- Fluid stasis
- Edema
- Venous gangrene

The amount of swelling can be determined by measuring the circumference of the affected extremity at various levels with a tape measure and comparing one extremity with the other at the same level to determine size differences. If both extremities are swollen, a size difference may be difficult to detect. The affected extremity may feel warmer than the unaffected extremity, and the superficial veins may appear more prominent.

Tenderness, which usually occurs later, is produced by inflammation of the vein wall and can be detected by gently palpating the affected extremity. Homans' sign (pain in the calf after the foot is sharply dorsiflexed) is not specific for deep vein thrombosis because it can be elicited in any painful condition of the calf. In some cases, signs of a pulmonary embolus are the first indication of deep vein thrombosis.

**SUPERFICIAL VEINS**

Thrombosis of superficial veins produces pain or tenderness, redness, and warmth in the involved area. The risk of the superficial venous thrombi becoming dislodged or fragmenting into emboli is very low because most of them dissolve spontaneously. This condition can be treated at home with bed rest, elevation of the leg, analgesics, and possibly anti-inflammatory medication.

**Assessment and Diagnostic Findings**

Careful assessment is invaluable in detecting early signs of venous disorders of the lower extremities. Patients with a history of varicose veins, hypercoagulation, neoplastic disease, cardiovascular disease, or recent major surgery or injury are at high risk. Other patients at high risk include those who are obese or elderly and women taking oral contraceptives.

When performing the nursing assessment, key concerns include limb pain, a feeling of heaviness, functional impairment, ankle engorgement, and edema; differences in leg circumference bilaterally from thigh to ankle; increase in the surface temperature of the leg, particularly the calf or ankle; and areas of tenderness or superficial thrombosis (ie, cordlike venous segment). Homans' sign (pain in the calf as the foot is sharply dorsiflexed) has been used historically to assess for DVT. It is not a reliable or valid sign for DVT and has no clinical value in the assessment of a patient for DVT.

**Prevention**

Venous thrombosis, thrombophlebitis, and DVT can be prevented, especially if patients who are considered at high risk are identified and preventive measures are instituted without delay.

Preventive measures include the application of elastic compression stockings, the use of intermittent pneumatic compression devices, and special body positioning and exercise (discussed later in the section on nursing management). A further method to prevent venous thrombosis in surgical patients is administration of subcutaneous unfractionated or low molecular weight heparin.

**Medical Management**

The objectives of treatment for deep vein thrombosis are to prevent the thrombus from growing and fragmenting (risking pulmonary embolism) and to prevent recurrent thromboemboli. Anticoagulant therapy (administration of a medication to delay the clotting time of blood, prevent the formation of a thrombus in postoperative patients, and forestall the extension of a thrombus after it has formed) can meet these objectives, although anticoagulants cannot dissolve a thrombus that has already formed.

**ANTICOAGULATION THERAPY**

Measures for preventing or reducing blood clotting within the vascular system are indicated in patients with thrombophlebitis, recurrent embolus formation, and persistent leg edema from heart failure. They are also indicated in elderly patients with a hip fracture that may result in lengthy immobilization.

**Unfractionated Heparin.** Unfractionated heparin (heparin) is administered subcutaneously to prevent development of deep vein thrombosis, or by intermittent intravenous infusion or continuous infusion for 5 to 7 days to prevent the extension of a thrombus and the development of new thrombi. Oral anticoagulants, such as warfarin (Coumadin), are administered with heparin therapy. Medication dosage is regulated by monitoring the partial thromboplastin time, the **international normalized ratio (INR)**, and the platelet count.

**Low-Molecular-Weight Heparin.** Subcutaneous low-molecular-weight heparin (LMWH) is an effective treatment for some cases of deep vein thrombosis. It has a longer half-life than unfractionated heparin, so doses can be given in one or two subcutaneous injections each day. Doses are adjusted according to weight. LMWH prevents the extension of a thrombus and development of new thrombi and is associated with fewer bleeding complications than unfractionated heparin. Because there are several preparations, the dosing schedule must be based on the product used and the protocol at each institution. The cost is higher than for unfractionated heparin; however, LMWH may be used safely in pregnant women, and the patients may be more mobile and have an improved quality of life.

**Thrombolytic Therapy.** Unlike the heparins, thrombolytic (fibrinolytic) therapy causes the thrombus to lyse and dissolve in 50% of patients. Thrombolytic therapy (eg, tissue plasminogen activator [t-PA, alteplase, Activase], reteplase [r-PA, Retavase], tenecteplase [TNKase], staphylokinase, urokinase, streptokinase) is given within the first 3 days after acute thrombosis. Therapy initiated beyond 5 days after the onset of symptoms is significantly less effective (Moore, 2002). The advantages of thrombolytic therapy include less long-term damage to the venous valves and a reduced incidence of postthrombotic syndrome and chronic venous insufficiency. However, thrombolytic therapy results in approximately a threefold greater incidence of bleeding than heparin. If bleeding occurs and cannot be stopped, the thrombolytic agent is discontinued.

## SURGICAL MANAGEMENT

Surgery is necessary for deep vein thrombosis when anticoagulant or thrombolytic therapy is contraindicated (Chart 31-8), the danger of pulmonary embolism is extreme, or the venous drainage is so severely compromised that permanent damage to the extremity will probably result. A thrombectomy (removal of the thrombosis) is the procedure of choice. A vena cava filter may be placed at the time of the thrombectomy; this filter traps large emboli and prevents pulmonary emboli (see Chap. 23).

## Nursing Management

If the patient is receiving anticoagulant therapy, the nurse must frequently monitor the partial thromboplastin time, prothrombin time, hemoglobin and hematocrit values, platelet count, and fibrinogen level. Close observation is also required to detect bleeding; if bleeding occurs, it must be reported immediately and anticoagulant therapy discontinued.

## ASSESSING AND MONITORING ANTICOAGULANT THERAPY

To prevent inadvertent infusion of large volumes of heparin, which could cause hemorrhage, continuous intravenous infusion by electronic infusion device is the preferred method of administering unfractionated heparin. Dosage calculations are based on the patient's weight, and any possible bleeding tendencies are detected by a pretreatment clotting profile. If renal insufficiency exists, lower doses of heparin are required. Periodic coagulation tests and hematocrit levels are obtained. Heparin is in the effective, or therapeutic, range when the partial thromboplastin time is 1.5 times the control.

Intermittent intravenous injection is another means of administering heparin; a dilute solution of heparin is administered every 4 hours. Administration may be facilitated by using a heparin lock, an intravenous catheter or a small, butterfly-type scalp vein needle with an injection site at the end of the tubing.

Oral anticoagulants, such as warfarin, are monitored by the prothrombin time or INR. Because their effect is delayed for 3 to

5 days, they are usually administered with heparin until desired anticoagulation has been achieved (ie, when the prothrombin time is 1.5 to 2 times normal or the INR is 2.0 to 3.0).

## MONITORING AND MANAGING POTENTIAL COMPLICATIONS

**Bleeding.** The principal complication of anticoagulant therapy is spontaneous bleeding anywhere in the body. Bleeding from the kidneys is detected by microscopic examination of the urine and is often the first sign of anticoagulant toxicity from excessive dosage. Bruises, nosebleeds, and bleeding gums are also early signs. To reverse the effects of heparin promptly, intravenous injections of protamine sulfate may be administered. Reversing the effects of warfarin, a coumarin derivative, is more difficult, but effective measures that may be prescribed include vitamin K and possibly transfusion of fresh frozen plasma.

**Thrombocytopenia.** Another complication of therapy may be heparin-induced thrombocytopenia (decrease in platelets), which may develop in patients who receive heparin for more than 5 days or on readministration after a brief interruption of heparin therapy. Beginning warfarin concomitantly with heparin can provide a stable INR or prothrombin time by day 5 of heparin treatment.

The use of LMWH is less frequently associated with heparin-induced thrombocytopenia. The thrombocytopenia is thought to result from an immunologic mechanism that causes aggregation of platelets. This serious complication results in thromboembolic manifestations, and the prognosis is extremely guarded.

Prevention of thrombocytopenia depends on regular monitoring of platelet counts. Early signs of thrombocytopenia are a falling platelet count to less than 100,000/mL, a decrease in platelet count exceeding 25% at one time, the need for increasing doses of heparin to maintain the therapeutic level, thromboembolic or hemorrhagic complications, and a history of heparin sensitivity (Stevens, 2000). If thrombocytopenia does occur, platelet aggregation studies are conducted, the heparin is discontinued, and protamine sulfate is administered to reverse heparin's effects.

**Drug Interactions.** Because oral anticoagulants interact with many other medications and herbal and nutritional supplements, close monitoring of the patient's medication schedule is necessary. Medications and supplements that potentiate oral anticoagulants include salicylates, anabolic steroids, chloral hydrate, glucagon, chloramphenicol, neomycin, quinidine, phenylbutazone (Butazolidin), coenzyme Q10, dong quai, garlic, ginkgo, ginseng, green tea, and vitamin E; those that decrease the anticoagulant effect include phenytoin, barbiturates, diuretics, estrogen, and vitamin C. It is advisable to identify medication interactions for patients taking specific oral anticoagulants. Contraindications to anticoagulant therapy are summarized in Chart 31-8.

## PROVIDING COMFORT

Bed rest, elevation of the affected extremity, elastic compression stockings, and analgesics for pain relief are adjuncts to therapy. They help to improve circulation and increase comfort. Depending on the extent and location of a venous thrombosis, bed rest may be required for 5 to 7 days after diagnosis. This is approximately the time necessary for the thrombus to adhere to the vein wall, preventing embolization.

Warm, moist packs applied to the affected extremity reduce the discomfort associated with deep vein thrombosis, as do mild analgesics prescribed for pain control. When the patient begins to ambulate, elastic compression stockings are used. Walking is

better than standing or sitting for long periods. Bed exercises, such as dorsiflexion of the foot, are also recommended.

### APPLYING ELASTIC COMPRESSION STOCKINGS

Elastic compression stockings usually are prescribed for patients with venous insufficiency. These stockings exert a sustained, evenly distributed pressure over the entire surface of the calves, reducing the caliber of the superficial veins in the legs and resulting in increased flow in the deeper veins. The stockings may be knee-high, thigh-high, or panty hose. Thigh-high stockings are difficult for the patient to wear, because they have a tendency to roll down. The roll of the stocking further restricts blood flow rather than the stocking providing evenly distributed pressure over the thigh.

**NURSING ALERT** Any type of stocking, including the elastic type, can inadvertently become a tourniquet if applied incorrectly (ie, rolled tightly at the top). In such instances, the stockings produce stasis rather than prevent it. For ambulatory patients, elastic compression stockings are removed at night and reapplied before the legs are lowered from the bed to the floor in the morning.

When the stockings are off, the skin is inspected for signs of irritation, and the calves are examined for possible tenderness. Any skin changes or signs of tenderness are reported. Stockings are contraindicated in patients with severe pitting edema because they can produce severe pitting at the knee.

### Gerontologic Considerations

Because of decreased strength and manual dexterity, elderly patients may be unable to apply elastic compression stockings properly. If such is the case, a family member or friend should be taught to assist the patient to apply the stockings so that they do not cause undue pressure on any part of the feet or legs.

### USING INTERMITTENT PNEUMATIC COMPRESSION DEVICES

These devices can be used with elastic compression stockings to prevent deep vein thrombosis. They consist of an electric controller that is attached by air hoses to plastic knee-high or thigh-high sleeves. The leg sleeves are divided into compartments, which sequentially fill to apply pressure to the ankle, calf, and thigh at 35 to 55 mm Hg of pressure. These devices can increase blood velocity beyond that produced by the stockings. Nursing measures include ensuring that prescribed pressures are not exceeded and assessing for patient comfort.

### POSITIONING THE BODY AND ENCOURAGING EXERCISE

When the patient is on bed rest, the feet and lower legs should be elevated periodically above the level of the heart. This position allows the superficial and tibial veins to empty rapidly and to remain collapsed. Active and passive leg exercises, particularly those involving calf muscles, should be performed to increase venous flow. Early ambulation is most effective in preventing venous stasis. Deep-breathing exercises are beneficial because they produce increased negative pressure in the thorax, which assists in emptying the large veins. Once ambulatory, patients are instructed to avoid sitting for more than 2 hours at a time. The goal is to walk at least 10 minutes every 1 to 2 hours. Patients are also instructed to perform active and passive leg exercises when they are not able to ambulate as frequently as necessary, such as during long car, train, and plane trips.

### PROMOTING HOME AND COMMUNITY-BASED CARE

In addition to teaching the patient how to apply elastic compression stockings and explaining the importance of elevating the legs and exercising adequately, the nurse teaches about the medication, its purpose, and the need to take the correct amount at the specific times prescribed (Chart 31-9). The patient should also be aware that blood tests are scheduled periodically to determine whether a change in medication or dosage is required. If the patient fails to adhere to the therapeutic regimen, continuation of the medication therapy should be questioned. A person who refuses to discontinue the use of alcohol should not receive anticoagulants because chronic alcohol use decreases their effectiveness. In patients with liver problems, the potential for bleeding may be exacerbated by anticoagulant therapy.

### CHRONIC VENOUS INSUFFICIENCY

Venous insufficiency results from obstruction of the venous valves in the legs or a reflux of blood back through the valves. Superficial and deep leg veins can be involved. Resultant venous hypertension can occur whenever there has been a prolonged increase in venous pressure, such as occurs with deep venous thrombosis. Because the walls of veins are thinner and more elastic than

Chart 31-9 • PATIENT EDUCATION  
Taking Anticoagulant Medications

- Take the anticoagulant at the same time each day, usually between 8:00 and 9:00 AM.
- Wear or carry identification indicating the anticoagulant being taken.
- Keep all appointments for blood tests.
- Because other medications affect the action of the anticoagulant, do not take any of the following medications or supplements without consulting with the primary health care provider: vitamins, cold medicines, antibiotics, aspirin, mineral oil, and anti-inflammatory agents, such as ibuprofen (Motrin) and similar medications or herbal or nutritional supplements. The primary health care provider should be contacted before taking any over-the-counter drugs.
- Avoid alcohol, because it may change the body's response to an anticoagulant.
- Avoid food fads, crash diets, or marked changes in eating habits.
- Do not take warfarin (Coumadin) unless directed.
- Do not stop taking Coumadin (when prescribed) unless directed.
- When seeking treatment from physician, a dentist, a podiatrist, or another health care provider, be sure to inform the caregiver that you are taking an anticoagulant.
- Contact your primary health care provider before having dental work or elective surgery.
- If any of the following signs appear, report them immediately to the primary health care provider:
  - Faintness, dizziness, or increased weakness
  - Severe headaches or abdominal pain
  - Reddish or brownish urine
  - Any bleeding—for example, cuts that do not stop bleeding
  - Bruises that enlarge, nosebleeds, or unusual bleeding from any part of the body
  - Red or black bowel movements
  - Rash
- Avoid injury that can cause bleeding.
- For women: Notify the primary health care provider if you suspect pregnancy.

the walls of arteries, they distend readily when venous pressure is consistently elevated. In this state, leaflets of the venous valves are stretched and prevented from closing completely, allowing a backflow or reflux of blood in the veins. Duplex ultrasonography confirms the obstruction and identifies the level of valvular incompetence.

## Clinical Manifestations

When the valves in the deep veins become incompetent after a thrombus has formed, postthrombotic syndrome may develop (Fig. 31-16). This disorder is characterized by chronic venous stasis, resulting in edema, altered pigmentation, pain, and stasis dermatitis. The patient may notice the symptoms less in the morning and more in the evening. Obstruction or poor calf muscle pumping in addition to valvular reflux must be present for the development of severe postthrombotic syndrome, which includes stasis ulceration (Caps et al., 1999). Superficial veins may be dilated. The disorder is long-standing, difficult to treat, and often disabling.

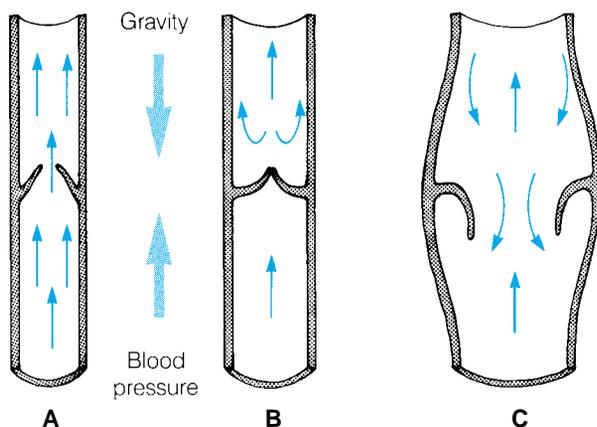

Stasis ulcers develop as a result of the rupture of small skin veins and subsequent ulcerations. When these vessels rupture, red blood cells escape into surrounding tissues and then degenerate, leaving a brownish discoloration of the tissues. The pigmentation and ulcerations usually occur in the lower part of the extremity, in the area of the medial malleolus of the ankle. The skin becomes dry, cracks, and itches; subcutaneous tissues fibrose and atrophy. The risk of injury and infection of the extremities is increased.

## Complications

Venous ulceration is the most serious complication of chronic venous insufficiency and can be associated with other conditions affecting the circulation of the lower extremities. Cellulitis or dermatitis may complicate the care of chronic venous insufficiency and venous ulcerations.

## Management

Management of the patient with venous insufficiency is directed at reducing venous stasis and preventing ulcerations. Measures that increase venous blood flow are antigravity activities, such as elevating the leg, and compression of superficial veins with elastic compression stockings.

**FIGURE 31-16** Competent valves showing blood flow patterns when the valve is open (A) and closed (B), allowing blood to flow against gravity. (C) With faulty or incompetent valves, the blood is unable to move toward the heart.

Elevating the legs decreases edema, promotes venous return, and provides symptomatic relief. The legs should be elevated frequently throughout the day (at least 15 to 30 minutes every 2 hours). At night, the patient should sleep with the foot of the bed elevated about 15 cm (6 inches). Prolonged sitting or standing still is detrimental; walking should be encouraged. When sitting, the patient should avoid placing pressure on the popliteal spaces, as occurs when crossing the legs or sitting with the legs dangling over the side of the bed. Constricting garments such as panty girdles or tight socks should be avoided.

Compression of the legs with elastic compression stockings reduces the pooling of venous blood and enhances venous return to the heart. Elastic compression stockings are recommended for people with venous insufficiency. The stocking should fit so that pressure is greater at the foot and ankle and then gradually declines to a lesser pressure at the knee or groin. If the top of the stocking is too tight or becomes twisted, a tourniquet effect is created, which worsens venous pooling. Stockings should be applied after the legs have been elevated for a period, when the amount of blood in the leg veins is at its lowest.

Extremities with venous insufficiency must be carefully protected from trauma; the skin is kept clean, dry, and soft. Signs of ulceration are immediately reported to the health care provider for treatment and follow-up.

## LEG ULCERS

A leg ulcer is an excavation of the skin surface that occurs when inflamed necrotic tissue sloughs off. About 75% of all leg ulcers result from chronic venous insufficiency. Lesions due to arterial insufficiency account for approximately 20%; the remaining 5% are caused by burns, sickle cell anemia, and other factors (Gloviczki & Yao, 2001).

## Pathophysiology

Inadequate exchange of oxygen and other nutrients in the tissue is the metabolic abnormality that underlies the development of leg ulcers. When cellular metabolism cannot maintain energy balance, cell death (necrosis) results. Alterations in blood vessels at the arterial, capillary, and venous levels may affect cellular processes and lead to the formation of ulcers.

## Clinical Manifestations

The clinical appearance and associated characteristics of leg ulcers are determined by the cause of the ulcer. Most ulcers, especially in an elderly patient, have more than one cause. The symptoms depend on whether the problem is arterial or venous in origin (see Table 31-2). The severity of the symptoms depends on the extent and duration of the vascular insufficiency. The ulcer itself appears as an open, inflamed sore. The area may be draining or covered by eschar (dark, hard crust).

## ARTERIAL ULCERS

Chronic arterial disease is characterized by intermittent claudication, which is pain caused by activity and relieved after a few minutes of rest. The patient may also complain of digital or forefoot pain at rest. If the onset of arterial occlusion is acute, ischemic pain is unrelenting and rarely relieved even with opioid analgesics. Typically, arterial ulcers are small, circular, deep ulcerations on the tips of toes or in the web spaces between toes. Ulcers often occur on the medial side of the hallux or lateral fifth toe and may be caused by a combination of ischemia and pressure (Fig. 31-17).

**FIGURE 31-17** (A) Ulcers resulting from arterial emboli. (B) Gangrene of the toes resulting from severe arterial ischemia. (C) Ulcer from venous stasis.

Arterial insufficiency may result in gangrene of the toe (digital gangrene), which usually is caused by trauma. The toe is stubbed and then turns black (see Fig. 31-17). Usually, patients with this problem are elderly people without adequate circulation to provide revascularization. Débridement is contraindicated in these instances. Although the toe is gangrenous, it is dry. Managing dry gangrene is preferable to debriding the toe and causing an open wound that will not heal because of insufficient circulation. If the toe were to be amputated, the lack of adequate circulation would prevent healing and might make further amputation necessary—a below-knee or an above-knee amputation. A higher-level amputation in the elderly could result in a loss of independence and possibly institutional care. Dry gangrene of the toe in an elderly person with poor circulation is usually left undisturbed. The nurse keeps the toe clean and dry until it separates (without creating an open wound).

### VENOUS ULCERS

Chronic venous insufficiency is characterized by pain described as aching or heaviness. The foot and ankle may be edematous. Ulcerations are in the area of the medial or lateral malleolus (gaiter area) and are typically large, superficial, and highly exudative. Venous hypertension causes extravasation of blood, which discolors the gaiter area (see Fig. 31-17). Patients with neuropathy frequently have ulcerations on the side of the foot over the metatarsal heads. These ulcers are painless and are described in further detail in Chapter 41.

## Assessment and Diagnostic Findings

Because ulcers have many causes, the cause of each ulcer needs to be identified so appropriate therapy can be prescribed. The history of the condition is important in determining venous or arterial insufficiency. The pulses of the lower extremities (femoral, popliteal, posterior tibial, and dorsalis pedis) are carefully examined. More conclusive diagnostic aids are Doppler and duplex ultrasound studies, arteriography, and venography. Cultures of the ulcer bed may be necessary to determine whether the infecting agent is the primary cause of the ulcer.

## Medical Management

Patients with ulcers can be effectively managed by advanced practice nurses or certified wound care nurses in collaboration with physicians. All ulcers have the potential to become infected.

### PHARMACOLOGIC THERAPY

Antibiotic therapy is prescribed when the ulcer is infected; the specific antibiotic is selected on the basis of culture and sensitivity test results. Oral antibiotics usually are prescribed because topical antibiotics have not proven to be effective for leg ulcers.

### DÉBRIDEMENT

To promote healing, the wound is kept clean of drainage and necrotic tissue. The usual method is to flush the area with normal saline solution. If this is unsuccessful, débridement may be necessary. Débridement is the removal of nonviable tissue from wounds. Removing the dead tissue is important, particularly in instances of infection. Débridement can be accomplished by several different methods:

- Sharp surgical débridement is the fastest method and can be performed by a physician, skilled advanced practice nurse, or certified wound care nurse in collaboration with the physician.
- Nonselective débridement can be accomplished by applying isotonic saline dressings of fine-mesh gauze to the ulcer. When the dressing dries, it is removed (dry), along with the debris adhering to the gauze. Pain management is usually necessary.
- Enzymatic débridement with the application of enzyme ointments may be prescribed to treat the ulcer. The ointment is applied to the lesion but not to normal surrounding skin. Most enzymatic ointments are covered with saline-soaked gauze that has been thoroughly wrung out. A dry gauze dressing and a loose bandage are then applied. The enzymatic ointment is discontinued when the necrotic tissue has been débrided and an appropriate wound dressing is applied.
- Débriding agents can be used. Dextranomer (Debrisan) beads are small, highly porous, spherical beads (0.1 to 0.3 mm in diameter) that can absorb wound secretions. Bacteria and the products of tissue necrosis and protein degradation are absorbed into the bead layer. When the beads are saturated, they take on a grayish yellow color, at which point their cleansing action stops. They are then flushed from the wound with normal saline, and a fresh layer is applied.
- Calcium alginate dressings can also be used for débridement when absorption of exudate is needed. These dressings are changed when the exudate seeps through the cover dressing or at least every 7 days. The dressing can also be used on areas that are bleeding, because the material helps stop the bleeding. As the dry fibers absorb exudate, they become a gel that is painlessly removed from the ulcer bed. Calcium alginate dressings should not be used on dry or nonexudative wounds.

## TOPICAL THERAPY

A variety of topical agents can be used in conjunction with cleansing and débridement therapies to promote healing of leg ulcers. The goals of treatment are to remove devitalized tissue and to keep the ulcer clean and moist while healing takes place. The treatment should not destroy developing tissue. For topical treatments to be successful, adequate nutritional therapy must be maintained.

## WOUND DRESSING

After the circulatory status has been assessed and determined to be adequate for healing (ABI of more than 0.5), surgical dressings can be used to promote a moist environment. The simplest method is to use a wound contact material (eg, Tegapore) next to the wound bed and cover it with gauze. Tegapore maintains a moist environment, can be left in place for several days, and does not disrupt the capillary bed when removed for evaluation. Hydrocolloids (eg, Comfeel, DuoDerm CGF, Restore, Tegisorb) are also available options to promote granulation tissue and re-epithelialization. They also provide a barrier for protection because they adhere to the wound bed and surrounding tissue. However, deep wounds and infected wounds are often more appropriately treated with other dressings.

Knowledge deficit, frustration, fear, and depression can result in the patient's and family's decreased compliance with the prescribed therapy; therefore, patient and family education is necessary before beginning and throughout the wound care program.

## STIMULATED HEALING

Tissue-engineered human skin equivalent along with therapeutic compression has been developed by Apligraf; it is a skin product cultured from human dermal fibroblasts and keratinocytes. When applied, it seems to react to factors in the wound and may interact with the patient's cells to stimulate the production of growth factors. Application is not difficult, no suturing is involved, and the procedure is painless.

## NURSING PROCESS: THE PATIENT WHO HAS LEG ULCERS

### Assessment

A careful nursing history and assessment of symptoms are important. The extent and type of pain are carefully assessed, as are the appearance and temperature of the skin of both legs. The quality of all peripheral pulses is assessed, and comparisons are made of the pulses in both legs. The legs are checked for edema. If the extremity is edematous, the degree of edema is determined. Any limitation of mobility and activity that results from the vascular insufficiency is identified. The patient's nutritional status is assessed, and a history of diabetes, collagen disease, or varicose veins is obtained.

### Diagnosis

#### NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses for the patient may include:

- Impaired skin integrity related to vascular insufficiency
- Impaired physical mobility related to activity restrictions of the therapeutic regimen and pain
- Imbalanced nutrition: less than body requirements, related to increased need for nutrients that promote wound healing

## COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include:

- Infection
- Gangrene

## Planning and Goals

The major goals for the patient may include restoration of skin integrity, improved physical mobility, adequate nutrition, and absence of complications.

## Nursing Interventions

The nursing challenge in caring for these patients is great, whether the patient is in the hospital, in a long-term care facility, or at home. The physical problem is often a long-term one that causes a substantial drain on the patient's physical, emotional, and economic resources.

### RESTORING SKIN INTEGRITY

To promote wound healing, measures are used to keep the area clean. Cleansing requires very gentle handling, a mild soap, and lukewarm water. Positioning of the legs depends on whether the ulcer is of arterial or venous origin. If there is arterial insufficiency, the patient should be referred to be evaluated for vascular reconstruction. If there is venous insufficiency, dependent edema can be avoided by elevating the lower extremities. A decrease in edema promotes the exchange of cellular nutrients and waste products in the area of the ulcer, promoting healing.

Avoiding trauma to the lower extremities is imperative in promoting skin integrity. Protective boots may be used (eg, the Rooke Vascular boot, Lunax Boot, Bunny Boot); they are soft and provide warmth and protection from injury. If the patient is on bed rest, it is important to relieve pressure on the heels to prevent pressure ulcerations. When the patient is in bed, a bed cradle can be used to relieve pressure from bed linens and to prevent anything from touching the legs. When the patient is ambulatory, all obstacles are moved from the patient's path so that the patient's legs will not be bumped. Heating pads, hot-water bottles, or hot baths are avoided. Heat increases the oxygen demands and thus the blood flow demands of the tissue, which in this case are already compromised. The patient with diabetes mellitus suffers from neuropathy with decreased sensation, and heating pads may produce injury before the patient is aware of being burned.

### IMPROVING PHYSICAL MOBILITY

Generally, physical activity is initially restricted to promote healing. When infection resolves and healing begins, ambulation should resume gradually and progressively. Activity promotes arterial flow and venous return and is encouraged after the acute phase of the ulcer process. Until full activity resumes, the patient is encouraged to move about when in bed, to turn from side to side frequently, and to exercise the upper extremities to maintain muscle tone and strength. Meanwhile, diversional activities that interest the patient are encouraged. Consultation with an occupational therapist may be helpful if a prolonged period of limited mobility and activity is anticipated.

If pain limits the patient's activity, analgesics may be prescribed by the physician. The pain of peripheral vascular disease, whether it is arterial or venous, is typically chronic. Analgesics may be taken before scheduled activities to help the patient participate more comfortably.

### PROMOTING ADEQUATE NUTRITION

Nutritional deficiencies are determined from the patient's report of usual dietary intake. Alterations in the diet are made to remedy these deficiencies. A diet that is high in protein, vitamins C and A, iron, and zinc is encouraged in an attempt to promote healing.

Many patients with peripheral vascular disease are elderly. Their caloric intake may need to be adjusted because of their decreased metabolic rate and level of activity. Particular consideration should also be given to their iron intake, because many elderly people are anemic.

After a diet plan has been developed that meets the patient's nutritional needs and promotes healing, diet instruction is provided to the patient and family. The nurse and patient design the diet plan to be compatible with the lifestyle and preferences of the patient and family.

### PROMOTING HOME AND COMMUNITY-BASED CARE

The self-care program is planned with the patient so that activities to promote arterial and venous circulation, relieve pain, and promote tissue integrity will be used. Reasons for each aspect of the program are explained to the patient and family. Leg ulcers are often chronic and difficult to heal; they frequently recur, even when patients rigorously follow the plan of care. Long-term care of the feet and legs to promote healing of wounds and prevent recurrence of ulcerations is the primary goal. Leg ulcers increase the patient's risk for infection, may be painful, and limit mobility, necessitating life-style changes. Participation of family members and home-health providers may be necessary for treatments such as dressing changes, reassessments, and evaluation of the plan of care. Regular follow-up with a primary health care provider is necessary.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Demonstrates restored skin integrity
  - a. Exhibits absence of inflammation
  - b. Exhibits absence of drainage; negative wound culture
  - c. Avoids trauma to the legs
2. Increases physical mobility
  - a. Progresses gradually to optimal level of activity
  - b. Reports that pain does not impede activity
3. Attains adequate nutrition
  - a. Selects foods high in protein, vitamins, iron, and zinc
  - b. Discusses with family members dietary modifications that need to be made at home
  - c. Plans, with the family, a diet that is nutritionally sound

## VARICOSE VEINS

Varicose veins (varicosities) are abnormally dilated, tortuous, superficial veins caused by incompetent venous valves (see Fig. 31-16). Most commonly, this condition occurs in the lower extremities, the saphenous veins, or the lower trunk; however, it can occur elsewhere in the body, such as esophageal varices (see Chap. 39).

It is estimated that varicose veins occur in up to 60% of the adult population in the United States, with an increased incidence correlated with increased age (Johnson, 1997). The condition is most common in women and in people whose occupations require prolonged standing, such as salespeople, hair stylists, teach-

ers, nurses, ancillary medical personnel, and construction workers. A hereditary weakness of the vein wall may contribute to the development of varicosities, and it is not uncommon to see this condition occur in several members of the same family. Varicose veins are rare before puberty. Pregnancy may cause varicosities. The leg veins dilate during pregnancy because of hormonal effects related to distensibility, increased pressure by the gravid uterus, and increased blood volume which all contribute to the development of varicose veins (Johnson, 1997).

## Pathophysiology

Varicose veins may be considered primary (without involvement of deep veins) or secondary (resulting from obstruction of deep veins). A reflux of venous blood in the veins results in venous stasis. If only the superficial veins are affected, the person may have no symptoms but may be troubled by the appearance of the dilated veins.

## Clinical Manifestations

Symptoms, if present, may take the form of dull aches, muscle cramps, and increased muscle fatigue in the lower legs. Ankle edema and a feeling of heaviness of the legs may occur. Nocturnal cramps are common. When deep venous obstruction results in varicose veins, patients may develop the signs and symptoms of chronic venous insufficiency: edema, pain, pigmentation, and ulcerations. Susceptibility to injury and infection is increased.

## Assessment and Diagnostic Findings

Diagnostic tests for varicose veins include the duplex scan, which documents the anatomic site of reflux and provides a quantitative measure of the severity of valvular reflux. Air plethysmography measures the changes in venous blood volume. Venography is not routinely performed to evaluate for valvular reflux. When it is used, however, it involves injecting an x-ray contrast agent into the leg veins so that the vein anatomy can be visualized by x-ray studies during various leg movements.

## Prevention

The patient should avoid activities that cause venous stasis, such as wearing tight socks or a constricting panty girdle, crossing the legs at the thighs, and sitting or standing for long periods. Changing position frequently, elevating the legs when they are tired, and getting up to walk for several minutes of every hour promote circulation. The patient should be encouraged to walk 1 or 2 miles each day if there are no contraindications. Walking up the stairs rather than using the elevator or escalator is helpful in promoting circulation. Swimming is also good exercise for the legs.

Elastic compression stockings, especially knee-high stockings, are useful. Patients are more likely to use knee-high stockings than thigh-high stockings. The overweight patient should be encouraged to begin a weight-reduction plan.

## Medical Management

Surgery for varicose veins requires that the deep veins be patent and functional. The saphenous vein is ligated and divided. The vein is ligated high in the groin, where the saphenous vein meets the femoral vein. Additionally, the vein may be removed (stripped). After the vein is ligated, an incision is made in the ankle, and a

metal or plastic wire is passed the full length of the vein to the point of ligation. The wire is then withdrawn, pulling (removing, “stripping”) the vein as it is removed (Fig. 31-18). Pressure and elevation keep bleeding at a minimum during surgery.

### SCLEROTHERAPY

In sclerotherapy, a chemical is injected into the vein, irritating the venous endothelium and producing localized phlebitis and fibrosis, thereby obliterating the lumen of the vein. This treatment may be performed alone for small varicosities or may follow vein ligation or stripping. Sclerosing is palliative rather than curative. After the sclerosing agent is injected, elastic compression bandages are applied to the leg and are worn for approximately 5 days. The health care provider who performed sclerotherapy removes the first bandages. Elastic compression stockings are then worn for an additional 5 weeks.

After sclerotherapy, patients are encouraged to perform walking activities as prescribed to maintain blood flow in the leg. Walking enhances dilution of the sclerosing agent.

### Nursing Management

Surgery can be performed in an outpatient setting, or patients can be admitted to the hospital on the day of surgery and discharged the next day, but nursing measures are the same as if the patient were hospitalized. Bed rest is maintained for 24 hours, after which the patient begins walking every 2 hours for 5 to 10 minutes. Elastic compression stockings are used to maintain compression of the leg. They are worn continuously for about 1 week after vein stripping. The nurse assists the patient to perform exercises and move the legs. The foot of the bed should be elevated. Standing still and sitting are discouraged.

### PROMOTING COMFORT AND UNDERSTANDING

Analgesics are prescribed to help patients move affected extremities more comfortably. Dressings are inspected for bleeding, particularly at the groin, where the risk of bleeding is greatest. The nurse is alert for reported sensations of “pins and needles.” Hyper-

sensitivity to touch in the involved extremity may indicate a temporary or permanent nerve injury resulting from surgery, because the saphenous vein and nerve are close to each other in the leg.

Usually, the patient may shower after the first 24 hours. The patient is instructed to dry the incisions well with a clean towel using a patting technique rather than rubbing. Application of skin lotion is to be avoided until the incisions are completely healed to decrease the chance of developing an infection.

If the patient underwent sclerotherapy, a burning sensation in the injected leg may be experienced for 1 or 2 days. The nurse may encourage the use of a mild analgesic (eg, propoxyphene napsylate and acetaminophen [Darvocet N], oxycodone and acetaminophen [Percocet], oxycodone and acetylsalicylic acid [Percodan]) as prescribed by a physician or nurse practitioner and walking to provide relief.

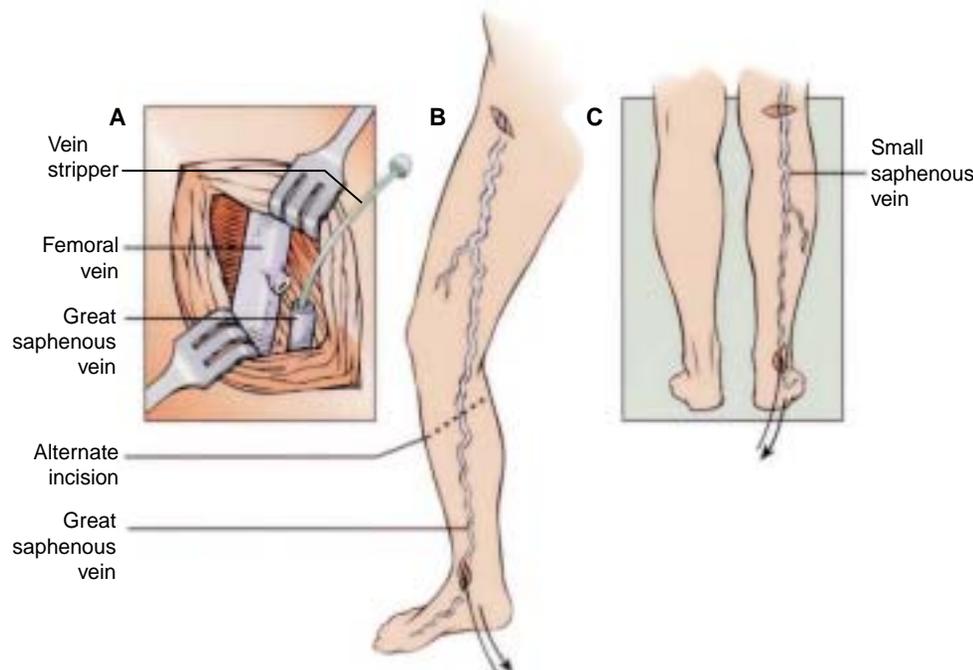

### PROMOTING HOME AND COMMUNITY-BASED CARE

Patients require long-term elastic support of the leg after discharge, and plans are made to obtain adequate supplies of elastic compression stockings or bandages as appropriate. Exercises of the legs are necessary; the development of an individualized plan requires consultation with the patient and the health care team.

## Cellulitis

### Pathophysiology and Clinical Manifestations

Cellulitis is the most common infectious cause of limb swelling. Cellulitis can occur as a single isolated event or a series of recurrent events. It is often misdiagnosed, usually as recurrent thrombophlebitis or chronic venous insufficiency. Cellulitis occurs when an entry point through normal skin barriers allows bacteria to enter and release their toxins in the subcutaneous tissues. The acute onset of swelling, localized redness, and pain is frequently associated with systemic signs of fever, chills, and sweating. The redness may not be uniform and often skips areas. Regional lymph nodes may also be tender and enlarged.

**FIGURE 31-18** Ligation and stripping of the great and the small saphenous veins. (A) The tributaries of the saphenous vein have been ligated at the saphenofemoral junction. (B) The vein stripper has been inserted from the ankle superiorly to the groin. The vein is removed (“stripped”) from above downward. A number of alternate incisions may be needed to remove separate varicose masses. (C) The small saphenous vein is stripped from its junction with the popliteal vein to a point posterior to the lateral malleolus.

## Medical Management

Mild cases of cellulitis can be treated on an outpatient basis with oral antibiotic therapy. If the cellulitis is severe, the patient is hospitalized and treated with intravenous antibiotics for at least 7 to 14 days. The key to preventing recurrent episodes of cellulitis lies in adequate antibiotic therapy for the initial event and in identifying the site of the bacterial entry. The most commonly overlooked areas are the cracks and fissures that occur in the skin between the toes. Other possible locations are drug use injection sites, contusions, abrasions, ulcerations, ingrown toenails, and hangnails.

## Nursing Management

The patient is instructed to elevate the affected area above heart level and apply warm, moist packs to the site every 2 to 4 hours. Individuals with sensory and circulatory deficits, such as diabetes and paralysis, should use caution when applying warm packs because burns may occur; it is advisable to use a thermometer or have a caregiver ensure that the temperature is not more than lukewarm. Education should focus on preventing a recurrent episode. The patient with peripheral vascular disease or diabetes mellitus should receive education or re-education about skin and foot care.

## Management of Lymphatic Disorders

The lymphatic system consists of a set of vessels that spread throughout most of the body. These vessels start as lymph capillaries that drain unabsorbed plasma from the interstitial spaces (spaces between the cells). The lymphatic capillaries unite to form the lymph vessels, which pass through the lymph nodes and then empty into the large thoracic duct that joins the jugular vein on the left side of the neck.

The fluid drained from the interstitial space by the lymphatic system is called lymph. The flow of lymph depends on the intrinsic contractions of the lymph vessels, the contraction of muscles, respiratory movements, and gravity. The lymphatic system of the abdominal cavity maintains a steady flow of digested fatty food (chyle) from the intestinal mucosa to the thoracic duct. In other parts of the body, the lymphatic system's function is regional; the lymphatic vessels of the head, for example, empty into clusters of lymph nodes located in the neck, and those of the extremities empty into nodes of the axillae and the groin.

## LYMPHANGITIS AND LYMPHADENITIS

Lymphangitis is an acute inflammation of the lymphatic channels. It arises most commonly from a focus of infection in an extremity. Usually, the infectious organism is a hemolytic *Streptococcus*. The characteristic red streaks that extend up the arm or the leg from an infected wound outline the course of the lymphatic vessels as they drain.

The lymph nodes located along the course of the lymphatic channels also become enlarged, red, and tender (acute lymphadenitis). They can also become necrotic and form an abscess (suppurative lymphadenitis). The nodes involved most often are those in the groin, axilla, or cervical region.

Because these infections are nearly always caused by organisms that are sensitive to antibiotics, it is unusual to see abscess formation. Recurrent episodes of lymphangitis are often associated with progressive lymphedema. After acute attacks, an elastic compres-

sion stocking or sleeve should be worn on the affected extremity for several months to prevent long-term edema.

## LYMPHEDEMA AND ELEPHANTIASIS

Lymphedemas are classified as primary (congenital malformations) or secondary (acquired obstructions). Tissue swelling occurs in the extremities because of an increased quantity of lymph that results from obstruction of lymphatic vessels. It is especially marked when the extremity is in a dependent position. Initially, the edema is soft, pitting, and relieved by treatment. As the condition progresses, the edema becomes firm, nonpitting, and unresponsive to treatment. The most common type is congenital lymphedema (lymphedema praecox), which is caused by hypoplasia of the lymphatic system of the lower extremity. This disorder is usually seen in women and first appears between ages 15 and 25.

The obstruction may be in the lymph nodes and the lymphatic vessels. Sometimes, it is seen in the arm after an axillary node dissection (eg, for breast cancer) and in the leg in association with varicose veins or chronic thrombophlebitis. In the latter case, the lymphatic obstruction usually is caused by chronic lymphangitis. Lymphatic obstruction caused by a parasite (filaria) is seen frequently in the tropics. When chronic swelling is present, there may be frequent bouts of acute infection characterized by high fever and chills and increased residual edema after the inflammation has resolved. These lead to chronic fibrosis, thickening of the subcutaneous tissues, and hypertrophy of the skin. This condition, in which chronic swelling of the extremity recedes only slightly with elevation, is referred to as elephantiasis.

## Medical Management

The goal of therapy is to reduce and control the edema and prevent infection. Active and passive exercises assist in moving lymphatic fluid into the bloodstream. External compression devices milk the fluid proximally from the foot to the hip or from the hand to the axilla. When the patient is ambulatory, custom-fitted elastic compression stockings or sleeves are worn; those with the highest compression strength (exceeding 40 mm Hg) are required. When the leg is affected, strict bed rest with the leg elevated may aid in mobilizing the fluids.

### PHARMACOLOGIC THERAPY

As initial therapy, the diuretic furosemide (Lasix) is prescribed as needed to prevent the fluid overload that can result from the mobilization of extracellular fluid. Diuretics have also been used palliatively for lymphedema in conjunction with elevating the leg and wearing elastic compression stockings or sleeves. However, the use of diuretics alone has little benefit because their main action is to limit capillary filtration by decreasing the circulating blood volume. If lymphangitis or cellulitis is present, antibiotic therapy is initiated. The patient is taught to inspect the skin for evidence of infection.

### SURGICAL MANAGEMENT

Surgery is performed if the edema is severe and uncontrolled by medical therapy, if mobility is severely compromised, or if infection persists. One surgical approach involves the excision of the affected subcutaneous tissue and fascia, with skin grafting to cover the defect. Another procedure involves the surgical relocation of superficial lymphatic vessels into the deep lymphatic system by means of a buried dermal flap to provide a conduit for lymphatic drainage.

## Nursing Management

After surgery, the management of skin grafts and flaps is the same as when these therapies are used for other conditions. Prophylactic antibiotics may be prescribed for 5 to 7 days. Constant elevation of the affected extremity and observations for complications are essential. Complications may include flap necrosis, hematoma or abscess under the flap, and cellulitis. The nurse instructs the patient or caregiver to inspect the dressing daily. Unusual drainage or any inflammation around the wound margin may suggest infection and should be reported to the physician. The patient is informed that there may be a loss of sensation in the skin graft area. The patient is also instructed to avoid the application of heating pads or exposure to sun to prevent burns or trauma to the area.

### Critical Thinking Exercises

1. Your patient has been diagnosed with an enlarging abdominal aortic aneurysm (AAA). The physician gives the patient two surgical options: repair of the AAA using an endovascular graft or open surgical repair. What factors would you include in discussing the surgical options, post-operative care, continuing care, and home care? If the patient is taking warfarin (Coumadin) for atrial fibrillation and insulin for diabetes, how would you incorporate these factors into the plan of care?
2. Your 96-year-old patient presents with a 1-year history of experiencing symptoms of claudication after walking four or five blocks. The patient lives alone, six blocks from the local shopping area, and no longer drives a vehicle. The patient does not wish to undergo surgery at this time and wants to continue living at his current location. What options would you discuss with the patient? If this patient also had a nonhealing foot wound and had smoked two packs of cigarettes each day for the past 80 years, how would your plan of care change?
3. Your patient has been diagnosed with deep vein thrombosis of a calf. The physician gives the patient two treatment options: hospitalization with intravenous sodium heparin therapy or home treatment with LMWH. What factors would you include in discussing the treatment options with the patient?

# ● Assessment and Management of Patients With Hypertension

## **LEARNING OBJECTIVES** ●

*On completion of this chapter, the learner will be able to:*

1. Define blood pressure and identify risk factors for hypertension.
2. Explain the difference between normal blood pressure and hypertension and discuss the significance of hypertension.
3. Describe the treatment approach for hypertension, including lifestyle changes and medication therapy.
4. Use the nursing process as a framework for care of the patient with hypertension.
5. Describe the necessity for immediate treatment of hypertensive crisis.

**B**lood pressure is the product of cardiac output multiplied by peripheral resistance. Cardiac output is the product of the heart rate multiplied by the stroke volume. In normal circulation, pressure is exerted by the flow of blood through the heart and blood vessels. High blood pressure, known as hypertension, can result from a change in cardiac output, a change in peripheral resistance, or both. The medications used for treating hypertension decrease peripheral resistance, blood volume, or the strength and rate of myocardial contraction.

## Hypertension Defined

Hypertension is a systolic blood pressure greater than 140 mm Hg and a diastolic pressure greater than 90 mm Hg over a sustained period, based on the average of two or more blood pressure measurements taken in two or more contacts with the health care provider after an initial screening (Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure [JNC VI], 1997). Table 32-1 shows the categories of blood pressure established in 1997 by the JNC VI. The classification shows the direct relation between the risk of morbidity and mortality from hypertension and the level of systolic and diastolic blood pressures. The higher the systolic or diastolic pressure, the greater the risk.

Three stages (1, 2, and 3) of hypertension are defined by the JNC VI, which used these terms, similar to those used to describe cancer progression, so that the public and health care professionals would be aware that sustained elevations in blood pressure are associated with increased risks to health. Even within the normotensive range, three levels of blood pressure—optimal, normal, and high-normal—were specified to emphasize that the lower the blood pressure, the lower the risk. The JNC VI also developed recommendations for follow-up monitoring according to initial blood pressure readings at the time of diagnosis (Table 32-2).

## Primary Hypertension

Between 20% and 25% of the adult population in the United States has hypertension (Burt et al., 1995b). Of this population, between 90% and 95% have **primary hypertension**, meaning that the reason for the elevation in blood pressure cannot be identified. The remaining 5% to 10% of this group have high blood pressure related to specific causes, such as narrowing of the renal arteries, renal parenchymal disease, hyperaldosteronism (mineralocorticoid hypertension) certain medications, pregnancy, and coarctation of the aorta (Kaplan, 2001). **Secondary hypertension**

**Table 32-1 • Classification of Blood Pressure for Adults Age 18 and Older\***

CATEGORY	SYSTOLIC (mm Hg)		DIASTOLIC (mm Hg)
Optimal	<120	and	<80
Normal†	<130	and	<85
High-normal	130–139	or	85–89
Hypertension‡			
Stage 1	140–159	or	90–99
Stage 2	160–179	or	100–109
Stage 3	≥180	or	≥110

\*Not taking antihypertensive drugs and not acutely ill. When systolic and diastolic blood pressures fall into different categories, the higher category should be selected to classify the individual's blood pressure status. For example, 160/92 mm Hg should be classified as stage 2 hypertension, and 174/120 mm Hg should be classified as stage 3 hypertension. Isolated systolic hypertension is defined as SBP of 140 mm Hg or greater and DBP below 90 mm Hg and staged appropriately (eg, 170/82 mm Hg is defined as stage 2 isolated systolic hypertension). In addition to classifying stages of hypertension on the basis of average blood pressure levels, clinicians should specify presence or absence of target organ disease and additional risk factors. This specificity is important for risk classification and treatment.

†Optimal blood pressure with respect to cardiovascular risk is below 120/80 mm Hg. However, unusually low readings should be evaluated for clinical significance.

‡Based on the average of two or more readings taken at each of two or more visits after an initial screening.

From the Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. (1997). *Archives of Internal Medicine*, 157(21), 2413–2446.

is the term used to signify high blood pressure from an identified cause.

Hypertension is sometimes called “the silent killer” because people who have it are often symptom free. In a national survey (1991 to 1994), 32% of people who had pressures exceeding 140/90 mm Hg were unaware of their elevated blood pressure (Burt et al., 1995a). Once identified, elevated blood pressure should be monitored at regular intervals because hypertension is a lifelong condition.

Hypertension often accompanies risk factors for atherosclerotic heart disease, such as **dyslipidemia** (abnormal blood fat levels) and diabetes mellitus. The incidence of hypertension is higher in the southeastern United States, particularly among African Americans. Cigarette smoking does not cause high blood pressure; however, if a person with hypertension smokes, his or her risk of dying from heart disease or related disorders increases significantly.

High blood pressure can be viewed in three ways: as a sign, a risk factor for atherosclerotic cardiovascular disease, or a disease.

## Glossary

**dyslipidemia:** abnormally high or low blood lipid levels

**hypertensive emergency:** a situation in which blood pressure must be lowered immediately to prevent damage to target organs

**hypertensive urgency:** a situation in which blood pressure must be lowered within a few hours to prevent damage to target organs

**JNC VI:** Sixth Joint National Committee on the Prevention, Detection, Evaluation and Treatment of High Blood Pressure; committee established to study and make recommendations about hypertension in the United States. Findings and recommendations of JNC VI are contained in an extensive report published in 1997.

**monotherapy:** medication therapy with a single medication

**primary hypertension:** also called essential hypertension; denotes high blood pressure from an unidentified cause

**rebound hypertension:** pressure that is controlled with therapy and that becomes uncontrolled (abnormally high) with the discontinuation of therapy

**secondary hypertension:** high blood pressure from an identified cause, such as renal disease

**Table 32-2 • Recommendations for Follow-up Based on Initial Blood Pressure Measurements for Adults**

INITIAL BLOOD PRESSURE (mm Hg)*		FOLLOW-UP RECOMMENDED†
Systolic	Diastolic	
<130	<85	Recheck in 2 years
130–139	85–89	Recheck in 1 year‡
140–159	90–99	Confirm within 2 months
160–179	100–109	Evaluate or refer to source of care within 1 month
≥180	≥110	Evaluate or refer to source of care immediately or within 1 week depending on clinical situation

\*If systolic and diastolic categories are different, follow recommendations for shorter follow-up time (eg, 160/86 mm Hg, evaluate or refer to source of care within 1 month).

†Modify the scheduling of follow-up according to reliable information about past blood pressure measurements, other cardiovascular risk factors, or target organ disease.

‡Provide advice about lifestyle modifications.

From the Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. (1997). *Archives of Internal Medicine*, 157 (21), 2413–2446.

As a sign, nurses and other health care professionals use blood pressure to monitor a patient's clinical status. Elevated pressure may indicate an excessive dose of vasoconstrictive medication or other problems. As a risk factor, hypertension contributes to the rate at which atherosclerotic plaque accumulates within arterial walls. As a disease, hypertension is a major contributor to death from cardiac, renal, and peripheral vascular disease.

Prolonged blood pressure elevation eventually damages blood vessels throughout the body, particularly in target organs such as the heart, kidneys, brain, and eyes. The usual consequences of prolonged, uncontrolled hypertension are myocardial infarction, heart failure, renal failure, strokes, and impaired vision. The left ventricle of the heart may become enlarged (left ventricular hypertrophy) as it works to pump blood against the elevated pressure. An echocardiogram is the recommended method of determining whether hypertrophy (enlargement) has occurred.

## Pathophysiology

Although the precise cause for most cases of hypertension cannot be identified, it is understood that hypertension is a multifactorial condition. Because hypertension is a sign, it is most likely to have many causes, just as fever has many causes. For hypertension to occur, there must be a change in one or more factors affecting peripheral resistance or cardiac output (some of these factors are outlined in Fig. 32-1). In addition, there must also be a problem with the control systems that monitor or regulate pressure. Single gene mutations have been identified for a few rare types of hypertension, but most types of high blood pressure are thought to be polygenic (mutations in more than one gene) (Dominiczak et al., 2000).

Several hypotheses about the pathophysiologic bases of elevated blood pressure are associated with the concept of hypertension as a multifactorial condition. Given the overlap among these hypotheses, it is likely that aspects of all of them will eventually prove correct. Hypertension may be caused by one or more of the following:

- Increased sympathetic nervous system activity related to dysfunction of the autonomic nervous system

- Increased renal reabsorption of sodium, chloride, and water related to a genetic variation in the pathways by which the kidneys handle sodium
- Increased activity of the renin-angiotensin-aldosterone system, resulting in expansion of extracellular fluid volume and increased systemic vascular resistance
- Decreased vasodilation of the arterioles related to dysfunction of the vascular endothelium
- Resistance to insulin action, which may be a common factor linking hypertension, type 2 diabetes mellitus, hypertriglyceridemia, obesity, and glucose intolerance

## Gerontologic Considerations

Structural and functional changes in the heart and blood vessels contribute to increases in blood pressure that occur with age. The changes include accumulation of atherosclerotic plaque, fragmentation of arterial elastins, increased collagen deposits, and impaired vasodilation. The result of these changes is a decrease in the elasticity of the major blood vessels. Consequently, the aorta and large arteries are less able to accommodate the volume of blood pumped out by the heart (stroke volume), and the energy that would have stretched the vessels instead elevates the systolic blood pressure. Isolated systolic hypertension is more common in older adults.

## Clinical Manifestations

Physical examination may reveal no abnormalities other than high blood pressure. Occasionally, retinal changes such as hemorrhages, exudates (fluid accumulation), arteriolar narrowing, and cotton-wool spots (small infarctions) occur. In severe hypertension, papilledema (swelling of the optic disc) may be seen. People with hypertension can be asymptomatic and remain so for many years. However, when specific signs and symptoms appear, they usually indicate vascular damage, with specific manifestations related to the organs served by the involved vessels. Coronary artery disease with angina or myocardial infarction is a common consequence of hypertension. Left ventricular hypertrophy occurs in response to the increased workload placed on the ventricle as it contracts against higher systemic pressure. When heart damage is extensive, heart failure ensues. Pathologic changes in the kidneys (indicated by increased blood urea nitrogen [BUN] and creatinine levels) may manifest as nocturia. Cerebrovascular involvement may lead to a stroke or transient ischemic attack (TIA), manifested by alterations in vision or speech, dizziness, weakness, a sudden fall, or temporary paralysis on one side (hemiplegia). Cerebral infarctions account for most of the strokes and TIAs in patients with hypertension.

## Assessment and Diagnostic Evaluation

A thorough health history and physical examination are necessary. The retinas are examined, and laboratory studies are performed to assess possible target organ damage. Routine laboratory tests include urinalysis, blood chemistry (ie, analysis of sodium, potassium, creatinine, fasting glucose, and total and high-density lipoprotein [HDL] cholesterol levels), and a 12-lead electrocardiogram. Left ventricular hypertrophy can be assessed by echocardiography. Renal damage may be suggested by elevations in BUN and creatinine levels or by microalbuminuria or macroalbuminuria. Additional studies, such as creatinine clearance, renin level, urine tests, and 24-hour urine protein, may be performed.

**FIGURE 32-1** Factors involved in control of blood pressure, which is cardiac output multiplied by peripheral resistance. Adapted from Kaplan, N. M., Lieberman, E., & Neal, W. (2002). *Kaplan's clinical hypertension* (8th ed.). Philadelphia: Lippincott Williams & Wilkins.

A risk factor assessment, as advocated by the JNC VI, is needed to classify and guide treatment of hypertensive people at risk for cardiovascular damage. Risk factors and cardiovascular problems related to hypertension are presented in Chart 32-1 and Table 32-3.

## Medical Management

The goal of hypertension treatment is to prevent death and complications by achieving and maintaining the arterial blood pressure at 140/90 mm Hg or lower. The JNC VI specified a lower goal pressure of 130/85 mm Hg for people with diabetes mellitus or with proteinuria greater than 1 g per 24 hours (JNC VI, 1997). The optimal management plan is inexpensive, simple, and causes the least possible disruption in the patient's life.

The management options for hypertension are summarized in the treatment algorithm issued in the Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure (1997) (Fig. 32-2) and in Chart 32-2, which lists recommended lifestyle modifications. The clinician uses the algorithm in conjunction with the risk factor assessment data and the patient's blood pressure category to choose the initial and subsequent treatment plans for patients. Research findings demonstrate that weight loss, reduced alcohol and sodium intake, and regular physical activity are effective life-

style adaptations to reduce blood pressure (Appel et al., 1997; Cushman et al., 1998; Hagberg et al., 2000; Sacks et al., 2001). Studies show that diets high in fruits, vegetables, and low-fat dairy products can prevent the development of hypertension and can lower elevated pressures. Table 32-4 delineates the Dietary Approaches to Stop Hypertension (DASH) diet.

### PHARMACOLOGIC THERAPY

For patients with uncomplicated hypertension and no specific indications for another medication, the recommended initial medications include diuretics, beta-blockers, or both. Patients are first given low doses of medication. If blood pressure does not fall to less than 140/90 mm Hg, the dose is increased gradually, and additional medications are included as necessary to achieve control. Table 32-5 describes the various pharmacologic agents used in treating hypertension. When the blood pressure has been less than 140/90 mm Hg for at least 1 year, gradual reduction of the types and doses of medication is recommended. To promote compliance, clinicians try to prescribe the simplest treatment schedule possible, ideally one pill once each day.

### Gerontologic Considerations

Hypertension, particularly elevated systolic blood pressure, increases the risk of death and complications in elderly patients. Treatment reduces this risk. Like younger patients, elderly patients should begin treatment with lifestyle modifications. If medications are needed to achieve the blood pressure goal of less than 140/90 mm Hg, the starting dose should be one-half that used in younger patients.

## NURSING PROCESS: THE PATIENT WITH HYPERTENSION

### Assessment

When hypertension is initially detected, nursing assessment involves carefully monitoring the blood pressure at frequent intervals and then, after diagnosis, at routinely scheduled intervals. The American Heart Association and the American Society of Hypertension have defined the standards for blood pressure measurement, in-

cluding conditions required before measurements are made, equipment specifications, and techniques for measuring blood pressure to obtain accurate and reliable readings (Chart 32-3) (American Society of Hypertension, 1992; Perloff et al., 1993) When the patient begins an antihypertensive treatment regimen, blood pressure assessments are needed to determine the effectiveness of medication therapy and to detect any changes in blood pressure that indicate the need for a change in the treatment plan.

A complete history is obtained to assess for symptoms that indicate target organ damage (whether other body systems have been affected by the elevated blood pressure). Such symptoms may include anginal pain; shortness of breath; alterations in speech, vision, or balance; nosebleeds; headaches; dizziness; or nocturia.

During the physical examination, the nurse must also pay specific attention to the rate, rhythm, and character of the apical and peripheral pulses to detect effects of hypertension on the heart and blood vessels. A thorough assessment can yield valuable information about the extent to which the hypertension has affected the body and about any other personal, social, or financial factors related to the condition.

### Diagnosis

#### NURSING DIAGNOSES

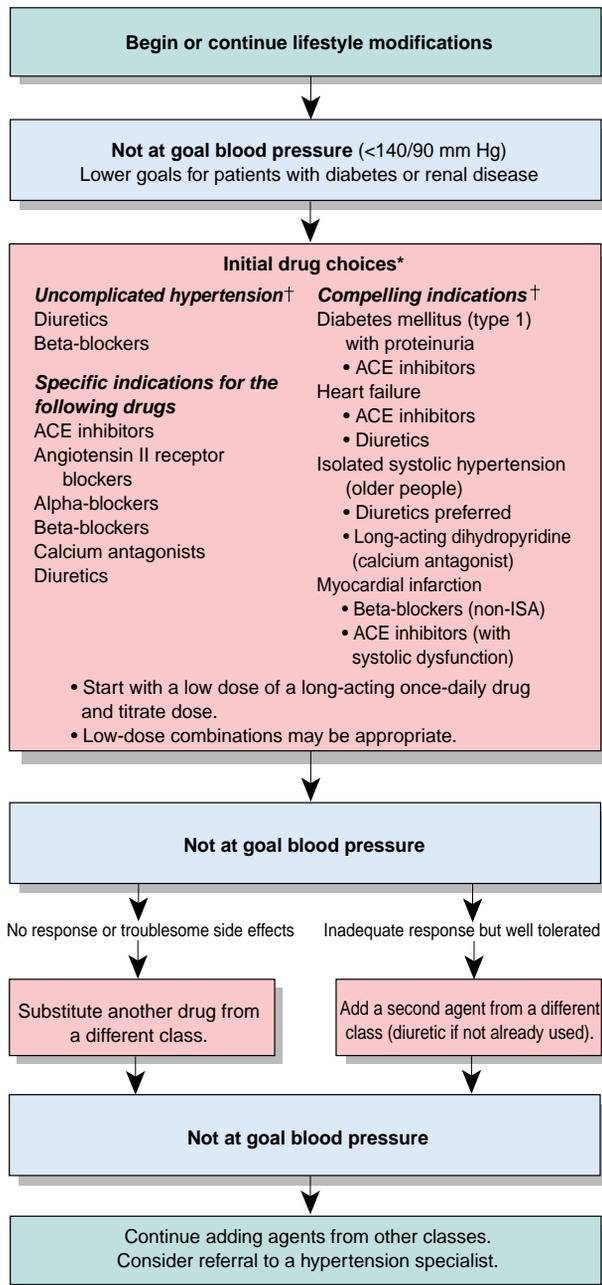

Based on the assessment data, nursing diagnoses for the patient may include the following:

- Deficient knowledge regarding the relation between the treatment regimen and control of the disease process
- Noncompliance with therapeutic regimen related to side effects of prescribed therapy

#### COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include the following:

- Left ventricular hypertrophy
- Myocardial infarction
- Heart failure
- TIAs
- Cerebrovascular accident (stroke or brain attack)

\* Unless contraindicated.  
 ACE = angiotensin-converting enzyme; ISA, intrinsic sympathomimetic activity.  
 †Based on randomized controlled trials

**FIGURE 32-2** Algorithm of hypertension treatment. Treatment begins with lifestyle modifications and continues with various medication regimens. From the Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. (1997). *Archives of Internal Medicine*, 157(21), 2413–2446.

- Renal insufficiency and failure
- Retinal hemorrhage

**Planning and Goals**

The major goals for the patient include understanding of the disease process and its treatment, participation in a self-care program, and absence of complications.

**Chart 32-2 Lifestyle Modifications for Hypertension Prevention and Management**

- Lose weight if overweight.
- Limit alcohol intake to no more than 1 oz (30 mL) ethanol (eg, 24 oz [720 mL] beer, 10 oz [300 mL] wine, or 2 oz [60 mL] 100-proof whiskey) per day or 0.5 oz (15 mL) ethanol per day for women and lighter weight people.
- Increase aerobic physical activity (30 to 45 minutes most days of the week).
- Reduce sodium intake to no more than 100 mmol per day (2.4 g sodium or 6 g sodium chloride).
- Maintain adequate intake of dietary potassium (approximately 90 mmol per day).
- Maintain adequate intake of dietary calcium and magnesium for general health.
- Stop smoking and reduce intake of dietary saturated fat and cholesterol for overall cardiovascular health.

From the Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. (1997). *Archives of Internal Medicine*, 157 (21), 2413–2446.

**Nursing Interventions**

The objective of nursing care for hypertensive patients focuses on lowering and controlling the blood pressure without adverse effects and without undue cost. To achieve these goals, the nurse must support and teach the patient to adhere to the treatment regimen by implementing necessary lifestyle changes, taking medications as prescribed, and scheduling regular follow-up appointments with the health care provider to monitor progress or identify and treat any complications of disease or therapy.

**INCREASING KNOWLEDGE**

The patient needs to understand the disease process and how lifestyle changes and medications can control hypertension. The nurse needs to emphasize the concept of controlling hypertension rather than curing it. The nurse can encourage the patient to consult a dietitian to help develop a plan for weight loss. The program usually consists of restricting sodium and fat intake, increasing intake of fruits and vegetables, and implementing regular physical activity. Explaining that it takes 2 to 3 months for the taste buds to adapt to changes in salt intake may help the patient adjust to reduced salt intake. The patient should be advised to limit alcohol

(text continues on page 863)

**Table 32-4 • The DASH (Dietary Approaches to Stop Hypertension) Diet\***

FOOD GROUP	NO. SERVINGS PER DAY
Grains and grain products	7–8
Vegetables	4–5
Fruits	4–5
Lowfat or fat-free dairy foods	2–3
Meat, fish, and poultry	2 or fewer
Nuts, seeds, and dry beans	4–5 weekly

\*Based on 2000 calories per day.  
 Source: www.nhlbi.nih.gov/health/public/heart/hbp/dash/new\_dash.pdf

Table 32-5 • Medication Therapy for Hypertension

MEDICATIONS	MAJOR ACTION	ADVANTAGES AND CONTRAINDICATIONS	EFFECTS AND NURSING CONSIDERATIONS
<p><b>Purpose:</b> To maintain blood pressure within normal ranges by the simplest and safest means possible with the fewest side effects for each individual patient</p> <p><b>Diuretics and Related Drugs</b></p>			
<i>Thiazide Diuretics</i>			
chlorthalidone (Hygroton) quinethazone (Hydromox) chlorothiazide (Diuril) hydrochlorothiazide (Esidrix; HydroDIURIL)	Decrease of blood volume, renal blood flow, and cardiac output Depletion of extracellular fluid Negative sodium balance (from natriuresis), mild hypokalemia Directly affect vascular smooth muscle	Effective orally Effective during long-term administration Mild side effects Enhance other antihypertensive medications Counter sodium retention effect of other antihypertensive medications <i>Contraindications:</i> Gout, known sensitivity to sulfonamide-derived medications, and severely impaired kidney function	Side effects include dry mouth, thirst, weakness, drowsiness, lethargy, muscle aches, muscular fatigue, tachycardia, GI disturbance. Postural hypotension may be potentiated by alcohol, barbiturates, opioids, or hot weather. Because thiazides cause loss of sodium, potassium, and magnesium, monitor for signs of electrolyte imbalance. Encourage intake of potassium-rich foods (eg, fruits). <i>Gerontological Considerations:</i> Risk of postural hypotension is significant because of volume depletion; measure blood pressure in three positions; caution patient to rise slowly.
<i>Loop Diuretics</i>			
furosemide (Lasix) bumetanide (Bumex)	Volume depletion Blocks reabsorption of sodium, chloride, and water in kidney	Action rapid Potent Used when thiazides fail or patient needs rapid diuresis <i>Contraindications:</i> Same as for thiazides	Volume depletion is rapid—profound diuresis can occur. Electrolyte depletion—replacement is required. Thirst, nausea, vomiting, skin rash, postural hypotension. Sweet taste noted; oral and gastric burning. <i>Gerontologic Considerations:</i> Same as for thiazides.
<i>Potassium-Sparing Diuretics</i>			
spironolactone (Aldactone)  triamterene (Dyrenium)	Competitive inhibitor of aldosterone  Acts on distal tubule independently of aldosterone	Spironolactone is effective in treating hypertension accompanying primary aldosteronism. Both spironolactone and triamterene cause retention of potassium. <i>Contraindications:</i> Renal disease, azotemia, severe hepatic disease, hyperkalemia	Drowsiness, lethargy, headache—decrease dosage. Monitor for hyperkalemia if given with ACE inhibitor. Diarrhea and other GI symptoms—administer medication after meals. Skin eruptions, urticaria Mental confusion, ataxia (with triamterene)—dosage may need to be reduced. Gynecomastia (not for triamterene)

(continued)

Table 32-5 • Medication Therapy for Hypertension (Continued)

MEDICATIONS	MAJOR ACTION	ADVANTAGES AND CONTRAINDICATIONS	EFFECTS AND NURSING CONSIDERATIONS
<b>Adrenergic Agents</b> <b>Peripheral Agents</b> reserpine (Serpasil)	Impairs synthesis and re-uptake of norepinephrine	Slows pulse, which counteracts tachycardia of hydralazine <i>Contraindications:</i> History of depression, psychosis, obesity, chronic sinusitis, peptic ulcer	May cause severe depression; report manifestations, as this may require that drug be omitted. Nasal stuffiness, which may require nasal vasoconstrictor. Increases appetite—therefore, weight control may be difficult. Recurrence of peptic ulcer—administer with meals or milk. <i>Gerontologic Considerations:</i> Depression and postural hypotension common in elderly
<b>Central Alpha Agonists</b> methyldopa (Aldomet)	Dopa-decarboxylase inhibitor; displaces norepinephrine from storage sites	Drug of choice for pregnant women with hypertension Useful in patients with renal failure Does not decrease cardiac output or renal blood flow Does not induce oliguria <i>Contraindications:</i> Liver disease	Drowsiness, dizziness Dry mouth; nasal stuffiness (troublesome at first but then tends to disappear) Hemolytic anemia (a hypersensitization reaction)—positive Coombs' test <i>Gerontologic Considerations:</i> May produce mental and behavioral changes in the elderly.
clonidine hydrochloride (Catapres)	Exact mode of action not understood, but acts through the central nervous system, apparently through centrally mediated alpha-adrenergic stimulation in the brain, producing blood pressure reduction	Little or no orthostatic effect. Moderately potent, and sometimes is effective when other medications fail to lower blood pressure. <i>Contraindications:</i> Severe coronary artery disease, pregnancy, children	Most common side effects are dry mouth, drowsiness, sedation, and occasional headaches and fatigue. Anorexia, malaise, and vomiting with mild disturbance of liver function have been reported. Rebound or withdrawal hypertension is relatively common; monitor blood pressure when stopping medication.
guanfacine (Tenex)	Stimulates central alpha-2 adrenergic receptors	Reduces heart rate and causes vasodilation. Serious adverse reactions are uncommon. Use with caution in persons with diminished liver function, recent myocardial infarction, or known cardiovascular disease.	Common side effects include dry mouth, dizziness, sleepiness, fatigue, headache, constipation, and impotence.
<b>Beta-Blockers</b> propranolol (Inderal) metoprolol (Lopressor) nadolol (Corgard)	Block the sympathetic nervous system (beta-adrenergic receptors), especially the sympathetic to the heart, producing a slower heart rate and lowered blood pressure	Reduce pulse rate in patients with tachycardia and blood pressure elevation and are useful as an adjunct with medications that act at the neuroeffector site of the blood vessel <i>Contraindications:</i> Bronchial asthma, allergic rhinitis, right ventricular failure from pulmonary hypertension, congestive heart failure, depression, diabetes mellitus, dyslipidemia, heart block, peripheral vascular disease, heart rate under 60 bpm	Mental depression manifested by insomnia, lassitude, weakness, and fatigue. Lightheadedness and occasional nausea, vomiting, and epigastric distress Check heart rate before giving. <i>Gerontologic Considerations:</i> Risk of toxicity is increased for elderly patients with decreased renal and liver function. Take blood pressure in three positions and observe for hypotension.

(continued)

Table 32-5 • Medication Therapy for Hypertension (Continued)

MEDICATIONS	MAJOR ACTION	ADVANTAGES AND CONTRAINDICATIONS	EFFECTS AND NURSING CONSIDERATIONS
<i>Alpha Blocker</i> prazosin hydrochloride (Minipress)	Peripheral vasodilator acting directly on the blood vessel; similar to hydralazine	Acts directly on the blood vessel and is an effective agent in patients with adverse reactions to hydralazine <i>Contraindications:</i> Angina pectoris and coronary artery disease. Induces tachycardia if not preceded by administration of propranolol and a diuretic.	Occasional vomiting and diarrhea, urinary frequency, and cardiovascular collapse, especially if given in addition to hydralazine without lowering the dose of the latter. Patients occasionally experience drowsiness, lack of energy, and weakness.
<i>Combined Alpha and Beta Blocker</i> labetalol hydrochloride (Normodyne, Trandate)	Blocks alpha- and beta-adrenergic receptors; causes peripheral dilation and decreases peripheral vascular resistance	Fast-acting No decrease in renal blood flow <i>Contraindications:</i> Asthma, cardiogenic shock, severe tachycardia, heart block	Orthostatic hypotension, tachycardia
<i>Vasodilators</i> fenoldopam mesylate	Stimulates dopamine and alpha-2 adrenergic receptors	Given intravenously for hypertensive emergencies. Use with caution in persons with glaucoma, recent stroke (brain attack), asthma, hypokalemia, or diminished liver function.	Headache, flushing, hypotension, sweating, tachycardia caused by vasodilation Observe for local reactions at the injection site.
hydralazine hydrochloride (Apresoline)	Decreases peripheral resistance but concurrently elevates cardiac output Acts directly on smooth muscle of blood vessels	Not used as initial therapy; used in combination with other medications. Used also in pregnancy-induced hypertension <i>Contraindications:</i> Angina or coronary disease, congestive heart failure, hypersensitivity	Headache, tachycardia, flushing, and dyspnea may occur—can be prevented by pretreating with reserpine. Peripheral edema may require diuretics. May produce lupus erythematosus-like syndrome
minoxidil	Direct vasodilating action on arteriolar vessels, causing decreased peripheral vascular resistance; reduces systolic and diastolic pressures	Hypotensive effect more pronounced than with hydralazine No effect on vasomotor reflexes so does not cause postural hypotension <i>Contraindications:</i> Pheochromocytoma	Tachycardia, angina pectoris, ECG changes, edema Take blood pressure and apical pulse before administration. Monitor intake and output and daily weights. Causes hirsutism
sodium nitroprusside (Nipride, Nitropress) nitroglycerin diazoxide (Hyperstat, NitroBid IV, Tridil)	Peripheral vasodilation by relaxation of smooth muscle	Fast-acting Used only in hypertensive emergencies <i>Contraindications:</i> Sepsis, azotemia, high intracranial pressure.	Dizziness, headache, nausea, edema, tachycardia, palpitations. Can cause thiocyanate and cyanide intoxication.
<i>Angiotensin-Converting Enzyme Inhibitors</i> benazepril (Lotensin) captopril (Capoten) enalaprilat (Vasotec IV) enalapril (Vasotec) lisinopril (Prinivil, Zestril) ramipril (Altace) trandolapril (Mavik)	Inhibit conversion of angiotensin I to angiotensin II Lower total peripheral resistance	Fewer cardiovascular side effects Can be used with thiazide diuretic and digitalis Hypotension can be reversed by fluid replacement. <i>Contraindications:</i> Renal impairment, pregnancy	<i>Gerontologic Considerations:</i> Require reduced dosages and the addition of loop diuretics when there is renal dysfunction
<i>Angiotensin II Receptor Blockers</i> candesartan (Atacand) losartan (Cozaar) valsartan (Diovan) irbesartan (Avapro)	Block the effects of angiotensin II at the receptor Reduce peripheral resistance	Minimal side effects <i>Contraindications:</i> Pregnancy, renovascular disease	Monitor for hypokalemia

(continued)

Table 32-5 • Medication Therapy for Hypertension (Continued)

MEDICATIONS	MAJOR ACTION	ADVANTAGES AND CONTRAINDICATIONS	EFFECTS AND NURSING CONSIDERATIONS
<b>Calcium Antagonists</b>			
<i>Nondihydropyridines</i>			
diltiazem hydrochloride (Cardizem SR, Cardizem CD, Dilacor XR, Tiazac)	Inhibits calcium ion influx Reduces cardiac afterload	Inhibits coronary artery spasm not controlled by beta-blockers or nitrates <i>Contraindications:</i> Sick sinus syndrome; AV block; hypotension; heart failure	Do not discontinue suddenly. Observe for hypotension. Report irregular heartbeat, dizziness, edema. Instruct on regular dental care because of potential gingivitis.
verapamil, (Isoptin SR Calan SR, Verelan, Covera HS)	Inhibits calcium ion influx Slows velocity of conduction of cardiac impulse	Effective antiarrhythmic Rapid IV onset Blocks SA and AV node channels <i>Contraindications:</i> Sinus or AV node disease; severe heart failure; severe hypotension	Administer on empty stomach or before meal. Do not discontinue suddenly. Depression may subside when medication is discontinued. To relieve headaches, reduce noise, monitor electrolytes. Decrease dose for patients with liver or renal failure.
<i>Dihydropyridines</i>			
nifedipine (Procardia Adalat CC)	Inhibit calcium ion influx across membranes	Rapid action	Administer on empty stomach.
amlodipine (Norvasc)	Vasodilating effects on coronary and peripheral arteriole	Effective by oral or sublingual route	Use with caution in diabetic patients.
felodipine (Plendil)	Decrease cardiac work and energy consumption, increase delivery of oxygen to myocardium	No tendency to slow SA nodal activity or prolong AV node conduction	Small frequent meals if nausea. Muscle cramps, joint stiffness, sexual difficulties may disappear when dose decreased.
nicardipine (Cardene)		Isolated systolic hypertension	Report irregular heartbeat, constipation, shortness of breath, edema.
nisoldipine (Sular)		<i>Contraindications:</i> None (except heart failure for nifedipine)	May cause dizziness.

Chart  
32-3

## Measuring Blood Pressure

**Instructions for Patient**

- Avoid smoking cigarettes or drinking caffeine for 30 minutes before blood pressure is measured.
- Sit quietly for 5 minutes before the reading.
- Sit comfortably with the forearm supported at heart level on a firm surface, with both feet on the ground; avoid talking during measurement.

**Equipment for Practitioner**

- Mercury sphygmomanometer, recently calibrated aneroid manometer, or validated electronic device
- Choose from several cuffs of different size so that rubber bladder width is at least 40% and length at least 80% of the arm circumference

**Equipment for Patient at Home**

- Automatic or semiautomatic device with digital display of readings

**Procedure**

Assessment is based on the average of at least two readings. (If two readings differ by more than 5 mm Hg, additional readings are taken and an average reading is calculated from the results.)

**Conclusion**

Inform patient of the numeric blood pressure value and what it means. Emphasize the need for periodic reassessment, and encourage patients who measure blood pressure at home to keep a written record of readings.

intake (see Chart 32-2 for specific recommendations), and tobacco should be avoided—not because smoking is related to hypertension, but because anyone with high blood pressure is already at increased risk for heart disease, and smoking amplifies this risk. Support groups for weight control, smoking cessation, and stress reduction may be beneficial for some patients; others can benefit from the support of family and friends. The nurse assists the patient to develop and adhere to an appropriate exercise regimen, because regular activity is a significant factor in weight reduction and a blood pressure–reducing intervention in the absence of any loss in weight (Sixth Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure, 1997).

**PROMOTING HOME AND COMMUNITY-BASED CARE**

Blood pressure screenings with the sole purpose of case finding are not recommended by the National High Blood Pressure Education Program because approximately 70% of persons with hypertension are already aware of their blood pressure levels (JNC VI, 1997). If asked to participate in a blood pressure screening, the nurse should be sure that proper blood pressure measurement technique is being used (see Chart 32-3), that the manometers used are calibrated (Perloff et al., 1993), and that provision has been made to provide follow-up for any person identified as having an elevated blood pressure. Adequate time should also be allowed to teach people what the blood pressure numbers mean. Each person

should be given a written record of his or her blood pressure at the screening.

### Teaching Patients Self-Care

The therapeutic regimen is the responsibility of the patient in collaboration with the health care provider. Education about high blood pressure and how to manage it, including medications, lifestyle changes of diet, weight control, and exercise (see Table 32-2), setting goal blood pressures, and assistance with social support, can help the patient achieve blood pressure control. Involving family members in education programs enables them to support the patient's efforts to control hypertension. The American Heart Association and the National Heart Lung and Blood Institute provide printed and electronic patient education materials.

Written information about the expected effects and side effects of medications is important. When side effects occur, patients need to understand the importance of reporting them and to whom they should be reported. Patients need to be informed that **rebound hypertension** can occur if antihypertensive medications are suddenly stopped. Female and male patients should be informed that some medications, such as beta-blockers, may cause sexual dysfunction and that, if a problem with sexual function or satisfaction occurs, other medications are available. The nurse can encourage and teach patients to measure their blood pressure at home. This practice involves patients in their own care and emphasizes the fact that failing to take medications may result in an identifiable rise in blood pressure. Patients need to know that blood pressure varies continuously and that the range within which their pressure varies should be monitored.

### Continuing Care

Regular follow-up care is imperative so that the disease process can be assessed and treated, depending on whether control or progression is found. A history and physical examination should be completed at each clinic visit. The history should include all data that pertain to any potential problem, specifically medication-related problems such as postural (orthostatic) hypotension (experienced as dizziness or lightheadedness).

Deviation from the therapeutic program is a significant problem for people with hypertension and other chronic conditions requiring lifetime management. It is estimated that 50% discontinue their medications within 1 year of beginning to take them. Blood pressure control is achieved by only 27% (JNC VI, 1997). However, when patients actively participate in self-care, including self-monitoring of blood pressure and diet, compliance increases—possibly because patients receive immediate feedback and have a greater sense of control.

Considerable effort is required by patients with hypertension to adhere to recommended lifestyle modifications and to take regularly prescribed medications. The effort needed to follow the therapeutic plan may seem unreasonable to some, particularly when they have no symptoms without medications but do have side effects with medications. The recommended lifestyle changes are listed in Chart 32-2. Continued education and encouragement are usually needed to enable patients to formulate an acceptable plan that helps them live with their hypertension and adhere to the treatment plan. Compromises may have to be made about some aspects of therapy to achieve success in higher-priority goals. The nurse can assist with behavior change by supporting patients in making small changes with each visit that move them toward their goals. Another important factor is following up at each visit to see how the patient has progressed with the plans

made at the prior visit. If the patient has had difficulty with a particular aspect of the plan, the patient and nurse can work together to develop an alternative or modification to the plan that the patient believes will be more successful.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Symptoms suggesting that hypertension is progressing to the extent that target organ damage is occurring must be detected early so that appropriate treatment can be initiated accordingly. When the patient returns for follow-up care, all body systems must be assessed to detect any evidence of vascular damage. Examining the eyes with an ophthalmoscope is particularly important because retinal blood vessel damage indicates similar damage elsewhere in the vascular system. The patient is questioned about blurred vision, spots in front of the eyes, and diminished visual acuity. The heart, nervous system, and kidneys are also carefully assessed and examined. Any significant findings are promptly reported to determine whether additional diagnostic studies are required. Based on the findings, medications may be changed to improve blood pressure control.

### Gerontologic Considerations

Compliance with the therapeutic program may be more difficult for elderly people. The medication regimen can be difficult to remember, and the expense can be a problem. **Monotherapy** (treatment with a single agent), if appropriate, may simplify the medication regimen and make it less expensive. Special care must be taken to ensure that the elderly patient understands the regimen and can see and read instructions, open the medication container, and get the prescription refilled. The elderly person's family or caregivers should be included in the teaching program so that they can understand the patient's needs, encourage adherence to the treatment plan, and know when and whom to call if problems arise or information is needed.

**NURSING ALERT** The patient and caregivers should be cautioned that antihypertensive medications can cause hypotension. Low blood pressure or postural hypotension should be reported immediately. Because elderly people have impaired cardiovascular reflexes, they are often more sensitive than younger people to the extracellular volume depletion caused by diuretic therapy and to the sympathetic inhibition caused by adrenergic antagonists. The nurse teaches patients to change positions slowly when moving from a lying or sitting position to a standing position. The nurse also counsels elderly patients to use supportive devices such as hand rails and walkers when necessary to prevent falls that could result from dizziness.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Maintains adequate tissue perfusion
  - a. Maintains blood pressure at less than 140/90 mm Hg (or less than 130/85 mm Hg for persons with diabetes mellitus or proteinuria greater than 1 g per 24 hours) with lifestyle modifications, medications, or both
  - b. Demonstrates no symptoms of angina, palpitations, or vision changes
  - c. Has stable BUN and serum creatinine levels
  - d. Has palpable peripheral pulses

2. Complies with the self-care program
  - a. Adheres to the dietary regimen as prescribed: reduces calorie, sodium, and fat intake; increases fruit and vegetable intake
  - b. Exercises regularly
  - c. Takes medications as prescribed and reports any side effects
  - d. Measures blood pressure routinely
  - e. Abstains from tobacco and excessive alcohol intake
  - f. Keeps follow-up appointments
3. Has no complications
  - a. Reports no changes in vision
  - b. Exhibits no retinal damage on vision testing
  - c. Maintains pulse rate and rhythm and respiratory rate within normal ranges
  - d. Reports no dyspnea or edema
  - e. Maintains urine output consistent with intake
  - f. Has renal function test results within normal range
  - g. Demonstrates no motor, speech, or sensory deficits
  - h. Reports no headaches, dizziness, weakness, changes in gait, or falls

## Hypertensive Crises

There are two hypertensive crises that require nursing intervention: hypertensive emergency and hypertensive urgency. Hypertensive emergencies and urgencies may occur in patients whose hypertension has been poorly controlled or in those who have abruptly discontinued their medications. Once the hypertensive crisis has been managed, a complete evaluation is performed to review the patient's ongoing treatment plan and strategies to minimize the occurrence of subsequent hypertensive crises.

### HYPERTENSIVE EMERGENCY

**Hypertensive emergency** is a situation in which blood pressure must be lowered immediately (not necessarily to less than 140/90 mm Hg) to halt or prevent damage to the target organs. Conditions associated with hypertensive emergency include acute myocardial infarction, dissecting aortic aneurysm, and intracranial hemorrhage. Hypertensive emergencies are acute, life-threatening blood pressure elevations that require prompt treatment in an intensive care setting because of the serious target organ damage that may occur. The medications of choice in hypertensive emergencies are those that have an immediate effect. Intravenous vasodilators, including sodium nitroprusside (Nipride, Nitropress), nicardipine hydrochloride (Cardene), fenoldopam mesylate (Corlopam), enalaprilat (Vasotec I.V.), and nitroglycerin (Nitro-Bid IV, Tridil), have an immediate action that is short lived (minutes to 4 hours), and they are therefore used as the initial treatment. Table 32-5 provides for more information about these medications.

### HYPERTENSIVE URGENCY

**Hypertensive urgency** is a situation in which blood pressure must be lowered within a few hours. Severe perioperative hypertension is considered a hypertensive urgency. Hypertensive urgencies are managed with oral doses of fast-acting agents such as loop diuretics (bumetanide [Bumex], furosemide [Lasix]), beta-blockers propranolol (Inderal), metoprolol (Lopressor), nadolol (Corgard),

angiotensin-converting enzyme inhibitors (benazepril [Lotensin], captopril [Capoten], enalapril [Vasotec]), calcium antagonists (diltiazem [Cardizem], verapamil [Isoptin SR, Calan SR, Covera HS]), or alpha<sub>2</sub>-agonists, such as clonidine (Catapres) and guanfacine (Tenex) (see Table 32-5).

Extremely close hemodynamic monitoring of the patient's blood pressure and cardiovascular status is required during treatment of hypertensive emergencies and urgencies. The exact frequency of monitoring is a matter of clinical judgment and varies with the patient's condition. The nurse may think that taking vital signs every 5 minutes is appropriate if the blood pressure is changing rapidly or may check vital signs at 15 or 30 minutes intervals if the situation is more stable. A precipitous drop in blood pressure can occur, which would require immediate action to restore blood pressure to an acceptable level.

### Critical Thinking Exercises

**1.** You are a nursing student assigned to a hypertension clinic. One of the patients is a 58-year-old telemarketer. During the physical assessment, the patient, who is 5 feet 6 inches tall and weighs 180 lb, asks you what he can do to reduce his blood pressure. How would you answer this patient's question? Identify what additional data you need to consider before you answer the patient's question. How would your assessment and plan change if the patient also had degenerative arthritis of his knees?

**2.** You are a home care nurse. One of your patients is an elderly man who lives alone and who has hypertension along with other health problems, including heart failure and atrial fibrillation. During a home visit, you learn that he has difficulty taking his medications as directed. What questions come to mind as you consider the situation? How will you direct your assessment to identify factors contributing to this problem? Using the factors identified, develop a sample follow-up home care teaching plan for this patient.

# ● Assessment and Management of Patients With Hematologic Disorders

## **LEARNING OBJECTIVES** ●

*On completion of this chapter, the learner will be able to:*

1. Describe the process of hematopoiesis.
2. Describe the processes involved in maintaining hemostasis.
3. Differentiate between the hypoproliferative and the hemolytic anemias and compare and contrast the physiologic mechanisms, clinical manifestations, medical management, and nursing interventions for each.
4. Use the nursing process as a framework for care of patients with anemia.
5. Compare the leukemias, their incidence, physiologic alterations, clinical manifestations, management, and prognosis.
6. Use the nursing process as a framework for care of patients with acute leukemia.
7. Use the nursing process as a framework for care of patients with lymphoma or multiple myeloma.
8. Use the nursing process as a framework for care of patients with bleeding disorders.
9. Identify therapies for blood disorders, including the nursing implications for the administration of blood and blood components.

Unlike many other body systems, the hematologic system truly encompasses the entire human body. Patients with hematologic disorders can be quite challenging to nurses because they often have significant abnormalities in blood tests but few or no symptoms. It is therefore imperative that nurses have a good understanding of the pathophysiology of the patient's condition and can make a thorough assessment that relies heavily on the interpretation of laboratory tests. It is equally important for the nurse to anticipate potential patient needs and to target nursing interventions accordingly. Because it is so important to the under-

standing of most hematologic diseases, a basic appreciation of blood cells and bone marrow function is necessary.

## Anatomic and Physiologic Overview

The hematologic system consists of the blood and the sites where blood is produced, including the bone marrow and the **reticuloendothelial system (RES)**. Blood is a specialized organ that differs from other organs in that it exists in a fluid state. Blood is

## Glossary

**absolute neutrophil count (ANC):** a mathematical calculation of the actual number of neutrophils in the circulation, derived from the total WBCs and the percentage of neutrophils counted in a microscope's visual field; provides a rough indication of infection risk

**anemia:** decreased RBC count

**anergy:** diminished reactivity to antigens (transient or complete)

**angiogenesis:** formation of new blood vessels, such as in a healing wound or in a malignant tumor

**angular cheilosis:** cracking sore at corner of mouth

**aplasia:** lack of cellular development (eg, of cells within the bone marrow)

**apoptosis:** complex process of programmed cell death

**band cell:** slightly immature neutrophil

**blast cell:** primitive WBC

**cytokines:** hormones produced by leukocytes that are vital to regulation of hematopoiesis, apoptosis, and immune responses

**D-dimer:** test that measures fibrin breakdown; considered to be more specific than fibrin degradation products in the diagnosis of disseminated intravascular coagulation (DIC)

**differentiation:** development of functions and characteristics that are different from those of the parent stem cell

**dysplasia:** abnormal development (eg, of blood cells); size, shape and appearance of cells are altered

**ecchymosis:** bruise

**erythrocyte:** see RBC

**erythrocyte sedimentation rate (ESR):** laboratory test that measures the rate of settling of RBCs; elevation is indicative of inflammation; also called the "sed rate"

**erythroid cells:** broad term used in reference to any cell that is or will become a mature RBC

**erythropoiesis:** process of formation of RBCs

**erythropoietin:** hormone produced primarily by the kidney; necessary for erythropoiesis

**fibrin:** filamentous protein; basis of thrombus and blood clot

**fibrinogen:** protein converted into fibrin to form thrombus and clot

**granulocyte:** granulated WBC (neutrophil, eosinophil, basophil); sometimes used synonymously with neutrophil

**granulocytopenia:** fewer than normal granulocytes

**hematocrit:** percentage of total blood volume consisting of RBCs

**hematopoiesis:** complex process of the formation and maturation of blood cells

**hemoglobin:** iron-containing protein of RBCs; delivers oxygen to tissues

**hemolysis:** destruction of RBCs; can occur within or outside of the vasculature

**hemosiderin:** iron-containing pigment derived from breakdown of hemoglobin

**hemostasis:** intricate balance between clot formation and clot dissolution

**histiocytes:** cells present in all loose connective tissue, capable of phagocytosis; part of the RES

**hyperplasia:** abnormally increased proliferation of normal cells

**hypochromia:** pallor within the RBC caused by decreased hemoglobin content

**left shift, or shift to the left:** increased release of immature forms of WBCs from the bone marrow in response to need

**leukocyte:** see WBC

**leukemia:** uncontrolled proliferation of WBCs, often immature

**leukopenia:** less than normal amount of WBCs in circulation

**lymphoid:** pertaining to lymphocytes

**lymphocyte:** form of WBC involved in immune functions

**lysis:** destruction of cells

**macrocytosis:** larger than normal RBCs

**macrophage:** cells of the RES that are capable of phagocytosis

**mast cell:** cells found in connective tissue involved in defense of the body and coagulation

**microcytosis:** smaller than normal RBCs

**monocyte:** large WBC that becomes a macrophage when it leaves the circulation and moves into body tissues

**myeloid:** pertaining to nonlymphoid blood cells that differentiate into RBCs, platelets, monocytes and macrophages, neutrophils, eosinophils, basophils, and mast cells

**myelopoiesis:** formation and maturation of cells derived from myeloid stem cell

**neutropenia:** lower than normal number of neutrophils

**neutrophil:** fully mature WBC capable of phagocytosis; primary defense against bacterial infection

**normochromic:** normal RBC color, indicating normal amount of hemoglobin

**normocytic:** normal size of RBC

**nucleated RBCs:** immature form of RBC; portion of nucleus remains within the red cell; not normally seen in circulating blood

**oxyhemoglobin:** combined form of oxygen and hemoglobin; found in arterial blood

**pancytopenia:** abnormal decrease in WBCs, RBCs, and platelets

**petechiae:** tiny capillary hemorrhages

**phagocytosis:** process of ingestion and digestion of bacteria

**plasma:** liquid portion of blood

**plasminogen:** protein that is converted to plasmin to dissolve thrombi and clots

**platelet:** thrombocyte; a cellular component of blood involved in blood coagulation

**poikilocytosis:** variation in shape of RBCs

**polycythemia:** excess RBCs

**RBC:** red blood cell, erythrocyte; a cellular component of blood involved in the transport of oxygen and carbon dioxide

**red blood cell:** see RBC

**reticulocytes:** slightly immature RBCs, usually only 1% of total circulating RBCs

**reticuloendothelial system (RES):** complex system of cells throughout body capable of phagocytosis

**serum:** portion of blood remaining after coagulation occurs

**stem cell:** primitive cell, capable of self-replication and differentiation into myeloid or lymphoid stem cell

**thrombin:** enzyme necessary to convert fibrinogen into fibrin clot

**thrombocyte:** see platelet

**thrombocytopenia:** lower than normal platelet count

**thrombocytosis:** higher than normal platelet count

**WBC:** white blood cells, leukocytes; cellular components of blood involved in defense of the body; subtypes include neutrophils, eosinophils, basophils, monocytes, and lymphocytes

**white blood cell:** see WBC

composed of plasma and various types of cells. **Plasma** is the fluid portion of blood; it contains various proteins, such as albumin, globulin, **fibrinogen**, and other factors necessary for clotting, as well as electrolytes, waste products, and nutrients. About 55% of blood volume is plasma.

## BLOOD

The cellular component of blood consists of three primary cell types (Table 33-1): **RBCs (red blood cells or erythrocytes)**, **WBCs (white blood cells or leukocytes)**, and **platelets (thrombocytes)**. These cellular components of blood normally make up 40% to 45% of the blood volume. Because most blood cells have a short life span, the need for the body to replenish its supply of cells is continuous; this process is termed **hematopoiesis**. The primary site for hematopoiesis is the bone marrow. During embryonic development and in other conditions, the liver and spleen may also be involved.

Under normal conditions, the adult bone marrow produces about 175 billion RBCs, 70 billion **neutrophils** (mature form of a WBC), and 175 billion platelets each day. When the body needs more blood cells, as in infection (when WBCs are needed to fight the invading pathogen) or in bleeding (when more RBCs are required), the marrow increases its production of the cells required. Thus, under normal conditions, the marrow responds to increased demand and releases adequate numbers of cells into the circulation.

The volume of blood in humans is approximately 7% to 10% of the normal body weight and amounts to 5 to 6 L. Circulating through the vascular system and serving as a link between body organs, the blood carries oxygen absorbed from the lungs and nutri-

ents absorbed from the gastrointestinal tract to the body cells for cellular metabolism. Blood also carries waste products produced by cellular metabolism to the lungs, skin, liver, and kidneys, where they are transformed and eliminated from the body. Blood also carries hormones, antibodies, and other substances to their sites of action or use.

To function, blood must remain in its normally fluid state. Because blood is fluid, the danger always exists that trauma can lead to loss of blood from the vascular system. To prevent this, an intricate clotting mechanism is activated when necessary to seal any leak in the blood vessels. Excessive clotting is equally dangerous, because it can obstruct blood flow to vital tissues. To prevent this, the body has a fibrinolytic mechanism that eventually dissolves clots (thrombi) formed within blood vessels. The balance between these two systems, clot (thrombus) formation and clot (thrombus) dissolution or fibrinolysis, is called **hemostasis**.

## BONE MARROW

The bone marrow is the site of hematopoiesis, or blood cell formation (Fig. 33-1). In a child all skeletal bones are involved, but as the child ages marrow activity decreases. By adulthood, marrow activity is usually limited to the pelvis, ribs, vertebrae, and sternum.

Marrow is one of the largest organs of the body, making up 4% to 5% of total body weight. It consists of islands of cellular components (red marrow) separated by fat (yellow marrow). As the adult ages, the proportion of active marrow is gradually replaced by fat; however, in the healthy person, the fat can again be replaced by active marrow when more blood cell production is required. In adults with disease that causes marrow destruction, fibrosis, or scarring, the liver and spleen can also resume production of blood cells by a process known as extramedullary hematopoiesis.

The marrow is highly vascular. Within it are primitive cells called **stem cells**. The stem cells have the ability to self-replicate, thereby ensuring a continuous supply of stem cells throughout the life cycle. When stimulated to do so, stem cells can begin a process of **differentiation** into either **myeloid** or **lymphoid** stem cells. These stem cells are committed to produce specific types of blood cells. Lymphoid stem cells produce either T or B **lymphocytes**. Myeloid stem cells differentiate into three broad cell types: RBCs, WBCs, and platelets. Thus, with the exception of lymphocytes, all blood cells are derived from the myeloid stem cell. A defect in the myeloid stem cell can cause problems not only with WBC production but also with RBC and platelet production. The entire process of hematopoiesis is highly complex. Research has identified many of the complex mechanisms involved, often at the molecular level. A thorough description of these processes is beyond the scope of this textbook; however, some mechanisms against which a specific treatment is targeted are briefly described in the relevant disease-specific sections of this chapter.

## BLOOD CELLS

### Red Blood Cells (RBCs)

The normal RBC is a biconcave disk that resembles a soft ball compressed between two fingers (Fig. 33-2). It has a diameter of about 8  $\mu\text{m}$  and is so flexible that it can pass easily through capillaries that may be as small as 2.8  $\mu\text{m}$  in diameter. The RBC membrane is so thin that gases, such as oxygen and carbon dioxide, can easily diffuse across it; the disk shape provides a large surface area that facilitates the absorption and release of oxygen molecules.

Table 33-1 • Blood Cells

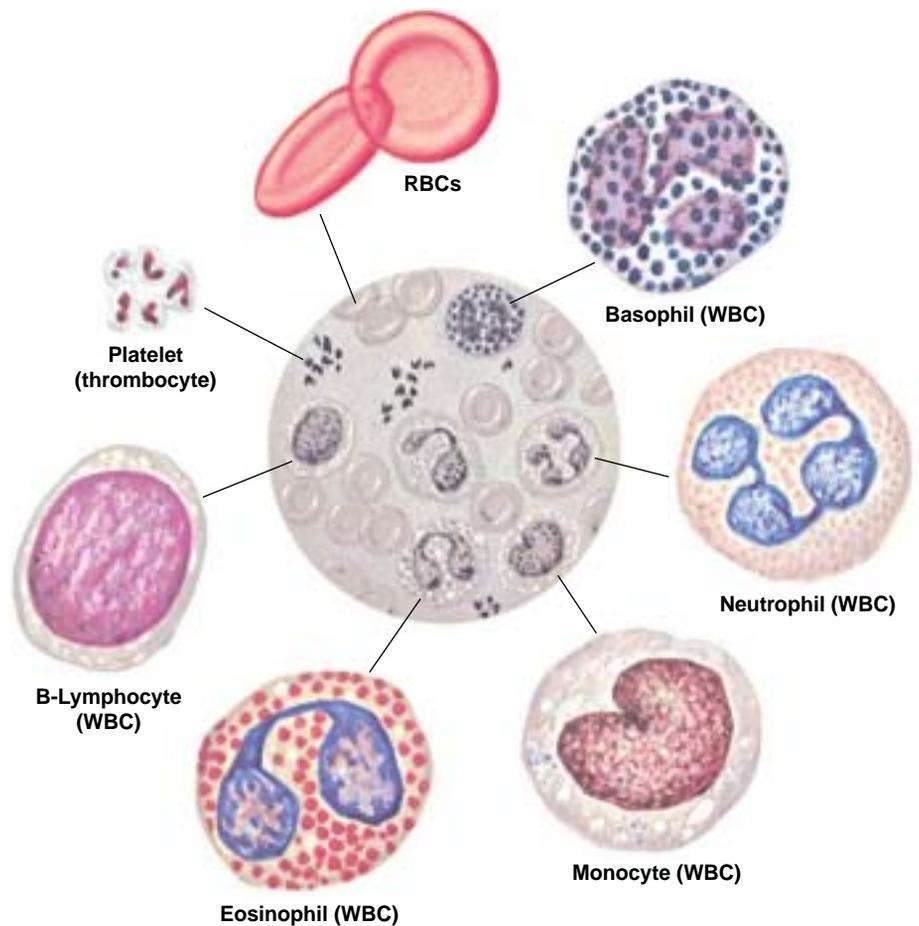

CELL TYPE	MAJOR FUNCTION
<b>WBC (Leukocyte)</b>	Fights infection
Neutrophil	Essential in preventing or limiting bacterial infection via phagocytosis; average life span is 2 to 4 h
Monocyte	Enters tissue as macrophage; highly phagocytic, especially against fungus; immune surveillance
Eosinophil	Involved in allergic reactions (neutralizes histamine); digests foreign proteins
Basophil	Contains histamine; integral part of hypersensitivity reactions
Lymphocyte	Integral component of immune system
T lymphocyte	Responsible for cell-mediated immunity; recognizes material as “foreign” (surveillance system)
B lymphocyte	Responsible for humoral immunity; many mature into plasma cells to form antibodies
Plasma cell	Secretes immunoglobulin (Ig, antibody); most mature form of B lymphocyte
<b>RBC (Erythrocyte)</b>	Carries hemoglobin to provide oxygen to tissues; average life span is 120 days
<b>Platelet (Thrombocyte)</b>	Fragment of megakaryocyte, not really a cell; provides basis for coagulation to occur; maintains hemostasis; average life span is 10 days

## Physiology/Pathophysiology

**FIGURE 33-1** Hematopoiesis. Uncommitted (pluripotent) stem cells can differentiate into myeloid or lymphoid stem cells. These stem cells then undergo a complex process of differentiation and maturation into normal cells that are released into the circulation. The myeloid stem cell is responsible not only for all nonlymphoid white blood cells (WBCs) but also for the production of red blood cells (RBCs) and platelets. Each step of the differentiation process depends in part on the presence of specific growth factors for each cell type. When the stem cells are dysfunctional, they may respond inadequately to the need for more cells, or they may respond excessively, sometimes uncontrollably, as in leukemia. Adapted from Amgen, Inc., 1995, Thousand Oaks, CA.

---

**FIGURE 33-2** Normal types of blood cells.

Mature RBCs consist primarily of **hemoglobin**, which contains iron and makes up 95% of the cell mass. RBCs have no nuclei, and they have many fewer metabolic enzymes than do most other cells. The presence of a large amount of hemoglobin enables the RBC to perform its principal function, the transport of oxygen between the lungs and tissues. Occasionally the marrow releases slightly immature forms of RBCs, called **reticulocytes**, into the circulation. This occurs as a normal response to an increased demand for RBCs (as in bleeding) or in some disease states.

The oxygen-carrying hemoglobin molecule is made up of four subunits, each containing a heme portion attached to a globin chain. Iron is present in the heme component of the molecule. An important property of heme is its ability to bind to oxygen loosely and reversibly. Oxygen readily binds to hemoglobin in the lungs and is carried as **oxyhemoglobin** in arterial blood. Oxyhemoglobin is a brighter red than hemoglobin that does not contain oxygen (reduced hemoglobin), which is why arterial blood is a brighter red than venous blood. The oxygen readily dissociates (detaches) from hemoglobin in the tissues, where the oxygen is needed for cellular metabolism. In venous blood, hemoglobin combines with hydrogen ions produced by cellular metabolism and thus buffers excessive acid. Whole blood normally contains about 15 g of hemoglobin per 100 mL of blood.

### ERYTHROPOIESIS

Erythroblasts arise from the primitive myeloid stem cells in bone marrow. The erythroblast is a nucleated cell that, in the process of maturing within the bone marrow, accumulates hemoglobin and

gradually loses its nucleus. At this stage, the cell is known as a reticulocyte. Further maturation into an RBC entails the loss of the dark-staining material and slight shrinkage. The mature RBC is then released into the circulation. Under conditions of rapid **erythropoiesis** (RBC production), reticulocytes and other immature cells (eg, **nucleated RBCs**) may be released prematurely into the circulation.

Differentiation of the primitive myeloid stem cell of the marrow into an erythroblast is stimulated by **erythropoietin**, a hormone produced primarily by the kidney. If the kidney detects low levels of oxygen (as would occur in **anemia**, in which fewer RBCs are available to bind oxygen, or in people living at high altitudes), the release of erythropoietin is increased. The increased erythropoietin then stimulates the marrow to increase production of RBCs. The entire process typically takes 5 days.

For normal RBC production, the bone marrow also requires iron, vitamin B<sub>12</sub>, folic acid, pyridoxine (vitamin B<sub>6</sub>), protein, and other factors. A deficiency of these factors during erythropoiesis can result in decreased RBC production and anemia.

**Iron Stores and Metabolism.** The average daily diet in the United States contains 10 to 15 mg of elemental iron; normally 0.5 to 1 mg of ingested iron is absorbed from the small intestine. The rate of iron absorption is regulated by the amount of iron already stored in the body and by the rate of RBC production. Additional amounts of iron, up to 2 mg daily, must be absorbed by women to replace blood lost during menstruation. Total body iron content in the average adult is approximately 3 g, most of which is present in

hemoglobin or in one of its breakdown products. Iron is stored in the small intestine as ferritin and in reticuloendothelial cells. When required, the iron is released into the plasma, binds to transferrin, and is transported into the membranes of the normoblasts (RBC precursor cells) within the marrow, where it is incorporated into hemoglobin. Iron is lost in the feces, either in bile, blood, or mucosal cells from the intestine.

The concentration of iron in blood is normally about 75 to 175  $\mu\text{g/dL}$  (13 to 31  $\mu\text{mol/L}$ ) for men and 65 to 165  $\mu\text{g/dL}$  (11 to 29  $\mu\text{mol/L}$ ) for women. With iron deficiency, bone marrow iron stores are rapidly depleted; hemoglobin synthesis is depressed, and the RBCs produced by the marrow are small and low in hemoglobin. Iron deficiency in the adult generally indicates that blood has been lost from the body (eg, from bleeding in the gastrointestinal tract or heavy menstrual flow). In the adult, lack of dietary iron is rarely the sole cause of iron deficiency anemia. The source of iron deficiency should be investigated promptly, because iron deficiency in an adult may be a sign of bleeding in the gastrointestinal tract or colon cancer.

**Vitamin B<sub>12</sub> and Folic Acid Metabolism.** Vitamin B<sub>12</sub> and folic acid are required for the synthesis of DNA in many tissues, but deficiencies of either of these vitamins have the greatest effect on erythropoiesis. Both vitamin B<sub>12</sub> and folic acid are derived from the diet. Folic acid is absorbed in the proximal small intestine, but only small amounts are stored within the body. If the diet is deficient in folic acid, stores within the body quickly become depleted. Because vitamin B<sub>12</sub> is found only in foods of animal origin, strict vegetarians may ingest little B<sub>12</sub>. Vitamin B<sub>12</sub> combines with intrinsic factor produced in the stomach. The vitamin B–intrinsic factor complex is absorbed in the distal ileum. People who have had a partial or total gastrectomy may have limited amounts of intrinsic factor, and therefore the absorption of B<sub>12</sub> may be diminished. The effects of either decreased absorption or decreased intake of B<sub>12</sub> are not apparent for 2 to 4 years.

Vitamin B<sub>12</sub> and folic acid deficiencies are characterized by the production of abnormally large RBCs called megaloblasts. Because these cells are abnormal, many are sequestered (trapped) while still in the bone marrow, and their rate of release is decreased. Some of these cells actually die in the marrow before they can be released into the circulation. This results in megaloblastic anemia.

### RED BLOOD CELL DESTRUCTION

The average life span of a normal circulating RBC is 120 days. Aged RBCs lose their elasticity and become trapped in small blood vessels, particularly in the spleen. They are removed from the blood by the reticuloendothelial cells, particularly in the liver and the spleen. As the RBCs are destroyed, their hemoglobin is largely recycled. Some hemoglobin also breaks down to form bilirubin and is secreted in the bile. Most of the iron is recycled to form new hemoglobin molecules within the bone marrow; small amounts are lost daily in the feces and urine and monthly in menstrual flow.

### White Blood Cells (WBCs)

Leukocytes are divided into two general categories: granulocytes and lymphocytes. In normal blood, the total leukocyte count is 5000 to 10,000 cells per cubic millimeter. Of these, approximately 60% to 70% are granulocytes and 30% to 40% are lymphocytes. Primarily, WBCs protect the body against infection and tissue injury.

### GRANULOCYTES

**Granulocytes** are defined by the presence of granules in the cytoplasm of the cell. Granulocytes are divided into three main subgroups, which are characterized by the staining properties of these granules (see Fig. 33-2). Eosinophils have bright-red granules in their cytoplasm, whereas the granules in basophils stain deep blue. The third and by far the most numerous cell in this class is the neutrophil, with granules that stain a pink to violet hue. Neutrophils are also called polymorphonuclear neutrophils (PMNs, or polys) or segmented neutrophils (segs).

The nucleus of the mature neutrophil has multiple lobes (usually two to five) that are connected by thin filaments of nuclear material, a “segmented” nucleus; it is usually twice the size of an RBC. The somewhat less mature granulocyte has a single-lobed, elongated nucleus and is called a **band cell**. Ordinarily, band cells account for only a small percentage of circulating granulocytes, although their percentage can increase greatly under conditions in which neutrophil production increases, such as infection. An increased number of band cells is sometimes called a “**left shift**” or “**shift to the left**.” (Traditionally, the diagram of neutrophil maturation shows the stem cell on the left with progressive maturation stages toward the right, ending with a fully mature neutrophil on the right side. A shift to the left indicates that more immature cells are present in the blood than normally occurs.)

Granulocyte production from the myeloid stem cell pool results in the gradual differentiation of these cells from a myeloid **blast cell** into a fully mature neutrophil. The process, called **myelopoiesis**, is highly complex and depends on many factors. These factors, including specific **cytokines** such as growth factors, are normally present within the marrow itself. As the blast cell matures, the cytoplasm of the cell changes in color (from blue to violet) and granules begin to form with the cytoplasm. The shape of the nucleus also changes. The entire process of maturation and differentiation takes about 10 days (see Fig. 33-1). Once the neutrophil is released into the circulation from the marrow, it stays there for only about 6 hours before it migrates into the body tissues to perform its function of **phagocytosis** (ingestion and digestion of bacteria and particles) (Fig. 33-3). Here, neutrophils last no more than 1 to 2 days before they die. The number of circulating granulocytes found in the healthy person is relatively constant, but in infection large numbers of these cells are rapidly released into the circulation.

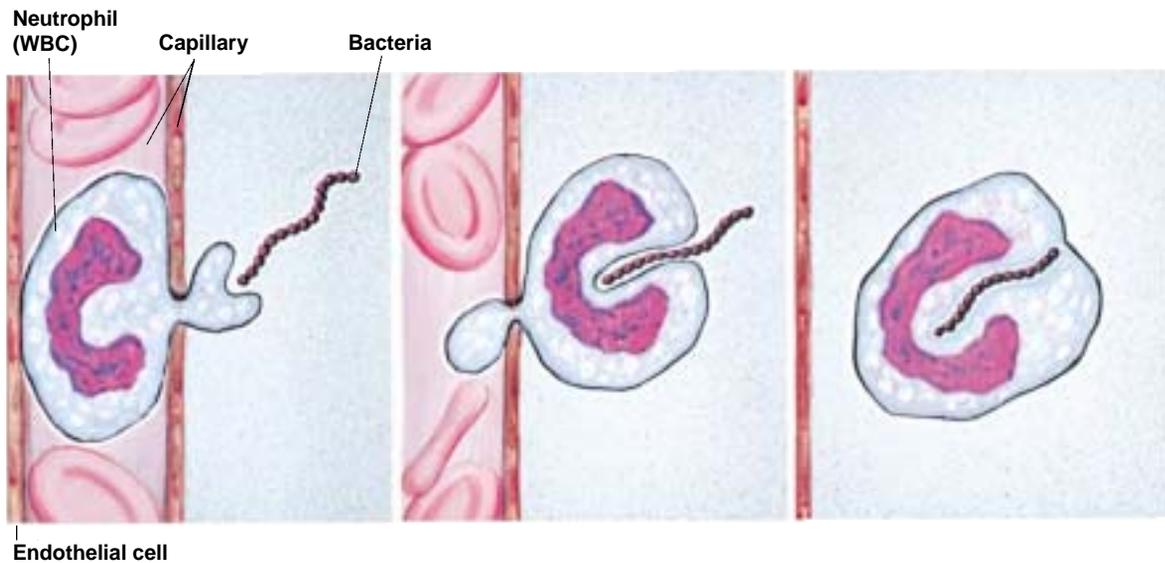

### MONONUCLEAR WHITE BLOOD CELLS (AGRANULOCYTES)

**Monocytes.** **Monocytes** (also called mononuclear leukocytes) are WBCs with a single-lobed nucleus and a granule-free cytoplasm—hence the term *agranulocyte*. In normal adult blood, monocytes account for approximately 5% of the total WBCs. Monocytes are the largest of the WBCs. Produced by the bone marrow, they remain in the circulation for a short time before entering the tissues and transforming into **macrophages**. Macrophages are particularly active in the spleen, liver, peritoneum, and the alveoli of the lungs.

**Lymphocytes.** Mature lymphocytes are small cells with scanty cytoplasm. Immature lymphocytes are produced in the marrow from the lymphoid stem cells. A second major source of production is the cortex of the thymus. Cells derived from the thymus are known as T lymphocytes (or T cells); those derived from the marrow can also be T cells but are more commonly B lymphocytes (or B cells). Lymphocytes complete their differentiation and maturation primarily in the lymph nodes and in the lymphoid tissue of the intestine and spleen after exposure to a specific antigen. Mature lymphocytes are antigen-specific cells.

## Physiology/Pathophysiology

**FIGURE 33-3** Phagocytosis. When foreign matter (such as bacteria or dead tissue) comes in contact with the cell membrane of the neutrophil, the membrane surrounds and pinches off the area, leaving the membrane intact. Thus, the engulfed material is left in a vacuole within the neutrophil, where enzymes within the cell destroy the foreign material.

### FUNCTION OF WHITE BLOOD CELLS

WBCs protect the body from invasion by bacteria and other foreign entities. The major function of neutrophils is phagocytosis (see Fig. 33-3). Neutrophils arrive at the site within 1 hour after the onset of an inflammatory reaction and initiate phagocytosis, but they are short-lived. An influx of monocytes follows; these cells continue their phagocytic activities for long periods as macrophages. This process constitutes a second line of defense for the body against inflammation and infection. Although neutrophils can often work adequately against bacteria without the need for excessive involvement with macrophages, macrophages are particularly effective against fungi and viruses. Macrophages also digest senescent (aging or aged) blood cells, such as RBCs, primarily within the spleen.

The primary function of lymphocytes is to produce substances that aid in attacking foreign material. One group of lymphocytes (T lymphocytes) kills foreign cells directly or releases a variety of lymphokines, substances that enhance the activity of phagocytic cells. T lymphocytes are responsible for delayed allergic reactions, rejection of foreign tissue (eg, transplanted organs), and destruction of tumor cells. This process is known as *cellular immunity*. The other group of lymphocytes (B lymphocytes) is capable of differentiating into plasma cells. Plasma cells, in turn, produce immunoglobulin (Ig), or antibodies, which are protein molecules that destroy foreign material by several mechanisms. This process is known as *humoral immunity*.

Eosinophils and basophils function in hypersensitivity reactions. Eosinophils are important in the phagocytosis of parasites. The increase in eosinophil levels in allergic states indicates that these cells are involved in the hypersensitivity reaction; their function there is to neutralize histamine. Basophils produce and store histamine as well as other substances involved in hypersensitivity reactions. The release of these substances provokes allergic reactions.

### Platelets (Thrombocytes)

Platelets, or thrombocytes, are not actually cells. Rather, they are granular fragments of giant cells in the bone marrow called megakaryocytes. Platelet production in the marrow is regulated in part by the hormone thrombopoietin, which stimulates the production and differentiation of megakaryocytes from the myeloid stem cell.

Platelets play an essential role in the control of bleeding. They circulate freely in the blood in an inactive state, where they nurture the endothelium of the blood vessels, maintaining the integrity of the vessel. When vascular injury does occur, platelets collect at the site and are activated. They adhere to the site of injury and to each other, forming a platelet plug that temporarily stops bleeding. Substances released from platelet granules activate coagulation factors in the blood plasma and initiate the formation of a stable clot composed of **fibrin**, a filamentous protein. Platelets have a normal life span of 7 to 10 days.

### PLASMA AND PLASMA PROTEINS

After cellular elements are removed from blood, the remaining liquid portion is called plasma. More than 90% of plasma is water. The remainder consists primarily of plasma proteins, clotting factors (particularly fibrinogen), and small amounts of other substances such as nutrients, enzymes, waste products, and gases. If plasma is allowed to clot, the remaining fluid is called **serum**. Serum has essentially the same composition as plasma, except that fibrinogen and several clotting factors have been removed in the clotting process.

Plasma proteins consist primarily of albumin and globulins. The globulins can be separated into three main fractions—alpha, beta, and gamma—each of which consists of distinct proteins

that have different functions. Important proteins in the alpha and beta fractions are the transport globulins and the clotting factors that are made in the liver. The transport globulins carry various substances in bound form around the circulation. For example, thyroid-binding globulin carries thyroxin, and transferrin carries iron. The clotting factors, including fibrinogen, remain in an inactive form in the blood plasma until activated by the clotting cascade. The gamma globulin fraction refers to the immunoglobulins, or antibodies. These proteins are produced by the well-differentiated lymphocytes and plasma cells. The actual fractionation of the globulins can be seen on a specific laboratory test (serum protein electrophoresis).

Albumin is particularly important for the maintenance of fluid balance within the vascular system. Capillary walls are impermeable to albumin, so its presence in the plasma creates an osmotic force that keeps fluid within the vascular space. Albumin, which is produced by the liver, has the capacity to bind to several substances that are transported in plasma (eg, certain medications, bilirubin, some hormones). People with poor hepatic function may have low concentrations of albumin, with a resultant decrease in osmotic pressure and the development of edema.

## RETICULOENDOTHELIAL SYSTEM (RES)

The RES is composed of special tissue macrophages, which are derived from monocytes. When released from the marrow, monocytes spend a short time in the circulation (about 24 hours) and then enter the body tissues. Within the tissues, the monocytes continue to differentiate into cells called macrophages, which can survive for months. Macrophages have a variety of important functions. They defend the body against foreign invaders (ie, bacteria and other pathogens) via phagocytosis. They remove old or damaged cells from the circulation. They stimulate the inflammatory process and present antigen to the immune system (see Chapter 50). Macrophages give rise to tissue **histiocytes**, including Kupffer cells of the liver, peritoneal macrophages, alveolar macrophages, and other components of the RES. Thus, the RES is a component of many other organs within the body, particularly the spleen, lymph nodes, lung, and liver.

The spleen is the site of activity for most macrophages. Most of the spleen (75%) is made of red pulp; here the blood enters the venous sinuses through capillaries that are surrounded by macrophages. Within the red pulp are tiny aggregates of white pulp, consisting of B and T lymphocytes. The spleen sequesters newly released reticulocytes from the marrow, removing nuclear fragments and other materials (eg, denatured hemoglobin, iron) before the now fully mature RBC returns to the circulation. Although a minority of RBCs (less than 5%) is pooled in the spleen, a significant proportion of platelets (20%–40%) is pooled here. If the spleen is enlarged, a greater proportion of RBCs and platelets can be sequestered. The spleen is a major source of hematopoiesis in fetal life. It can resume hematopoiesis later in adulthood if necessary (eg, in bone marrow fibrosis). The spleen has important immunologic functions as well. It forms a substance that promotes the phagocytosis of neutrophils; it also forms the antibody IgM after exposure to antigen.

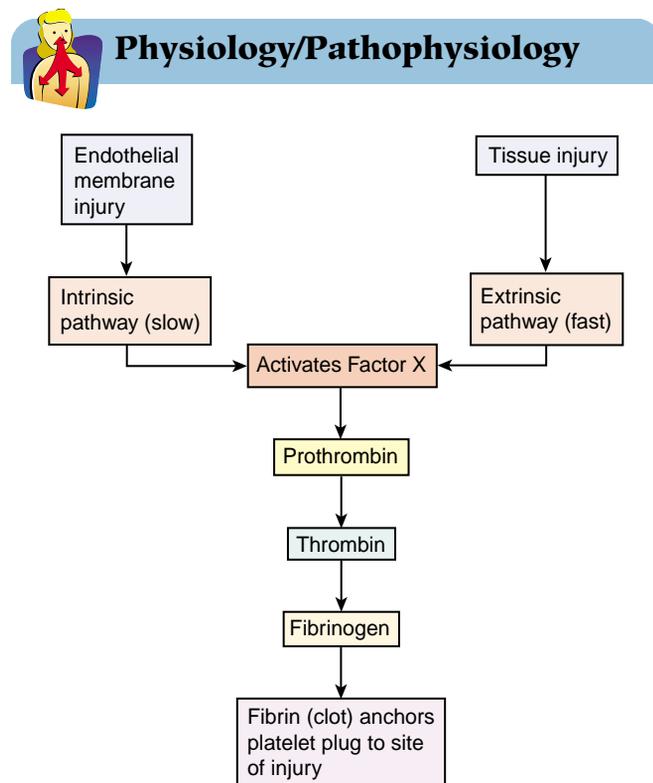

## HEMOSTASIS

Hemostasis is the process of preventing blood loss from intact vessels and of stopping bleeding from a severed vessel. The prevention of blood loss from intact vessels requires adequate numbers of functional platelets. Platelets nurture the endothelium

and thereby maintain the structural integrity of the vessel wall. Two processes are involved in arresting bleeding: primary and secondary hemostasis.

In primary hemostasis, the severed blood vessel constricts. Circulating platelets aggregate at the site and adhere to the vessel and to one another. An unstable hemostatic plug is formed. For the coagulation process to be correctly activated, circulating inactive coagulation factors must be converted to active forms. This process occurs on the surface of the aggregated platelets at the site of vessel injury. The end result is the formation of fibrin, which reinforces the platelet plug and anchors it to the injury site. This process is termed secondary hemostasis (Fig. 33-4). The process of blood coagulation is highly complex. It can be activated by the intrinsic or the extrinsic pathway. Both pathways are needed for maintenance of normal hemostasis.

Many factors are involved in the reaction cascade that forms fibrin. When tissue is injured, the extrinsic pathway is activated by the release from the tissue of a substance called thromboplastin. As the result of a series of reactions, prothrombin is converted to **thrombin**, which in turn catalyzes the conversion of fibrinogen to fibrin. Clotting by the intrinsic pathway is activated when the collagen that lines blood vessels is exposed. Clotting factors are activated sequentially until, as with the extrinsic pathway, fibrin is ultimately formed. Although the intrinsic pathway is slower, this sequence is probably most often responsible for clotting in vivo.

**FIGURE 33-4** Secondary hemostasis. Based on the type of stimulus (injury to the endothelial membrane of a blood vessel or a tissue), one of two clotting pathways is initiated. The end result from either pathway is the conversion of prothrombin to thrombin. Thrombin is necessary for fibrinogen to be converted into fibrin, the stabilizing protein that anchors the fragile platelet plug to the site of injury to prevent further bleeding and permit the injured vessel or site to heal.

As the injured vessel is repaired and again covered with endothelial cells, the fibrin clot is no longer needed. The fibrin is digested via two systems: the plasma fibrinolytic system and the cellular fibrinolytic system. The substance **plasminogen** is required to lyse (break down) the fibrin. Plasminogen, which is present in all body fluids, circulates with fibrinogen and is therefore incorporated into the fibrin clot as it forms. When the clot is no longer needed (eg, after an injured blood vessel has healed), the plasminogen is activated to form plasmin. Plasmin actually digests the fibrinogen, and the breakdown particles of the clot (fibrin degradation products) are released into the circulation. Through this system, clots are dissolved as tissue is repaired, and the vascular system returns to its normal baseline state.

## PATHOPHYSIOLOGY OF THE HEMATOLOGIC SYSTEM

Most hematologic diseases reflect a defect in the hematopoietic, hemostatic, or RES systems. The defect can be quantitative (eg, increased or decreased production of cells), qualitative (eg, the cells that are produced are defective in their normal functional capacity), or both.

### Gerontologic Considerations

In elderly patients, a common problem is decreased ability of the bone marrow to respond to the body's need for blood cells (RBCs, WBCs, and platelets). This inability is a result of many factors, including diminished production of the growth factors necessary for hematopoiesis by stromal cells within the marrow or a diminished response to the growth factors (in the case of erythropoietin). When an elderly person needs more blood cells (eg, WBCs in infection, RBCs in anemia), the bone marrow may not be able to increase production of these cells adequately. **Leukopenia** (a decreased number of circulating WBCs) or anemia can result. In the elderly, the bone marrow may be more susceptible to the myelosuppressive effects of medications.

Anemia is the most common hematologic condition affecting elderly patients; with each successive decade of life, the incidence of anemia increases. Anemia frequently results from iron deficiency (in the case of blood loss) or from a nutritional deficiency, particularly folate or B<sub>12</sub> deficiency or protein-calorie malnutrition; it may also result from inflammation or chronic disease. Management of the disorder varies depending on the etiology. Therefore, it is important to identify the cause of the anemia rather than to consider it an inevitable consequence of aging. Elderly people with concurrent cardiac or pulmonary problems may not tolerate anemia very well, and a prompt, thorough evaluation is warranted.

## Assessment and Diagnostic Findings

Many hematologic conditions cause few symptoms. Therefore, the use of extensive laboratory tests is often required to diagnose a hematologic disorder. For most hematologic conditions, continued monitoring via specific blood tests is required because it is very important to assess for changes in test results over time.

### HEMATOLOGIC STUDIES

The most common tests used are the complete blood count (CBC) and the peripheral blood smear (Table 33-2). The CBC identifies the total number of blood cells (WBCs, RBCs, and platelets) as well as the hemoglobin, **hematocrit** (percentage of blood consisting of RBCs), and RBC indices. Because cellular

morphology (shape and appearance of the cells) is particularly important in most hematologic disorders, the physician needs to examine the blood cells involved. This process is referred to as the manual examination of the peripheral smear, which may be part of the CBC. In this test, a drop of blood is spread on a glass slide, stained, and examined under a microscope. The shape and size of the RBCs and platelets as well as the actual appearance of the WBCs provides useful information in identifying hematologic conditions. Blood for the CBC is typically obtained by venipuncture.

### BONE MARROW ASPIRATION AND BIOPSY

The bone marrow aspiration and biopsy are crucial when additional information is needed to assess how an individual's blood cells are being formed and to assess the quantity and quality of each type of cell produced within the marrow. These tests are also used to document infection or tumor within the marrow.

Normal bone marrow is in a semifluid state and can be aspirated through a special large needle. In adults, bone marrow is usually aspirated from the iliac crest and occasionally from the sternum. The aspirate provides only a sample of cells. Aspirate alone may be adequate for evaluating certain conditions, such as anemia. However, when more information is required, a biopsy is also performed. Biopsy samples are taken from the posterior iliac crest; occasionally, an anterior approach is required. A marrow biopsy shows the architecture of the bone marrow as well as its degree of cellularity.

Most patients need no more preparation than a careful explanation of the procedure, but for some very anxious patients, an antianxiety agent may be useful. It is always important for the physician or nurse to describe and explain to the patient the procedure and the sensations that will be experienced. The risks, benefits, and alternatives are also discussed. A signed informed consent is needed before the procedure is performed.

Before aspiration, the skin is cleansed as for any minor surgery, using aseptic technique. Then a small area is anesthetized with a local anesthetic through the skin and subcutaneous tissue to the periosteum of the bone. It is not possible to anesthetize the bone itself. The bone marrow needle is introduced with a stylet in place. When the needle is felt to go through the outer cortex of bone and enter the marrow cavity, the stylet is removed, a syringe is attached, and a small volume (0.5 mL) of blood and marrow is aspirated. Patients typically feel a pressure sensation as the needle is advanced into position. The actual aspiration always causes sharp but brief pain, resulting from the suction exerted as the marrow is aspirated into the syringe; the patient should be forewarned about this. Taking deep breaths or using relaxation techniques often helps ease the discomfort.

If a bone marrow biopsy is necessary, it is best performed after the aspiration and in a slightly different location, because the marrow structure may be altered after aspiration. A special biopsy needle is used. Because these needles are large, the skin is punctured first with a surgical blade to make a 3- or 4-mm incision. The biopsy needle is advanced well into the marrow cavity. When the needle is properly positioned, a portion of marrow is cored out, using a twisting or gentle rocking motion to free the sample and permit its removal within the biopsy needle. Patients feel a pressure sensation but should not feel actual pain. The nurse should instruct the patient to inform the physician if pain occurs so that additional anesthetic can be administered.

The major hazard of either bone marrow aspiration or biopsy is a slight risk of bleeding and infection. The bleeding risk is somewhat increased if the patient's platelet count is low or if the patient has been taking a medication (eg, aspirin) that alters platelet func-

Table 33-2 • Frequently Used Laboratory Tests in Hematology

TEST	NORMAL RANGE	DESCRIPTION	INDICATIONS/COMMENTS
<b>Complete blood count (CBC)</b>		General survey of bone marrow function; evaluates all three cell lines (WBCs, RBCs, platelets)	Important to note changes over time; many hematologic conditions show changes in CBC long before patient becomes symptomatic
<b>Red blood cells (RBCs)</b>	M: $4.7\text{--}6.1 \times 10^6$ F: $4.2\text{--}5.4 \times 10^6$	Carries hemoglobin; survival time, 120 days	
<b>Hemoglobin (Hgb)</b>	M: 13.5–17.5 g/dL F: 11.5–15.5 g/dL	Delivers O <sub>2</sub> through circulation to body tissues and returns CO <sub>2</sub> from tissues to lungs	Decreased in anemia; increased in polycythemia
<b>Hematocrit (Hct)</b>	M: 40–52% F: 36–48%	Indicates relative proportions of plasma and RBCs (volume of RBCs/L whole blood)	Usually three times the Hgb
<b>Mean corpuscular volume (MCV)</b>	81–96 $\mu\text{m}^3$	Indicates size of RBCs; very useful in differentiating types of anemia	If < 80, cells are microcytic; if > 100, cells are macrocytic
<b>Mean corpuscular hemoglobin concentration (MCHC)</b>	33–36 g/dL	Average concentration of Hgb in RBCs; independent of cell size	
<b>Red cell distribution width (RDW)</b>	11–14.5%	Measures degree of variation in size of RBCs	
<b>Reticulocyte count</b>	0.5–1.5%	Measure of marrow production of erythrocytes; 1% of RBC mass is produced daily (to replace the 1% of old cells that die)	Indicates marrow's response to anemia (when anemia is present, reticulocyte level should rise)
<b>Platelets</b>	150,000–400,000/mm <sup>3</sup>	Total number of platelets in circulation; average life span, 7–10 days	Thrombocytopenia: < 20,000/mm <sup>3</sup> , serious; < 10,000/mm <sup>3</sup> , potentially life-threatening
<b>White blood cells (WBCs)</b>	4,500–11,000/mm <sup>3</sup>	Total WBC count	
<b>Differential</b>	Percentages of various types of WBCs	% of cell type $\times$ total WBC = absolute number of that cell type	Left shift: bone marrow $\uparrow$ production of WBCs; more immature forms released into the bloodstream
<b>Prothrombin time (PT)</b>	Varies (compare with control), 11–12.5 sec	Measure time elapsed until clot forms; measures extrinsic and common pathways	Increased in liver disease, disseminated intravascular coagulation (DIC), obstructive biliary disease, clotting factor depletion, warfarin (Coumadin) use
<b>International normalized ratio (INR)</b>	1.0 Standard warfarin (Coumadin) treatment, 2.0–3.0 INR; high-dose warfarin (Coumadin) treatment, 3.0–4.5 INR	A standard method of measuring PT independent of the thromboplastin reagent used in the test; calculated by dividing the PT result by the mean normal PT	Increased with anticoagulant excess and conditions that cause increased PT; decreased with insufficient anticoagulant and conditions that cause decreased PT
<b>Partial thromboplastin time (PTT)</b>	Varies (compare with control): 25–35 sec	Surface active agent added to plasma; measures time elapsed until clot forms; measures intrinsic and common pathways	Increased in clotting factor depletion, DIC, liver disease, biliary obstruction, circulating anticoagulants (heparin)
<b>Thrombin time (TT)</b>	Varies (compare with control), 8–11 sec	Tests conversion of fibrinogen to fibrin	Time to clot is inversely proportional to fibrinogen level
<b>Fibrinogen</b>	170–340 mg/100 mL	Measurement of fibrinogen concentration within plasma available for conversion to fibrin clot	Decreased in bleeding disorders, pregnancy, malignancy, inflammatory disease
<b>D-dimer</b>	0–0.5 $\mu\text{g}/\text{mL}$	Measures the amount of fragments of fibrin when it is lysed (broken down); useful for distinguishing fibrinolysis from fibrinogenolysis	Increased with fibrinolytic activity, rheumatoid arthritis, ovarian cancer (with increased CA 125)

(continued)

Table 33-2 • Frequently Used Laboratory Tests in Hematology (Continued)

TEST	NORMAL RANGE	DESCRIPTION	INDICATIONS/COMMENTS
<b>Fibrin degradation products (FDP)</b>	<10 µg/mL	Byproduct of fibrinolysis	>40 µg/mL indicates DIC
<b>Neutrophils</b>	40–75% (2,500–7,500/mm <sup>3</sup> )	Essential in preventing/limiting bacterial infection; average life span: 2–4 hr	If >8,000: infection, some inflammatory states, stress, steroids, other drugs, myeloproliferative disease Absolute neutrophil count (ANC) <500: increased risk for infection; ANC <100: infection certain (if neutropenia persists)
<b>Lymphocytes</b>	20–50% (1,500–5,500/mm <sup>3</sup> )	Integral component of immune system	<1,500: lymphopenia; >4,000: lymphocytosis; increased in convalescent phase after bacterial or viral infection, lymphoproliferative disease
<b>Monocytes</b>	1–10% (100–800/mm <sup>3</sup> )	Enter tissue as macrophages; phagocytosis	Increased in acute and chronic infection, inflammation, some myeloproliferative disorders, chronic myelomonocytic leukemia (CMML)
<b>Eosinophils</b>	0–6% (0–440/mm <sup>3</sup> )	Involved in allergic reactions (neutralizes histamine); digest foreign proteins	Increased in allergic states, medications, parasites, chronic myeloid leukemia (CML), metastatic/necrotic tumors
<b>Basophils</b>	0–2% (0–200/mm <sup>3</sup> )	Contain histamine; integral part of hypersensitivity reactions	Increase is very rare (CML)

tion. After the marrow sample is obtained, pressure is applied to the site for several minutes. The site is then covered with a sterile dressing. Most patients have no discomfort after a bone marrow aspiration, but the site of a biopsy may ache for 1 or 2 days. Warm tub baths and use of a mild analgesic (eg, acetaminophen) may be useful. Aspirin-containing analgesics should be avoided because they can aggravate or potentiate any bleeding that may occur.

## Management of Hematologic Disorders

Commonly encountered blood disorders are anemia, polycythemia, leukopenia and **neutropenia**, leukocytosis, lymphoma, myeloma, **leukemia**, and various bleeding and coagulation disorders. Nursing management of patients with these disorders requires skillful assessment and monitoring as well as meticulous care and teaching to prevent deterioration and complications.

### ANEMIA

Anemia, per se, is not a specific disease state but a sign of an underlying disorder. It is by far the most common hematologic condition. Anemia, a condition in which the hemoglobin concentration is lower than normal, reflects the presence of fewer than normal RBCs within the circulation. As a result, the amount of oxygen delivered to body tissues is also diminished.

There are many different kinds of anemia (Table 33-3), but all can be classified into three broad etiologic categories:

- Loss of RBCs—occurs with bleeding, potentially from any major source, such as the gastrointestinal tract, the uterus, the nose, or a wound
- Decreased production of RBCs—can be caused by a deficiency in cofactors (including folic acid, vitamin B<sub>12</sub>, and iron) required for erythropoiesis; RBC production may also be reduced if the bone marrow is suppressed (eg, by tumor, medications, toxins) or is inadequately stimulated because of a lack of erythropoietin (as occurs in chronic renal disease).
- Increased destruction of RBCs—may occur because of an overactive RES (including hypersplenism) or because the bone marrow produces abnormal RBCs that are then destroyed by the RES (eg, sickle cell anemia).

A conclusion as to whether the anemia is caused by destruction or by inadequate production of RBCs usually can be reached on the basis of the following factors:

- The marrow's ability to respond to the decreased RBCs (as evidenced by an increased reticulocyte count in the circulating blood)
- The degree to which young RBCs proliferate in the bone marrow and the manner in which they mature (as observed on bone marrow biopsy)
- The presence or absence of end products of RBC destruction within the circulation (eg, increased bilirubin level, decreased haptoglobin level)

Table 33-3 • Classification of Anemias

TYPE OF ANEMIA	LABORATORY FINDINGS
<b>Hypoproliferative (Resulting From Defective RBC Production)</b>	
Iron deficiency	Decreased reticulocytes, iron, ferritin, iron saturation, MCV; increased TIBC
Vitamin B <sub>12</sub> deficiency (megaloblastic)	Decreased vitamin B <sub>12</sub> level; increased MCV
Folate deficiency	Decreased folate level; increased MCV
Decreased erythropoietin production (eg, from renal dysfunction)	Decreased erythropoietin level; normal MCV and MCH; increased creatinine level
Cancer/inflammation	Normal MCV, MCH, normal or decreased erythropoietin level; increased % of iron saturation, ferritin level; decreased iron; TIBC
<b>Bleeding (Resulting From RBC Loss)</b>	
Bleeding from gastrointestinal tract, menorrhagia (excessive menstrual flow), epistaxis (nosebleed), trauma	Increased reticulocyte level; normal Hgb and Hct if measured soon after bleeding starts, but levels decrease thereafter; normal MCV initially but later decreases; decreased ferritin and iron levels (later)
<b>Hemolytic (Resulting From RBC Destruction)</b>	
Altered erythropoiesis (sickle cell anemia, thalassemia, other hemoglobinopathies)	Decreased MCV; fragmented RBCs; increased reticulocyte level
Hypersplenism (hemolysis)	Increased MCV
Drug-induced anemia	Increased spherocyte level
Autoimmune anemia	Increased spherocyte level
Mechanical heart valve-related anemia	Fragmented red cells

Hct, hematocrit; Hgb, hemoglobin concentration; MCH, mean corpuscular hemoglobin; MCV, mean corpuscular volume; RBCs, red blood cells; TIBC, total iron binding capacity.

## Classification of Anemias

Anemia may be classified in several ways. The physiologic approach is to determine whether the deficiency in RBCs is caused by a defect in their production (hypoproliferative anemia), by their destruction (hemolytic anemia), or by their loss (bleeding).

In the hypoproliferative anemias, RBCs usually survive normally, but the marrow cannot produce adequate numbers of these cells. The decreased production is reflected in a low reticulocyte count. Inadequate production of RBCs may result from marrow damage due to medications or chemicals (eg, chloramphenicol, benzene) or from a lack of factors necessary for RBC formation (eg, iron, vitamin B<sub>12</sub>, folic acid, erythropoietin).

Hemolytic anemias stem from premature destruction of RBCs, which results in a liberation of hemoglobin from the RBC into the plasma. The increased RBC destruction results in tissue hypoxia, which in turn stimulates erythropoietin production. This increased production is reflected in an increased reticulocyte count, as the bone marrow responds to the loss of RBCs. The released hemoglobin is converted in large part to bilirubin; therefore, the bilirubin concentration rises. **Hemolysis** can result from an abnormality within the RBC itself (eg, sickle cell anemia, glucose-6-phosphate

dehydrogenase [G-6-PD] deficiency) or within the plasma (eg, immune hemolytic anemias), or from direct injury to the RBC within the circulation (eg, hemolysis caused by mechanical heart valve). Chart 33-1 identifies the causes of hemolytic anemia.

## Clinical Manifestations

Aside from the severity of the anemia itself, several factors influence the development of anemia-associated symptoms:

- The speed with which the anemia has developed
- The duration of the anemia (ie, its chronicity)
- The metabolic requirements of the individual
- Other concurrent disorders or disabilities (eg, cardiopulmonary disease)
- Special complications or concomitant features of the condition that produced the anemia

In general, the more rapidly an anemia develops, the more severe its symptoms. An otherwise healthy person can often tolerate as much as a 50% gradual reduction in hemoglobin without pronounced symptoms or significant incapacity, whereas the rapid loss of as little as 30% may precipitate profound vascular collapse in the same individual. A person who has been anemic for a very long time, with hemoglobin levels between 9 and 11 g/dL, usually has few or no symptoms other than slight tachycardia on exertion and fatigue.

Bacterial

Parasitic

Disseminated intravascular coagulation (DIC)\*

Toxins

Hypersplenism\*

\*Discussed in text.

Patients who customarily are very active or who have significant demands on their lives (eg, a single, working mother of small children) are more likely to have symptoms, and those symptoms are more likely to be pronounced than in a more sedentary person. A patient with hypothyroidism with decreased oxygen needs may be completely asymptomatic, without tachycardia or increased cardiac output, at a hemoglobin level of 10 g/dL. Similarly, patients with coexistent cardiac, vascular, or pulmonary disease may develop more pronounced symptoms of anemia (eg, dyspnea, chest pain, muscle pain or cramping) at a higher hemoglobin level than those without these concurrent health problems.

Finally, some anemic disorders are complicated by various other abnormalities that do not result from the anemia but are inherently associated with these particular diseases. These abnormalities may give rise to symptoms that completely overshadow those of the anemia, as in the painful crises of sickle cell anemia.

## Assessment and Diagnostic Findings

A variety of hematologic studies are performed to determine the type and cause of the anemia. In an initial evaluation, the hemoglobin, hematocrit, reticulocyte count, and RBC indices, particularly the mean corpuscular volume (MCV), are particularly useful. Iron studies (serum iron level, total iron-binding capacity [TIBC], percent saturation, and ferritin), as well as serum vitamin B<sub>12</sub> and folate levels, are also frequently obtained. Other tests include haptoglobin and erythropoietin levels. The remaining CBC values are useful in determining whether the anemia is an isolated problem or part of another hematologic condition, such as leukemia or myelodysplastic syndrome (MDS). Bone marrow aspiration may be performed. In addition, other diagnostic studies may be performed to determine the presence of underlying chronic illness, such as malignancy, and the source of any blood loss, such as polyps or ulcers within the gastrointestinal tract.

## Complications

General complications of severe anemia include heart failure, paresthesias, and confusion. At any given level of anemia, patients with underlying heart disease are far more likely to have angina or symptoms of heart failure than those without heart disease. Complications associated with specific types of anemia are included in the description of each type.

## Medical Management

Management of anemia is directed toward correcting or controlling the cause of the anemia; if the anemia is severe, the RBCs that are lost or destroyed may be replaced with a transfusion of packed RBCs (PRBCs). The management of the various types of anemia is covered in the discussions that follow.

## NURSING PROCESS: THE PATIENT WITH ANEMIA

### Assessment

The health history and physical examination provide important data about the type of anemia involved, the extent and type of symptoms it produces, and the impact of those symptoms on the patient's life. Weakness, fatigue, and general malaise are common, as are pallor of the skin and mucous membranes (sclera, oral mucosa).

Jaundice may be present in patients with megaloblastic anemia or hemolytic anemia. The tongue may be smooth and red (in iron deficiency anemia) or beefy red and sore (in megaloblastic anemia); the corners of the mouth may be ulcerated (**angular cheilosis**) in both types of anemia. Individuals with iron deficiency anemia may crave ice, starch, or dirt (known as pica); their nails may be brittle, ridged, and concave.

The health history should include a medication history, because some medications can depress bone marrow activity or interfere with folate metabolism. An accurate history of alcohol intake, including the amount and duration, should be obtained. Family history is important, because certain anemias are inherited. Athletic endeavors should be assessed, because extreme exercise can decrease erythropoiesis and RBC survival in some athletes.

A nutritional assessment is important, because it may indicate deficiencies in essential nutrients such as iron, vitamin B<sub>12</sub>, and folic acid. Children of indigent families may be at higher risk for anemia because of nutritional deficiencies. Strict vegetarians are also at risk for megaloblastic types of anemia if they do not supplement their diet with vitamin B<sub>12</sub>.

Cardiac status should be carefully assessed. When the hemoglobin level is low, the heart attempts to compensate by pumping faster and harder in an effort to deliver more blood to hypoxic tissue. This increased cardiac workload can result in such symptoms as tachycardia, palpitations, dyspnea, dizziness, orthopnea, and exertional dyspnea. Heart failure may eventually develop, as evidenced by an enlarged heart (cardiomegaly) and liver (hepatomegaly) and by peripheral edema.

Assessment of the gastrointestinal system may disclose complaints of nausea, vomiting (with specific questions as to the appearance of any emesis [eg, looks like "coffee grounds"]), melena or dark stools, diarrhea, anorexia, and glossitis (inflammation of the tongue). Stools should be tested for occult blood. Women should be questioned about their menstrual periods (eg, excessive menstrual flow, other vaginal bleeding) and the use of iron supplements during pregnancy.

The neurologic examination is also important because of the effect of pernicious anemia on the central and peripheral nervous systems. Assessment should include the presence and extent of peripheral numbness and paresthesias, ataxia, poor coordination, and confusion. Finally, it is important to monitor relevant laboratory test results and to note any changes over time.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses for the anemic patient may include:

- Activity intolerance related to weakness, fatigue, and general malaise
- Imbalanced nutrition, less than body requirements, related to inadequate intake of essential nutrients
- Ineffective tissue perfusion related to inadequate blood volume or hematocrit
- Noncompliance with prescribed therapy

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include:

- Heart failure
- Paresthesias
- Confusion

## Planning and Goals

The major goals for the patient may include increased tolerance of normal activity, attainment or maintenance of adequate nutrition, maintenance of adequate tissue perfusion, compliance with prescribed therapy, and absence of complications.

## Nursing Interventions

### MANAGING FATIGUE

The most frequent symptom and complication of anemia is fatigue. This distressing symptom is too often minimized by health care providers. Fatigue is often the symptom that has the greater negative impact on the individual's level of functioning and consequent quality of life. Patients describe the fatigue from anemia as oppressive. Fatigue can be significant, yet the anemia may not be severe enough to warrant transfusion. Fatigue can interfere with an individual's ability to work, both inside and outside the home. It can harm relationships with family and friends. Patients often lose interest in hobbies and activities, including sexual activity. The distress from fatigue is often related to an individual's responsibilities and life demands as well as the amount of assistance and support received from others.

Nursing interventions can focus on assisting the patient to prioritize activities and to establish a balance between activity and rest that is realistic and feasible from the patient's perspective. Patients with chronic anemia need to maintain some physical activity and exercise to prevent the deconditioning that results from inactivity.

### MAINTAINING ADEQUATE NUTRITION

Inadequate intake of essential nutrients, such as iron, vitamin B<sub>12</sub>, folic acid, and protein can cause some anemias. The symptoms associated with anemia (eg, fatigue, anorexia) can in turn interfere with maintaining adequate nutrition. A healthy diet should be encouraged. Because alcohol interferes with the utilization of essential nutrients, the nurse should advise the patient to avoid alcoholic beverages or to limit their intake and should provide the rationale for this recommendation. Dietary teaching sessions should be individualized, including cultural aspects related to food preferences and food preparation. The involvement of family members enhances compliance with dietary recommendations. Dietary supplements (eg, vitamins, iron, folate, protein) may be prescribed as well.

Equally important, the patient and family must understand the role of nutritional supplements in the proper context, because many forms of anemia are not the result of a nutritional deficiency. In such cases, excessive intake of nutritional supplements will not improve the anemia. A potential problem in individuals with chronic transfusion requirements occurs with the indiscriminate use of iron. Unless an aggressive program of chelation therapy is implemented, these individuals are at risk for iron overload from their transfusions alone. The addition of an iron supplement only exacerbates the situation.

### MAINTAINING ADEQUATE PERFUSION

Patients with acute blood loss or severe hemolysis may have decreased tissue perfusion from decreased blood volume or reduced circulating RBCs (decreased hematocrit). Lost volume is replaced with transfusions or intravenous fluids, based on the symptoms and the laboratory findings. Supplemental oxygen may be necessary, but it is rarely needed on a long-term basis unless there is underlying severe cardiac or pulmonary disease as well. The nurse monitors vital signs closely; other medica-

tions, such as antihypertensive agents, may need to be adjusted or withheld.

### PROMOTING COMPLIANCE WITH PRESCRIBED THERAPY

For patients with anemia, medications or nutritional supplements are often prescribed to alleviate or correct the condition. These patients need to understand the purpose of the medication, how to take the medication and over what time period, and how to manage any side effects of therapy. To enhance compliance, the nurse can assist patients in developing ways to incorporate the therapeutic plan into their lives, rather than merely giving the patient a list of instructions. For example, many patients have difficulty taking iron supplements because of related gastrointestinal effects. Rather than seeking assistance from a health care provider in managing the problem, some of these patients simply stop taking the iron.

Abruptly stopping some medications can have serious consequences, as in the case of high-dose corticosteroids to manage hemolytic anemias. Some medications, such as growth factors, are extremely expensive. Patients receiving these medications may need assistance with obtaining needed insurance coverage or with exploring alternatives for obtaining these medications.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

A significant complication of anemia is heart failure from chronic diminished blood volume and the heart's compensatory effort to increase cardiac output. Patients with anemia should be assessed for signs and symptoms of heart failure. A serial record of body weights can be more useful than a record of dietary intake and output, because the intake and output measurements may not be accurate. In the case of fluid retention resulting from congestive heart failure, diuretics may be required.

In megaloblastic forms of anemia, the significant potential complications are neurologic. A neurologic assessment should be performed for patients with known or suspected megaloblastic anemia. Patients may initially complain of paresthesias in their lower extremities. These paresthesias are usually manifested as numbness and tingling on the bottom of the foot, and they gradually progress. As the anemia progresses and damage to the spinal cord occurs, other signs become apparent. Position and vibration sense may be diminished; difficulty maintaining balance is not uncommon, and some patients have gait disturbances as well. Initially mild but gradually progressive confusion may develop.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Tolerates activity at a safe and acceptable level
  - a. Follows a progressive plan of rest, activity, and exercise
  - b. Prioritizes activities
  - c. Paces activities according to energy level
2. Attains and maintains adequate nutrition
  - a. Eats a healthy diet
  - b. Develops meal plan that promotes optimal nutrition
  - c. Maintains adequate amounts of iron, vitamins, and protein from diet or supplements
  - d. Adheres to nutritional supplement therapy when prescribed
  - e. Verbalizes understanding of rationale for using recommended nutritional supplements
  - f. Verbalizes understanding of rationale for avoiding non-recommended nutritional supplements

3. Maintains adequate perfusion
  - a. Has vital signs within baseline for patient
  - b. Has pulse oximetry (arterial oxygenation) value within normal limits
4. Absence of complications
  - a. Avoids or limits activities that cause dyspnea, palpitations, dizziness, or tachycardia
  - b. Uses rest and comfort measures to alleviate dyspnea
  - c. Has vital signs within baseline for patient
  - d. Has no signs of increasing fluid retention (eg, peripheral edema, decreased urine output, neck vein distention)
  - e. Remains oriented to time, place, and situation
  - f. Ambulates safely, using assistive devices as necessary
  - g. Remains free of injury
  - h. Verbalizes understanding of importance of serial CBC measurements
  - i. Maintains safe home environment; obtains assistance as necessary.

## Hypoproliferative Anemias

### IRON DEFICIENCY ANEMIA

Iron deficiency anemia typically results when the intake of dietary iron is inadequate for hemoglobin synthesis. The body can store about one fourth to one third of its iron, and it is not until those stores are depleted that iron deficiency anemia actually begins to develop. Iron deficiency anemia is the most common type of anemia in all age groups, and it is the most common anemia in the world. More than 500 million people are affected, more commonly in underdeveloped countries, where inadequate iron stores can result from inadequate intake of iron (seen with vegetarian diets) or from blood loss (eg, from intestinal hookworm). Iron deficiency is also common in the United States. In children, adolescents, and pregnant women, the cause is typically inadequate iron in the diet to keep up with increased growth. However, for most adults with iron deficiency anemia, the cause is blood loss. In fact, in adults, the cause of iron deficiency anemia should be considered to be bleeding until proven otherwise.

The most common cause of iron deficiency in men and postmenopausal women is bleeding (from ulcers, gastritis, inflammatory bowel disease, or gastrointestinal tumors). The most common cause of iron deficiency anemia in premenopausal women is menorrhagia (excessive menstrual bleeding) and pregnancy with inadequate iron supplementation. Patients with chronic alcoholism often have chronic blood loss from the gastrointestinal tract, which causes iron loss and eventual anemia. Other causes include iron malabsorption, as is seen after gastrectomy or with celiac disease.

### Clinical Manifestations

Patients with iron deficiency primarily have the symptoms of anemia. If the deficiency is severe or prolonged, they may also have a smooth, sore tongue, brittle and ridged nails, and angular cheilosis (an ulceration of the corner of the mouth). These signs subside after iron-replacement therapy. The health history may be significant for multiple pregnancies, gastrointestinal bleeding, and pica (a craving for unusual substances, such as ice, clay, or laundry starch).

### Assessment and Diagnostic Findings

The most definitive method of establishing the diagnosis of iron deficiency anemia is bone marrow aspiration. The aspirate is stained to detect iron, which is at a low level or even absent. How-

ever, few patients with suspected iron deficiency anemia undergo bone marrow aspiration. In many patients, the diagnosis can be established with other tests, particularly in patients with a history of conditions that predispose them to this type of anemia.

There is a strong correlation between laboratory values measuring iron stores and levels of hemoglobin. After the iron stores are depleted (as reflected by low serum ferritin levels), the hemoglobin level falls. The diminished iron stores cause small RBCs. Therefore, as the anemia progresses, the MCV, which measures the size of the RBC, also decreases. Hematocrit and RBC levels are also low in relation to the hemoglobin level. Other laboratory tests that measure iron stores are useful but are not as consistent indicators as a low ferritin level, which reflects low iron stores. Typically, patients with iron deficiency anemia have a low serum iron level and an elevated TIBC, which measures the transport protein supplying the marrow with iron as needed (also referred to as transferrin). However, other disease states, such as infection and inflammatory conditions, can also cause a low serum iron level and TIBC with an elevated ferritin level. Therefore, the most reliable laboratory findings in evaluating iron deficiency anemia are the ferritin and hemoglobin values.

### Medical Management

Except in the case of pregnancy, the cause of iron deficiency should be investigated. Anemia may be a sign of a curable gastrointestinal cancer or of uterine fibroid tumors. Stool specimens should be tested for occult blood. People 50 years of age or older should have a colonoscopy, endoscopy, or other examination of the gastrointestinal tract to detect ulcerations, gastritis, polyps, or cancer. Several oral iron preparations—ferrous sulfate, ferrous gluconate, and ferrous fumarate—are available for treating iron deficiency anemia. In some cases, oral iron is poorly absorbed or poorly tolerated, or iron supplementation is needed in large amounts. In these situations, intravenous or intramuscular administration of iron dextran may be needed. Before parenteral administration of a full dose, a small test dose should be administered to avoid the risk of anaphylaxis with either intravenous or intramuscular injections. Emergency medications (eg, epinephrine) should be close at hand. If no signs of allergic reaction have occurred after 30 minutes, the remaining dose of iron may be administered. Several doses are required to replenish the patient's iron stores.

### Nursing Management

Preventive education is important, because iron deficiency anemia is common in menstruating and pregnant women. Food sources high in iron include organ meats (beef or calf's liver, chicken liver), other meats, beans (black, pinto, and garbanzo), leafy green vegetables, raisins, and molasses. Taking iron-rich foods with a source of vitamin C enhances the absorption of iron.

The nurse helps the patient select a healthy diet. Nutritional counseling can be provided for those whose usual diet is inadequate. Patients with a history of eating fad diets or strict vegetarian diets are counseled that such diets often contain inadequate amounts of absorbable iron. The nurse encourages patients to continue iron therapy as long as it is prescribed, although they may no longer feel fatigued.

Because iron is best absorbed on an empty stomach, patients should be advised to take the supplement an hour before meals. Most patients can use the less expensive, more standard forms of ferrous sulfate. Tablets with enteric coating may be poorly

### Chart 33-2 • PATIENT EDUCATION Taking Iron Supplements

Iron supplementation is usually given in oral form, typically as ferrous sulfate, or  $\text{FeSO}_4$ . Many patients have difficulty tolerating iron supplements, primarily due to gastrointestinal toxicities (eg, nausea, abdominal discomfort, constipation). Here are some helpful guidelines for taking iron supplements:

- Take iron on an empty stomach (1 hour before or 2 hours after a meal). Iron absorption is reduced with food, especially dairy products.
- To prevent gastrointestinal distress, the following schedule may work better if more than one tablet a day is prescribed: Start with only one tablet per day for a few days, then increase

to two tablets per day, then three tablets per day. This method permits the body to adjust gradually to the iron.

- Increase the intake of vitamin C (citrus fruits and juices, strawberries, tomatoes, broccoli), to enhance iron absorption.
- Eat foods high in fiber to minimize problems with constipation.
- Remember that stools will become dark in color.

Polysaccharide iron complex forms are better tolerated but are more expensive. Liquid forms of iron supplementation may be better tolerated than solid forms, although they are more expensive. The liquid forms can discolor teeth. Use a straw or place the spoon at the back of the mouth to take the supplement; rinse mouth thoroughly afterward.

absorbed and should be avoided. Other patients have difficulty taking iron supplements because of gastrointestinal side effects (primarily constipation, but also cramping, nausea, and vomiting). Some iron formulations are designed to limit gastrointestinal side effects by the addition of a stool softener or use of sustained-release formulations to limit nausea or gastritis. Specific patient teaching aids, such as the accompanying patient education guide (Chart 33-2), can assist patients with the use of iron supplements.

If taking iron on an empty stomach causes gastric distress, the patient may need to take the iron supplement with meals. However, doing so diminishes iron absorption by as much as 50%, thus prolonging the time required to replenish iron stores. Antacids or dairy products should not be taken with iron, because they greatly diminish the absorption of iron. Polysaccharide iron complex forms that have less gastrointestinal toxicity are also available, but they are more expensive.

Liquid forms of iron that cause less gastrointestinal distress are available. However, they can stain the teeth; patients should be instructed to take this medication through a straw, to rinse the mouth with water, and to practice good oral hygiene after taking this medication. Finally, patients should be informed that iron salts may color the stool dark green or black. However, iron replacement therapy does not cause a false-positive result on stool analyses for occult blood.

Intramuscular supplementation is used infrequently. The volume of iron required may be excessive. The intramuscular injection causes some local pain and can stain the skin. These side effects are minimized by using the Z-track technique for administering iron dextran deep into the gluteus maximus muscle (buttock). Avoid vigorously rubbing the injection site after the injection. Because of the problems with intramuscular administration, the intravenous route is preferred for administration of iron dextran.

## ANEMIAS IN RENAL DISEASE

The degree of anemia in patients with end-stage renal disease varies greatly, but in general patients do not become significantly anemic until the serum creatinine level exceeds 3 mg/100 mL. The symptoms of anemia are often the most disturbing of the patient's symptoms. The hematocrit usually falls to between 20% and 30%, although in rare cases it may fall to less than 15%. The RBCs appear normal on the peripheral smear.

This anemia is caused by both a mild shortening of RBC life span and a deficiency of erythropoietin (necessary for erythro-

poiesis). As renal function decreases, erythropoietin, which is produced by the kidney, also decreases. Because erythropoietin is also produced outside the kidney, some erythropoiesis does continue, even in patients whose kidneys have been removed. However, the amount is small and the degree of erythropoiesis is inadequate.

Patients undergoing long-term hemodialysis lose blood into the dialyzer and therefore may become iron deficient. Folic acid deficiency develops because this vitamin passes into the dialysate. Therefore, patients who receive hemodialysis and who are anemic should be evaluated for iron and folate deficiency and treated appropriately.

The availability of recombinant erythropoietin (epoetin alfa [Epoen, Procrit]) has dramatically altered the management of anemia in end-stage renal disease by decreasing the need for RBC transfusion, with its associated risks. Erythropoietin, in combination with oral iron supplements, can raise and maintain hematocrit levels to between 33% and 38%. This treatment has been successful with dialysis patients. Many patients report decreased fatigue, increased energy, increased feelings of well-being, improved exercise tolerance, better tolerance of dialysis treatments, and improved quality of life. Hypertension is the most serious side effect in this patient population when the hematocrit rapidly increases to a high level. Therefore, the hematocrit should be checked frequently when a patient with renal disease begins erythropoietin therapy. The dose of erythropoietin (epoetin alfa) should be titrated to the hematocrit. In some patients, the elevated hematocrit and associated hypertension may necessitate antihypertensive therapy.

## ANEMIA OF CHRONIC DISEASE

The term "anemia of chronic disease" is a misnomer in that only the chronic diseases of inflammation, infection, and malignancy cause this type of anemia. Many chronic inflammatory diseases are associated with a **normochromic, normocytic** anemia (ie, the RBCs are normal in color and size). These disorders include rheumatoid arthritis; severe, chronic infections; and many cancers. It is therefore imperative that the "chronic disease" be diagnosed when this form of anemia is identified so that it can be appropriately managed.

The anemia is usually mild to moderate and nonprogressive. It develops gradually over 6 to 8 weeks and then stabilizes at a hematocrit seldom less than 25%. The hemoglobin level rarely falls below 9 g/dL, and the bone marrow has normal cellularity

with increased stores of iron as the iron is diverted from the serum (and thus is unavailable as a growth factor for invading pathogens). Erythropoietin levels are low, perhaps because of decreased production, and iron use is blocked by **erythroid cells** (cells that are or will become mature RBCs). A moderate shortening of RBC survival also occurs.

Most of these patients have few symptoms and do not require treatment for the anemia. With successful treatment of the underlying disorder, the bone marrow iron is used to make RBCs and the hemoglobin level rises.

## APLASTIC ANEMIA

Aplastic anemia is a rather rare disease caused by a decrease in or damage to marrow stem cells, damage to the microenvironment within the marrow, and replacement of the marrow with fat. It results in bone marrow **aplasia** (markedly reduced hematopoiesis). Therefore, in addition to severe anemia, significant neutropenia and thrombocytopenia (a deficiency of platelets) are also seen.

### Pathophysiology

Aplastic anemia can be congenital or acquired, but most cases are idiopathic (ie, without apparent cause). Infections and pregnancy can trigger it, or it may be caused by certain medications, chemicals, or radiation damage (Chart 33-3). Agents that regularly produce marrow aplasia include benzene and benzene derivatives (eg, airplane glue). Certain toxic materials, such as inorganic arsenic and several pesticides (including DDT, which is no longer used or available in the United States), have also been implicated as potential causes. Various medications have been associated with aplastic anemia.

### Clinical Manifestations

The manifestations of aplastic anemia are often insidious. Complications resulting from bone marrow failure may occur before

the diagnosis is established. Typical complications are infection and symptoms of anemia (eg, fatigue, pallor, dyspnea). Purpura (bruising) may develop later and should trigger a CBC and hematologic evaluation if these were not performed initially. If the patient has had repeated throat infections, cervical lymphadenopathy may be seen. Other lymphadenopathies and splenomegaly sometimes occur. Retinal hemorrhages are common.

### Assessment and Diagnostic Findings

In many situations, aplastic anemia occurs when a medication or chemical is ingested in toxic amounts. However, in a few people, it develops after a medication has been taken at the recommended dosage. This may be considered an idiosyncratic reaction in those who are highly susceptible, possibly caused by a genetic defect in the medication biotransformation or elimination process. A bone marrow aspirate shows an extremely hypoplastic or even aplastic (very few to no cells) marrow replaced with fat.

### Medical Management

It is presumed that the lymphocytes of patients with aplastic anemia destroy the stem cells and consequently impair the production of RBCs, WBCs, and platelets. Despite its severity, aplastic anemia can be successfully treated in most people. Potentially, those who are younger than 60 years of age, who are otherwise healthy, and who have a compatible donor can be cured of the disease by a bone marrow transplant (BMT) or peripheral stem cell transplantation (BSCT). In others, the disease can be managed with immunosuppressive therapy. A combination of antithymocyte globulin and cyclosporine is used most commonly. Immunosuppressants prevent the patient's lymphocytes from destroying the stem cells. If relapse occurs (ie, the patient becomes pancytopenic again), reinstitution of the same immunologic agents may induce another remission. Corticosteroids are not very useful as an immunosuppressive agent, because patients with aplastic anemia appear particularly susceptible to the development of bone complications from corticosteroids (ie, aseptic necrosis of the head of the femur).

Supportive therapy plays a major role in the management of aplastic anemia. Any offending agent is discontinued. The patient is supported with transfusions of RBCs and platelets as necessary. Death usually is caused by hemorrhage or infection.

### Nursing Management

Patients with aplastic anemia are vulnerable to problems related to RBC, WBC, and platelet deficiencies. They should be assessed carefully for signs of infection and bleeding. Specific interventions are delineated in the sections on neutropenia and thrombocytopenia.

## MEGALOBLASTIC ANEMIAS

In the anemias caused by deficiencies of vitamin B<sub>12</sub> or folic acid, identical bone marrow and peripheral blood changes occur, because both vitamins are essential for normal DNA synthesis. In either anemia, the RBCs that are produced are abnormally large and are called megaloblastic RBCs. Other cells derived from the myeloid stem cell (nonlymphoid WBCs, platelets) are also abnor-

- Sedatives

\*Most common.

mal. A bone marrow analysis reveals **hyperplasia** (abnormal increase in the number of cells), and the precursor erythroid and myeloid cells are large and bizarre in appearance. Many of these abnormal RBCs and myeloid cells are destroyed within the marrow, however, so the mature cells that do leave the marrow are actually fewer in number. Thus, **pancytopenia** (a decrease in all myeloid-derived cells) can develop. In an advanced situation, the hemoglobin value may be as low as 4 to 5 g/dL, the WBC count 2,000 to 3,000/mm<sup>3</sup>, and the platelet count less than 50,000/mm<sup>3</sup>. Those cells that are released into the circulation are often abnormally shaped. The neutrophils are hypersegmented. The platelets may be abnormally large. The RBCs are abnormally shaped, and the shapes may vary widely (**poikilocytosis**). Because the RBCs are very large, the MCV is very high, usually exceeding 110  $\mu\text{m}^3$ .

## Pathophysiology

### FOLIC ACID DEFICIENCY

Folic acid, a vitamin that is necessary for normal RBC production, is stored as compounds referred to as folates. The folate stores in the body are much smaller than those of vitamin B<sub>12</sub>, and they are quickly depleted when the dietary intake of folate is deficient (within 4 months). Folate is found in green vegetables and liver. Folate deficiency occurs in people who rarely eat uncooked vegetables. Alcohol increases folic acid requirements, and, at the same time, patients with alcoholism usually have a diet that is deficient in the vitamin. Folic acid requirements are also increased in patients with chronic hemolytic anemias and in women who are pregnant, because the need for RBC production is increased in these conditions. Some patients with malabsorptive diseases of the small bowel, such as sprue, may not absorb folic acid normally.

### VITAMIN B<sub>12</sub> DEFICIENCY

A deficiency of vitamin B<sub>12</sub> can occur in several ways. Inadequate dietary intake is rare but can develop in strict vegetarians who consume no meat or dairy products. Faulty absorption from the gastrointestinal tract is more common. This occurs in conditions such as Crohn's disease, or after ileal resection or gastrectomy. Another cause is the absence of intrinsic factor, as in pernicious anemia. Intrinsic factor is normally secreted by cells within the gastric mucosa; normally it binds with the dietary vitamin B<sub>12</sub> and travels with it to the ileum, where the vitamin is absorbed. Without intrinsic factor, orally consumed vitamin B<sub>12</sub> cannot be absorbed, and RBC production is eventually diminished. Even if adequate vitamin B<sub>12</sub> and intrinsic factor are present, a deficiency may occur if disease involving the ileum or pancreas impairs absorption. Pernicious anemia, which tends to run in families, is primarily a disorder of adults, particularly the elderly. The abnormality is in the gastric mucosa: the stomach wall atrophies and fails to secrete intrinsic factor. Therefore, the absorption of vitamin B<sub>12</sub> is significantly impaired.

The body normally has large stores of vitamin B<sub>12</sub>, so years may pass before the deficiency results in anemia. Because the body compensates so well, the anemia can be severe before the patient becomes symptomatic. For unknown reasons, patients with pernicious anemia have a higher incidence of gastric cancer than the general population; these patients should have endoscopies at regular intervals (every 1 to 2 years) to screen for early gastric cancer.

## Clinical Manifestations

Symptoms of folic acid and vitamin B<sub>12</sub> deficiencies are similar, and the two anemias may coexist. However, the neurologic manifestations of vitamin B<sub>12</sub> deficiency do not occur with folic acid deficiency, and they persist if B<sub>12</sub> is not replaced. Therefore, careful distinction between the two anemias must be made. Serum levels of both vitamins can be measured. In the case of folic acid deficiency, even small amounts of folate will increase the serum folate level, sometimes to normal. Measuring the amount of folate within the RBC itself (red cell folate) is therefore a more sensitive test in determining true folate deficiency.

After the body stores of vitamin B<sub>12</sub> are depleted, patients may begin to show signs of the anemia. However, because the onset and progression of the anemia are so gradual, the body can compensate very well until the anemia is severe, so that the typical manifestations of anemia (weakness, listlessness, fatigue) may not be apparent initially. The hematologic effects of deficiency are accompanied by effects on other organ systems, particularly the gastrointestinal tract and nervous system. Patients with pernicious anemia develop a smooth, sore, red tongue and mild diarrhea. They are extremely pale, particularly in the mucous membranes. They may become confused; more often they have paresthesias in the extremities (particularly numbness and tingling in the feet and lower legs). They may have difficulty maintaining their balance because of damage to the spinal cord, and they also lose position sense (proprioception). These symptoms are progressive, although the course of illness may be marked by spontaneous partial remissions and exacerbations. Without treatment, patients can die after several years, usually from heart failure secondary to anemia.

## Assessment and Diagnostic Findings

The classic method of determining the cause of vitamin B<sub>12</sub> deficiency is the Schilling test, in which the patient receives a small oral dose of radioactive vitamin B<sub>12</sub>, followed in a few hours by a large, nonradioactive parenteral dose of vitamin B<sub>12</sub> (this aids in renal excretion of the radioactive dose). If the oral vitamin is absorbed, more than 8% will be excreted in the urine within 24 hours; therefore, if no radioactivity is present in the urine (ie, the radioactive vitamin B<sub>12</sub> stays within the gastrointestinal tract), the cause is gastrointestinal malabsorption of the vitamin B<sub>12</sub>. Conversely, if the urine is radioactive, the cause of the deficiency is not ileal disease or pernicious anemia. Later, the same procedure is repeated, but this time intrinsic factor is added to the oral radioactive vitamin B<sub>12</sub>. If radioactivity is now detected in the urine (ie, the B<sub>12</sub> was absorbed from the gastrointestinal tract in the presence of intrinsic factor), the diagnosis of pernicious anemia can be made. The Schilling test is useful only if the urine collections are complete; therefore, the nurse must promote the patient's understanding and ability to comply with this collection.

Another useful, easier test is the intrinsic factor antibody test. A positive test indicates the presence of antibodies that bind the vitamin B<sub>12</sub>-intrinsic factor complex and prevent it from binding to receptors in the ileum, thus preventing its absorption. Unfortunately, this test is not specific for pernicious anemia alone, but it can aid in the diagnosis.

## Medical Management

Folate deficiency is treated by increasing the amount of folic acid in the diet and administering 1 mg of folic acid daily. Folic acid is administered intramuscularly only for people with malab-

sorption problems. With the exception of the vitamins administered during pregnancy, most proprietary vitamin preparations do not contain folic acid, so it must be administered as a separate tablet. After the hemoglobin level returns to normal, the folic acid replacement can be stopped. However, patients with alcoholism should continue receiving folic acid as long as they continue alcohol consumption.

Vitamin B<sub>12</sub> deficiency is treated by vitamin B<sub>12</sub> replacement. Vegetarians can prevent or treat deficiency with oral supplements through vitamins or fortified soy milk. When, as is more common, the deficiency is due to defective absorption or absence of intrinsic factor, replacement is by monthly intramuscular injections of vitamin B<sub>12</sub>, usually at a dose of 1000 µg. The reticulocyte count rises within 1 week, and in several weeks the blood counts are all normal. The tongue improves in several days. However, the neurologic manifestations require more time for recovery; if there is severe neuropathy, the patient may never recover fully. To prevent recurrence of pernicious anemia, vitamin B<sub>12</sub> therapy must be continued for life.

**NURSING ALERT** Even when the anemia is severe, RBC transfusions should not be used because the patient's body has compensated over time by expanding the total blood volume. Administration of blood transfusions to such patients, particularly those who are elderly or who have cardiac dysfunction, can precipitate pulmonary edema. If transfusions are required, the RBCs should be transfused slowly, with careful attention to signs and symptoms of fluid overload.

## Nursing Management

Assessment of patients who have or are at risk for megaloblastic anemia includes inspection of the skin and mucous membranes. Mild jaundice may be apparent and is best seen in the sclera without using fluorescent lights. Vitiligo (patchy loss of skin pigmentation) and premature graying of the hair are often seen in patients with pernicious anemia. The tongue is smooth, red, and sore. Because of the neurologic complications associated with these anemias, a careful neurologic assessment is important, including tests of position and vibration sense.

### PROMOTING HOME AND COMMUNITY-BASED CARE

The nurse needs to pay particular attention to ambulation and should assess the patient's gait and stability as well as the need for assistive devices (eg, canes, walkers) and for assistance in managing daily activities. Of particular concern is ensuring safety when position sense, coordination, and gait are affected. Physical and occupational therapy referrals may be needed.

If sensation is altered, patients need to be instructed to avoid excessive heat and cold.

Because mouth and tongue soreness may restrict nutritional intake, the nurse can advise patients and families to prepare bland, soft foods and to eat small amounts frequently. The nurse also may explain that other nutritional deficiencies, such as alcohol-induced anemia, can induce neurologic problems.

Patients must also be taught about the chronicity of their disorder and the necessity for monthly vitamin B<sub>12</sub> injections even in the absence of symptoms. Many patients can be instructed to self-administer their injections. The gastric atrophy associated with pernicious anemia increases the risk of gastric carcinoma, so these patients need to understand that ongoing medical follow-up and screening are important.

## MYELODYSPLASTIC SYNDROMES (MDS)

The MDSs are a group of disorders of the myeloid stem cell that cause **dysplasia** (abnormal development) in one or more types of cell lines. The most common feature of MDS—dysplasia of the RBCs—is manifested as a macrocytic anemia; however, the WBCs (myeloid cells, particularly neutrophils) and platelets can also be affected. Although the bone marrow is actually hypercellular, many of the cells within it die before being released into the circulation. Therefore, the number of affected cells in the circulation is typically lower than normal. In addition to the quantitative defect (ie, fewer cells than normal), there is also a qualitative defect: the cells are not as functional as normal. The neutrophils have diminished ability to destroy bacteria by phagocytosis; platelets are less able to aggregate and are less adhesive than usual. The result of these qualitative defects is an increased risk for infection and bleeding, even when the actual number of circulating cells may not be excessively low. A significant proportion of MDS cases evolve into acute myeloid leukemia (AML); this type of leukemia tends to be nonresponsive to standard therapy.

Primary MDS tends to be a disease of the elderly; more than 80% of patients with MDS are older than 60 years of age. Secondary MDS may occur at any age and results from prior toxic exposure to chemicals, including chemotherapeutic medications (particularly alkylating agents). Secondary MDS tends to have a poorer prognosis than does primary MDS.

## Clinical Manifestations

The manifestations of MDS can vary widely. Many patients are asymptomatic, with the illness being discovered incidentally when a CBC is performed for other purposes. Other patients have profound symptoms and complications from the illness. Fatigue is often present, at varying levels. Neutrophil dysfunction renders the person at risk for infection; recurrent pneumonias are not uncommon. Because platelet function can also be altered, bleeding can occur. These problems may persist in a fairly steady state for months, even years. They may also progress over time; as the dysplasia evolves into a leukemic state, the complications increase in severity.

## Assessment and Diagnostic Findings

The CBC typically reveals a macrocytic anemia; WBC and platelet counts may be diminished as well. Serum erythropoietin levels may be inappropriately low, as is the reticulocyte count. As the disease evolves into AML, more immature blast cells are noted on the CBC.

## Medical Management

With the exception of allogeneic bone marrow transplantation (BMT), there is no known cure for MDS. Chemotherapy has been used, particularly in patients with more aggressive forms of the illness, typically with disappointing results (Deeg & Applebaum, 2000; Beran, 2000). However, patients with mild cytopenias (low blood counts) actually require no therapy. For most patients with MDS, transfusions of RBCs are required to control the anemia and its symptoms. These patients can develop significant problems with iron overload from the repeated transfusions; this problem can be diminished with prompt initiation of chelation therapy to remove the excess iron (see Nursing Management). In some patients, the use of erythropoietin can be successful in

reducing the need for transfusions and their attendant complications. Some patients may also require ongoing platelet transfusions to prevent significant bleeding. Infections need to be managed aggressively and promptly. Administration of growth factors, particularly granulocyte colony-stimulating factor (G-CSF), erythropoietin, or both, has been successful in increasing neutrophils and diminishing anemia in certain patients; however, these agents are expensive and the effect is lost if the medications are stopped. Because MDS tend to occur in elderly people, other chronic conditions may limit treatment options. Secondary MDS and MDS that evolves into AML tend to be much more refractory to conventional therapy for leukemia.

## Nursing Management

Caring for patients with MDS can be challenging because the illness is unpredictable. As with other hematologic conditions, some patients (especially those with no symptoms) have difficulty perceiving that they have a serious illness that can place them at risk for life-threatening complications. At the other extreme, many patients have tremendous difficulty coping with the uncertain trajectory of the illness and fear that the illness will evolve into AML at a time when they are feeling very well physically.

Patients with MDS need extensive instruction about infection risk, measures to avoid it, signs and symptoms of developing infection, and appropriate actions to initiate should such symptoms occur. Instruction should also be given regarding the risk for bleeding. Patients with MDS who are hospitalized may require neutropenic precautions.

Laboratory values need to be monitored closely to anticipate the need for transfusion and to determine response to treatment with growth factors. Patients with chronic transfusion requirements usually benefit from a vascular access device for this purpose. Patients receiving growth factors or chelation therapy must be educated about these medications, their side effects, and administration techniques.

Chelation therapy is a process that is used to remove excess iron acquired from chronic transfusions. Iron is bound to a substance, the chelating agent, and then excreted in the urine. Oral forms of chelating agents have not been successful (due to either diminished efficacy or excessive toxicity). Chelation therapy is most effective as a subcutaneous infusion administered over 8 to 12 hours; most patients prefer to do this at night. Because chelation therapy removes only a small amount of iron with each treatment, patients with chronic transfusion requirements (and iron overload) need to continue chelation therapy as long as the iron overload exists, potentially for the rest of their lives. Patients who are embarking on chelation therapy must be highly motivated and need instruction in the subcutaneous infusion technique, infusion pump maintenance, and side effect management. Local erythema at the injection site is the most common reaction and typically requires no intervention. Patients should have baseline and annual auditory and eye examinations, because hearing loss and visual changes can occur with treatment.

## Hemolytic Anemias

In hemolytic anemias, the RBCs have a shortened life span; thus, the number of RBCs in circulation is reduced. Fewer RBCs result in decreased available oxygen causes hypoxia, which in turn stimulates an increase in erythropoietin release from the kidney. The erythropoietin stimulates the bone marrow to compensate by

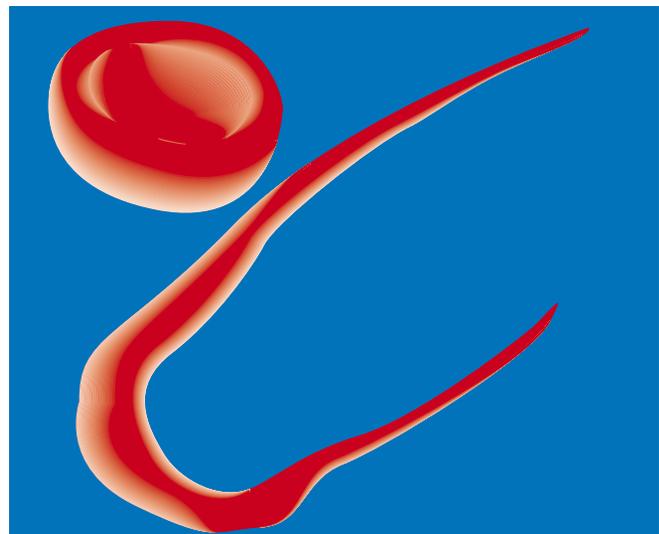

producing new RBCs and releasing some of them into the circulation somewhat prematurely as reticulocytes. If the RBC destruction persists, the hemoglobin is broken down excessively; about 80% of the heme is converted to bilirubin, conjugated in the liver, and excreted in the bile.

The mechanism of RBC destruction varies, but all types of hemolytic anemia share certain laboratory features: the reticulocyte count is elevated, the fraction of indirect (unconjugated) bilirubin is increased, and the supply of haptoglobin (a binding protein for free hemoglobin) is depleted as more hemoglobin is released. As a result, the plasma haptoglobin level is low. If the marrow cannot compensate to replace the RBCs (indicated by a decreased reticulocyte count), the anemia will progress.

Hemolytic anemia has various forms. Among the inherited forms are sickle cell anemia, thalassemia and thalassemia major, G-6-PD deficiency, and hereditary spherocytosis. Acquired forms include autoimmune hemolytic anemia, nonimmune-mediated paroxysmal nocturnal hemoglobinuria, microangiopathic hemolytic anemia, and heart valve hemolysis, as well as anemias associated with hypersplenism.

## SICKLE CELL ANEMIA

Sickle cell anemia is a severe hemolytic anemia that results from inheritance of the sickle hemoglobin gene. This gene causes the hemoglobin molecule to be defective. The sickle hemoglobin (HbS) acquires a crystal-like formation when exposed to low oxygen tension. The oxygen level in venous blood can be low enough to cause this change; consequently, the RBC containing (HbS) loses its round, very pliable, biconcave disk shape and becomes deformed, rigid, and sickle-shaped (Fig. 33-5). These long, rigid RBCs can adhere to the endothelium of small vessels; when they pile up against each other, blood flow to a region or an organ may be reduced (Hoffman, et al., 2000). If ischemia or infarction results, the patient may have pain, swelling, and fever. The sickling process takes time; if the RBC is again exposed to adequate amounts of oxygen (eg, when it travels through the pulmonary circulation) before the membrane becomes too rigid, it can revert to a normal shape. For this reason, the “sickling crises” are intermittent. Cold can aggravate

**FIGURE 33-5** A normal red blood cell (upper left) and a sickled red blood cell.

the sickling process, because vasoconstriction slows the blood flow. Oxygen delivery can also be impaired by an increased blood viscosity, with or without occlusion due to adhesion of sickled cells; in this situation, the effects are seen in larger vessels, such as arterioles.

The *HbS* gene is inherited in people of African descent and to a lesser extent in people from the Middle East, the Mediterranean area, and aboriginal tribes in India. Sickle cell anemia is the most severe form of sickle cell disease. Less severe forms include sickle cell hemoglobin C (SC) disease, sickle cell hemoglobin D (SD) disease, and sickle cell beta-thalassemia. The clinical manifestations and management are the same as for sickle cell anemia. The term *sickle cell trait* refers to the carrier state for SC diseases; it is the most benign type of SC disease, in that less than 50% of the hemoglobin within an RBC is HbS. However, in terms of genetic counseling, it is still an important condition. If two people with sickle cell trait have children, the children may inherit two abnormal genes. These children will produce only HbS and therefore will have sickle cell anemia.

### Clinical Manifestations

Symptoms of sickle cell anemia vary and are only somewhat based on the amount of HbS. Symptoms and complications result from chronic hemolysis or thrombosis. The sickled RBCs have a shortened life span. Patients are always anemic, usually with hemoglobin values of 7 to 10 g/dL. Jaundice is characteristic and is usually obvious in the sclerae. The bone marrow expands in childhood in a compensatory effort to offset the anemia, sometimes leading to enlargement of the bones of the face and skull. The chronic anemia is associated with tachycardia, cardiac murmurs, and often an enlarged heart (cardiomegaly). Dysrhythmias and heart failure may occur in adults.

Virtually any organ may be affected by thrombosis, but the primary sites involve those areas with slowed circulation, such as the spleen, lungs, and central nervous system. All the tissues and organs are constantly vulnerable to microcirculatory interruptions by the sickling process and therefore are susceptible to hypoxic damage or true ischemic necrosis. Patients with sickle cell anemia are unusually susceptible to infection, particularly pneumonia and osteomyelitis. Complications of sickle cell anemia include infection, stroke, renal failure, impotence, heart failure, and pulmonary hypertension. Table 33-4 summarizes the complications resulting from sickle cell anemia.

### SICKLE CELL CRISIS

There are three types of sickle cell crisis in the adult population. The most common is the very painful *sickle crisis*, which results from tissue hypoxia and necrosis due to inadequate blood flow to a specific region of tissue or organ. *Aplastic crisis* results from infection with the human parvovirus. The hemoglobin level falls rapidly and the marrow cannot compensate, as evidenced by an absence of reticulocytes. *Sequestration crisis* results when other organs pool the sickled cells. Although the spleen is the most common organ responsible for sequestration in children, by 10 years of age most children with sickle cell anemia have had a splenic infarction and the spleen is then no longer functional (autosplenectomy). In adults, the common organs involved in sequestration are the liver and, more seriously, the lungs.

### ACUTE CHEST SYNDROME

Acute chest syndrome is manifested by a rapidly falling hemoglobin level, tachycardia, fever, and bilateral infiltrates seen on the chest x-ray. These signs often mimic infection; in fact, recent studies have identified infection as a major cause of acute chest syndrome (Vichinsky, et al., 2000). Another common cause is pulmonary fat embolism. Increased secretory phospholipase A<sub>2</sub>

Table 33-4 • Summary of Complications in Sickle Cell Anemia\*

ORGAN INVOLVED	MECHANISMS*	ASSESSMENT FINDINGS	SYMPTOM
<b>Spleen</b>	Primary site of sickling → infarctions → ↓ phagocytic function of macrophages	Autosplenectomy; ↑ infection (esp. pneumonia, osteomyelitis)	Abdominal pain; fever, signs of infection
<b>Lungs</b>	Infection Infarction → ↑ pulmonary pressure → pulmonary hypertension	Pulmonary infiltrate ↑ sPLA <sub>2</sub> †	Chest pain; dyspnea
<b>Central Nervous System</b>	Infarction	CVA (cerebral vascular accident, brain attack)	Weakness (if severe); learning difficulties (if mild)
<b>Kidney</b>	Sickling → damage to renal medulla	Hematuria; inability to concentrate urine; renal failure	Dehydration
<b>Heart</b>	Anemia	Tachycardia; cardiomegaly → heart failure	Weakness, fatigue, dyspnea
<b>Bone</b>	↑ Erythroid production	Widening of medullary spaces and cortical thinning	Ache
<b>Liver</b>	Infarction of bone Hemolysis	Osteosclerosis → avascular necrosis Jaundice and gallstone formation; hepatomegaly	Bone pain, especially hips Abdominal pain
<b>Skin and peripheral vasculature</b>	↑ Viscosity/stasis → infarction → skin ulcers	Skin ulcers; ↓ wound healing	Pain
<b>Eye</b>	Infarction	Scarring, hemorrhage, retinal detachment	↓ Vision; blindness
<b>Penis</b>	Sickling	Priapism → impotence	Pain, impotence

\* Problems encountered in sickle cell anemia vary and are the result of a variety of mechanisms, as depicted in this table. Common physical findings and symptoms are also variable.

† sPLA<sub>2</sub>: Secretory phospholipase A<sub>2</sub>, a laboratory test that can predict impending acute chest syndrome (see text).

concentration has been identified as a predictor of impending acute chest syndrome; the increased amounts of free fatty acids can cause increased permeability of the pulmonary endothelium and leakage of the pulmonary capillaries. Although this syndrome is potentially lethal, prompt intervention can result in a favorable outcome.

## Assessment and Diagnostic Findings

The patient with sickle cell trait usually has a normal hemoglobin level, a normal hematocrit, and a normal blood smear. In contrast, the patient with sickle cell anemia has a low hematocrit and sickled cells on the smear. The diagnosis is confirmed by hemoglobin electrophoresis.

## Prognosis

Patients with sickle cell anemia are usually diagnosed in childhood, because they become anemic in infancy and begin to have sickle cell crises at 1 or 2 years of age. Some children die in the first years of life, typically from infection, but the use of antibiotics and parent teaching have greatly improved the outcomes for these children. However, with current management strategies, the average life expectancy is still suboptimal, at 42 years. Young adults are often forced to live with multiple, often severe, complications from their disease. In some patients, the symptoms and complications diminish by 30 years of age; these patients live into the sixth decade or longer. At this time, there is no way to predict which patients will fall into this subgroup.

## Medical Management

Treatment for sickle cell anemia is the focus of continued research (Steinberg, 1999). Many trials of medications that have antisickling properties are being conducted, as is research using antiadhesion treatment for vasoocclusive crises. However, aside from the equally important aggressive management of symptoms and complications, currently there are only three primary treatment modalities for sickle cell diseases: BMT, hydroxyurea, and long-term RBC transfusion.

BMT offers the potential for cure for this disease. However, this treatment modality is available to only a small subset of the patient population, because of either the lack of a compatible donor or the severe organ (eg, renal, liver, lung) damage already present in the patient.

## PHARMACOLOGIC THERAPY

Hydroxyurea (Hydrea), a chemotherapy agent, has been shown to be effective in increasing hemoglobin F levels in patients with sickle cell anemia, thereby decreasing the permanent formation of sickled cells. Patients who receive hydroxyurea appear to have fewer painful episodes of sickle cell crisis, a lower incidence of acute chest syndrome, and less need for transfusions (Ferster et al., 2001). However, whether hydroxyurea can prevent or reverse actual organ damage remains unknown. Side effects of hydroxyurea include chronic suppression of WBC formation, teratogenesis, and potential for later development of a malignancy. Patient response to the medication varies significantly. The incidence and severity of side effects are also highly variable within a dose range. Some patients have toxicity when receiving a very small dose (5 mg/kg per day), whereas others have little toxicity with a much higher dose (35 mg/kg per day). More research is needed to identify specific patient subgroups that are more likely to respond to this medication.

## TRANSFUSION THERAPY

Chronic transfusions with RBCs have been shown to be highly effective in several situations: in an acute exacerbation of anemia (eg, aplastic crisis), in the prevention of severe complications from anesthesia and surgery, and in improving the response to infection (when it results in exacerbated anemia) (Ohene-Frempong, 2001). Chronic transfusions have also been shown to be effective in diminishing episodes of sickle cell crisis in pregnant women; however, these transfusions have not been shown to improve fetal survival. Transfusion therapy may be effective in preventing complications from sickle cell disease. Although controversial, some data support the use of chronic transfusions in patients with cerebral ischemic injury (as seen on magnetic resonance imaging [MRI] or Doppler studies) to prevent more severe injury (eg, CVA). More than 50% of asymptomatic patients have some cerebral ischemia documented by MRI. In a recent study (Adams, 2000), chronic transfusion with RBCs resulted in a 90% reduction of stroke in children at risk for this complication, as demonstrated by elevated blood viscosity on transcranial Doppler ultrasonography. Transfusions may also be useful in the management of severe cases of acute chest syndrome.

The risk of complications from transfusion is important to consider. These risks include iron overload, which necessitates chronic chelation therapy (see MDS Nursing Management); poor venous access, which necessitates a vascular access device (and its attendant risk for infection or thrombosis); infections (hepatitis, human immunodeficiency virus [HIV]); and alloimmunization from repeated transfusions. Another complication from transfusion is the increased viscosity of blood before the concentration of hemoglobin S is reduced. Exchange transfusion (in which the patient's own blood is removed and replaced via transfusion) may be performed to diminish the risk of increasing the viscosity excessively; the objective is to reduce the hematocrit to less than 30%, with transfusions supplying more than 80% of the patient's blood volume. Finally, it is important to consider the significant financial cost of an aggressive transfusion and chelation program.

Patients with sickle cell anemia require daily folic acid replacements to maintain the supply required for increased erythropoiesis from hemolysis. Infections must be treated promptly with appropriate antibiotics; infection remains a major cause of death in these patients.

Acute chest syndrome is managed by prompt initiation of antibiotic therapy. Incentive spirometry has been shown to decrease the incidence of pulmonary complications significantly. In severe cases, bronchoscopy may be required to identify the source of pulmonary disease. Fluid restriction may be more beneficial than aggressive hydration. Corticosteroids may also be useful. Transfusions reverse the hypoxia and decrease the level of secretory phospholipase A<sub>2</sub>. Pulmonary function should be monitored regularly to detect pulmonary hypertension early, when therapy (hydroxyurea, transfusions, or transplantation) may have a positive impact.

Because repeated blood transfusions are necessary, patients may develop multiple autoantibodies, making cross-matching difficult. In this patient population, a hemolytic transfusion reaction (see later discussion) may mimic the signs and symptoms of a sickle cell crisis. The classic distinguishing factor is that, with a hemolytic transfusion reaction, the patient becomes more anemic after being transfused. These patients need very close observation. Further transfusion is avoided if possible until the hemolytic process abates. If possible, the patient is supported with corticosteroids (Prednisone), intravenous immunoglobulin (IVIg; Gammagard, Sando-globulin, Venoglobulin), and erythropoietin (Epoen, Procrit).

## SUPPORTIVE THERAPY

Supportive care is equally important. A significant issue is pain management. The incidence of painful sickle cell crises is highly variable; many patients have pain on a daily basis. The severity of the pain may not be enough to cause the patient to seek assistance from health care providers but severe enough to interfere with the ability to work and function within the family. Acute pain episodes tend to be self-limited, lasting hours to days. If the patient cannot manage the pain at home, intervention is frequently sought in the acute care setting, usually at an urgent care facility or emergency department. Adequate hydration is important during a painful sickling episode. Oral hydration is acceptable if the patient can maintain adequate amounts of fluids; intravenous hydration with dextrose 5% in water (D5W) or dextrose 5% in 0.25 normal saline solution (3 L/m<sup>2</sup>/24 hours) is usually required for sickle crisis. Supplemental oxygen may also be needed.

The use of medication to relieve pain is important (see Chap. 13 for a discussion of pain management). Aspirin is very useful in diminishing mild to moderate pain; it also diminishes inflammation and potential thrombosis (due to its ability to diminish platelet adhesion). Nonsteroidal anti-inflammatory drugs (NSAIDs) are useful for moderate pain or in combination with opioid analgesics. Although no tolerance develops with NSAIDs, a “ceiling effect” does develop whereby an increase in dosage does not increase analgesia. NSAID use must be carefully monitored, because these medications can precipitate renal dysfunction. When opioid analgesics are used, morphine is the medication of choice for acute pain. Patient-controlled analgesia is frequently used.

Chronic pain increases in incidence as the patient ages. Here, the pain is caused by complications from the sickling, such as avascular necrosis of the hip. With chronic pain management, the principal goal is to maximize functioning; pain may not be completely eliminated without sacrificing function. This concept may be difficult for patients to accept; they may need repeated explanations and support from nonjudgmental health care providers. Nonpharmacologic approaches to pain management are crucial in this setting. Examples include physical and occupational therapy, physiotherapy (including the use of heat, massage, and exercise), cognitive and behavioral intervention (including distraction, relaxation, and motivational therapy), and support groups.

Working with patients who have multiple episodes of severe pain can be challenging. It is important for health care providers to realize that patients with sickle cell disease must face a lifelong experience with severe and unpredictable pain. Such pain is disruptive to the person’s level of functioning, including social functioning, and may result in a feeling of helplessness. Patients with inadequate social support systems may have more difficulty coping with chronic pain.

## NURSING PROCESS: THE PATIENT WITH SICKLE CELL CRISIS

Patients in sickle cell crisis should be assessed for factors that could have precipitated the crisis, such as symptoms of infection or dehydration, or situations that promote fatigue or emotional stress.

### Assessment

Patients are asked to recall factors that seemed to precipitate previous crises and measures they use to prevent and manage crises. Pain levels should always be monitored; a pain-rating scale, such as a 0-to-10 scale, best accomplishes this. The quality of the pain (eg, sharp, dull, burning), the frequency of the pain (constant versus intermittent), and factors that aggravate or alleviate the pain

are included in this assessment. If a sickle cell crisis is suspected, the nurse needs to determine whether the pain currently experienced is the same as or different than the pain typically encountered in crisis.

Because the sickling process can interrupt circulation in any tissue or organ, with resultant hypoxia and ischemia, a careful assessment of all body systems is necessary. Particular emphasis is placed on assessing for pain, swelling, and fever. All joint areas are carefully examined for pain and swelling. The abdomen is assessed for pain and tenderness because of the possibility of splenic infarction.

The respiratory system must be assessed carefully, including auscultation of breath sounds, measurement of oxygen saturation levels, and signs of cardiac failure, such as the presence and extent of dependent edema, an increased point of maximal impulse, and cardiomegaly (as seen on chest x-ray). The patient should be assessed for signs of dehydration by a history of fluid intake and careful examination of mucous membranes, skin turgor, urine output, and serum creatinine and blood urea nitrogen values.

A careful neurologic examination is important to elicit symptoms of cerebral hypoxia. However, ischemic findings on MRI or Doppler studies may significantly precede the findings on the physical examination. MRI and Doppler studies are used for early diagnosis and may be more beneficial to improve patient outcome, because therapy can be initiated more promptly.

Because patients with sickle cell anemia are so susceptible to infections, they are assessed for the presence of any infectious process. Particular attention is given to examination of the chest, long bones, and femoral head, because pneumonia and osteomyelitis are especially common. Leg ulcers, which may be infected and are slow to heal, are common.

The extent of anemia (as measured by the hemoglobin level and the hematocrit) and the ability of the marrow to replenish RBCs (as measured by the reticulocyte count) should be monitored and compared with the patient’s baseline values. The patient’s current and past history of medical management should also be assessed, particularly chronic transfusion therapy, hydroxyurea use, and prior treatment for infection.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses for the patient with sickle cell crisis may include:

- Acute pain related to tissue hypoxia due to agglutination of sickled cells within blood vessels
- Risk for infection
- Risk for powerlessness related to illness-induced helplessness
- Deficient knowledge regarding sickle crisis prevention

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications may include:

- Hypoxia, ischemia, infection, and poor wound healing leading to skin breakdown and ulcers
- Dehydration
- Cerebrovascular accident (CVA, brain attack, stroke)
- Anemia
- Renal dysfunction
- Heart failure, pulmonary hypertension, and acute chest syndrome
- Impotence
- Poor compliance
- Substance abuse related to poorly managed chronic pain

## Planning and Goals

The major goals for the patient are relief of pain, decreased incidence of crisis, enhanced sense of self-esteem and power, and absence of complications.

## Nursing Interventions

### MANAGING PAIN

Acute pain during a sickle cell crisis can be severe and unpredictable. The patient's subjective description and rating of pain on a pain scale must guide the use of analgesics, which are valuable in controlling the acute pain of a sickle crisis. Any joint that is acutely swollen should be supported and elevated until the swelling diminishes. Relaxation techniques, breathing exercises, and distraction are helpful for some patients. After the acute painful episode has diminished, aggressive measures should be implemented to preserve function. Physical therapy, whirlpool baths, and transcutaneous nerve stimulation are examples of such modalities.

### PREVENTING AND MANAGING INFECTION

Nursing care focuses on monitoring the patient for signs and symptoms of infection. Prescribed antibiotics should be initiated promptly, and the patient should be assessed for signs of dehydration. If the patient is to take prescribed oral antibiotics at home, he or she must understand the need to complete the entire course of antibiotic therapy and must be able to identify a feasible administration schedule.

### PROMOTING COPING SKILLS

This illness, because of its acute exacerbations that often result in chronic health problems, frequently leaves the patient feeling powerless and with decreased self-esteem. These feelings can be exacerbated by inadequate pain management. The patient's ability to use normal coping resources of physical strength, psychological stamina, and positive self-esteem is dramatically diminished. Enhancing pain management can be extremely useful in establishing a therapeutic relationship based on mutual trust. Nursing care that focuses on the patient's strengths rather than deficits can enhance effective coping skills. Providing the patient with opportunities to make decisions about daily care may increase the patient's feelings of control.

### MINIMIZING DEFICIENT KNOWLEDGE

Patients with sickle cell anemia benefit from understanding what situations can precipitate a sickle cell crisis and the steps they can take to prevent or diminish such crises. Keeping warm and maintaining adequate hydration can be very effective in diminishing the occurrence and severity of attacks. Avoiding stressful situations is more challenging. Group education may be more effective if it is carried out by members of the community who are from the same ethnic group as those with the disease.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Management measures for many of the potential complications were delineated in previous sections. Other measures follow.

### Leg Ulcers

Leg ulcers require careful management and protection from trauma and contamination. Referral to a wound care specialist may facilitate healing and assist with prevention. If leg ulcers fail to heal, skin

grafting may be necessary. Scrupulous aseptic technique is warranted to prevent nosocomial infections.

### Priapism Leading to Impotence

Male patients may develop sudden, painful episodes of priapism (persistent penile erection). The patient is taught to empty his bladder at the onset of the attack, exercise, and take a warm bath. If an episode persists longer than 3 hours, medical attention is recommended. Repeated episodes may lead to extensive vascular thrombosis, resulting in impotence.

### Chronic Pain and Substance Abuse

Many patients have considerable difficulty coping with chronic pain and repeated episodes of sickle crisis. Those who feel they have little control over their health and the physical complications that result from this illness may find it difficult to understand the importance of complying with a prescribed treatment plan. Being nonjudgmental and actively seeking involvement from the patient in establishing a treatment plan are useful strategies.

Some patients with sickle cell anemia develop problems with substance abuse. For many, this abuse results from inadequate management of acute pain during episodes of crisis. Some clinicians suggest that abuse may result from prescribing inadequate amounts of opioid analgesics for an inadequate time. The patient's pain may never be adequately relieved, promoting mistrust of the health care system and (from the patient's perspective) the need to seek care from a variety of sources when the pain is not severe. This cycle is best managed by prevention. Receiving care from a single provider over time is much more beneficial than receiving care from rotating physicians and staff in an emergency department. When crises do arise, the staff in the emergency department should be in contact with the patient's primary health care provider so that optimal management can be achieved. Once the pattern of substance abuse is established, it is very difficult to manage, but continuity of care and establishing written contracts with the patient can be useful management strategies.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

Because patients with sickle cell anemia are typically diagnosed as children, parents participate in the initial education. Based on the parents' education, literacy, socioeconomic level, and interest, teaching focuses on the disease process (including some pathophysiology), treatment, and the assessment and monitoring skills for potential complications (see previous discussion). As the child ages, educational interventions with the child prepare the child to assume more responsibility for self-care.

Vascular access device management and chelation therapy can be taught to most families. Follow-up and care for patients with vascular access devices may also need to be provided by nurses in an outpatient facility or by a home care agency.

#### Continuing Care

The illness trajectory of sickle cell anemia is highly varied, with unpredictable episodes of complications and crises. Care is often provided on an emergency basis, especially for some patients with pain management problems (see previous section). Nurses in all settings used by this patient population need to communicate regularly with each other. Patients need to learn which parameters are important for them to monitor and how

to monitor them. Parameters should also be given as to when to seek urgent care.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Control of pain
  - a. Acute pain is controlled with analgesics
  - b. Uses relaxation techniques, breathing exercises, distraction to help relieve pain
2. Is free of infection
  - a. Has normal temperature
  - b. Shows WBC count within normal range (5000 to 10,000/mm<sup>3</sup>)
  - c. Identifies importance of continuing antibiotics at home (if applicable)
3. Expresses improved sense of control
  - a. Participates in goal setting and in planning and implementing daily activities
  - b. Participates in decisions about care
4. Increases knowledge about disease process
  - a. Identifies situations and factors that can precipitate sickle cell crisis
  - b. Describes lifestyle changes needed to prevent crisis
  - c. Describes the importance of warmth, adequate hydration, and prevention of infection in preventing crisis
5. Absence of complications

## THALASSEMIA

The thalassemias are a group of hereditary disorders associated with defective hemoglobin-chain synthesis. These anemias occur worldwide, but the highest prevalence is found in people of Mediterranean, African, and Southeast Asian ancestry (Hoffman et al., 2000). Thalassemias are characterized by **hypochromia** (an abnormal decrease in the hemoglobin content of RBCs), extreme **microcytosis** (smaller-than-normal RBCs), destruction of blood elements (hemolysis), and variable degrees of anemia.

In thalassemia, the production of one or more globulin chains within the hemoglobin molecule is reduced. When this occurs, the imbalance in the configuration of the hemoglobin causes it to precipitate in the erythroid precursors or the RBCs themselves. This increases the rigidity of the RBCs and thus the premature destruction of these cells.

The thalassemias are classified into two major groups according to the globin chain diminished: alpha and beta. The alpha-thalassemias occur mainly in people from Asia and the Middle East; the beta-thalassemias are most prevalent in Mediterranean populations but also occur in people from the Middle East or Asia. The alpha-thalassemias are milder than the beta forms and often occur without symptoms. The RBCs are extremely microcytic, but the anemia, if present, is mild.

The severity of beta-thalassemia varies depending on the extent to which the hemoglobin chains are affected. Patients with mild forms have a microcytosis and mild anemia. If left untreated, severe beta-thalassemia (thalassemia major, or Cooley's anemia) can be fatal within the first few years of life. If it is treated with regular transfusion of RBCs, patients may survive into their 20s and 30s. Patient teaching during the reproductive years should include pre-conception counseling about the risk of congenital thalassemia major.

## Thalassemia Major

Thalassemia major (Cooley's anemia) is characterized by severe anemia, marked hemolysis, and ineffective erythropoiesis (production of RBCs). With early regular transfusion therapy, growth and development through childhood are facilitated. Organ dysfunction due to iron overload results from the excessive amounts of iron obtained through the RBC transfusions. Regular chelation therapy (eg, via subcutaneous deferoxamine) has reduced the complications of iron overload and prolonged the life of these patients. This disease is potentially curable by BMT if the procedure can be performed before damage to the liver occurs (ie, during childhood).

## GLUCOSE-6-PHOSPHATE DEHYDROGENASE DEFICIENCY

The abnormality in this disorder is in the G-6-PD gene; this gene produces an enzyme within the RBC that is essential for membrane stability. A few patients have inherited an enzyme so defective that they have a chronic hemolytic anemia; however, the most common type of defect results in hemolysis only when the RBCs are stressed by certain situations, such as fever or the use of certain medications. The disorder came to the attention of researchers during World War II, when some soldiers developed hemolysis while taking primaquine, an antimalarial agent. African Americans and people of Greek or Italian origin are those primarily affected by this disorder. The type of deficiency found in the Mediterranean population is more severe than that in the African Caribbean population, resulting in greater hemolysis and sometimes in life-threatening anemia. All types of G-6-PD deficiency are inherited as X-linked defects; therefore, many more men are at risk than women. In the United States, about 12% of African American males are affected. The deficiency is also common in those of Asian ancestry and in certain Jewish populations.

Medications that have hemolytic effects for people with G-6-PD deficiency are oxidant drugs. These medications include antimalarial agents (eg, chloroquine [Aralen]), sulfonamides (eg, trimethoprim and sulfamethoxazole [Septra]), nitrofurantoin (eg, Macrochantin), common coal tar analgesics (including aspirin in high doses), thiazide diuretics (eg, hydrochlorothiazide [HydroDIURIL], chlorothiazide [Diuril]), oral hypoglycemic agents (eg, glyburide [Micronase], metformin [Glucophage]), chloramphenicol (Chloromycetin), and vitamin K (phytonadione [Aqua-Mephyton]). In affected people, a severe hemolytic episode can result from ingestion of fava beans.

## Clinical Manifestations

Patients are asymptomatic and have normal hemoglobin levels and reticulocyte counts most of the time. However, several days after exposure to an offending medication, they may develop pallor, jaundice, and hemoglobinuria (hemoglobin in the urine). The reticulocyte count rises, and symptoms of hemolysis develop. Special stains of the peripheral blood may then disclose Heinz bodies (degraded hemoglobin) within the RBCs. Hemolysis is often mild and self-limited. However, in the more severe Mediterranean type of G-6-PD deficiency, spontaneous recovery may not occur and transfusions may be necessary.

## Assessment and Diagnostic Findings

The diagnosis is made by a screening test or by a quantitative assay of G-6-PD.

## Medical Management

The treatment is to stop the offending medication. Transfusion is necessary only in the severe hemolytic state, which is more commonly seen in the Mediterranean variety of G-6-PD deficiency.

## Nursing Management

The patient should be educated about the disease and given a list of medications to avoid. If hemolysis does develop, nursing interventions are the same as for hemolysis from other causes.

## HEREDITARY SPHEROCYTOSIS

Hereditary spherocytosis is a relatively common (1 in 5,000 people) hemolytic anemia characterized by an abnormal permeability of the RBC membrane; this permits the cells to change into a spherical shape. These RBCs are destroyed prematurely in the spleen. The severity of this hemolytic anemia varies; jaundice can be intermittent, and splenomegaly (enlarged spleen) also can occur. Surgical removal of the spleen is the principal treatment for this disorder.

## IMMUNE HEMOLYTIC ANEMIA

Hemolytic anemias can result from exposure of the RBC to antibodies. Alloantibodies (ie, antibodies against the host, or “self”) result from the immunization of an individual with foreign antigens (eg, the immunization of an Rh-negative person with Rh-positive blood). Alloantibodies tend to be large (IgM type) and cause immediate destruction of the sensitized RBCs, either within the blood vessel (intravascular hemolysis) or within the liver. The most common type of alloimmune hemolytic anemia in adults results from a hemolytic transfusion reaction.

Autoantibodies are developed by an individual for varying reasons. In many instances, the person’s immune system is dysfunctional, so that it falsely recognizes its own RBCs as foreign and produces antibodies against them. This mechanism is seen in people with chronic lymphocytic leukemia (CLL). Another mechanism is a deficiency in suppressor lymphocytes, which normally prevent antibody formation against a person’s own antigens. Autoantibodies tend to be of the IgG type. The RBCs are sequestered in the spleen and destroyed by the macrophages outside the blood vessel (extravascular hemolysis).

Autoimmune hemolytic anemias can be classified based on the body temperature involved when the antibodies react with the RBC antigen. Warm-body antibodies bind to RBCs most actively in warm conditions (37°C); cold-body antibodies react in cold (0°C). Most autoimmune hemolytic anemias are the warm-body type. Autoimmune hemolytic anemia is associated with other disorders in most cases (eg, medication exposure, lymphoma, CLL, other malignancy, collagen vascular disease, autoimmune disease, infection). In idiopathic autoimmune hemolytic states, the reason why the immune system produces the antibodies is not known. All ages and genders are equally vulnerable to this form, whereas the incidence of secondary forms is greater in people older than 45 years of age and in females.

## Clinical Manifestations

Clinical manifestations can vary, and they usually reflect the degree of anemia. The hemolysis may be very mild, so that the patient’s marrow compensates adequately and the patient is asymptomatic. At the other extreme, the hemolysis can be so severe that the resul-

tant anemia is life-threatening. Most patients complain of fatigue and dizziness. Splenomegaly is the most common physical finding, occurring in more than 80% of patients; hepatomegaly, lymphadenopathy, and jaundice are also common.

## Assessment and Diagnostic Findings

The laboratory tests show a low hemoglobin level and hematocrit, most often with an accompanying increase in the reticulocyte count. RBCs appear abnormal; spherocytes are common. The serum bilirubin level is elevated, and if the hemolysis is severe, the haptoglobin level is low or absent. The Coombs test (also referred to as the direct antiglobulin test [DAT]), which detects antibodies on the surface of RBCs, shows a positive result.

## Medical Management

Any possibly offending medication should be immediately discontinued. The treatment consists of high doses of corticosteroids (1 mg/kg per day) until hemolysis decreases. Corticosteroids decrease the macrophage’s ability to clear the antibody-coated RBCs. If the hemoglobin level returns toward normal, usually after several weeks, the corticosteroid dose can be lowered or, in some cases, tapered and discontinued. However, corticosteroids rarely produce a lasting remission. In severe cases, blood transfusions may be required. Because the antibody may react with all possible donor cells, careful blood typing is necessary, and the transfusion should be administered slowly and cautiously.

Splenectomy (removal of the spleen) removes the major site of RBC destruction; therefore, splenectomy may be performed if corticosteroids do not produce a remission. If neither corticosteroid therapy nor splenectomy is successful, immunosuppressive agents may be administered. The two immunosuppressive agents most frequently used are cyclophosphamide (eg, Cytoxan), which has a more rapid effect but more toxicity, or azathioprine (Imuran), which has a less rapid effect but less toxicity. The synthetic androgen danazol (Cyclomen, Danocrine) can be useful in some patients, particularly in combination with corticosteroids. The mechanism for this success is unclear. If corticosteroids or immunosuppressive agents are used, the taper must be very gradual to prevent a rebound “hyperimmune” response and exacerbation of the hemolysis. Immunoglobulin administration is effective in about one third of patients, but the effect is transient and the medication is expensive. Transfusions may be necessary if the anemia is severe; it may be extremely difficult to cross-match samples of available units of RBCs with that of the patient.

For patients with cold-antibody hemolytic anemia, treatment may not be required, other than to advise the patient to keep warm; relocation to a warm climate may be necessary.

## Nursing Management

Patients may have great difficulty understanding the pathologic mechanisms underlying the disease and need repeated explanations in terms they can understand. Patients who have had a splenectomy should be vaccinated against pneumococcal infections (Pneumovax) and informed that they are permanently at greater risk for infection. Patients receiving long-term corticosteroid therapy, particularly those with concurrent diabetes or hypertension, need careful monitoring. They must understand the need for this medication and the importance of never abruptly discontinuing it. A written explanation and a tapering schedule should be provided, and adjustments based on hemoglobin levels

should be emphasized. Similar teaching should be provided when immunosuppressive agents are used. Corticosteroid therapy is not without significant risk, and patients need to be monitored closely for complications. The short- and long-term complications of corticosteroid therapy are presented in Chart 33-4 and in Chap. 42.

**NURSING ALERT** It can be difficult to cross-match blood when antibodies are present. If imperfectly cross-matched RBCs must be transfused, the nurse begins the infusion very slowly (10 to 15 mL over 20 to 30 minutes) and monitors the patient very closely for signs and symptoms of a hemolytic transfusion reaction.

## HEREDITARY HEMOCHROMATOSIS

Hemochromatosis is a genetic condition in which iron is abnormally (excessively) absorbed from the gastrointestinal tract. The excessive iron is deposited in various organs, particularly the liver,

myocardium, testes, thyroid, and pancreas. Eventually, the affected organs become dysfunctional. The actual incidence of hemochromatosis is unknown; however, hereditary hemochromatosis is diagnosed in 0.5% of the population in the United States (ie, 1 million people). Recent data suggest that this defect may be a common cause of diabetes (Schechter, et al., 2000). Because of their natural loss of iron through menses, women are less affected than men.

Because the accumulation of iron in body organs occurs gradually, there often is no evidence of tissue injury until middle age. Symptoms of weakness, lethargy, arthralgia, weight loss, and loss of libido are common. The skin may be hyperpigmented with melanin deposits (occasionally **hemosiderin**, an iron-containing pigment) and appears bronze in color. Cardiac dysrhythmias and cardiomyopathy can occur, with resulting dyspnea and edema. Endocrine dysfunction is manifested as hypothyroidism, diabetes mellitus, and hypogonadism (testicular atrophy, diminished libido, and impotence). A significant effect of hemochromatosis is the

### Chart 33-4 • PHARMACOLOGY Complications Associated with Corticosteroid Therapy

Whenever a patient begins a course of corticosteroid therapy, the potential for complications is great. Dosing regimens vary widely, depending on the underlying hematologic condition and the patient's response to the medication. For example, several chemotherapy protocols include high doses of corticosteroids for a period of several days. After that time, the medication is stopped abruptly without tapering the dosage. In other conditions, such as idiopathic thrombocytopenic purpura or hemolytic anemias, the corticosteroids are very carefully tapered to prevent a flare up of the underlying disease. With the exception of patients with preexisting conditions such as diabetes, hypertension, and osteoporosis, it is difficult to predict which complications will occur in a given patient. Patients who receive high doses of corticosteroids for longer than a few weeks should be screened for symptoms related to the potential complications listed here. If at all possible, patients who require long-term corticosteroid use should be switched to an alternate-day dosing schedule; this method may diminish the severity of complications that arise.

#### Short-Term Complications

##### Fluid and Electrolyte Complications

- Fluid retention
- Sodium retention
- Potassium loss
- Hypokalemic alkalosis
- Hypertension

##### Endocrine Complications

- Decreased carbohydrate tolerance
- Diabetes mellitus
- Uncontrolled glucose levels in diabetes mellitus

##### Neurologic Complications

- Headache

##### Musculoskeletal Complications

- Muscle weakness

##### Psychologic Complications

- Depression
- Euphoria
- Mood swings
- Insomnia
- Psychosis

#### Long-Term Complications

##### Endocrine Complications

- Decreased adrenocortical activity
- Decreased ability to respond to stress
- Decreased carbohydrate tolerance
- Decreased growth rate (children)
- Cushingoid state
- Menstrual irregularities
- Increased sweating

##### Metabolic Complications

- Protein catabolism causing negative nitrogen balance

##### Gastrointestinal Complications

- Gastritis
- Ulcerative esophagitis
- Peptic ulcer
- Pancreatitis

##### Musculoskeletal Complications

- Decreased muscle mass
- Osteoporosis
- Vertebral compression fracture
- Pathologic fracture
- Aseptic necrosis of femoral and humeral heads

##### Neurologic Complications

- Vertigo
- Increased intracranial pressure
- Seizures

##### Ophthalmic Complications

- Cataract formation
- Glaucoma
- Exophthalmos

##### Dermatologic Complications

- Impaired wound healing
- Ecchymoses
- Increased skin fragility
- Decreased skin thickness
- Petechiae

##### Immunologic Complications

- Decreased response to infection
- Masked signs of (early stages of infection)
- Suppressed reaction to skin tests
- Increased risk for opportunistic infection (eg, *Pneumocystis*, herpes zoster)

development of hepatocellular carcinoma in one third of those affected. CBC values are typically normal. The most useful laboratory findings are an elevated serum iron level and high transferrin saturation (more than 60% in men, more than 50% in women). The definitive diagnostic test is a liver biopsy. Recently, a mutation in the *HFE* gene has been shown to occur in most patients with hereditary hemochromatosis (Gochee & Powell, 2001). Patients who are homozygous for the gene are at high risk for development of the disorder.

### Medical Management

Therapy involves the removal of excess iron via therapeutic phlebotomy (removal of whole blood from a vein). Each unit of blood removed results in a decrease of 200–250 mg of iron. The objective typically is to reduce the serum ferritin to less than 50 µg/L and the transferrin saturation to 35% or less. To achieve this, a frequent phlebotomy schedule is required (1 to 2 units weekly), with a gradual reduction in frequency of phlebotomies over a 1- to 3-year period. After 1 to 3 years, the frequency of phlebotomy can be reduced to 1 unit of blood every several months to prevent reaccumulation of iron deposits. Removal of excess iron appears to diminish the severity of diabetes and skin hyperpigmentation; cardiac function also tends to improve.

### Nursing Management

Patients with hemochromatosis often believe that it is important to limit their dietary intake of iron, although this management method has been shown to be very ineffective and need not be encouraged. However, it is important for these patients to avoid any additional insults to the liver, such as alcohol abuse. Serial screening tests for hepatoma are important; alpha-fetoprotein is used for this purpose. Other body systems should be monitored for signs of organ dysfunction, particularly the endocrine and cardiac systems. These systems should also be screened routinely for dysfunction so that appropriate management can be implemented quickly. Because patients with hemochromatosis require frequent phlebotomies, problems with venous access are common. Patients who are heterozygous for the *HFE* do not develop the disease but need to be counseled that they can transmit the gene to their children.

## The Polycythemias

**Polycythemia** refers to an increased volume of RBCs. It is a term used when the hematocrit is elevated (to more than 55% in males, more than 50% in females). Dehydration (decreased volume of plasma) can cause an elevated hematocrit, but not typically to the level to be considered polycythemia. Polycythemia is classified as either primary or secondary.

### POLYCYTHEMIA VERA

Polycythemia vera, or primary polycythemia, is a proliferative disorder in which the myeloid stem cells seem to have escaped normal control mechanisms. The bone marrow is hypercellular, and the RBC, WBC, and platelet counts in the peripheral blood are elevated. However, the RBC elevation is predominant; the hematocrit can exceed 60%. This phase can last for an extended period (10 years or longer). The spleen resumes its embryonic function of hematopoiesis and enlarges. Over time, the bone marrow may become fibrotic, with a resultant inability to produce as many cells

(“burnt out” or spent phase). The disease evolves into myeloid metaplasia with myelofibrosis or AML in a significant proportion of patients; this form of AML is usually refractory to standard treatments (Hoffman, et al., 2000). The median survival time exceeds 15 years (Gruppo Italiano Studio Policitemia, 1995).

### Clinical Manifestations

Patients typically have a ruddy complexion and splenomegaly (enlarged spleen). The symptoms result from the increased blood volume (headache, dizziness, tinnitus, fatigue, paresthesias, and blurred vision) or from increased blood viscosity (angina, claudication, dyspnea, and thrombophlebitis), particularly if the patient has atherosclerotic blood vessels. Another common and bothersome problem is generalized pruritus, which may be caused by histamine release due to the increased number of basophils. Erythromelalgia, a burning sensation in the fingers and toes, may be reported and is only partially relieved by cooling.

### Assessment and Diagnostic Findings

Diagnosis is made by finding an elevated RBC mass (a nuclear medicine procedure), a normal oxygen saturation level, and an enlarged spleen. Other factors useful in establishing the diagnosis include elevated WBC and platelet counts. The erythropoietin level is not as low as would be expected with an elevated hematocrit; it is normal or only slightly low. Causes of secondary erythrocytosis should not be present (see later discussion).

### Complications

Patients with polycythemia vera are at increased risk for thromboses resulting in a CVA (brain attack, stroke) or heart attack (MI); thrombotic complications are the most frequent cause of death. Bleeding is also a complication, possibly due to the fact that the platelets (often very large) are somewhat dysfunctional. The bleeding can be significant and can occur in the form of nosebleeds, ulcers, and frank gastrointestinal bleeding.

### Medical Management

The objective of management is to reduce the high blood cell mass. Phlebotomy is an important part of therapy and can be performed repeatedly to keep the hematocrit within normal range. This is achieved by removing enough blood (initially 500 mL once or twice weekly) to deplete the patient’s iron stores, thereby rendering the patient iron deficient and consequently unable to continue to manufacture RBCs excessively. Patients need to be instructed to avoid iron supplements, including those within multivitamin supplements. If the patient has an elevated uric acid concentration, allopurinol (Zyloprim) is used to prevent gouty attacks. Antihistamines are not particularly effective in controlling itching. If the patient develops ischemic symptoms, dipyridamole (eg, Persantine) is sometimes used. Radioactive phosphorus (<sup>32</sup>P) or chemotherapeutic agents (eg, hydroxyurea [Hydrea]) can be used to suppress marrow function, but they may increase the risk for leukemia. Patients receiving hydroxyurea appear to have a lower incidence of thrombotic complications; this may result from a more controlled platelet count. The use of aspirin to prevent thrombotic complications is controversial. Low-dose aspirin is frequently used in patients with cardiovascular disease, but even this dose is often avoided in patients with prior bleeding, especially bleeding from the gastrointestinal tract. Aspirin

is also useful in diminishing pain associated with erythromelalgia. Anagrelide (Agrylin) inhibits platelet aggregation and can also be useful in controlling the thrombocytosis associated with polycythemia vera. Interferon alfa-2b (Intron-A) has also been studied, but it may be difficult for patients to tolerate due to the frequent side effects experienced (Tefferi et al., 2000; Lengfelder, Berger, & Hehlmann, 2000).

## Nursing Management

The nurse's role is primarily that of educator. Risk factors for thrombotic complications should be assessed, and patients should be instructed regarding the signs and symptoms of thrombosis. Patients with a history of bleeding are usually advised to avoid aspirin and aspirin-containing medications, because these medications alter platelet function. Minimizing alcohol intake should also be emphasized to further diminish any risk for bleeding. For pruritus, the nurse may recommend bathing in tepid or cool water, along with applications of cocoa butter-based lotions and bath products.

## SECONDARY POLYCYTHEMIA

Secondary polycythemia is caused by excessive production of erythropoietin. This may occur in response to a reduced amount of oxygen, which acts as a hypoxic stimulus, as in cigarette smoking, chronic obstructive pulmonary disease, or cyanotic heart disease, or in nonpathologic conditions such as high altitude. It can also result from certain hemoglobinopathies in which the hemoglobin has an abnormally high affinity for oxygen (eg, hemoglobin Chesapeake). Secondary polycythemia can also occur from neoplasms (eg, renal cell carcinoma) that stimulate erythropoietin production.

## Medical Management

Management of secondary polycythemia may not be necessary; when it is, it involves treating the primary problem. If the cause cannot be corrected (eg, by treating the renal cell carcinoma or improving pulmonary function), therapeutic phlebotomy may be necessary in symptomatic patients to reduce blood viscosity and volume.

## Leukopenia and Neutropenia

Leukopenia, a condition in which there are fewer WBCs than normal, results from neutropenia (diminished neutrophils) or lymphopenia (diminished lymphocytes). Even if other types of WBCs (eg, monocytes, basophils) are diminished, their numbers are too few to reduce the total WBC count significantly. Lymphopenia (lymphocytes less than 1500/mm<sup>3</sup>) can result from ionizing radiation, long-term use of corticosteroids, uremia, some neoplasms (eg, breast and lung cancers, advanced Hodgkin's disease), and some protein-losing enteropathies (in which the lymphocytes within the intestines are lost).

## NEUTROPENIA

Neutropenia (neutrophils less than 2000/mm<sup>3</sup>) results from decreased production of neutrophils or increased destruction of these cells (Chart 33-5). Neutrophils are essential in preventing and limiting bacterial infection. A patient with neutropenia is at increased risk for infection, both exogenous and endogenous (the gastro-

Chart  
33-5

### Causes of Neutropenia

#### Decreased Production of Neutrophils

- Aplastic anemia, due to medications or toxins
- Metastatic cancer, lymphoma, leukemia
- Myelodysplastic syndromes
- Chemotherapy
- Radiation therapy

#### Ineffective Granulocytopoiesis

- Megaloblastic anemia

#### Increased Destruction of Neutrophils

- Hypersplenism
- Medication-induced\*
- Immunologic disease (eg, systemic lupus erythematosus [SLE])
- Viral disease (eg, infectious hepatitis, mononucleosis)
- Bacterial infections

\*Formation of antibody to medication, leading to a rapid decrease in neutrophils.

intestinal tract and skin are common endogenous sources). The risk for infection is based not only on the severity of the neutropenia (low neutrophil count), but also on the duration of the neutropenia. The actual number of neutrophils, known as the **absolute neutrophil count (ANC)**, is determined by a simple mathematical calculation using data obtained from the CBC and differential test (Chart 33-6). The risk of infection increases proportionately with the decrease in neutrophil count. The risk is significant when the ANC is less than 1000, is high when it is less than 500, and is almost certain when it is less than 100. The risk

Chart  
33-6

### Calculating the Absolute Neutrophil Count (ANC)

$$\text{ANC} = \frac{\text{Total WBC count} \times (\% \text{ neutrophils} + \% \text{ bands})}{100}$$

Normally, the neutrophil count is greater than 2000/mm<sup>3</sup>. The actual (or absolute) neutrophil count (ANC) is calculated using the above formula.

For example, if the total white blood cell (WBC) count is 3000/mm<sup>3</sup> with 72% neutrophils and 3% bands, the ANC would be calculated as follows:

$$\text{ANC} = \frac{3000(72 + 3)}{100} = 2250$$

This result is not indicative of neutropenia, because the ANC is greater than 2000 despite the low total WBC count (3000/mm<sup>3</sup>).

Conversely, in the following example, neutropenia is evident despite a normal WBC count (5500/mm<sup>3</sup>) with 8% neutrophils and 0% bands:

$$\text{ANC} = \frac{5500(8 + 0)}{100} = 440$$

Here, the ANC is severely low (440) despite the normal total WBC count (5500/mm<sup>3</sup>).

When evaluating neutropenia, it is important to calculate the ANC and not to rely solely on the total WBCs and percentage of neutrophils alone.

of developing infection increases with the length of time during which neutropenia persists, even if it is fairly mild. Conversely, even a severe neutropenia may not result in infection if the duration of the neutropenia is brief, as is often seen after chemotherapy (Chart 33-7).

## Clinical Manifestations

There are no definite symptoms of neutropenia until the patient becomes infected. Routine CBC with differential tests, such as those obtained after chemotherapy treatment, can reveal neutropenia before the onset of infection.

## Medical Management

Treatment of the neutropenia varies depending on its cause. If the neutropenia is medication induced, the offending agent needs to be stopped, if possible. Treatment of an underlying neoplasm can temporarily make the neutropenia worse, but with bone marrow recovery treatment may improve it. Corticosteroids may be used if the cause is an immunologic disorder. The use of growth factors such as G-CSF or granulocyte/macrophage colony-stimulating factor (GM-CSF) can be effective in increasing neutrophil production when the cause of the neutropenia is decreased production. Withholding or reducing the dose of chemotherapy or radiation therapy may be required when the neutropenia is caused by these treatments; however, in the case of potentially curative therapy, administration of growth factor is considered to be preferable, so that the maximum antitumor effect can be achieved. Should the neutropenia be accompanied by fever, the patient is automatically considered to be infected and usually is admitted to the hospital. Cultures of blood, urine, and sputum should be obtained, as well as a chest radiograph. To ensure adequate therapy

against the invading infectious organisms, broad-spectrum antibiotics are initiated as soon as the samples for culture are obtained, although the medications may be changed after culture and sensitivity results become available.

## Nursing Management

Nurses in all settings have a crucial role in assessing the severity of neutropenia and in preventing and managing infectious complications. Patient teaching is equally important, particularly in the outpatient setting, so that the patient can implement appropriate self-care measures and know when and how to seek medical care (Chart 33-8). Patients at risk for neutropenia should have blood drawn for CBCs; the frequency is based on the suspected severity and duration of the neutropenia. Nurses need to be able to calculate the ANC (see Chart 33-6) and to assess the severity of neutropenia and the risk for infection. Chart 33-9 identifies nursing interventions related to neutropenia.

## Leukocytosis and the Leukemias

The term *leukocytosis* refers to an increased level of WBCs in the circulation. Typically, only one specific cell type is increased. Usually, because the proportions of several types of WBCs are small (eg, eosinophils, basophils, monocytes), only an increase in neutrophils or lymphocytes can be great enough to elevate the total WBC count. Although leukocytosis can be a normal response to increased need (eg, in acute infection), the elevation in WBCs should decrease as the need decreases. A prolonged or progressively increasing elevation in WBCs is abnormal and should be evaluated. A significant cause for persistent leukocytosis is malignancy.

Hematopoiesis is characterized by a rapid, continuous turnover of cells. Normally, production of specific blood cells

Chart 33-7

### Risk Factors for Development of Infection and Bleeding in Patients with Hematologic Disorders

#### Risk for Infection

*Severity of neutropenia:* Risk of infection is proportional to duration and severity of neutropenia

*Duration of neutropenia:* Increased duration leads to increased risk of infection

*Nutritional status:* Decreased protein stores lead to decreased immune response and energy

*Deconditioning:* Decreased mobility leads to decreased respiratory effort, leading to increased pooling of secretions

*Lymphocytopenia; disorders of lymphoid system (chronic lymphocytic leukemia [CLL], lymphoma, myeloma):* Decreased cell-mediated and humoral immunity

*Invasive procedures:* Break in skin integrity leads to increased opportunity for organisms to enter blood system

*Hypogammaglobulinemia:* Decreased antibody formation

*Poor hygiene:* Increased organisms on skin, mucous membranes

*Poor dentition; mucositis:* Decreased endothelial integrity leads to increased opportunity for organisms to enter blood system

*Antibiotic therapy:* Increased risk for superinfection, often fungal

*Certain medications:* See text

#### Risk for Bleeding

*Severity of thrombocytopenia:* Risk increases when platelet count decreases; usually not a significant risk until platelet count is lower

than 20,000/mm<sup>3</sup>; lower than 50,000/mm<sup>3</sup> when invasive procedure performed

*Duration of thrombocytopenia:* Risk increases when duration increases (eg, risk is less when duration is transient after chemotherapy than when duration is permanent with poor marrow production)

*Sepsis:* Mechanism unknown; appears to cause increased platelet consumption

*Increased intracranial pressure (eg, vomiting/coughing):* Increased blood pressure leads to rupture of blood vessels

*Liver dysfunction:* Decreased synthesis of clotting factors

*Renal dysfunction:* Decreased platelet function

*Dysproteinemia:* Protein coats surface of platelet, leading to decreased platelet function; protein causes increased viscosity, which leads to increased stretching of capillaries and thus increased bleeding

*Alcohol abuse:* Suppressive effect on marrow leads to decreased platelet production, decreased platelet function; decreased liver function, resulting in decreased production of clotting factors

*Splenomegaly:* Increased platelet destruction; spleen traps circulating platelets

*Concurrent medications:* See text

Chart 33-8

## Home Care Checklist • The Patient at Risk for Infection

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Describe consequences of alterations in neutrophils, lymphocytes, immunoglobulins, or their sources.	✓	✓
• Verbalize the rationale for being at risk for infection.	✓	✓
• Identify signs and symptoms of infection.	✓	✓
• Demonstrate how to monitor for signs of infection.	✓	✓
• Describe to whom, how, and when to report signs of infection.	✓	✓
• Identify appropriate behaviors to take to prevent infection: <ul style="list-style-type: none"> <li>– Maintain good hand hygiene technique, total body hygiene, and skin integrity.</li> <li>– Avoid fresh flowers, plants, garden work (soil), bird cages, and litter boxes.</li> <li>– Avoid fresh salads and unpeeled fruits or vegetables.</li> <li>– Maintain a high-calorie, high-protein diet, with fluid intake of 3000 mL (unless fluids are restricted).</li> <li>– Avoid people with infections, crowds.</li> <li>– Perform deep breathing, use incentive spirometer every 4 hr while awake.</li> <li>– Provide adequate lubrication with gentle vaginal manipulation during sexual intercourse; avoid anal intercourse.</li> </ul>	✓	✓
• Describe appropriate actions to take should infection occur.	✓	✓

from their stem cell precursors is carefully regulated according to the body's needs. If the mechanisms that control the production of these cells are disrupted, the cells can proliferate to an excessive, potentially dangerous degree. Hematopoietic malignancies are often classified according to the cells involved. **Leukemia**, literally “white blood,” is a neoplastic proliferation of one particular cell type (granulocytes, monocytes, lymphocytes, or megakaryocytes). The defect originates in the hematopoietic stem cell, the myeloid, or the lymphoid stem cell. The lymphomas are neoplasms of lymphoid tissue, usually derived from B lymphocytes. Multiple myeloma is a malignancy of the most mature form of B lymphocyte, the plasma cell.

The common feature of the leukemias is an unregulated proliferation of WBCs in the bone marrow. In acute forms (or late stages of chronic forms), the proliferation of leukemic cells leaves little room for normal cell production. There can also be a proliferation of cells in the liver and spleen (extramedullary hematopoiesis). With acute forms, there can be infiltration of other organs, such as the meninges, lymph nodes, gums, and skin. The cause of leukemia is not fully known, but there is some evidence that genetic influence and viral pathogenesis may be involved. Bone marrow damage from radiation exposure or from chemicals such as benzene and alkylating agents (eg, melphalan [Alkeran]) can cause leukemia.

The leukemias are commonly classified according to the stem cell line involved, either lymphoid or myeloid. They are also classified as either acute or chronic, based on the time it takes for symptoms to evolve and the phase of cell development that is halted (ie, with few WBCs differentiating beyond that phase).

In acute leukemia, the onset of symptoms is abrupt, often occurring within a few weeks. WBC development is halted at the blast phase, so that most WBCs are undifferentiated or are blasts. Acute leukemia progresses very rapidly; death occurs within weeks to months without aggressive treatment. In chronic leukemia, symptoms evolve over a period of months to years, and the majority of WBCs produced are mature. Chronic leukemia progresses more slowly; the disease trajectory can extend for years.

## ACUTE MYELOID LEUKEMIA (AML)

AML results from a defect in the hematopoietic stem cell that differentiates into all myeloid cells: monocytes, granulocytes (neutrophils, basophils, eosinophils), erythrocytes, and platelets. All age groups are affected; the incidence rises with age, with a peak incidence at age 60 years. AML is the most common nonlymphocytic leukemia.

The prognosis is highly variable and is not consistently based on patient or disease variables. Patients with AML have a potentially curable disease. However, patients who are older or have a more undifferentiated form of AML tend to have a worse prognosis. Those who have preexisting MDS or who had previously received alkylating agents for cancer (secondary AML) have a much worse prognosis; the leukemia tends to be more resistant to treatment, resulting in a much shorter duration of remission. With treatment, these patients survive an average of less than 1 year, with death usually a result of infection or hemorrhage. Patients receiving supportive care also usually survive less than 1 year, again dying from infection or bleeding.

## Clinical Manifestations

Most of the signs and symptoms evolve from insufficient production of normal blood cells. Fever and infection result from neutropenia, weakness and fatigue from anemia, and bleeding tendencies from thrombocytopenia. The proliferation of leukemic cells within organs leads to a variety of additional symptoms: pain from an enlarged liver or spleen, hyperplasia of the gums, and bone pain from expansion of marrow.

## Assessment and Diagnostic Findings

The disorder develops without warning, with symptoms occurring over a period of weeks to months. CBC results show a decrease in both erythrocytes and platelets. Although the total leukocyte count can be low, normal, or high, the percentage of normal cells is usually vastly decreased. A bone marrow analysis shows an ex-

Chart

## Neutropenia Precautions

**Nursing Diagnosis**

Risk for infection secondary to impaired immunoincompetence due to:

- Diminished neutrophil count (see below) secondary to bone marrow invasion or hypocellularity secondary to medications
- Dysfunctional neutrophils (eg, secondary to myelodysplastic syndrome [MDS])
- Dysfunctional or diminished lymphocytes
- Hypogammaglobulinemia
- Diminished immune response or anergy
- Malnutrition
- Surgery or invasive procedures
- Antibiotic therapy (increased risk for superimposed infection)
  - Neutropenic, infected patients often do *not* exhibit the classic signs of inflammation/infection (ie, redness, cloudiness of any drainage); the only initial sign may be fever (and it often occurs later in the infectious process with neutropenia).
  - Skin and mucous membranes are the body's first line of defense against infection; loss of endothelial cell integrity allows organisms to enter the blood and lymph system.

**Assessment****Patient**

Assess the following areas thoroughly every shift or visit (with spot checks throughout shift if hospitalized) and notify physician of any signs of infection or worsening of status:

- **Skin:** Check for tenderness, edema, breaks in skin integrity, moisture, drainage, lesions (especially under breasts, axillae, groin, skin folds, bony prominences, perineum); check all puncture sites (eg, intravenous sites) for signs and symptoms of inflammation/infection.
- **Oral mucosa:** Check for moisture, lesions, color (check palate, tongue, buccal mucosa, gums, lips, oropharynx).
- **Respiratory:** Check for presence of cough, sore throat; auscultate breath sounds.
- **Gastrointestinal:** Check for abdominal discomfort/distention, nausea, change in bowel pattern; auscultate bowel sounds.
- **Genitourinary:** Check for dysuria, urgency, frequency; check urine for color, clarity, odor.
- **Neurologic:** Check for complaints of headache, neck stiffness, visual disturbances; assess level of consciousness, orientation, behavior.
- **Temperature:** Check every 4 hr or every visit; call primary health care provider if temperature is  $>38^{\circ}\text{C}$  ( $>101^{\circ}\text{F}$ ), fever is unresponsive to acetaminophen, or patient shows a decline in hemodynamic status.

**Diagnostic Studies**

- Monitor complete blood count (CBC) and differential daily (especially absolute neutrophil count [ANC], lymphocyte count).
- Call physician if ANC is  $<1000$ , significantly different from previous count, or whenever patient becomes symptomatic (eg, febrile).
- Monitor globulin, albumin, total protein levels.
- Monitor all culture and sensitivity reports.
- Monitor radiology reports.

**Nursing Interventions****Environment and Staff**

- **Thorough hand hygiene must be done by everyone before entering patient's room each and every time.**

- Allow no one with a cold or sore throat to care for the patient or to enter room, or come in contact with patient at home.
- Care for neutropenic patients before caring for other patients (as much as possible).
- Use private room for patient if ANC is  $<1000$ .
- Allow no fresh flowers (stagnant water).
- Change water in containers every shift (include  $\text{O}_2$  humidification systems every 24 hr).
- Ensure room is cleaned daily.

**Dietary**

- Provide low microbial diet.
- Eliminate fresh salads and unpeeled fresh fruits or vegetables.

**Patient**

- Avoid suppositories, enemas, rectal temperatures.
- Practice deep breathing (with incentive spirometer) every 4 hr while awake.
- Ambulate; wear high-efficiency particulate air (HEPA) filter mask if neutropenia is severe.
- Prevent skin dryness with water-soluble lubricants, especially in high-risk areas (eg, lips, corners of mouth, elbows, feet, bony prominences).

**Hygiene**

- Provide meticulous total body hygiene daily (preferably with antimicrobial solution), including perineal care after every bowel movement.
- Provide thorough oral hygiene after meals and every 4 hr while awake; warm saline, or salt and soda solution, is effective; avoid use of lemon-glycerine swabs, commercial mouthwashes, and hydrogen peroxide.

**Intravenous (IV) Therapy**

- Do not use plastic cannulas for peripheral IVs when ANC is  $<500$  (if possible per agency); a central vascular access device is preferred for long-term or intensive IV therapy.
- Inspect IV sites every shift; monitor closely for any discomfort; erythema may not be present.
- Maintain meticulous IV site care.
- Cleanse skin with antimicrobial solution before venipuncture (unless patient is allergic).
- Moisture-vapor-permeable dressings are permissible with strict adherence to institutional protocol.
- Change IV tubing per institution policy, using aseptic technique.
- Administer antimicrobial agents on time.

**Expected Patient Outcomes**

- Patient demonstrates an absence of infection as evidenced by an absence of fever, chills, inflammation, drainage, cough, dyspnea, sore throat, dysuria, or urinary frequency.
- Patient demonstrates an absence of infection as evidenced by the presence of vital signs within normal limits, including intact neurologic status and intact skin.

**Duration of Evaluation**

Until patient is no longer neutropenic and any infection is resolved.

cess of immature blast cells (more than 30%). AML can be further classified into seven different subgroups, based on cytogenetics, histology, and morphology (appearance) of the blasts. The actual prognosis varies somewhat between subgroups, but the clinical course and treatment differ substantially with only one subtype, acute promyelocytic leukemia (APL, or AML-M3). Patients with this leukemia often have significantly more problems with bleed-

ing, in that they have underlying coagulopathy and a higher incidence of disseminated intravascular coagulation (DIC).

**Complications**

Complications of AML include bleeding and infection, the major causes of death. The risk of bleeding correlates with the level of

platelet deficiency (thrombocytopenia). The low platelet count can result in **ecchymoses** (bruises) and **petechiae** (pinpoint red or purple hemorrhagic spots on the skin). Major hemorrhages also may develop when the platelet count drops to less than 10,000/mm<sup>3</sup>. The most common sites of bleeding are gastrointestinal, pulmonary, and intracranial. For undetermined reasons, fever and infection also increase the likelihood of bleeding.

Because of the lack of mature and normal granulocytes, patients with leukemia are always threatened by infection. The likelihood of infection increases with the degree and duration of neutropenia; neutrophil counts that persist at less than 100/mm<sup>3</sup> make the chances of systemic infection extremely high. As the duration of severe neutropenia increases, the patient's risk for developing fungal infection also increases.

## Medical Management

The overall objective of treatment is to achieve complete remission, in which there is no detectable evidence of residual leukemia remaining in the bone marrow. Attempts are made to achieve remission by the aggressive administration of chemotherapy, called induction therapy, which usually requires hospitalization for several weeks. Induction therapy typically involves high doses of cytarabine (Cytosar, Ara-C) and daunorubicin (DaunoXome) or mitoxantrone (Novantrone) or idarubicin (Idamycin); sometimes etoposide (VP-16, VePesid) is added to the regimen. The choice of agents is based on the patient's physical status and history of prior antineoplastic treatment.

The aim of induction therapy is to eradicate the leukemic cells, but this is often accompanied by the eradication of normal types of myeloid cells. Thus, the patient becomes severely neutropenic (an ANC of 0 is not uncommon), anemic, and thrombocytopenic (a platelet count of less than 10,000/mm<sup>3</sup> is common). During this time, the patient is typically very ill, with bacterial, fungal, and occasionally viral infections, bleeding, and severe mucositis, which causes diarrhea and a marked decline in the ability to maintain adequate nutrition. Supportive care consists of administering blood products (RBCs and platelets) and promptly treating infections. The use of granulocytic growth factors, either G-CSF (filgrastim [Neupogen]) or GM-CSF (sargramostim [Leukine]), can shorten the period of significant neutropenia by stimulating the bone marrow to produce leukocytes more quickly; these agents do not appear to increase the risk of producing more leukemic cells.

When the patient has recovered from the induction therapy (ie, the WBC and platelet counts have returned to normal and any infection has resolved), the patient typically receives consolidation therapy (postremission therapy). The goal of consolidation therapy is to eliminate any residual leukemia cells that are not clinically detectable, thereby diminishing the chance for recurrence. Multiple treatment cycles of various agents are used, usually containing some form of cytarabine (eg, Cytosar, Ara-C). Frequently, the patient receives one cycle of treatment that is almost the same, if not identical, to the induction treatment but uses lower dosages (therefore resulting in less toxicity).

Despite the aggressive use of chemotherapy, the likelihood of remaining in remission for a prolonged period is not great. About 70% of patients with AML experience a relapse (Hiddemann & Buchner, 2001). A recent study of long-term survival of patients with AML found that only 11% survived 10 years or longer (Micallef et al., 2001).

Another aggressive treatment option is bone marrow transplantation (BMT) or peripheral blood stem cell transplantation

(PBSCT). When a suitable tissue match can be obtained, the patient embarks on an even more aggressive regimen of chemotherapy (sometimes in combination with radiation therapy), with the treatment goal of destroying the hematopoietic function of the patient's bone marrow. The patient is then "rescued" with the infusion of the donor stem cells to reinitiate blood cell production. Patients who undergo PBSCT transplantation have a significant risk for problems with infection, potential graft-versus-host disease (in which the donor's lymphocytes [graft] recognize the patient's body as "foreign" and set up reactions to attack the "foreign" host), and other complications. PBSCT has been shown to cure AML in 25% to 50% of patients who are at high risk for relapse or who have relapsed (Radich & Sievers, 2000).

Recent advances in understanding of the molecular biology of myeloid blast cells have resulted in a new therapeutic option. After the uncommitted stem cell differentiates into a myeloid stem cell, it expresses a specific antigen on the cell surface, called CD33. It appears that 90% of blast cells found in AML express CD33; normal hematopoietic stem cells do not express this antigen (Radich & Sievers, 2000). Armed with that discovery, researchers developed a monoclonal antibody to target cells with the CD33 antigen. The anti-CD33 antibody is linked to a potent antitumor antibiotic, calicheamicin; this medication is called gemtuzumab ozogamicin (Mylotarg). When administered, the anti-CD33 antibody binds to cells with CD33 antigens, and the calicheamicin causes cell death. Normal myeloid and megakaryocyte precursors have the CD33 antigen, so the Mylotarg destroys them. Patients develop severe neutropenia and thrombocytopenia after receiving this medication. Nonetheless, Mylotarg shows promise as an effective agent against AML. In elderly patients, it appears to be somewhat less toxic than conventional induction therapy regimens.

Another important option for the patient to consider is supportive care alone. In fact, supportive care may be the only option if the patient has significant comorbidity, such as extremely poor cardiac, pulmonary, renal, or hepatic function. In such cases, aggressive antileukemia therapy is not used; occasionally, hydroxyurea (eg, Hydrea) may be used briefly to control the increase of blast cells. Patients are more commonly supported with antimicrobial therapy and transfusions as needed. This treatment approach provides the patient with some additional time at home; however, death frequently occurs within months, typically from infection or bleeding.

## COMPLICATIONS OF TREATMENT

The massive leukemic cell destruction from chemotherapy results in release of electrolytes and fluids within the cell into the systemic circulation. Increases in uric acid levels, potassium, and phosphate are seen; this process is referred to as tumor **lysis** syndrome (see Chap. 16). The increased uric acid and phosphorus levels make patients vulnerable to renal stone formation and renal colic, which can progress to acute renal failure. Hyperkalemia and hypocalcemia can lead to cardiac dysrhythmias, hypertension, neuromuscular effects such as muscle cramps, weakness, spasm/tetany, confusion, and seizure. Patients require a high fluid intake, alkalization of the urine, and prophylaxis with allopurinol to prevent crystallization of uric acid and subsequent stone formation. Gastrointestinal problems may result from the infiltration of abnormal leukocytes into the abdominal organs and from the toxicity of the chemotherapeutic agents. Anorexia, nausea, vomiting, diarrhea, and severe mucositis are common. Because of the profound myelosuppressive effects of chemotherapy, significant neutropenia and thrombocytopenia typically result in serious infection and increased risk for bleeding.

## Nursing Management

Nursing management of the patient with acute leukemia is discussed at the end of the leukemia section in this chapter.

## CHRONIC MYELOID LEUKEMIA

Chronic myeloid leukemia (CML) arises from a mutation in the myeloid stem cell. Normal myeloid cells continue to be produced, but there is a preference for immature (blast) forms. Therefore, a wide spectrum of cell types exists within the blood, from blast forms through mature neutrophils. Because there is an uncontrolled proliferation of cells, the marrow expands into the cavities of long bones (eg, the femur), and cells are also formed in the liver and spleen (extramedullary hematopoiesis), resulting in enlargement of these organs that is sometimes painful. In 90% to 95% of patients with CML, a section of DNA is found to be missing from chromosome 22 (the Philadelphia chromosome [Ph1]); it is, in fact, translocated onto chromosome 9. The specific location of these changes is on the *BCR* gene of chromosome 22 and the *ABL* gene of chromosome 9. When these two genes fuse (*BCR-ABL* gene), they produce an abnormal protein (a tyrosine kinase protein) that causes WBCs to divide rapidly. This *BCR-ABL* gene is present in virtually all patients with this disease. CML is uncommon in people younger than 20 years of age, but the incidence increases with age (median age, 40 to 50 years).

Patients diagnosed with CML in the chronic phase have an overall median life expectancy of 3 to 5 years. During that time, they have very few symptoms and complications from the disease itself. Problems with infections and bleeding are rare. However, once the disease transforms to the acute phase (blast crisis), the overall survival time rarely exceeds several months.

## Clinical Manifestations

The clinical picture of CML varies. Many patients are asymptomatic, and leukocytosis is detected by a CBC performed for some other reason. The WBC count commonly exceeds 100,000/mm<sup>3</sup>. Patients with extremely high WBC counts may be somewhat short of breath or slightly confused due to decreased capillary perfusion to the lungs and brain from leukostasis (the excessive amount of WBCs inhibits blood flow through the capillaries). Patients may complain of an enlarged, tender spleen. The liver may also be enlarged. Some patients have somewhat insidious symptoms, such as malaise, anorexia, and weight loss. Lymphadenopathy is rare. There are three stages in CML: chronic, transformation, and accelerated or blast crisis. Patients have more symptoms and complications as the disease progresses.

## Medical Management

Advances in understanding of the pathology of CML at a molecular level have led to dramatic changes in its medical management. An oral formulation of a tyrosine kinase inhibitor, imatinib mesylate (Gleevec) works by blocking signals within the leukemia cells that express the *BCR-ABL* protein, thus preventing a series of chemical reactions that cause the cell to grow and divide (Tennant, 2001; Goldman & Melo, 2001). Gleevec appears to be more useful in the chronic phase of the illness. In clinical trials, it has been generally well tolerated. Antacids and grapefruit juice may limit drug absorption, and large doses of acetaminophen can cause hep-

atotoxicity. The long-term effects of Gleevec, its impact on survival, and the optimal length of treatment are being determined.

Conventional therapy depends on the stage of disease. In the chronic phase, the expected outcome is correction of the chromosomal abnormality (ie, conversion of the malignant stem cell population back to normal). Agents that have been used successfully for this purpose are interferon-alfa (Roferon-A) and cytosine, often in combination. These agents are administered daily as subcutaneous injections. This therapy is not benign; many patients cannot tolerate the profound fatigue, depression, anorexia, mucositis, and inability to concentrate. A less aggressive therapeutic approach focuses on reducing the WBC count to a more normal level, but does not alter cytogenetic changes. This goal can be achieved by using oral chemotherapeutic agents, typically hydroxyurea (eg, Hydrea) or busulfan (eg, Myleran). In the case of an extreme leukocytosis at diagnosis (eg, WBC count higher than 300,000/mm<sup>3</sup>), a more emergent treatment may be required. In this instance, leukopheresis (in which the patient's blood is removed and separated, with the leukocytes withdrawn, and the remaining blood returned to the patient) can temporarily reduce the number of WBCs. An anthracycline chemotherapeutic agent (eg, daunomycin) may also be used to bring the WBC count down quickly to a safer level, where more conservative therapy can be instituted.

The transformation phase can be insidious, but it marks the process of evolution (or transformation) to the acute form of leukemia (blast crisis). In the transformation phase, the patient may complain of bone pain and may report fevers (without any obvious sign of infection) and weight loss. Even with chemotherapy, the spleen may continue to enlarge. The patient may become more anemic and thrombocytopenic; an increased basophil level is detected by the CBC. Despite its being a myeloid stem cell disease, CML will transform in up to 25% of patients to resemble not AML, but acute lymphoid leukemia (ALL), with lymphoid-appearing blasts (Derderian et al., 1993). Transformation into the acute phase can be gradual or rapid.

In the more acute form of leukemia (blast crisis), treatment may resemble induction therapy for acute leukemia, using the same medications as for AML or ALL. Patients whose disease evolves into a "lymphoid" blast crisis are more likely to be able to reenter a chronic phase after induction therapy. For those whose disease evolves into AML, therapy is largely ineffective in achieving a second chronic phase. Life-threatening infections and bleeding occur frequently in this phase. CML is a disease that can potentially be cured with BMT or PBSCT. Patients who receive such transplants while still in the chronic phase of the illness tend to have a greater chance for cure than those who receive them in the acute phase. The transplantation procedure may now be considered for otherwise healthy patients who are younger than 70 years of age.

## ACUTE LYMPHOCYTIC LEUKEMIA

ALL results from an uncontrolled proliferation of immature cells (lymphoblasts) derived from the lymphoid stem cell. The cell of origin is the precursor to the B lymphocyte in approximately 75% of ALL cases; T-lymphocyte ALL occurs in approximately 25% of ALL cases. The *BCR-ABL* translocation (see earlier discussion) is found in 20% of ALL blast cells. ALL is most common in young children, with boys affected more often than girls; the peak incidence is 4 years of age. After age 15 years, ALL is relatively uncommon. Increasing age appears to be associated with diminished survival (Nachman, 1999). Because of improvements in therapy for ALL, more than 80% of children survive at least

5 years. Even if relapse occurs, resumption of induction therapy can often achieve a second complete remission. Moreover, BMT may be successful even after a second relapse.

### Clinical Manifestations

Immature lymphocytes proliferate in the marrow and crowd the development of normal myeloid cells. As a result, normal hematopoiesis is inhibited, resulting in reduced numbers of leukocytes, erythrocytes, and platelets. Leukocyte counts may be either low or high, but there is always a high proportion of immature cells. Manifestations of leukemic cell infiltration into other organs are more common with ALL than with other forms of leukemia and include pain from an enlarged liver or spleen, bone pain, and headache and vomiting (because of meningeal involvement).

### Medical Management

The expected outcome of treatment is complete remission. Lymphoid blast cells are typically very sensitive to corticosteroids and to vinca alkaloids; therefore, these medications are an integral part of the initial induction therapy. Because ALL frequently invades the central nervous system, prophylaxis with cranial irradiation or intrathecal chemotherapy (eg, methotrexate [Folex]) or both is an integral part of the treatment plan.

Treatment protocols for ALL tend to be complex, using a wide variety of chemotherapeutic agents. They often include a maintenance phase, when lower doses of medications are given for up to 3 years. Despite the complexity, treatment can be provided in the outpatient setting in some circumstances until severe complications develop.

Infections are common, especially viral infections. The use of corticosteroids to treat ALL increases the patient's susceptibility to infection. Patients with ALL tend to have a better response to treatment than patients with AML do. BMT or PBSCT offers a chance for prolonged remission or even cure if the illness recurs after therapy.

### Nursing Management

Nursing management of the patient with acute leukemia is discussed at the end of the leukemia section in this chapter.

## CHRONIC LYMPHOCYTIC LEUKEMIA (CLL)

CLL is a common malignancy of older adults; two thirds of all patients are older than 60 years of age at diagnosis. It is the most common form of leukemia in the United States and Europe, affecting more than 120,000 people, but is rarely seen in Asia. The average survival time for patients with CLL ranges from 14 years (early stage) to 2.5 years (late stage).

### Pathophysiology

CLL typically derives from a malignant clone of B lymphocytes (T-lymphocyte CLL is rare). In contrast to the acute forms of leukemia, most of the leukemia cells in CLL are fully mature. It appears that these cells can escape **apoptosis** (programmed cell death), with the result being an excessive accumulation of the cells in the marrow and circulation. The antigen CD52 is prevalent on the surface of many of these leukemic B cells. The disease is classified into three or four stages (two classification systems are

in use). In the early stage, an elevated lymphocyte count is seen and can exceed 100,000/mm<sup>3</sup>. Because the lymphocytes are small, they can easily travel through the small capillaries within the circulation, and the pulmonary and cerebral complications of leukocytosis (as seen with myeloid leukemias) typically are not found in CLL.

Lymphadenopathy occurs as the lymphocytes are trapped within the lymph nodes. The nodes can become very large and are sometimes painful. Hepatomegaly and splenomegaly then develop.

In later stages, anemia and thrombocytopenia may develop. Treatment is typically initiated in the later stages; earlier treatment does not appear to increase survival. Autoimmune complications can also occur at any stage, as either autoimmune hemolytic anemia or idiopathic thrombocytopenic purpura (ITP). In the autoimmune process, the RES destroys the body's own RBCs or platelets.

### Clinical Manifestations

Many patients are asymptomatic and are diagnosed incidentally during routine physical examinations or during the course of treatment for another disease. An increased lymphocyte count (lymphocytosis) is always present. The RBC and platelet counts may be normal or, in later stages of the illness, decreased. Enlargement of lymph nodes (lymphadenopathy) is common; it can be severe and sometimes painful. The spleen can also be enlarged (splenomegaly).

Patients with CLL can develop "B symptoms," a constellation of symptoms including fevers, drenching sweating (especially at night), and unintentional weight loss. These patients have defects in their humoral and cell-mediated immune systems; therefore, infections are common. The defect in cellular immunity is evidenced by an absent or decreased reaction to skin sensitivity tests (eg, *Candida*, mumps), which is known as **anergy**. Problems with life-threatening infections are common. Viral infections, such as herpes zoster, can become widely disseminated.

### Medical Management

In early stages, CLL may require no treatment. When symptoms are severe (drenching night sweats, painful lymphadenopathy), or when the disease progresses to later stages (with resultant anemia and thrombocytopenia), chemotherapy with corticosteroids and chlorambucil (Leukeran) is often used. Other useful agents include cyclophosphamide (eg, Cytosan), vincristine (eg, Oncovin), and doxorubicin (eg, Adriamycin). A significant number of patients who do not respond to these medications have achieved remission with fludarabine (Fludara), and this medication is increasingly being used as front-line therapy. The major side effect of fludarabine is prolonged bone marrow suppression, manifested by prolonged periods of neutropenia, lymphopenia, and thrombocytopenia. Patients are then at risk for such infections as *Pneumocystis carinii*, *Listeria*, mycobacteria, herpes viruses, and cytomegalovirus (CMV). The monoclonal antibody rituximab (Rituxan) also has efficacy in CLL therapy. It is often used in combination with other chemotherapeutic medications. Research has shown that the monoclonal antibody alemtuzumab (Campath) targets the CD52 antigen commonly found on CLL cells and that it is effective in clearing the marrow and circulation of these cells without affecting the stem cells. Because CD52 is present on both B and T lymphocytes, patients receiving alemtuzumab are at significant risk for infection; prophylactic use of antiviral agents and

antibiotics (eg, trimethoprim and sulfamethoxazole [Septra]) is important and needs to continue for a minimum of 2 months after the patient stops treatment. Because bacterial infections are common in patients with CLL, intravenous treatment with immunoglobulin may be given to selected patients.

## NURSING PROCESS: THE PATIENT WITH ACUTE LEUKEMIA

### Assessment

Although the clinical picture varies with the type of leukemia involved as well as the treatment implemented, the health history may reveal a range of subtle symptoms reported by the patient before the problem is manifested by findings on physical examination. Weakness and fatigue are common manifestations, not only of the leukemia but also of the resulting complications of anemia

and infection. If the patient is hospitalized, the assessments should be performed daily, or more frequently as warranted. Because the physical findings may be subtle initially, a thorough, systematic assessment incorporating all body systems is essential. For example, a dry cough, mild dyspnea, and diminished breath sounds may indicate a pulmonary infection. However, the infection may not be seen initially on the chest x-ray. The lack of neutrophils delays the inflammatory response against the pulmonary infection, and it is the inflammatory response that causes the x-ray changes. The platelet count can become dangerously low, leaving the patient at risk for significant bleeding. The specific body system assessments are delineated in the neutropenic precautions and bleeding precautions, found in Charts 33-9 and 33-10, respectively. When serial assessments are performed, current findings are compared with previous findings to evaluate improvement or worsening.

The nurse also must closely monitor the results of laboratory studies. Flow sheets and spreadsheets are particularly useful in

Chart  
33-10

### Bleeding Precautions

#### Nursing Diagnosis

Potential bleeding\* and injury secondary to thrombocytopenia/altered coagulation due to:

- Malignant invasion in bone marrow
- Bone marrow suppression resulting from chemotherapy (particularly alkylators, antitumor antibiotics, antimetabolites) and radiation therapy
- Hypersplenism
- Disseminated intravascular coagulation (DIC)
- Altered coagulation

#### Assessment

##### Patient

Assess the following areas thoroughly every shift or visit (with spot checks throughout the shift if patient is hospitalized), and notify physician if there is new onset of the following and/or worsening of status:

- *Integument:* Petechiae (usually located on trunk, thighs), ecchymoses or hematomas, conjunctival hemorrhages, bleeding gums, bleeding at puncture sites (venipuncture, lumbar puncture, bone marrow)
- *Cardiovascular:* Hypotension, tachycardia, complaints of dizziness, epistaxis
- *Pulmonary:* Respiratory distress, tachypnea
- *Gastrointestinal:* Hemoptysis, abdominal distention, rectal bleeding
- *Genitourinary:* Vaginal or urethral bleeding
- *Neurologic:* Headache, blurred vision, mental status changes

#### Laboratory Tests

- Monitor complete blood count (CBC), platelets daily (at least); coagulation panel.
- Notify physician if platelet count is  $<10,000/\text{mm}^3$  or if count has changed significantly from previous count (including coagulation), or whenever patient becomes symptomatic.
- Ensure patient's blood was human leukocyte antigen (HLA) typed before transfusions or chemotherapy begins if admitted for induction therapy (eg, for acute leukemia).
- Obtain 1-hour posttransfusion platelet count if warranted.
- Test all urine, emesis, stools for occult blood.

\*Serious hemorrhage is unusual in mildly thrombocytopenic patients in absence of local lesions (peptic ulcer, bleeding from hemorrhoids, cystitis).

#### Nursing Interventions

##### Prevent Complications

- Avoid aspirin and aspirin-containing medications or other medications known to inhibit platelet function, if possible.
- Do not give intramuscular injections.
- Do not insert indwelling catheters.
- Take no rectal temperatures; do not give suppositories, enemas.
- Use stool softeners, oral laxatives to prevent constipation.
- Use smallest possible needles when performing venipuncture.
- Apply pressure to venipuncture sites for 5 min or until bleeding has stopped.
- Permit no flossing of teeth and no commercial mouthwashes.
- Use only soft-bristled toothbrush for mouth care.
- Use only toothettes for mouth care if platelet count is  $<10,000/\text{mm}^3$ , or if gums bleed.
- Lubricate lips with water-soluble lubricant every 2 hr while awake.
- Avoid suctioning if at all possible; if unavoidable, use only gentle suctioning.
- Discourage vigorous coughing or blowing of the nose.
- Use only electric razor for shaving.
- Pad side rails as needed.
- Prevent falls by ambulating with patient as necessary.

##### Control Bleeding

- Apply direct pressure.
- For epistaxis, position patient in high Fowler's position; apply ice pack to back of neck and direct pressure to nose.
- Notify physician for prolonged bleeding (eg, unable to stop within 10 min).
- Administer platelets, fresh frozen plasma, packed red blood cells, as prescribed.

##### Evaluation and Expected Patient Outcomes

- Patient demonstrates an absence of bleeding as evidenced by absence of spontaneous petechiae, ecchymoses, epistaxis, hemoptysis, bleeding gums, conjunctival hemorrhage, vaginal bleeding, hematuria, guaiac positive stool, blurred vision, orthostatic hypotension, and prolonged bleeding from puncture sites.
- Patient demonstrates an absence of bleeding as evidenced by the presence of vital signs within normal limits and intact neurologic status.

tracking the WBC count, ANC, hematocrit, platelet, and creatinine levels, hepatic function tests, and electrolyte levels. Culture results need to be reported immediately so that appropriate antimicrobial therapy can begin or be modified.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses for the patient with acute leukemic may include:

- Risk for infection and bleeding
- Risk for impaired skin integrity related to toxic effects of chemotherapy, alteration in nutrition, and impaired mobility
- Impaired gas exchange
- Impaired mucous membranes due to changes in epithelial lining of the gastrointestinal tract from chemotherapy or prolonged use of antimicrobial medications
- Imbalanced nutrition, less than body requirements, related to hypermetabolic state, anorexia, mucositis, pain, and nausea
- Acute pain and discomfort related to mucositis, WBC infiltration of systemic tissues, fever, and infection
- Hyperthermia related to tumor lysis and infection
- Fatigue and activity intolerance related to anemia and infection
- Impaired physical mobility due to anemia and protective isolation
- Risk for excess fluid volume related to renal dysfunction, hypoproteinemia, need for multiple intravenous medications and blood products
- Diarrhea due to altered gastrointestinal flora, mucosal denudation
- Risk for deficient fluid volume related to potential for diarrhea, bleeding, infection, and increased metabolic rate
- Self-care deficit due to fatigue, malaise, and protective isolation
- Anxiety due to knowledge deficit and uncertain future
- Disturbed body image related to change in appearance, function, and roles
- Grieving related to anticipatory loss and altered role functioning
- Potential for spiritual distress
- Deficient knowledge about disease process, treatment, complication management, and self-care measures

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include:

- Infection
- Bleeding
- Renal dysfunction
- Tumor lysis syndrome
- Nutritional depletion
- Mucositis

## Planning and Goals

The major goals for the patient may include absence of complications and pain, attainment and maintenance of adequate nutrition, activity tolerance, ability for self-care and to cope

with the diagnosis and prognosis, positive body image, and an understanding of the disease process and its treatment.

## Nursing Interventions

### PREVENTING OR MANAGING INFECTION AND BLEEDING

The nursing interventions related to diminishing the risk for infection and for bleeding are delineated in Charts 33-9 and 33-10.

### MANAGING MUCOSITIS

Although emphasis is placed on the oral mucosa, it is important to realize that the entire gastrointestinal mucosa can be altered, not only by the effects of chemotherapy but also from prolonged administration of antibiotics. Assessment of the oral mucosa must be thorough; therefore, dentures must be removed. Areas to assess include the palate, buccal mucosa, tongue, gums, lips, oropharynx, and the area under the tongue. In addition to identifying and describing lesions, the color and moisture of the mucosa should be noted.

Oral hygiene is very important to diminish the bacteria within the mouth, maintain moisture, and provide comfort. Soft-bristled toothbrushes should be used until the neutrophil and platelet counts become very low; at that time, sponge-tipped applicators should be substituted. Lemon-glycerin swabs and commercial mouthwashes should never be used because the glycerin and alcohol within them are extremely drying to the tissues. Simple rinses with saline (or saline and baking soda) solutions are inexpensive but effective in cleaning and moistening the oral mucosa. Because the risk of yeast or fungal infection in the mouth is great, other medications are often prescribed, such as chlorhexidine rinses (eg, Peridex) or clotrimazole troches (eg, Mycelex). The nurse reminds the patient about the importance of these medications to enhance adherence to the therapeutic regimen. Chlorhexidine rinses may discolor the teeth.

To diminish perineal–rectal complications, it is important to cleanse the perineal–rectal area thoroughly after each bowel movement. Women are instructed to cleanse the perineum from front to back. Sitz baths are a comfortable method of cleansing; the perineal–anal region and buttocks must be carefully dried afterward to minimize the chance of excoriation. Stool softeners should be used to increase the moisture of bowel movements; however, the stool texture must be monitored so that the softeners can be decreased or stopped if the stool becomes too loose.

### IMPROVING NUTRITIONAL INTAKE

The disease process can increase, and sepsis further increases, the patient's metabolic rate and nutritional requirements. Nutritional intake is often reduced because of pain and discomfort associated with stomatitis. Mouth care before and after meals and administration of analgesics before eating can help increase intake. If oral anesthetics are used, the patient must be warned to chew with extreme care to avoid inadvertently biting the tongue or buccal mucosa.

Nausea should not be a major contributing factor, because recent advances in antiemetic therapy are highly effective. However, nausea can result from antimicrobial therapy, so some antiemetic therapy may still be required after the chemotherapy has been completed.

Small, frequent feedings of foods that are soft in texture and moderate in temperature may be better tolerated. Low-microbial diets are typically prescribed (avoiding uncooked fruits or vegetables and those without a peelable skin). Nutritional supplements are frequently used. Daily body weights (as well as in-

take and output measurements) are useful in monitoring fluid status.

Calorie counts are useful, as are more formal nutritional assessments. Parenteral nutrition is often required to maintain adequate nutrition.

### EASING PAIN AND DISCOMFORT

Recurrent fevers are common in acute leukemia; at times, they are accompanied by shaking chills, which can be severe (rigors). Myalgias and arthralgias can result. Acetaminophen is typically given to decrease fever, but it does so by increasing diaphoresis. Sponging with cool water may be useful, but cold water or ice packs should be avoided because the heat cannot dissipate from constricted blood vessels. Bedclothes need frequent changing as well. Gentle back and shoulder massage may provide comfort.

Stomatitis can also cause significant discomfort. In addition to oral hygiene practices, patient-controlled analgesia can be effective in controlling the pain (see Chap. 13).

Because patients with acute leukemia require hospitalization for extensive nursing care (either during induction or consolidation therapy or during resultant complications), sleep deprivation frequently results. Nurses need to implement creative strategies that permit uninterrupted sleep for at least a few hours while still administering necessary medications on time.

With the exception of severe mucositis, less pain is associated with acute leukemia than with many other forms of cancer. However, the amount of psychologic suffering that the patient must endure can be immense. Patients greatly benefit from active listening.

### DECREASING FATIGUE AND DECONDITIONING

Fatigue is a common and oppressive problem. Nursing interventions should focus on assisting the patient to establish a balance between activity and rest. Patients with acute leukemia need to maintain some physical activity and exercise to prevent the deconditioning that results from inactivity. Use of a high-efficiency particulate air (HEPA) filter mask can permit the patient to ambulate outside the room despite severe neutropenia. Although many patients lack the motivation to use them, stationary bicycles within the room can also be used. At a minimum, patients should be encouraged to sit up in a chair while awake rather than staying in bed; even this simple activity can improve the patient's tidal volume and enhance circulation. Physical therapy can also be beneficial.

### MAINTAINING FLUID AND ELECTROLYTE BALANCE

Febrile episodes, bleeding, and inadequate or overly aggressive fluid replacement can alter the patient's fluid status. Similarly, persistent diarrhea, vomiting, and long-term use of certain antimicrobial agents can cause significant deficits in electrolytes. Intake and output need to be measured accurately, and daily weights should also be monitored. The patient should be assessed for signs of dehydration as well as fluid overload, with particular attention to pulmonary status and the development of dependent edema. Laboratory test results, particularly electrolytes, blood urea nitrogen, creatinine, and hematocrit, should be monitored and compared with previous results. Replacement of electrolytes, particularly potassium and magnesium, is commonly required. Patients receiving amphotericin or certain antibiotics are at increased risk for electrolyte depletion.

### IMPROVING SELF-CARE

Because hygiene measures are so important in this patient population, they must be performed by the nurse when the patient cannot do so. However, the patient should be encouraged to do as

much as possible, to preserve mobility and function as well as self-esteem. Patients may have negative feelings, even disgust that they can no longer care for themselves. Empathetic listening is helpful, as is realistic reassurance that these deficits are temporary. As the patient recovers, it is important to assist him or her to resume more self-care. Patients are usually discharged from the hospital with a central vascular access device (eg, Hickman catheter, PICC), and most patients can care for the catheter with adequate instruction and practice under observation.

### MANAGING ANXIETY AND GRIEF

Being diagnosed with acute leukemia can be extremely frightening. In many instances, the need to begin treatment is emergent, and patients have little time to process the fact that they have the illness before making decisions about therapy. Providing emotional support and discussing the uncertain future are crucial. The nurse also needs to assess how much information patients want to have regarding the illness, its treatment, and potential complications. This desire should be reassessed at intervals, because needs and interest in information change throughout the course of the disease and treatment. Priorities must be identified so that procedures, assessments, and self-care expectations are adequately explained even to those who do not wish extensive information.

Many patients become depressed and begin to grieve for the losses they feel, such as normal family functioning, professional roles and responsibilities, and social roles, as well as physical functioning. Nurses can assist patients to identify the source of the grief and encourage them to allow time to adjust to the major life changes produced by the illness. Role restructuring, in both family and professional life, may be required. Again, when possible, permitting patients to identify options and to take time making significant decisions regarding such restructuring is helpful.

Discharge from the hospital can also provoke anxiety. Although most patients are extremely eager to go home, they may lack confidence in their ability to manage potential complications and to resume their normal activity. Close communication between nurses across care settings can reassure patients that they will not be abandoned.

### ENCOURAGING SPIRITUAL WELL-BEING

Because acute leukemia is a serious, potentially life-threatening illness, the nurse may offer support to enhance the patient's spiritual well-being. The patient's spiritual and religious practices should be assessed and pastoral services offered. Throughout the patient's illness, it is important that the nurse assist the patient to maintain hope. However, that hope should be realistic and will certainly change over the course of the illness. For example, the patient may initially hope to be cured, but with repeated relapses and a change to terminal care the same patient may hope for a quiet, dignified death.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Nursing interventions for potential complications were described previously.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

Most patients cope better when they have an understanding of what is happening to them. Based on their education, literacy level, and interest, teaching of patient and family should focus on

the disease (including some pathophysiology), its treatment, and certainly the significant risk for infection and bleeding (Charts 33-8 and 33-11) that results.

Management of a vascular access device can be taught to most patients or family members. Follow-up and care for the devices may also need to be provided by nurses in an outpatient facility or by a home care agency or a health care provider.

**Continuing Care.** Shortened hospital stays and outpatient care have significantly altered care for patients with acute leukemia. In many instances, when the patient is clinically stable but still requires parenteral antibiotics or blood products, these procedures can be performed in an outpatient setting. Nurses in these various settings must communicate regularly. Patients need to learn which parameters are important for them to monitor, and how to monitor them. Specific instructions need to be given as to when the patient should seek care from the physician or a health care provider.

Patients and their families need to have a clear understanding of the disease and the prognosis. The nurse acts as an advocate to ensure that this information is provided. When patients no longer respond to therapy, it is important to respect their choices about treatment, including measures to prolong life and other end-of-life measures. Advance directives and living wills provide patients with some measure of control during terminal illness.

Many patients in this stage still choose to be cared for at home, and families often need support when considering this option. Coordination of home care services and instruction can help to alleviate anxiety about managing the patient's care in the home. As the patient becomes weaker, the caregivers must assume more of the patient's care. In addition, caregivers often need to be encouraged to take care of themselves, allowing time for rest and accepting emotional support. Hospice staff can assist in providing respite for family members as well as care for the patient. Patients and families also need assistance to cope with changes in their roles and responsibilities. Anticipatory grieving is an essential task during this time (see Chap. 17).

In patients with acute leukemia, death typically occurs from infection or bleeding. Family members need to have information about these complications and the measures to take should either occur. Many family members cannot cope with the care required when a patient begins to bleed actively. It is important to delineate alternatives to keeping the patient at home. Should

another option be sought, family members who may feel guilty that they could not keep the patient at home will require support from the nurse.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Shows no evidence of infection
2. Experiences no bleeding
3. Has intact oral mucous membranes
  - a. Participates in oral hygiene regimen
  - b. Reports no discomfort in mouth
4. Attains optimal level of nutrition
  - a. Maintains weight with increased food and fluid intake
  - b. Maintains adequate protein stores (albumin)
5. Reports satisfaction with pain and discomfort levels
6. Has less fatigue and increased activity
7. Maintains fluid and electrolyte balance
8. Participates in self-care
9. Copes with anxiety and grief
  - a. Discusses concerns and fears
  - b. Uses stress management strategies appropriately
  - c. Participates in decisions regarding end-of-life care
10. Absence of complications

## AGNOGENIC MYELOID METAPLASIA (AMM)

Agnogenic myeloid metaplasia (AMM), also known as myelofibrosis, is a chronic myeloproliferative disorder that arises from neoplastic transformation of an early hematopoietic stem cell. The disease is characterized by marrow fibrosis or scarring, splenomegaly, extramedullary hematopoiesis (typically spleen, liver, or both), leukocytosis and thrombocytosis, and anemia. Some patients have suppressed WBC and platelet counts as well as anemia (pancytopenia). Patients with AMM have increased **angiogenesis** (formation of new blood vessels) within the marrow. Early forms of blood cells (including nucleated RBCs and megakaryocyte fragments) are frequently found in the circulation. AMM is a disease of the elderly, with a median age at diagnosis of 60 to 65 years. Survival time varies from as little as 1 year to more than 30 years; the average is 4 to 5 years (Anderson, Hamblin, & Traynor, 1999). Heart failure, complications of marrow failure, and transformation to AML are the common causes of death.

Chart 33-11

### Home Care Checklist • The Patient at Risk for Bleeding

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Describe the source and function of platelets and clotting factors.	✓	✓
• Verbalize the rationale for being at risk for bleeding.	✓	✓
• Identify medications and other substances to avoid (eg, aspirin-containing medications, alcohol).	✓	✓
• Demonstrate how to monitor for signs of bleeding.	✓	✓
• Describe to whom, how, and when to report signs of bleeding.	✓	✓
• Notify health care professional before having dental work.	✓	✓
• Describe appropriate ways to prevent bleeding (avoid use of suppositories, enemas, tampons; avoid constipation, vigorous sexual intercourse, anal sex; use only electric razor for shaving and a soft-bristled toothbrush for teeth).	✓	✓
• Demonstrate appropriate actions to take should bleeding occur.	✓	✓

## Medical Management

Medical management is directed toward palliation, reducing symptoms related to cytopenias, splenomegaly, and hypermetabolic state. Although one third of anemic patients respond to the combination of an androgen plus a corticosteroid, the primary treatment remains RBC transfusion. Because of the prolonged requirement for RBC transfusion, iron overload is a common problem. Iron chelation therapy should be initiated for those individuals in whom survival is expected to exceed a few years (Anderson Hamblin, Traynor, 1999). Hydroxyurea is often used to control high WBC and platelet counts and to reduce the size of the spleen. Splenic irradiation or splenectomy may also be used to control the massive splenomegaly that can develop. However, both modalities render the patient at significant risk for development of infection. BMT may be a useful treatment modality in younger, otherwise healthy individuals.

## Nursing Management

The extent of splenomegaly can be profound in patients with AMM, with enlargement of the spleen that extends to the pelvic rim. This condition is extremely uncomfortable to the patient and can severely limit nutritional intake. Analgesics are often ineffective. Methods to reduce the spleen's size are usually more effective in controlling pain. Splenomegaly, coupled with a hypermetabolic state, results in weight loss (often severe) and muscle wasting. Patients benefit from very small, frequent meals of foods that are high in calories and protein. Weakness, fatigue, and altered body image are other significant problems. Energy conservation methods and active listening are important nursing interventions. Patients need to be educated about signs and symptoms of infection as well as appropriate interventions when an infection is suspected.

## The Lymphomas

The lymphomas are neoplasms of cells of lymphoid origin. These tumors usually start in lymph nodes but can involve lymphoid tissue in the spleen, the gastrointestinal tract (eg, the wall of the stomach), the liver, or the bone marrow. They are often classified according to the degree of cell differentiation and the origin of the predominant malignant cell. Lymphomas can be broadly classified into two categories: Hodgkin's disease and non-Hodgkin's lymphoma (NHL).

## HODGKIN'S DISEASE

Hodgkin's disease is a relatively rare malignancy that has an impressive cure rate. It is somewhat more common in men than women and has two peaks of incidence: one in the early 20s and the other after 50 years of age. Unlike other lymphomas, Hodgkin's disease is unicentric in origin in that it initiates in a single node. The disease spreads by contiguous extension along the lymphatic system. The cause of Hodgkin's disease is unknown, but a viral etiology is suspected. In fact, fragments of the Epstein-Barr virus have been found in 40% to 50% of patients; this occurs more commonly in the younger patient population (Weiss, 2000). There is a familial pattern associated with Hodgkin's disease: first-degree relatives have a higher-than-normal frequency of the disease. There is no increased incidence documented for non-blood relatives (eg, spouses).

The malignant cell of Hodgkin's disease is the Reed-Sternberg cell, a gigantic tumor cell that is morphologically unique and is

thought to be of immature lymphoid origin. It is the pathologic hallmark and essential diagnostic criterion for Hodgkin's disease. However, the tumor is very heterogeneous and may actually contain few Reed-Sternberg cells. Repeated biopsies may be required to establish the diagnosis.

Hodgkin's disease is customarily classified into five subgroups based on pathologic analyses that reflect the natural history of the malignancy and suggest the prognosis. For example, when lymphocytes predominate, with few Reed-Sternberg cells and minimal involvement of the lymph nodes, the prognosis is much more favorable than when the lymphocyte count is low and the lymph nodes are virtually replaced by tumor cells of the most primitive type. The majority of patients with Hodgkin's disease have the types currently designated "nodular sclerosis" or "mixed cellularity." The nodular sclerosis type tends to occur more often in young women, at an earlier stage but with a worse prognosis than the mixed cellularity subgroup, which occurs more commonly in men and causes more constitutional symptoms but has a better prognosis.

## Clinical Manifestations

Hodgkin's disease usually begins as a painless enlargement of one or more lymph nodes on one side of the neck. The individual nodes are painless and firm but not hard. The most common sites for lymphadenopathy are the cervical, supraclavicular, and mediastinal nodes; involvement of the iliac or inguinal nodes or spleen is much less common. A mediastinal mass may be seen on chest x-ray; occasionally, the mass is large enough to compress the trachea and cause dyspnea. Pruritus is common; it can be extremely distressing, and the cause is unknown. Approximately 20% of patients experience brief but severe pain after drinking alcohol (Cavalli, 1998). The pain is usually at the site of the Hodgkin's disease; again, the cause is unknown.

All organs are vulnerable to invasion by Hodgkin's disease. The symptoms result from compression of organs by the tumor, such as cough and pulmonary effusion (from pulmonary infiltrates), jaundice (from hepatic involvement or bile duct obstruction), abdominal pain (from splenomegaly or retroperitoneal adenopathy), or bone pain (from skeletal involvement). Herpes zoster infections are common. A cluster of constitutional symptoms has important prognostic implications. Referred to as "B symptoms," they include fever (without chills), drenching sweats (particularly at night), and unintentional weight loss of more than 10%. "B symptoms" are found in 40% of patients and are more common in advanced disease.

A mild anemia is the most common hematologic finding. The WBC count may be elevated or decreased. The platelet count is typically normal, unless the tumor has invaded the bone marrow, suppressing hematopoiesis. The **erythrocyte sedimentation rate (ESR)** and the serum copper level are used by some clinicians to assess disease activity. Patients with Hodgkin's disease have impaired cellular immunity, as evidenced by an absent or decreased reaction to skin sensitivity tests (eg, *Candida*, mumps).

## Assessment and Diagnostic Findings

Because many manifestations are similar to those occurring with infection, diagnostic studies are performed to rule out an infectious origin for the disease. The diagnosis is made by means of an excisional lymph node biopsy and the finding of the Reed-Sternberg cell. Once the diagnosis is confirmed and the histologic type is established, it is necessary to assess the extent of the disease, a process referred to as staging.

During the health history, the nurse should assess for any “B symptoms.” Physical examination requires a careful, systematic evaluation of the lymph node chains, as well as the size of the spleen and liver. A chest x-ray and a CT scan of the chest, abdomen, and pelvis are crucial to identify the extent of lymphadenopathy within these regions. Laboratory tests include CBC, platelet count, ESR, and liver and renal function studies. A bone marrow biopsy is performed if there are signs of marrow involvement, and some physicians routinely perform bilateral biopsies. Bone scans may be performed to identify any involvement in these areas. A staging laparotomy and lymphangiography are no longer considered mandatory, primarily because of the accuracy of CT.

## Medical Management

The general intent in treating Hodgkin’s disease, regardless of stage, is cure. Treatment is determined primarily by the stage of the disease, not the histologic type; however, extensive research is ongoing to target treatment regimens to histologic subtypes or prognostic features. Traditionally, early Hodgkin’s disease was treated by a staging laparotomy followed by radiation therapy. Recent data show improved results and decreased complications with a short course (2 to 4 months) of chemotherapy followed by radiation therapy in certain subsets of early-stage disease (IA and IIA); patients with early-stage disease and good prognostic features may receive radiation therapy alone (Hoppe et al., 2000). Combination chemotherapy, for example with doxorubicin (Adriamycin), bleomycin (Blenoxane), vinblastine (Velban), and dacarbazine (DTIC), referred to as ABVD, is now the standard treatment for more advanced disease (stages III and IV and all B stages).

Radiation therapy is still very useful for patients with extensive adenopathy (often termed bulky disease). In this group, residual disease often persists after the chemotherapy treatment is finished; radiation therapy to the areas of remaining adenopathy has been shown to improve survival.

Even when Hodgkin’s disease does recur, the use of high doses of chemotherapeutic agents, followed by autologous BMT or stem cell transplantation (PBSCT), can be very effective in controlling the disease and extending survival time.

## Long-Term Complications of Therapy

Much is now known about the long-term effects of chemotherapy and radiation therapy, primarily from the large numbers of people who were cured of Hodgkin’s disease by these treatments. The various complications of treatment are listed in Chart 33-12. Risk factors for other cancers should be assessed, and long-term surveillance is crucial. The potential development of a second malignancy is obviously of concern to patients, and this potential should be addressed with the patient when treatment decisions are made. However, it is important to consider that Hodgkin’s disease is curable. Revised treatment approaches are aimed at diminishing the risk for complications without sacrificing the potential for cure.

## NON-HODGKIN’S LYMPHOMAS (NHLs)

The NHLs are a heterogeneous group of cancers that originate from the neoplastic growth of lymphoid tissue. As in CLL, the neoplastic cells are thought to arise from a single clone of lymphocytes; however, in NHL, the cells may vary morphologically. Most NHLs involve malignant B lymphocytes; only 5% involve T lymphocytes. In contrast to Hodgkin’s disease, the lymphoid tissues involved are largely infiltrated with malignant cells. The spread of these ma-

Chart  
33-12

## Potential Long-Term Complications of Therapy for Hodgkin’s Disease

- Immune dysfunction
- Herpes infections (zoster and varicella)
- Pneumococcal sepsis
- Acute myeloid leukemia (AML)
- Myelodysplastic syndromes (MDS)
- Non-Hodgkin’s lymphoma
- Solid tumors
- Thyroid cancer
- Thymic hyperplasia
- Hypothyroidism
- Pericarditis (acute or chronic)
- Cardiomyopathy
- Pneumonitis (acute or chronic)
- Avascular necrosis
- Growth retardation
- Infertility
- Impotence
- Dental caries

lignant lymphoid cells occurs unpredictably, and true localized disease is uncommon. Lymph nodes from multiple sites may be infiltrated, as may sites outside the lymphoid system (extranodal tissue).

The incidence of NHL has increased dramatically over the past decade; it is now the fourth most common type of cancer diagnosed in the United States and the fifth most common cause of cancer death (Greenlee, Hill-Horton, Murray, & Thun, 2001; Zelenetz et al., 2000). The incidence increases with each decade of life; the average age at diagnosis is 50 to 60 years. Although no common etiologic factor has been identified, there is an increased incidence of NHL in people with immunodeficiencies or autoimmune disorders, viral infections (including Epstein-Barr virus and HIV), or exposure to pesticides, solvents, or dyes. Prognosis varies greatly among the various types of NHL. Long-term survival (more than 10 years) is commonly achieved in low-grade, localized lymphomas. Even with aggressive disease forms, cure is possible in at least one third of patients who receive aggressive treatment.

## Clinical Manifestations

Symptoms are highly variable, reflecting the diverse nature of these diseases. With early-stage disease, or with the types that are considered more indolent, symptoms may be virtually absent or very minor, and the illness typically is not diagnosed until it progresses to a later stage, when the patient is more symptomatic. At these stages (III or IV), lymphadenopathy is noticeable. One third of patients have “B symptoms” (recurrent fever, drenching night sweats, and unintentional weight loss of 10% or more).

## Assessment and Diagnostic Findings

The actual diagnosis of NHL is categorized into a highly complex classification system based on histopathology, immunophenotyping, and cytogenetic analyses of the malignant cells. The specific histopathologic type of the disease has important prognostic implications. Treatment also varies and is based on these features. Indolent (less aggressive) types tend to have small cells and are distributed in a follicular pattern. Aggressive types tend to have

large or immature cells distributed through the nodes in a diffuse pattern. Staging, also an important factor, is typically based on data obtained from CT scans, bone marrow biopsies, and occasionally cerebrospinal fluid analysis. The stage is based on the site of disease and its spread to other sites. For example, in stage I disease, only one area of involvement is detected; thus, stage I disease is highly localized and may respond well to localized therapy (eg, radiation therapy). In contrast, stage IV disease is detected in at least one extranodal site. Although low-grade lymphomas may not require treatment until the disease progresses to a later stage, historically they have also been relatively unresponsive to treatment in that most therapeutic modalities did not improve overall survival. More aggressive types of NHL (eg, lymphoblastic lymphoma, Burkitt's lymphoma) require prompt initiation of chemotherapy; however, these types tend to be more responsive to treatment.

### Medical Management

Treatment is based on the actual classification of disease, the stage of disease, prior treatment (if any), and the patient's ability to tolerate therapy. If the disease is not an aggressive form and is truly localized, radiation alone may be the treatment of choice. With aggressive types of NHL, aggressive combinations of chemotherapeutic agents are given even in early stages. More intermediate forms are commonly treated with combination chemotherapy and radiation therapy for stage I and II disease. The biologic agent interferon has been approved for the treatment of follicular low-grade lymphomas, and an antibody to CD20, rituximab (Rituxan), has been effective in achieving partial responses in patients with recurrent low-grade lymphoma. Studies of this agent in combination with conventional chemotherapy have demonstrated an improvement in survival as well (Coiffier, 2002; Emmanouilides et al., 2000; Petryk & Grossbard, 2000). Central nervous system involvement is also common with some aggressive forms of NHL; in this situation, cranial radiation or intrathecal chemotherapy is used in addition to systemic chemotherapy. Treatment after relapse is controversial. BMT or PBSCT may be considered for patients younger than 60 years of age (See Chap. 16).

### Nursing Management

Most of the care for patients with Hodgkin's disease or NHL is performed in the outpatient setting, unless complications occur (eg, infection, respiratory compromise due to mediastinal mass). For patients who require treatment, chemotherapy and radiation therapy are most commonly used. Chemotherapy causes systemic side effects (eg, myelosuppression, nausea, hair loss, risk for infection), whereas the side effects from radiation therapy are specific to the area being irradiated. For example, patients receiving abdominal radiation therapy may experience nausea and diarrhea but not hair loss. Regardless of the type of treatment, all patients may experience fatigue.

The risk of infection is significant for these patients, not only from treatment-related myelosuppression but also from the defective immune response that results from the disease itself. Patients need to be taught to minimize the risks for infection, to recognize signs of possible infection, and to contact the health care professional should such signs develop (see Chart 33-8).

Many lymphomas can be cured with current treatments. However, as survival rates increase, the incidence of second malignancies, particularly AML or MDS, also increases. Therefore, survivors should be screened regularly for the development of second malignancies.

Lymphoma is a highly complex constellation of diseases. When caring for the patient with lymphoma, it is extremely important to know the specific disease type, stage of disease, treatment history, and current treatment plan.

## MULTIPLE MYELOMA

Multiple myeloma is a malignant disease of the most mature form of B lymphocyte, the plasma cell. It is not classified as a lymphoma. Plasma cells secrete immunoglobulins, proteins necessary for antibody production to fight infection.

### Pathophysiology

In myeloma, the malignant plasma cells produce an increased amount of a specific immunoglobulin that is nonfunctional. Functional types of immunoglobulin are still produced by nonmalignant plasma cells, but in lower-than-normal quantity. The specific immunoglobulin secreted by the myeloma cells is detectable in the blood or urine and is referred to as the monoclonal protein, or M protein. This protein serves as a useful marker to monitor the extent of disease and the patient's response to therapy. It is measured by serum or urine protein electrophoresis. Moreover, the patient's total protein level is typically elevated, again due to the production of M protein. Malignant plasma cells also secrete certain substances to stimulate the creation of new blood vessels to enhance the growth of these clusters of plasma cells; this process is referred to as angiogenesis. Occasionally the plasma cells infiltrate other tissue, in which case they are referred to as plasmacytomas. Plasmacytomas can occur in the sinuses, spinal cord, and soft tissues. Median survival time is 3 to 5 years. Death usually results from infection.

### Clinical Manifestations

The classic presenting symptom of multiple myeloma is bone pain, usually in the back or ribs. Bone pain is reported by two thirds of all patients at diagnosis. Unlike arthritic pain, the bone pain associated with myeloma increases with movement and decreases with rest; patients may report that they have less pain on awakening but the pain intensity increases during the day. In myeloma, a substance secreted by the plasma cells, osteoclast activating factor, as well as other substances (eg, interleukin-6 [IL-6]) are involved in stimulating osteoclasts. Both mechanisms appear to be involved in the process of bone breakdown. Thus, lytic lesions as well as osteoporosis may be seen on bone x-rays. (They are not well visualized on bone scans.) The bone destruction can be severe enough to cause fractures, including spinal fractures, which can impinge on the spinal cord and result in spinal cord compression. It is this bone destruction that causes significant pain.

**NURSING ALERT** Any elderly patient whose chief complaint is back pain, and who has an elevated total protein level, should be evaluated for possible myeloma.

If the bone destruction is fairly extensive, excessive ionized calcium is lost from the bone and enters the serum; patients may therefore become hypercalcemic (frequently manifested by excessive thirst, dehydration, constipation, altered mental status, confusion, and perhaps coma). Renal failure may also be seen; the configuration of the circulating immunoglobulin molecule (particularly the shape of lambda light chains) can damage the renal tubules.

As more and more malignant plasma cells are produced, the marrow has less space for RBC production, and the patient can become anemic. This anemia is also caused to a great extent by a diminished production of erythropoietin (a glycoprotein necessary for RBC production) by the kidney. Patients may complain of fatigue and weakness due to the anemia. In the late stage of the disease, a reduced number of WBCs and platelets may also be seen because the bone marrow is infiltrated by malignant plasma cells.

When plasma cells secrete excessive amounts of immunoglobulin, particularly IgA, the serum viscosity can be elevated. Hyperviscosity may be manifested by bleeding from the nose or mouth, headache, blurred vision, paresthesias, or heart failure.

## Assessment and Diagnostic Findings

Finding an elevated monoclonal protein spike in the serum (via serum protein electrophoresis) or urine (via urine protein electrophoresis) or light chain in the urine (sometimes referred to as Bence Jones protein) is considered to be a major criterion in the diagnosis of multiple myeloma. The presence of lytic bone lesions on x-ray aids in the diagnosis, as does the presence of anemia or hypercalcemia. The diagnosis of myeloma can be confirmed by bone marrow biopsy; the presence of sheets of plasma cells is the hallmark diagnostic criterion. Because the infiltration of the marrow by these malignant plasma cells is not uniform, the extent of plasma cells may not be increased in a given sample (a false-negative result).

### Gerontologic Considerations

The incidence of multiple myeloma increases with age; the disease rarely occurs in patients younger than 40 years of age. Because of the increasing older population, more patients are seeking treatment for this disease. BMT or PBSCT is an option that can prolong remission and potentially cure some patients. However, it is unavailable to most because of age limitations. Back pain, which is often a presenting symptom in this disease, should be closely investigated in elderly patients.

## Medical Management

There is no cure for multiple myeloma. Even BMT or PBSCT is considered by most authorities to extend remission rather than provide a cure. However, for many patients, it is possible to control the illness and maintain their level of functioning quite well for several years or longer. Chemotherapy is the primary treatment; corticosteroids, particularly dexamethasone (Decadron), are especially effective and are often combined with other agents (such as melphalan (Alkeran), cyclophosphamide (Cytosan), doxorubicin (Adriamycin), vincristine (Oncovin), and BCNU (Carmustine)).

Radiation therapy is very useful in strengthening a specific bone lesion, particularly one at risk for bone fracture or spinal cord compression. It is also useful in relieving bone pain and reducing the size of plasma cell tumors that occur outside the skeletal system. However, because it is a nonsystemic form of treatment, it does not diminish the source of the bone problems (ie, the production of malignant plasma cells). Therefore, radiation therapy is typically used with systemic treatment such as chemotherapy.

The biologic agent alpha-interferon has been used successfully to maintain remission in selected types of myeloma, particularly IgA type; however, its role in prolonging survival is controversial. Newer forms of bisphosphonates, such as pamidronate (Aredia) and zoledronic acid (Zometa), have been shown to strengthen bone

in this disease (by diminishing the secretion of osteoclast activating factor) (Terpos et al., 2000), controlling bone pain and potentially preventing bone fracture. They are also effective in managing and preventing hypercalcemia. Some evidence suggests that bisphosphonates may actually have activity against the myeloma cells themselves by inhibiting a growth factor necessary for myeloma cell survival (Berenson, 2001) (see later discussion).

When patients manifest signs and symptoms of hyperviscosity, plasmapheresis may be used to lower the immunoglobulin level. Symptoms may be more useful than serum viscosity levels in determining the need for this intervention.

Recent advances in the understanding of the process of angiogenesis have resulted in new therapeutic options. The sedative thalidomide (Thalomid), initially used as an antiemetic, has significant antimyeloma effects. It inhibits cytokines necessary for new vascular generation, such as, vascular endothelial growth factor (VEGF) and for myeloma cell growth and survival, such as IL-6 and tumor necrosis factor, by boosting the body's immune response against the tumor and by creating favorable conditions for apoptosis of the myeloma cells. Thalidomide is effective in refractory myeloma and in "smoldering" disease states, and may prevent progression to a more active state. Thalidomide is not a typical chemotherapeutic agent and has a unique side effect profile. Fatigue, dizziness, constipation, rash, and peripheral neuropathy are commonly encountered; myelosuppression is not (Goldman, 2001). Thalidomide is contraindicated in pregnancy because of associated severe birth defects.

## Nursing Management

Pain management is very important in this patient population. NSAIDs can be very useful for mild pain, or in combination with opioid analgesics. However, care needs to be taken, because NSAIDs can cause renal dysfunction. Patients need to be educated about activity restrictions (eg, lifting no more than 10 pounds, use of proper body mechanics). Braces are occasionally needed to provide support to the spinal column.

Patients also need to be instructed about the signs and symptoms of hypercalcemia. Maintaining mobility and hydration is important to diminish exacerbations of this complication; however, the primary cause is the disease itself. Renal function should also be monitored closely. Renal failure can become severe, and dialysis may be needed. Maintaining high urine output (3 L/day) can be very useful in preventing this complication.

Because antibody production is impaired, infections, particularly bacterial infections, are common and can be life-threatening. Patients need to be instructed in appropriate infection prevention measures (see Chart 33-8) and should be advised to contact their health care provider immediately if they have a fever or other signs and symptoms of infection. Patients should receive Pneumovax and flu vaccines. Prophylactic antibiotics are sometimes used. Intravenous gamma globulin (IVIG) can be useful for patients with recurrent infections.

## Bleeding Disorders

Normal hemostatic mechanisms can control bleeding from vessels and prevent spontaneous bleeding. The bleeding vessel constricts and platelets aggregate at the site, forming an unstable hemostatic plug. Circulating coagulation factors are activated on the surface of these aggregated platelets, forming fibrin, which anchors the platelet plug to the site of injury.

The failure of normal hemostatic mechanisms can result in bleeding, which is severe at times. This bleeding is commonly provoked by trauma, but in certain circumstances it can occur spontaneously. When the source is platelet or coagulation factor abnormalities, the site of spontaneous bleeding can be anywhere in the body. When the defect is caused by vascular abnormalities, the site of bleeding may be more localized. Some patients have defects in more than one hemostatic mechanism simultaneously.

In a variety of situations, the bone marrow may be stimulated to increase platelet production (thrombopoiesis). The increased production may be a reactive response, as in a compensatory response to significant bleeding, or a more general response to increase hematopoiesis, as in iron deficiency anemia. Sometimes, the increase in platelets does not result from increased production but from a loss in platelet pooling within the spleen. The spleen typically holds about one third of the circulating platelets at any time. If the spleen is lost (eg, splenectomy), the platelet reservoir is also lost, and an abnormally high amount of platelets enter the circulation. In time, the rate of thrombopoiesis slows to reestablish a more normal platelet level.

## Clinical Manifestations

Signs and symptoms of bleeding disorders vary depending on the type of defect. A careful history and physical examination can be very useful in determining the source of the hemostatic defect. Abnormalities of the vascular system give rise to local bleeding, usually into the skin. Because platelets are primarily responsible for stopping bleeding from small vessels, patients with platelet defects develop petechiae, often in clusters; these are seen on the skin and mucous membranes but also occur throughout the body. Bleeding from platelet disorders can be severe. Unless the platelet disorder is severe, bleeding can often be stopped promptly when local pressure is applied; it does not typically recur when the pressure is released.

In contrast, coagulation factor defects do not tend to cause superficial bleeding, because the primary hemostatic mechanisms are still intact. Instead, bleeding occurs deeper within the body (eg, subcutaneous or intramuscular hematomas, hemorrhage into joint spaces). External bleeding diminishes very slowly when local pressure is applied; it often recurs several hours after pressure is removed. For example, severe bleeding may start several hours after a tooth extraction. Risk factors for bleeding are provided in Chart 33-7.

## Medical Management

Management varies based on the underlying cause of the bleeding disorder. If bleeding is significant, transfusions of blood products are indicated. The specific blood product used is determined by the underlying defect. In specific situations in which fibrinolysis is excessive, hemostatic agents such as aminocaproic acid (Amicar) can be used to inhibit this process. This agent must be used with caution, because excessive inhibition of fibrinolysis can result in thrombosis.

## Nursing Management

Patients who have bleeding disorders or who have the potential for development of such disorders as a result of disease or therapeutic agents must be taught to observe themselves carefully and frequently for bleeding. They need to understand the importance of avoiding activities that increase the risk of bleeding, such as

contact sports. The skin is observed for petechiae and ecchymoses (bruises) and the nose and gums for bleeding. Hospitalized patients may be monitored for bleeding by testing all drainage and excreta (feces, urine, emesis, and gastric drainage) for occult as well as obvious blood. Outpatients are often given fecal occult blood screening cards to detect occult blood in stools.

## PRIMARY THROMBOCYTHEMIA

Primary thrombocythemia (also called essential thrombocythemia) is a stem cell disorder within the bone marrow. A marked increase in platelet production occurs, with the platelet count consistently greater than 600,000/mm<sup>3</sup>. Platelet size may be abnormal, but platelet survival is typically normal. Occasionally, the platelet increase is accompanied by an increase in RBCs or WBCs or both; however, these cells are not increased to the extent that they are in polycythemia vera, CML, or myelofibrosis. Although the exact cause is unknown, primary thrombocythemia is similar to other myeloproliferative disorders, particularly polycythemia vera. Unlike the other myeloproliferative disorders, however, it rarely evolves into acute leukemia.

## Clinical Manifestations

Many patients with primary thrombocythemia are asymptomatic; the illness is diagnosed as the result of finding an elevated platelet count on a CBC. Symptoms, when they do occur, result primarily from hemorrhage or vasoocclusion in the microvasculature. Symptoms may occur more when the platelet count exceeds 1 million/mm<sup>3</sup>. However, symptoms do not always correlate with the extent to which the platelet count is elevated. Thrombosis is common and can be either arterial or venous; major thromboses occur in 15% to 40% of these patients (Jantunen et al., 2001). Because these platelets can be dysfunctional, minor or major hemorrhage can also occur. Bleeding from the mucous membranes of the nose and mouth is common, and significant gastrointestinal bleeding is also possible. Bleeding typically does not occur until the platelet count exceeds 1 million/mm<sup>3</sup>.

Vasoocclusive manifestations are most frequently seen in the form of erythromelalgia. The toxic effects of platelet substances include painful burning, warmth, and redness in a localized distal area of the extremities. Neurologic manifestations may also be seen, such as numbness, tingling, and visual disturbance; these occlusive manifestations can progress to stroke and seizure and, less commonly, to myocardial infarction. The spleen may be enlarged, but usually not to a significant extent.

## Assessment and Diagnostic Findings

The diagnosis of primary thrombocythemia is made by ruling out other potential disorders. Iron deficiency should be excluded, because a reactive increase in the platelet count often accompanies this deficiency. The myeloproliferative disorders (CML, polycythemia vera) should also be excluded. Examination of the CBC shows markedly abnormal platelets. Analysis of the bone marrow (by aspiration and biopsy) shows a marked increase in megakaryocytes (platelet precursors) and is useful in excluding CML as a possible cause for the elevated platelet count. The disease, which affects men and women equally, tends to occur in late middle age. The median survival time exceeds 10 years.

No data reliably predict the development of complications. Risk factors for the development of thrombotic complications are

age greater than 65 years, prior thrombotic events, and long duration of thrombocytosis. Major bleeding tends to occur when the platelet count is very high.

### Medical Management

The management of primary thrombocythemia is highly controversial. The risk of significant thrombotic or hemorrhagic complications may not be increased until the platelet count exceeds 1 million/mm<sup>3</sup> (Briere & Guilmin, 2001). A careful assessment of other risk factors, such as history of peripheral vascular disease, history of tobacco use, atherosclerosis, and prior thrombotic events, should be used in making the decision as to when to initiate therapy. In younger patients with no risk factors, low-dose aspirin therapy may be sufficient to prevent thrombotic complications; however, the use of aspirin can increase the risk for hemorrhagic complications and may be considered a contraindication in patients with a history of gastrointestinal bleeding. The neurologic symptoms (eg, headache and erythromelalgia) and visual symptoms of primary thrombocytopenia can be relieved by low-dose aspirin.

More aggressive measures may be required in older patients and in those with concurrent risk factors. Hydroxyurea (eg, Hydrea), a chemotherapeutic medication, is effective in lowering the platelet count. It is taken orally and causes minimal side effects other than dose-related leukopenia. However, its potential for leukogenesis is in question. The medication anagrelide (Agrylin) is more specific in lowering the platelet count than is hydroxyurea, but it has more side effects. Severe headaches cause many patients to stop taking the medication. Tachycardia and chest pain may also occur, and anagrelide is contraindicated in patients with concurrent cardiac problems. Interferon-alfa-2b (eg, Intron-A) has been shown to lower platelet counts by an unknown mechanism. The medication is administered subcutaneously at varying frequency, commonly three times per week. Significant side effects, such as fatigue, weakness, memory defects, dizziness, anemia, and liver dysfunction, limit its usefulness.

Rarely, the occlusive symptoms are so great that the platelet count must be reduced immediately. Platelet pheresis (see later discussion) can reduce the amount of circulating platelets, but only transiently. The extent by which symptoms and complications (eg, thromboses) are reduced remains unclear.

### Nursing Management

Patients with primary thrombocythemia need to be instructed about the accompanying risks of hemorrhage and thrombosis. Patients should be informed about signs and symptoms of thrombosis, particularly the neurologic manifestations, such as visual changes, numbness, tingling, and weakness. Risk factors for thrombosis should be assessed, and measures to diminish risk factors (particularly cessation of tobacco use) should be encouraged. Patients receiving aspirin therapy should be informed about the increased risk for bleeding. Patients who are at risk for bleeding should be instructed about medications that can alter platelet function, such as aspirin, NSAIDs, and alcohol. Patients receiving interferon therapy should be taught to self-administer the medication and manage side effects.

## SECONDARY THROMBOCYTOSIS

Increased platelet production is the primary mechanism of secondary, or reactive, **thrombocytosis**. The platelet count is above

normal, but, in contrast to primary thrombocythemia, an increase above 1 million/mm<sup>3</sup> is rare. Platelet function is normal; the platelet survival time is normal or decreased. Symptoms associated with hemorrhage or thrombosis are rare. Many disorders can cause a reactive increase in platelets, including chronic inflammatory disorders, iron deficiency, malignant disease, acute hemorrhage, and splenectomy (see previous discussion of primary thrombocythemia). Treatment is aimed at the underlying disorder. With successful management, the platelet count usually returns to normal.

## THROMBOCYTOPENIA

**Thrombocytopenia** (low platelet level) can result from various factors: decreased production of platelets within the bone marrow, increased destruction of platelets, or increased consumption of platelets. Causes and treatments are summarized in Table 33-5.

### Clinical Manifestations

Bleeding and petechiae usually do not occur with platelet counts greater than 50,000/mm<sup>3</sup>, although excessive bleeding can follow surgery or other trauma. When the platelet count drops below

**Table 33-5 • Causes and Management of Thrombocytopenia**

CAUSE	MANAGEMENT
<b>Decreased Production</b>	
Hematologic malignancy, especially acute leukemias	Treat leukemia; platelet transfusion
Myelodysplastic syndromes (MDS): metastatic involvement of bone marrow from solid tumors	Treat MDS; platelet transfusion Treat solid tumor
Aplastic anemia	Treat underlying condition
Megaloblastic anemia	Treat underlying anemia
Toxins	Remove toxin
Medications	Stop medication
Infection (esp. septicemia, viral infection, tuberculosis)	Treat infection
Alcohol	Refrain from alcohol consumption
Chemotherapy	Delay or decrease dose; growth factor; platelet transfusion
<b>Increased Destruction</b>	
Due to Antibodies	Treat condition
Idiopathic thrombocytopenic purpura	
Lupus erythematosus	
Malignant lymphoma	
Chronic lymphocytic leukemia (CLL)	Treat CLL and/or treat as ITP
Medications	Stop medication
Due to Infection	Treat infection
Bacteremia	
Postviral infection	
Sequestration of platelets in an enlarged spleen	If thrombocytopenia is severe, splenectomy may be needed
<b>Increased Consumption</b>	
Disseminated intravascular coagulation (DIC)	Treat underlying condition triggering DIC; administer heparin, EACA, blood products

20,000/mm<sup>3</sup>, petechiae can appear, along with nose and gingival bleeding, excessive menstrual bleeding, and excessive bleeding after surgery or dental extractions. When the platelet count is less than 5000/mm<sup>3</sup>, spontaneous, potentially fatal central nervous system or gastrointestinal hemorrhage can occur. If the platelets are dysfunctional due to disease (eg, MDS) or medications (eg, aspirin), the risk of bleeding may be much greater even when the actual platelet count is not significantly reduced.

### Assessment and Diagnostic Findings

A platelet deficiency that results from decreased production (eg, leukemia, MDS) can usually be diagnosed by examining the bone marrow via aspiration and biopsy. When platelet destruction is the cause of thrombocytopenia, the marrow shows increased megakaryocytes (the cells from which the platelets originate) and normal or even increased platelet production as the body attempts to compensate for the decreased platelets in circulation. Another cause of thrombocytopenia is sequestration. Approximately one third of the circulating platelets are within the spleen, and a greatly enlarged spleen results in increased sequestration of platelets.

### Medical Management

The management for secondary thrombocytopenia is usually treatment of the underlying disease. If platelet production is impaired, platelet transfusions may raise the platelet count and stop bleeding or prevent spontaneous hemorrhage. If excessive platelet destruction occurs, transfused platelets will also be destroyed, and the platelet count will not rise. The most common cause of excessive platelet destruction is ITP (see the following discussion). In some instances splenectomy can be a useful therapeutic intervention, but often it is not a therapeutic option, for example in patients in whom the enlarged spleen is due to portal hypertension related to excessive alcohol consumption.

### Nursing Management

The interventions for a patient with thrombocytopenia are delineated in Chart 33-10.

## IDIOPATHIC THROMBOCYTOPENIC PURPURA (ITP)

ITP is a disease that affects people of all ages, but it is more common among children and young women. There are two forms of ITP: acute and chronic. The acute form, which occurs predominantly in children, often appears 1 to 6 weeks after a viral illness. This form is self-limited; remission often occurs spontaneously within 6 months. Occasionally, corticosteroids are needed for a brief time. Chronic ITP is often diagnosed by exclusion of other causes of thrombocytopenia.

### Pathophysiology

Although the precise cause remains unknown, viral infections sometimes precede ITP in children. Occasionally medications such as sulfa drugs can induce ITP. Other conditions, such as systemic lupus erythematosus (SLE) or pregnancy, can also induce ITP. Anti-platelet autoantibodies that bind to the patient's platelets are found in the blood of patients with ITP. When the platelets are bound by the antibodies, the RES or tissue macrophage system

ingests the platelets, destroying them. The body attempts to compensate for this destruction by increasing platelet production within the marrow.

### Clinical Manifestations

Many patients have no symptoms, and the low platelet count (often less than 20,000/mm<sup>3</sup>, and less than 5000/mm<sup>3</sup> is not uncommon) is an incidental finding. Common physical manifestations are easy bruising, heavy menses, and petechiae on the extremities or trunk. Patients with simple bruising or petechiae ("dry purpura") tend to have fewer complications from bleeding than those with bleeding from mucosal surfaces, such as the gastrointestinal tract (including the mouth) and pulmonary system (eg, hemoptysis), which is termed "wet purpura." Patients with wet purpura have a greater risk for intracranial bleeding than do those with dry purpura. Despite low platelet counts, the platelets are young and very functional. They adhere to endothelial surfaces and to one another, so spontaneous bleeding does not always occur.

### Assessment and Diagnostic Findings

Patients may have an isolated decrease in platelets (less than 20,000/mm<sup>3</sup> is common), but they may also have an increase in megakaryocytes (platelet precursors) within the marrow, as detected on bone marrow aspirate.

### Medical Management

The primary goal of treatment is a safe platelet count. Because the risk of bleeding typically does not increase until the platelet count is lower than 10,000/mm<sup>3</sup>, patients whose counts exceed 30,000 to 50,000/mm<sup>3</sup> may be carefully observed without additional intervention. However, if the count is lower than 20,000/mm<sup>3</sup>, or if bleeding occurs, the goal is to improve the patient's platelet count, rather than to cure the disease. Treatment for ITP usually requires several approaches. If the patient is taking a medication that is known to cause ITP (eg, quinine, sulfa-containing medications), that medication must be stopped immediately. The mainstay of short-term therapy is the use of immunosuppressive agents. The immunosuppressants block the binding receptors on macrophages so that the platelets are not destroyed. Prednisone is the agent typically used (at a dose of 1 mg/kg), and it is effective in about 75% of patients. Cyclophosphamide (eg, Cytosan) and azathioprine (Imuran) can also be used, and dexamethasone (eg, Decadron) may be effective. Platelet counts rise within a few days after institution of corticosteroid therapy; this effect takes longer with azathioprine. Because of the associated side effects, patients cannot take high doses of corticosteroids indefinitely. It is not unusual for the platelet count to drop once the corticosteroid dose is tapered. Some patients can be successfully maintained on low doses of prednisone (eg, 2.5 to 10 mg every other day).

Intravenous gamma globulin (IVIG) is also commonly used to treat ITP. It is effective in binding the receptors on the macrophages; however, high doses (1 g/kg for 2 days) are required, and the drug is very expensive. Splenectomy is an alternative treatment but results in a normal platelet count only 50% of the time; however, many patients can maintain a "safe" platelet count of more than 30,000/mm<sup>3</sup> after removal of the spleen. Even those who do respond to splenectomy may have recurrences of severe thrombocytopenia months or years later. Patients who

have splenectomy are permanently at risk for sepsis; these patients should receive Pneumovax, *Haemophilus influenzae* B, and meningococcal vaccines, preferably 2 to 3 weeks before the splenectomy is preferred. Pneumovax vaccine should be repeated at 5- to 10-year intervals.

Other options for management include use of the chemotherapy agent vincristine (Oncovin). Vincristine appears to work by blocking the receptors on the macrophages and therefore inhibiting platelet destruction; it may also stimulate thrombopoiesis. Some data support the efficacy of certain monoclonal antibodies (eg, rituximab) in increasing platelet counts, but more research is needed (Stasi, Pagano, Stipa, & Amadori, 2001; Saleh et al., 2000).

Another approach to the management of chronic ITP involves the use of anti-D (eg, WinRho) in patients who are Rh(D)-positive. The actual mechanism of action is unknown. One theory is that the anti-D binds to the patient's RBCs, which are in turn destroyed by the body's macrophages. While the macrophages destroy the anti-D/RBC complex, they are not able to destroy platelets. Anti-D produces a transient decreased hematocrit and increased platelet count in many, but not all, patients with ITP. Anti-D appears to be most effective in children with ITP and least effective in patients who have undergone splenectomy.

Despite the extremely low platelet count, platelet transfusions are usually avoided. Transfusions tend to be ineffective because the patient's anti-platelet antibodies bind with the transfused platelets, causing them to be destroyed. Platelet counts can actually drop after platelet transfusion. Occasionally, transfusion of platelets may protect against catastrophic bleeding in patients with severe wet purpura. Epsilon-aminocaproic acid (EACA; Amicar) may be useful for patients with significant mucosal bleeding refractory to other treatments.

## Nursing Management

Nursing care for these patients should include an assessment of the patient's life style to determine the risk of bleeding from activity. A careful medication history should also be obtained, including use of over-the-counter medications, herbs, and nutritional supplements. The nurse must be alert for sulfa-containing medications and medications that alter platelet function (eg, medications that contain aspirin or other NSAIDs). The nurse should assess for any history of recent viral illness and reports of headache or visual disturbances (which could be initial symptoms of intracranial bleeding). Patients who are admitted to the hospital with wet purpura and low platelet counts should have a neurologic assessment incorporated into their routine vital sign measurements. No intramuscular injections or rectal medications should be administered, and rectal temperature measurements should not be performed, because they can stimulate bleeding.

Patient teaching should address signs of exacerbation of disease (petechiae, ecchymoses); how to contact appropriate health care personnel; the name and type of medication inducing ITP (if appropriate); current medical treatment (medications, tapering schedule if relevant, side effects); and the frequency of monitoring the platelet count. Patients should be instructed to avoid all agents that interfere with platelet function. The patient should avoid constipation, the Valsalva maneuver (eg, straining at stool), and flossing of the teeth. Electric razors should be used for shaving, and soft-bristled toothbrushes should replace stiff-bristled ones. Patients should also be counseled to refrain from vigorous sexual intercourse when the platelet count is less than 10,000/mm<sup>3</sup>. Patients who are receiving chronic corticosteroids are at risk for

complications including osteoporosis, proximal muscle wasting, cataract formation, and dental caries (see Chart 33-4). Bone mineral density should be monitored, and these patients may benefit from calcium and vitamin D supplementation and bisphosphonate therapy to prevent significant bone disease.

## PLATELET DEFECTS

Quantitative platelet defects are relatively common (thrombocytopenia), but qualitative defects can also occur. With qualitative defects, the number of platelets may be normal, but the platelets do not function normally. Platelet function is most commonly evaluated by the bleeding time; however, this test is a crude measurement at best.

An important functional platelet disorder is that induced by aspirin. Even small amounts of aspirin reduce normal platelet aggregation, and the prolonged bleeding time lasts for several days after aspirin ingestion. Although this does not cause bleeding in most people, patients with a coagulation disorder (eg, hemophilia) or thrombocytopenia can have significant bleeding after taking aspirin, particularly if invasive procedures or trauma has occurred.

NSAIDs can also inhibit platelet function, but the effect is not as prolonged as with aspirin (about 5 days versus 7 to 10 days). Other causes of platelet dysfunction include end-stage renal disease, possibly from metabolic products affecting platelet function; MDS; multiple myeloma (due to abnormal protein interfering with platelet function); cardiopulmonary bypass; and other medications and substances (Chart 33-13).

## Clinical Manifestations

Bleeding may be mild or severe. Its extent is not necessarily correlated with the platelet count or with tests that measure coagulation (prothrombin time [PT], partial thromboplastin time [PTT]). Ecchymoses are common, particularly on the extremities. Patients with platelet dysfunction may be at risk for significant bleeding after trauma or invasive procedures (eg, biopsy, dental extraction).

## Medical Management

If the platelet dysfunction is caused by medication, use of the offending medication should be stopped, if possible, particularly when bleeding occurs. If platelet dysfunction is marked, bleeding can often be prevented by transfusion of normal platelets before invasive procedures. Amniocaproic acid (EACA; Amicar) may be required to prevent significant bleeding after such procedures.

## Nursing Management

Patients with significant platelet dysfunction need to be instructed to avoid agents that can diminish platelet function, such as certain over-the-counter medications, herbs, nutritional supplements, and alcohol. They also need to be assisted to serve as their own advocates and to inform their health care providers (including dentists) of the underlying condition before any invasive procedure is performed, so that appropriate steps can be initiated to diminish the risk of bleeding. Bleeding precautions should be initiated as appropriate (see Chart 33-10).

## HEMOPHILIA

Two inherited bleeding disorders—hemophilia A and hemophilia B—are clinically indistinguishable, although they can be distinguished by laboratory tests. Hemophilia A is caused by a

secondary to trauma. In contrast, spontaneous hemorrhages, particularly hemarthroses and hematomas, can frequently occur in patients with severe factor VIII deficiency (ie, less than 1% of normal levels). These patients require frequent factor replacement therapy.

About 75% of all bleeding in patients with hemophilia occurs into joints. The most commonly affected joints are the knees, elbows, ankles, shoulders, wrists, and hips. Patients often note pain in a joint before they are aware of swelling and limitation of motion. Recurrent joint hemorrhages can result in damage so severe that chronic pain or ankylosis (fixation) of the joint occurs. Many patients with severe factor deficiency are crippled by the joint damage before they become adults. Hematomas can be superficial or deep hemorrhages into muscle or subcutaneous tissue. With severe factor deficiency, they can occur without known trauma and progressively extend in all directions. When the hematomas occur within muscle, particularly in the extremities, peripheral nerves can be compressed. Over time, this compression results in decreased sensation, weakness, and atrophy of the area involved. Spontaneous hematuria and gastrointestinal bleeding can occur. Bleeding is also common in other mucous membranes, such as the nasal passages. The most dangerous site of hemorrhage is in the head (intracranial or extracranial). Any head trauma requires prompt evaluation and treatment. Surgical procedures typically result in excessive bleeding at the surgical site. Because clot formation is poor, wound healing is also poor. Such bleeding is most commonly associated with dental extraction.

## Medical Management

In the past, the only treatment for hemophilia was infusion of fresh frozen plasma, which had to be administered in such large quantities that patients experienced fluid volume overload. Now factor VIII and factor IX concentrates are available to all blood banks. Recombinant forms of these factors have been made available and may diminish the use of factor concentrates. Patients are given concentrates when they are actively bleeding or as a preventive measure before traumatic procedures (eg, lumbar puncture, dental extraction, surgery). The patient and family are taught how to administer the concentrate intravenously at home at the first sign of bleeding. It is crucial to initiate treatment as soon as possible so that bleeding complications can be avoided. A few patients eventually develop antibodies to the concentrates, so their factor levels cannot be increased. Treatment of this problem is extremely difficult and often unsuccessful.

Aminocaproic acid (EACA; Amicar) is a fibrinolytic enzyme inhibitor that can slow the dissolution of blood clots that do form; it is very effective as an adjunctive measure after oral surgery. It is also useful in treating mucosal bleeding. Another agent, desmopressin (eg, DDAVP), induces a transient rise in factor VIII levels; the mechanism for this response is unknown. In patients with mild forms of hemophilia A, desmopressin is extremely useful, significantly reducing the amount of blood products required. However, desmopressin is not effective in patients with severe factor VIII deficiency.

## Nursing Management

Most patients with hemophilia are diagnosed as children. They often require assistance in coping with the condition because it is chronic, places restrictions on their lives, and is an inherited disorder that can be passed to future generations. From childhood, patients are helped to accept themselves and the disease and to identify the positive aspects of their lives. They are encouraged to be

genetic defect that results in deficient or defective factor VIII; hemophilia B (also called Christmas disease) stems from a genetic defect that causes deficient or defective factor IX. Hemophilia is a relatively rare disease; hemophilia A, which occurs in 1 of every 10,000 births, is three times more common than hemophilia B. Both types of hemophilia are inherited as X-linked traits, so almost all affected people are males; females can be carriers but are almost always asymptomatic. The disease is recognized in early childhood, usually in the toddler age group. However, patients with mild hemophilia may not be diagnosed until they experience severe trauma (eg, a high-school football injury) or surgery. Hemophilia occurs in all ethnic groups.

## Clinical Manifestations

The disease, which can be severe, is manifested by hemorrhages into various parts of the body. Hemorrhage can occur even after minimal trauma. The frequency and severity of the bleeding depend on the degree of factor deficiency as well as the intensity of the precipitating trauma. For example, patients who have a mild factor VIII deficiency (ie, 6% to 50% of normal levels) rarely develop hemorrhage spontaneously; hemorrhage tends to occur

self-sufficient and to maintain independence by preventing unnecessary trauma that can cause acute bleeding episodes and temporarily interfere with normal activities. As they work through their feelings about the condition and progress to accepting it, they can assume more and more responsibility for maintaining optimal health.

Patients with mild factor deficiency may not be diagnosed until adulthood if they do not experience significant trauma or surgery as children. These patients need extensive teaching about activity restrictions and self-care measures to diminish the chance of hemorrhage and complications of bleeding. The nurse should emphasize safety at home and in the workplace.

Patients with hemophilia are instructed to avoid any agents that interfere with platelet aggregation, such as aspirin, NSAIDs, herbs, nutritional supplements, and alcohol. This restriction applies to over-the-counter medications such as cold remedies. Dental hygiene is very important as a preventive measure because dental extractions are so hazardous. Applying pressure may be sufficient to control bleeding resulting from minor trauma if the factor deficiency is not severe. Nasal packing should be avoided, because bleeding frequently resumes when the packing is removed. Splints and other orthopedic devices may be useful in patients with joint or muscle hemorrhages. All injections should be avoided; invasive procedures (eg, endoscopy, lumbar puncture) should be minimized or performed after administration of appropriate factor replacement. Patients with hemophilia should be encouraged to carry or wear medical identification.

During hemorrhagic episodes, the extent of bleeding must be assessed carefully. Patients who are at risk for significant compromise (eg, bleeding into the respiratory tract or brain) warrant close observation and systematic assessment for emergent complications (eg, respiratory distress, altered level of consciousness). If the patient has had recent surgery, the nurse frequently and carefully assesses the surgical site for bleeding. Frequent vital sign monitoring is needed until the nurse is certain that there is no excessive postoperative bleeding.

Analgesics are commonly required to alleviate the pain associated with hematomas and hemorrhage into joints. Many patients report that warm baths promote relaxation, improve mobility, and lessen pain. However, during bleeding episodes, heat, which can accentuate bleeding, is avoided; applications of cold are used instead.

Although recent technology (ie, the formulation of heat-solvent or detergent-treated factor concentrates) has rendered factor VIII and IX preparations free from viruses such as HIV and hepatitis, many patients have already been exposed to these infections. These patients and their families may need assistance in coping with the diagnosis and the consequences of these infections.

Between 15% and 50% of patients with hemophilia A and between 1% and 3% of patients with hemophilia B develop antibodies (inhibitors) to factor concentrates, complicating factor replacement management (Lusher, 2000; White, Greenwood, Escobar, & Frelinger, 2000). These patients may require plasmapheresis or concurrent immunosuppressive therapy, particularly in the setting of significant bleeding. Patients with severe factor deficiency should be screened for antibodies, particularly before major surgery.

## VON WILLEBRAND'S DISEASE

Von Willebrand's disease, a common bleeding disorder affecting males and females equally, is usually inherited as a dominant trait. The disease is caused by a deficiency of von Willebrand factor (vWF), which is necessary for factor VIII activity. vWF is also nec-

essary for platelet adhesion at the site of vascular injury. Although synthesis of factor VIII is normal, its half-life is shortened; therefore, factor VIII levels commonly are mildly low (15% to 50% of normal).

## Clinical Manifestations

Patients commonly have nosebleeds, excessively heavy menses, bleeding from cuts, and postoperative bleeding, although they do not suffer from massive soft tissue or joint hemorrhages. As the laboratory values fluctuate, so does the bleeding. For example, a careful history of prior bleeding may show little problem with postoperative bleeding on one occasion but significant bleeding from a dental extraction at another time.

## Assessment and Diagnostic Findings

Laboratory test results show a normal platelet count but prolonged bleeding time and slightly prolonged PTT. These defects are not static, and laboratory test results can vary widely within the same patient over time.

## Medical Management

Both the factor deficiency and the platelet impairment can be corrected by administration of cryoprecipitate, which contains factor VIII, fibrinogen, and factor XIII (or fresh frozen plasma, if cryoprecipitate is unavailable). Replacement continues for several days to ensure correction of the factor VIII deficiency; up to 7 to 10 days of treatment may be necessary after major surgery. Desmopressin (DDAVP), a synthetic vasopressin analog, can be used to prevent bleeding associated with dental or surgical procedures or to manage mild bleeding after surgery. Desmopressin provides a transient increase in factor VIII coagulant activity and may also correct the bleeding time. It can be administered as an intravenous infusion or intranasally. With major surgery or invasive procedures, both desmopressin and cryoprecipitate may be needed to prevent hemorrhage.

## Acquired Coagulation Disorders

### LIVER DISEASE

With the exception of factor VIII, most blood coagulation factors are synthesized in the liver. Therefore, hepatic dysfunction (due to cirrhosis, tumor, or hepatitis; see Chap. 39) can result in diminished amounts of the factors needed to maintain coagulation and hemostasis. Prolongation of the PT, unless it is caused by vitamin K deficiency, may indicate severe hepatic dysfunction. Although minor bleeding is common (eg, ecchymoses), these patients are also at risk for significant bleeding, related especially to trauma or surgery. Transfusion of fresh frozen plasma may be required to replace clotting factors and to prevent or stop bleeding. Patients may also have life-threatening hemorrhage from peptic ulcers or esophageal varices. In these cases, replacement with fresh frozen plasma, PRBCs, and platelets is usually required.

### VITAMIN K DEFICIENCY

The synthesis of many coagulation factors depends on vitamin K. Vitamin K deficiency is typical in malnourished patients, and some antibiotics decrease the intestinal flora that produce vitamin K, depleting vitamin K stores. Administration of vitamin K (phyton-

azdione [eg, Mephyton], either orally or as a subcutaneous injection) can correct the deficiency quickly; adequate synthesis of coagulation factors is reflected by normalization of the PT.

## COMPLICATIONS OF ANTICOAGULANT THERAPY

Anticoagulants are used in the treatment or prevention of thrombosis. These agents, particularly warfarin or heparin, can result in bleeding. If the PT or PTT is longer than desired and bleeding has not occurred, the medication can be stopped or the dose decreased. Vitamin K is administered for warfarin toxicity. Protamine sulfate is rarely needed for heparin toxicity, because the half-life of heparin is very short. With significant bleeding, fresh frozen plasma replaces the vitamin K–dependent coagulation factors. Other complications of anticoagulant therapy are discussed in Chapter 31.

## DISSEMINATED INTRAVASCULAR COAGULATION (DIC)

DIC is not a disease but a sign of an underlying condition. DIC may be triggered by sepsis, trauma, cancer, shock, abruptio placentae, toxins, or allergic reactions (Chart 33-14). It is potentially life-threatening.

### Pathophysiology

In DIC, the normal hemostatic mechanisms are altered so that a massive amount of tiny clots forms in the microcirculation. Initially, the coagulation time is normal. However, as the platelets and clotting factors are consumed to form the microthrombi, coagulation fails. Thus, the paradoxical result of excessive clotting is bleeding. The clinical manifestations of DIC are reflected in the organs, which are affected either by excessive clot formation (with resultant ischemia to all or part of the organ) or by bleeding. The bleeding is characterized by low platelet and fibrinogen levels; prolonged PT, PTT, and thrombin time; and elevated fibrin degradation products (**D-dimers**) (Table 33-6).

The mortality rate can exceed 80% of patients who develop DIC. Identification of patients who are at risk for DIC and recognition of the early clinical manifestations of this syndrome can result in earlier medical intervention, which may improve the prognosis. However, the primary prognostic factor is the ability to treat the underlying condition that precipitated DIC.

### Clinical Manifestations

Patients with DIC may bleed from mucous membranes, venipuncture sites, and the gastrointestinal and urinary tracts. The bleeding can range from minimal occult internal bleeding to profuse hem-

orrhage from all orifices. Patients may also develop organ dysfunction, such as renal failure and pulmonary and multifocal central nervous system infarctions as a result of microthromboses, macrothromboses, or hemorrhages.

During the initial process of DIC, the patient may have no new symptoms, the only manifestation being a progressive decrease in the platelet count. As the thrombosis becomes more extensive, the patient exhibits signs and symptoms of thrombosis in the organs involved. Then, as the clotting factors and platelets are consumed to form these thrombi, bleeding occurs. Initially the bleeding is subtle, but it can develop into frank hemorrhage. Signs and symptoms depend on the organs involved and are listed in Table 33-7.

### Medical Management

The most important management issue is treating the underlying cause of the DIC. Until the cause is controlled, the mechanism for DIC will persist. A second goal is to correct the secondary effects of tissue ischemia by improving oxygenation, replacing fluids, correcting electrolyte imbalances, and administering vasopressor medications. If serious hemorrhage occurs, the depleted coagulation factors and platelets may be replaced to reestablish the potential for normal hemostasis and thereby diminish bleeding. Cryoprecipitate is given to replace fibrinogen and factors V and VII; fresh frozen plasma is administered to replace other coagulation factors.

A controversial method to interrupt the thrombosis process is the use of heparin infusion. Heparin may inhibit the formation of microthrombi and thus permit perfusion of the organs (skin, kidneys, or brain) to resume. Heparin is typically reserved for the patient in whom thrombotic manifestations predominate or in whom extensive blood component replacement fails to halt the hemorrhage or increase fibrinogen and other clotting levels. When heparin is administered, bleeding may actually worsen initially until the thrombotic process is interrupted. Consumed platelets and clotting factors need to be replaced. The effectiveness of heparin can best be determined by observing for normalization of the plasma fibrinogen concentration and diminishing signs of bleeding.

## NURSING PROCESS: THE PATIENT WITH DISSEMINATED INTRAVASCULAR COAGULATION (DIC)

### Assessment

Nurses need to be aware of patients who are at risk for DIC. Sepsis and acute promyelocytic leukemia are the most common causes of DIC. Patients need to be assessed thoroughly and frequently for signs and symptoms of thrombi and bleeding and monitored for any progression of these signs (see Table 33-7).

### Diagnosis

#### NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses for the patient with DIC may include the following:

- Risk for deficient fluid volume related to bleeding
- Risk for impaired skin integrity related to ischemia or bleeding
- Potential for excess fluid volume related to excessive blood/factor component replacement
- Ineffective tissue perfusion related to microthrombi
- Anxiety and fear of the unknown and possible death

Chart 33-14

### Risk Factors for Disseminated Intravascular Coagulation (DIC)

Sepsis  
 Obstetric complications  
 Acute hemolysis (eg, transfusion reaction)  
 Trauma  
 Shock  
 Cancer (especially prostate cancer and acute promyelocytic leukemia)  
 Allergic reactions

**Table 33-6 • Laboratory Values Commonly Found in Disseminated Intravascular Coagulation (DIC)\***

TEST	FUNCTION EVALUATED	NORMAL RANGE	CHANGES IN DIC
Platelet count	Platelet number	150,000–450,000/mm <sup>3</sup>	↓
Prothrombin time (PT)	Extrinsic pathway	11–12.5 sec	↑
Partial thromboplastin time (PTT)	Intrinsic pathway	23–35 sec	↑
Thrombin time (TT)	Clot formation	8–11 sec	↑
Fibrinogen	Amount available for coagulation	170–340 mg/dL	↓
D-dimer	Local fibrinolysis	0–250 ng/mL	↑
Fibrin degradation products (FDPs)	Fibrinolysis	0–5 µg/mL	↑
Euglobulin clot lysis	Fibrinolytic activity	≥2 hours	≤1 hour

\* Because DIC is a dynamic condition, the laboratory values measured will change over time. Therefore, a progressive increase or decrease in a given laboratory value is likely to be more important than the actual value of a test at a single point in time.

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Collaborative problems include the clinical conditions that precipitated the DIC. Based on the assessment data, potential complications may include:

- Renal failure
- Gangrene
- Pulmonary embolism or hemorrhage
- Altered level of consciousness
- Acute respiratory distress syndrome
- Stroke

### Planning and Goals

Major patient goals include maintenance of hemodynamic status, maintenance of intact skin and oral mucosa, maintenance

of fluid balance, maintenance of tissue perfusion, enhanced coping, and absence of complications (see Plan of Nursing Care).

### Nursing Interventions

See Plan of Nursing Care: The Patient with Disseminated Intravascular Coagulation.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Despite aggressive measures, the lack of renal perfusion may result in acute renal failure, sometimes necessitating dialysis. Placement of a large-bore dialysis catheter is extremely hazardous in this patient population and should be accompanied by adequate platelet and plasma transfusions.

**Table 33-7 • Recognizing Thrombosis and Bleeding in Disseminated Intravascular Coagulation (DIC)\***

SYSTEM	SIGNS AND SYMPTOMS OF MICROVASCULAR THROMBOSIS	SIGNS AND SYMPTOMS OF MICROVASCULAR AND FRANK BLEEDING
<b>Integumentary system (skin)</b>	↓ Temperature, sensation; ↑ pain; cyanosis in extremities, nose, earlobes; focal ischemia, superficial gangrene	Petechiae, including periorbital and oral mucosa; bleeding; gums, oozing from wounds, previous injection sites, around catheters (IVs, tracheostomies); epistaxis; diffuse ecchymoses; subcutaneous hemorrhage; joint pain
<b>Circulatory system</b>	↓ Pulses; capillary filling time > 3 sec	Tachycardia
<b>Respiratory system</b>	Hypoxia (secondary to clot in lung); dyspnea; chest pain with deep inspiration; ↓ breath sounds over areas of large embolism	High-pitched bronchial breath sounds; tachypnea; ↑ consolidation; signs and symptoms of acute respiratory distress syndrome
<b>Gastrointestinal system</b>	Gastric pain; “heartburn”	Hematemesis (heme <sup>+</sup> NG output) melana (heme <sup>+</sup> stools → tarry stools → bright-red blood from rectum) retroperitoneal bleeding (abdomen firm and tender to palpation; distended; ↑ abdominal girth)
<b>Renal system</b>	↓ Urine output; ↑ creatinine, ↑ blood urea nitrogen	Hematuria
<b>Neurologic system</b>	↓ Alertness and orientation; ↓ pupillary reaction; ↓ response to commands; ↓ strength and movement ability	Anxiety; restlessness; ↓ mentation, altered level of consciousness; headache; visual disturbances; conjunctival hemorrhage

\* Note: Signs of microvascular thrombosis are the result of an inappropriate activation of the coagulation system, causing thrombotic occlusion of small vessels within all body organs. As the clotting factors and platelets are consumed, signs of microvascular bleeding appear. This bleeding can quickly extend into frank hemorrhage. Treatment must be aimed at the disorder underlying the DIC; otherwise, the stimulus for the syndrome will persist.

<sup>+</sup>heme<sup>+</sup>, positive for hemoglobin

## Plan of Nursing Care

### The Patient With Disseminated Intravascular Coagulation (DIC)

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Potential for fluid volume deficit related to bleeding

**Goals:** Hemodynamic status maintained

Urine output  $\geq 30$  mL/hr

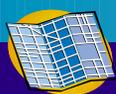

1. Avoid procedures/activities that can increase intracranial pressure (eg, coughing, straining to have a bowel movement).	1. Prevents intracranial bleeding.	<ul style="list-style-type: none"> <li>• Level of consciousness (LOC) stable</li> <li>• CVP 5–12 cm H<sub>2</sub>O, systolic BP <math>\geq</math> 70 mm Hg</li> <li>• Urine output <math>\geq 30</math> mL/hour</li> <li>• Decreased bleeding</li> <li>• Decreased oozing</li> <li>• Decreased ecchymoses</li> <li>• Amenorrhea</li> <li>• Absence of oral and bronchial bleeding</li> <li>• Oral mucosa clean, moist, intact</li> <li>• Absence of bleeding</li> </ul>
2. Monitor vital signs closely, including neurologic checks: <ol style="list-style-type: none"> <li>a. Monitor hemodynamics</li> <li>b. Monitor abdominal girth</li> <li>c. Monitor urine output</li> </ol>	2. Identifies signs of hemorrhage/shock quickly.	
3. Avoid medications that interfere with platelet function if possible (eg, ASA, NSAIDs, beta-lactam antibiotics).	3. Decreases problems with platelet aggregation and adhesion.	
4. Avoid rectal probes, rectal medications.	4. Decreases chance for rectal bleeding.	
5. Avoid IM injections.	5. Decreases chance for intramuscular bleeding.	
6. Monitor amount of external bleeding carefully <ol style="list-style-type: none"> <li>a. Monitor number of dressings, % of dressing saturated; time to saturate a dressing is more objective than “dressing saturated a moderate amount.”</li> <li>b. Monitor suction output, all excreta</li> <li>c. Monitor pad counts in menstruating females.</li> <li>d. Females may receive progesterone to prevent menses.</li> </ol>	6. <ol style="list-style-type: none"> <li>a. Provides accurate, objective assessment of extent of bleeding.</li> <li>b. Identifies presence of or quantifies extent of bleeding.</li> <li>c. Quantifies extent of bleeding</li> <li>d. Decreases chance for gynecologic source of hemorrhage.</li> </ol>	
7. Use low pressure with any suctioning needed.	7. Prevents excessive trauma that could cause bleeding.	
8. Administer oral hygiene carefully. <ol style="list-style-type: none"> <li>a. Avoid lemon-glycerine swabs, hydrogen peroxide, commercial mouthwashes.</li> <li>b. Use sponge-tipped swabs, salt/baking soda (bicarbonate of soda) mouth rinses.</li> </ol>	8. Prevents excessive trauma that could cause bleeding. Glycerin and alcohol (in commercial mouthwashes) will dry mucosa, increasing risk for bleeding.	
9. Avoid dislodging any clots, including those around IV sites and injection sites.	9. Prevents excessive bleeding at sites.	

**Nursing Diagnosis:** Potential for impaired skin integrity secondary to ischemia or bleeding

**Goals:** Skin integrity remains intact; oral mucosa remains intact

1. Assess skin, with particular attention to bony prominences, skin folds.	1. Prompt identification of any area at risk for skin breakdown or showing early signs of breakdown can facilitate prompt intervention and thus prevent complications.	<ul style="list-style-type: none"> <li>• Skin integrity remains intact; skin is warm, and of normal color</li> <li>• Oral mucosa is intact, pink, moist, without bleeding</li> </ul>
2. Reposition carefully; use pressure-reducing mattress.	2–4. Meticulous skin care and use of measures to prevent pressure on bony prominences decrease the risk of skin trauma.	
3. Perform careful skin care every 2 hr, emphasizing dependent areas, all bony prominences, perineum.		
4. Use lamb’s wool between digits, around ears, as needed.		
5. Use prolonged pressure after injection or procedure when such measures must be performed (at least 5 min)	5. Initial platelet plug is very unstable and easily dislodged, which can lead to increased bleeding.	
6. Administer oral hygiene carefully (see above).	6. Meticulous care to decreased trauma, bleeding, and risk of infection.	

(continued)

## Plan of Nursing Care

### The Patient With Disseminated Intravascular Coagulation (DIC) (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Potential for fluid volume excess

**Goals:** Absence of edema; absence of rales; Intake not greater than output

- |  |  |   |
|--|--|---|
| <ol style="list-style-type: none"> <li>1. Auscultate breath sounds every 2–4 hr.</li> <li>2. Monitor extent of edema</li> <li>3. Monitor volume of IVs, blood products; decrease volume of IV medications if possible.</li> <li>4. Administer diuretics as prescribed</li> </ol> | <ol style="list-style-type: none"> <li>1. Additional professional intervention may be necessary, particularly if previous coping mechanisms are maladaptive or ineffective. Spiritual dimension should be supported.</li> </ol> | <ul style="list-style-type: none"> <li>• Previously used coping strategies identified and tried, to extent patient is able to do so</li> <li>• Patient indicates understanding of procedures and situation as condition permits</li> </ul> |
|---|---|--|

## Evaluation

See the Plan of Nursing Care for evaluation and expected outcomes for the patient with DIC.

## THROMBOTIC DISORDERS

As in many bleeding disorders, several conditions can alter the balance within the normal hemostasis process and cause exces-

sive thrombosis. Abnormalities that predispose a person to thrombotic events include decreased clotting inhibitors within the circulation (which enhances coagulation), altered hepatic function (which may decrease production of clotting factors or clearance of activated coagulation factors), lack of fibrinolytic enzymes, and tortuous vessels (which promote platelet aggregation). Thrombosis can be caused by more than one predisposing factor. Several conditions can result from thrombosis, such as myocardial infarction (see Chap. 28), cerebral vascular accident

(CVA, brain attack, or stroke; see Chap. 62), and peripheral arterial occlusion (see Chap. 31). Several inherited or acquired deficiency conditions, including hyperhomocystinemia, antithrombin III (AT III) deficiency, Protein C deficiency, activated Protein C (APC) resistance, factor V Leiden, and Protein S deficiency can predispose a patient to repeated episodes of thrombosis; they are referred to as hypercoagulable states or thrombophilia. Table 33-8 delineates these disorders, their abnormal laboratory values, and the need for family testing.

Thrombosis requires anticoagulation therapy. The duration of therapy varies with the location and extent of the thrombosis, precipitating events (eg, trauma, immobilization), and concurrent risk factors (eg, use of oral contraceptives, tortuous blood vessels, history of thrombotic events).

## HYPERHOMOCYSTEINEMIA

Increased plasma levels of homocystine are a significant risk factor not only for venous thrombosis (eg, deep venous thrombosis [DVT], pulmonary embolism) but also for arterial thrombosis (eg, stroke, myocardial infarction). This disorder can be heredi-

tary, or it can result from a nutritional deficiency of folic acid and, to a lesser extent, of vitamin B<sub>12</sub> and B<sub>6</sub>, because these vitamins are cofactors in homocystine metabolism. For unknown reasons, people who are elderly, have renal failure, or smoke tobacco may also have elevated levels of homocystine in the absence of nutritional deficiencies of these vitamins. Although a simple fasting measurement of plasma homocystine can serve as a useful screening test, people with heterozygous defects in this gene and those who are vitamin B<sub>6</sub> deficient may have normal or minimally elevated levels. A much more sensitive method involves obtaining a second measurement 4 hours after the patient consumes methionine; the prevalence of hyperhomocystinemia is twice as great when this method is used. In hyperhomocystinemia, the endothelial lining of the vessel walls is denuded; this can precipitate unnecessary thrombus formation. Recent studies have determined that this disorder is much more common than previously thought. In a long-term epidemiologic study on nurses' health (Rimm et al., 1998), women who used dietary supplements with folic acid and vitamin B<sub>6</sub> were found to have a lower incidence of thrombotic conditions such as DVT. Patients who are found to have hyperhomocystinemia should receive folic acid, B<sub>6</sub>, and/or B<sub>12</sub> supplements and should be instructed in the rationale for their use to enhance compliance.

**Table 33-8 • Hypercoagulable States**

DISORDER	ABNORMAL LABORATORY VALUE*
<b>Inherited Disorders (Family Testing Necessary)</b>	
Hyperhomocysteinemia	Homocystine ↑ after methionine load
Antithrombin III (AT III) deficiency	AT III ↓
Protein C deficiency	Protein C activity ↓ (must be measured off warfarin [Coumadin])
Activated protein C (APC) resistance	Must be measured off anticoagulant; <2× prolongation of PTT when APC added. Patients with APC resistance have a smaller increase in clotting time than normal (ie, the prolongation of clotting time is less than normal).
Factor V Leiden	Positive
Protein S deficiency	Protein S activity ↓; must be measured off warfarin (Coumadin)
Dysfibrinogenemia	↑ thrombin time; ↑ reptilase time; ↓ functional fibrinogen; often requires special fibrinogen assays
<b>Acquired Disorders (Family Testing Unnecessary)</b>	
Anticardiolipin antibody	Positive
Cancer	
Lupus anticoagulant	Positive
Hyperhomocysteinemia	Homocystine ↑ after methionine load
AT III Deficiency	AT III ↓
Paroxysmal nocturnal hemoglobinuria	+ Hamm's test; acid hemolysis
Myeloproliferative disorders	Varied, depending on disorder
Nephrotic syndrome	Varied, depending on disorder
Cancer chemotherapy	Varied, depending on disorder

\*Protein C and protein S are vitamin K–dependent proteins. Warfarin (Coumadin) interferes with the hepatic synthesis of vitamin K–dependent factors, which may decrease levels of protein C or protein S; therefore, protein C and protein S should be measured while the patient is off warfarin.

## ANTITHROMBIN III DEFICIENCY

Antithrombin is a protein that inhibits thrombin and certain coagulation factors. AT III deficiency is an extremely common hereditary condition that can cause venous thrombosis, particularly when the level is less than 60% of normal. Patients with AT III deficiency can develop venous thrombosis as young adults; by 50 years of age, two thirds of patients with AT III deficiency have developed a venous thrombosis. The most common sites for thrombosis are the deep veins of the leg and the mesentery. Recurrent thrombosis often occurs. There is an increased resistance to heparin anticoagulation, so these patients may require greater amounts of heparin to achieve adequate anticoagulation. Patients with ATIII deficiency should be encouraged to have their family members tested for the deficiency.

## PROTEIN C DEFICIENCY

Protein C is an enzyme that, when activated, inhibits coagulation. When levels of Protein C are deficient, the risk of thrombosis increases, and thrombosis can often occur spontaneously. Protein C deficiency is at least as prevalent as AT III deficiency, and people who are Protein C–deficient can develop thrombosis early in life, as early as 15 years of age. Warfarin-induced skin necrosis is a rare but significant complication of anticoagulation management in patients with Protein C deficiency (Hoffman et al., 2000). This complication appears to result from progressive thrombosis in the capillaries within the skin; the extent of the necrosis can be extreme.

## ACTIVATED PROTEIN C RESISTANCE AND FACTOR V LEIDEN MUTATION

Activated protein C (APC) resistance is a common condition that can occur with other hypercoagulable states. APC is an anticoagulant, and resistance to APC increases the risk for venous thrombosis. A molecular defect in the factor V gene has been identified in

most (90%) of those with APC resistance; this defect is called factor V Leiden mutation. It has been identified as the most common cause of inherited hypercoagulability in Caucasians, but its incidence appears to be much lower in other ethnic groups. Factor V Leiden mutation synergistically increases the risk for thrombosis in patients with other risk factors (eg, use of oral contraceptives, hyperhomocystinemia, increased age). It does not appear that the use of postmenopausal hormone therapy in women increases the risk for thrombotic events as does the use of oral contraceptives; the dose of estrogen in the former situation is much lower than in the latter. People who are homozygous for the factor V Leiden mutation are at extremely high risk for thrombosis.

## PROTEIN S DEFICIENCY

Protein S is another natural anticoagulant normally produced in the liver. APC requires Protein S to inactivate certain clotting factors. When the level of Protein S is deficient, this inactivation process is diminished, and the risk for thrombosis can be increased. Like patients with Protein C deficiency, those with Protein S deficiency have a greater risk for recurrent venous thrombosis at a young age, as young as 15 years.

## ACQUIRED THROMBOPHILIA

Antibodies to phospholipids are common, acquired causes for thrombophilia (hypercoagulable states). The most common antibodies present against phospholipids are either lupus or anti-cardiolipin antibodies. Both of these antibodies can be transient, resulting from infection or certain medications. Most thrombotic events are venous, but arterial thrombosis can occur in up to one third of the cases. Patients who persistently test positive for either antibody and who have had a thrombotic event are at significant risk for recurrent thrombosis (greater than 50%). Recurrent thromboses tend to be of the same type—that is, venous thrombosis after an initial venous thrombosis, arterial thrombosis after an initial arterial thrombosis.

Another common acquired cause for thrombophilia is cancer. Specific types of stomach, pancreatic, lung, and ovarian cancers are most commonly associated with thrombophilia. The type of thrombosis that results is unusual. Rather than deep vein thrombosis or pulmonary embolism, the thrombosis occurs in unusual sites, such as the portal, hepatic, or renal vein or the inferior vena cava. Migratory superficial thrombophlebitis or nonbacterial thrombotic endocarditis can also occur. In these patients, anticoagulation can be difficult to manage in that the thrombosis can progress despite standard amounts of anticoagulation.

## Medical Management

The primary method of treating thrombotic disorders is anticoagulation. However, in thrombophilic conditions, when to treat (prophylaxis or not) and how long to treat (lifelong or not) can be controversial. Anticoagulation therapy is not without risks; the most significant risk is bleeding. Risks of anticoagulation therapy are identified in Chapter 31. The most common anticoagulant medications are identified in the following section.

## PHARMACOLOGIC THERAPY

Along with administering anticoagulant therapy, concerns include minimizing any risk factors that predispose a patient to

thrombosis. When risk factors (eg, immobility after surgery, pregnancy) cannot be avoided, prophylactic anticoagulation may be necessary.

**Unfractionated Heparin Therapy.** Heparin is a naturally occurring anticoagulant that enhances AT III and inhibits platelet function. To prevent thrombosis, heparin is typically given as a subcutaneous injection, two or three times daily. To treat thrombosis, heparin is usually administered intravenously. The therapeutic effect of heparin is monitored by serial measurements of the activated partial prothrombin time; the dose is adjusted to maintain the range at 1.5 to 2.5 times the laboratory control. Oral forms are being evaluated, but their absorption remains variable (Money & York, 2001).

A significant potential complication of heparin-based therapy is heparin-induced thrombocytopenia (HIT). Antibodies are formed within the body against the heparin complex. The actual incidence of HIT is unknown, but it is thought to occur in as many as 5% patients receiving heparin (Kelton, 1999). Whereas most patients remain asymptomatic, a significant proportion of those individuals with serologic HIT develop actual thrombocytopenia. A decline in platelet count typically develops after 5 to 8 days of heparin therapy, and the platelets can drop significantly, although in most instances the level stays higher than 50,000/mm<sup>3</sup>. These patients are at increased risk for thrombosis, either venous or arterial, and the thrombosis can range from DVT to myocardial infarction, CVA (brain attack, stroke), and ischemic damage to an extremity necessitating amputation. The risk for development of HIT appears to be increased when heparin is used at higher concentrations (ie, therapeutic versus prophylactic dosage) and with preexisting comorbidity, such as underlying cardiac disease.

**Low-Molecular-Weight Heparin Therapy.** Low molecular-weight heparin (LMWH; eg, Dalteparin, Enoxaparin) is a special form of heparin that has a more selective effect on coagulation. Based on its biochemical properties, LMWH has a longer half-life and a less variable anticoagulant response than does standard heparin. These differences permit LMWH to be safely administered only once or twice daily, without the need for laboratory monitoring for dose adjustments. The incidence of HIT is much lower when LMWH is used. In certain conditions, the use of LMWH has allowed anticoagulation therapy to be moved entirely to the outpatient setting. Many cases of uncomplicated DVT are being managed outside the hospital setting. LMWH is also being increasingly used as “bridge therapy” when patients receiving anticoagulation therapy (warfarin) require an invasive procedure (eg, biopsy, surgery). In this situation, warfarin is stopped and LMWH is used in its place until the procedure is completed. After the procedure, warfarin therapy is resumed. LMWH is discontinued after a therapeutic level of warfarin is achieved.

**Warfarin (Coumadin) Therapy.** Coumarin anticoagulants (warfarin; eg, Coumadin) are antagonists of vitamin K and therefore interfere with the synthesis of vitamin K–dependent clotting factors. Coumarin anticoagulants bind to albumin, are metabolized in the liver, and have an extremely long half-life. Typically, a patient is initially treated with both heparin (either the unfractionated form or LMWH) and warfarin. When the international normalized ratio (INR) reaches the desired therapeutic range, the heparin is stopped. The dosage required to maintain the thera-

peutic range (typically using an INR of 2.0 to 3.0) varies widely among patients and even within the same patient. Frequent monitoring of the INR is extremely important so that the dosage of warfarin can be adjusted as needed. Warfarin is affected by many medications; consultation with a pharmacist is important to assess the extent to which concurrently administered medications, herbs, and nutritional supplements may interact with warfarin. It is also affected by many foods, so patients need dietary instruction and may benefit from consultation with a dietitian when receiving warfarin therapy. See Chart 33-15 for a listing of agents that interact with warfarin.

## Nursing Management

Patients with thrombotic disorders should avoid activities that promote circulatory stasis (eg, immobility, crossing the legs). Exercise, especially ambulation, should be performed frequently throughout the day, particularly during long trips by car or plane.

### Chart 33-15 • PHARMACOLOGY Agents That Interact with Warfarin (Coumadin)

Although warfarin (Coumadin), an anticoagulant medication, is commonly used to treat and prevent thrombosis, many drug–drug and drug–food interactions are associated with its use. A careful medication history (including over-the-counter medications, herbs, and other substances, such as vitamins and minerals) is important when oral anticoagulation therapy is prescribed. Consultation with a pharmacist is recommended to assess the extent to which concurrent medications may affect the anticoagulant and for appropriate dosage adjustments. The following list contains a few examples of agents that interact with warfarin.

#### Agents That Inhibit Warfarin Function

Barbiturates	Glutethimide
Carbamazepine	Griseofulvin
Cholestyramine	Haloperidol
Corticosteroids	Oral contraceptives
Digitalis	Phenytoin
Estrogens	Rifampin
Ethanol	Spironolactone

#### Agents That Potentiate Warfarin Function

Acetaminophen	Ginkgo
Allopurinol	Ginseng
Amiodarone	Vitamin C (in very large doses)
Anabolic steroids	Vitamin E (in very large doses)
Anti-inflammatory agents	Isoniazid
Antimalarial agents	Mefenamic acid
Aspirin	Methotrexate
Broad-spectrum antibiotics	Metronidazole
Chloral hydrate	Oral hypoglycemic agents
Chloramphenicol	Oxyphenbutazone
Cimetidine	Phenytoin
Colchicine	Probenecid
Clofibrate	Propylthiouracil
Chlorpromazine	Quinidine
Danazol	Quinine
Disulfiram	Salicylates
Ethacrynic acid	Sulfapyrazone
Feprozone	Sulfonamides (long-acting)
Herbal medicines	Thyroxine
Feverfew	Triclofos
Garlic	Tricyclic antidepressants

Medications that alter platelet aggregation, such as low-strength aspirin, may be prescribed. Some patients require life-long therapy with anticoagulants such as warfarin (eg, Coumadin).

Patients with thrombotic disorders, particularly those with thrombophilia, should be assessed for concurrent risk factors for thrombosis and should avoid concomitant risk factors if possible. For example, use of tobacco and nicotine products exacerbates the problem and should be avoided.

Just as for other conditions, patients with thrombotic disorders, particularly thrombophilia, should know the name of their specific condition and understand its significance. In many instances, younger patients with thrombophilia may not require prophylactic anticoagulation; however, with concomitant risk factors (eg, pregnancy), increasing age, or subsequent thrombotic events, prophylactic or lifelong anticoagulation therapy may be required. Being able to provide the health care provider with an accurate health history can be extremely useful and can help guide the selection of appropriate therapeutic interventions. Patients with hereditary disorders should be encouraged to have their siblings and children tested for the disorder.

When patients with thrombotic disorders are hospitalized, frequent assessments should be performed for signs and symptoms of beginning thrombus formation, particularly in the legs (DVT) and lungs (pulmonary embolism). Ambulation or range-of-motion exercises as well as the use of elastic compression stockings should be initiated promptly to decrease stasis. Prophylactic anticoagulants are commonly prescribed.

## Therapies for Blood Disorders

### SPLENECTOMY

The surgical removal of the spleen (splenectomy) is sometimes necessary after trauma to the abdomen. Because the spleen is very vascular, severe hemorrhage can result if the spleen is ruptured. Under such circumstances, splenectomy becomes an emergency procedure.

Splenectomy is also a possible treatment for other hematologic disorders. For example, an enlarged spleen may be the site of excessive destruction of blood cells. If the destruction is life-threatening, surgery may be lifesaving. This is the case in autoimmune hemolytic anemia or ITP when these disorders do not respond to more conservative measures, such as corticosteroid therapy. Some patients with severe anemia due to inherited RBC defects (eg, thalassemia) may also benefit from splenectomy.

In general, the mortality rate after splenectomy is low. Laparoscopic splenectomy can be used in selected patients, with a resultant decrease in the postoperative morbidity rate. Complications that may result from surgery are atelectasis, pneumonia, abdominal distention, and abscess formation. Although young children are at the highest risk after splenectomy, all age groups are vulnerable to overwhelming lethal infections and should receive pneumovax before undergoing this surgical procedure if possible.

Patients are instructed to seek prompt medical attention if even relatively minor symptoms of infection occur. Often, patients with high platelet counts have even higher counts after splenectomy—more than 1 million/mm<sup>3</sup>—which can predispose them to serious thrombotic or hemorrhagic problems. This increase is, however, transient.

## THERAPEUTIC APHERESIS

Apheresis is a Greek word meaning separation. In therapeutic apheresis (or pheresis), blood is taken from the patient and passed through a centrifuge, where a specific component is separated from the blood and removed (Table 33-9). The remaining blood is then returned to the patient. The entire system is closed, so the risk of bacterial contamination is extremely low. When platelets or WBCs are removed, the decrease in these cells within the circulation is temporary. However, the temporary decrease provides a window of time until suppressive medications (eg, chemotherapy) can have therapeutic effects. Sometimes plasma is removed rather than blood cells—typically so that specific, abnormal proteins within the plasma will be transiently lowered until a long-term therapy can be initiated.

Apheresis is also used to obtain larger amounts of platelets from a donor than can be provided from a single unit of whole blood. A unit of platelets obtained in this way is equivalent to six to eight units of platelets obtained from six to eight separate donors via standard blood donation methods. Platelet donors can have their platelets apheresed as often as every 14 days. WBCs can be obtained similarly, typically after the donor has received growth factors (G-CSF, GM-CSF) to stimulate the formation of additional WBCs and thereby increase the WBC count. The use of these growth factors also stimulates the release of stem cells within the circulation. Apheresis is used to harvest these stem cells (typically over a period of several days) for use in PBSCT (peripheral blood stem cell transplant; see Chap. 16).

## THERAPEUTIC PHLEBOTOMY

Therapeutic phlebotomy is the removal of a certain amount of blood under controlled conditions. Patients with elevated hematocrits (eg, those with polycythemia vera) or excessive iron absorption (eg, hemochromatosis) can usually be managed by periodically removing 1 unit (about 500 mL) of whole blood. Eventually this process can produce iron deficiency, leaving the patient

unable to produce as many RBCs. The actual procedure for therapeutic phlebotomy is similar to that for blood donation (see later discussion).

## BLOOD AND BLOOD COMPONENT THERAPY

A single unit of whole blood contains 450 mL of blood and 50 mL of an anticoagulant. A unit of whole blood can be processed and dispensed for administration. However, it is more appropriate, economical, and practical to separate that unit of whole blood into its primary components: RBCs, platelets, and plasma (WBCs are rarely used; see later discussion). Because the plasma is removed, a unit of RBCs (packed RBCs, PRBCs) is very concentrated (hematocrit, approximately 70%). Each component must be processed and stored differently to maximize the longevity of the viable cells and factors within it; each individual blood component has a different storage life. PRBCs are stored at 4°C. With special preservatives, they can be stored safely for up to 42 days before they must be discarded. In contrast, platelets must be stored at room temperature because they cannot withstand cold temperatures, and they last for only 5 days before they must be discarded. To prevent clumping, platelets are gently agitated while stored. Plasma is immediately frozen to maintain the activity of the clotting factors within; it lasts for 1 year if it remains frozen. Plasma can be further pooled and processed into blood derivatives, such as albumin, immune globulin, factor VIII, and factor IX. Table 33-10 describes each blood component and how it is commonly used.

## SPECIAL PREPARATIONS

Factor VIII concentrate (antihemophilic factor) is a lyophilized, freeze-dried concentrate of pooled fractionated human plasma. It is used in treating hemophilia A. Factor IX concentrate (prothrombin complex) is similarly prepared and contains factors II,

**Table 33-9 • Types of Apheresis\***

PROCEDURE	PURPOSE	EXAMPLES OF CLINICAL USE
Platelet pheresis	Remove platelets	Extreme thrombocytosis, essential thrombocytopenia (temporary measure); single-donor platelets transfusion
Leukapheresis	Remove WBCs (can be specific to neutrophils or lymphocytes)	Extreme leukocytosis (eg, AML, CML) (very temporary measure); harvest WBCs for transfusion
Erythrocytapheresis (RBC exchange)	Remove RBCs	RBC dyscrasias (eg, sickle cell disease); RBCs replaced via transfusion
Plasmapheresis (plasma exchange)	Remove plasma proteins	Hyperviscosity syndromes; treatment for some renal and neurologic diseases (eg, Goodpasture's syndrome, Guillain-Barré)
Stem cell harvest	Remove circulating stem cells	Transplantation (donor harvest or autologous)

\*Therapeutic apheresis can be used to treat a wide variety of conditions. When it is used to treat a disease that causes an increase in a specific cell type with a short life in circulation (ie, WBCs, platelets), the reduction in those cells is temporary. However, this temporary reduction permits a margin of safety while waiting for a longer-lasting treatment modality (eg, chemotherapy) to take effect. Apheresis can also be used to obtain stem cells for transplantation, either from a matched donor (allogenic) or from the patient (autologous). AML, acute myeloid leukemia; CML, chronic myeloid leukemia; RBC, red blood cell; WBC, white blood cell.

Table 33-10 • Blood and Blood Components Commonly Used in Transfusion Therapy\*

	COMPOSITION	INDICATIONS AND CONSIDERATIONS
<b>Whole blood</b>	Cells and plasma, hematocrit about 40%	Volume replacement and oxygen-carrying capacity; usually used only in significant bleeding (> 25% blood volume lost)
<b>Packed red blood cells (PRBCs)</b>	RBCs with little plasma (hematocrit about 75%); some platelets and WBCs remain	↑ RBC mass Symptomatic anemia: platelets in the unit are not functional; WBCs the unit may cause reaction and are not functional
<b>Platelets—random</b>	Platelets ( $5.5 \times 10^{10}$ platelets/unit) Plasma; some RBCs, WBCs	Bleeding due to severe ↓ platelets Prevent bleeding when platelets $<5,000\text{--}10,000/\text{mm}^3$ Survival ↓ in presence of fever, chills, infection Repeated treatment → ↓ survival due to alloimmunization
<b>Platelets—single donor</b>	Platelets ( $3 \times 10^{11}$ platelets/unit) 1 unit is equivalent to 6–8 units of random platelets	Used for repeated treatment: ↓ alloimmunization risk by limiting exposure to multiple donors
<b>Plasma (FFP)</b>	Plasma; all coagulation factors Complement	Bleeding in patients with coagulation factor deficiencies; plasmapheresis
<b>Granulocytes (pheresed)</b>	Neutrophils ( $>1 \times 10^{10}/\text{unit}$ ); lymphocytes; some RBCs and platelets	Severe neutropenia in selected patients; controversial
<b>Lymphocytes (WBCs) (aphersed)</b>	Lymphocytes (number varies)	Stimulate graft-versus-disease effect
<b>Cryoprecipitate</b>	Fibrinogen $\geq 150$ mg/bag, AHF (VIII:C) 80–110 units/bag, von Willebrand factor; fibronectin	von Willebrand's disease Hypofibrinogenemia Hemophilia A
<b>Antihemophilic factor (AHF)</b>	Factor VIII	Hemophilia A
<b>Factor IX concentrate</b>	Factor IX	Hemophilia B (Christmas disease)
<b>Factor IX complex</b>	Factor II, VII, IX, X	Hereditary factor VII, IX, X deficiency; Hemophilia A with factor VII inhibitors
<b>Albumin</b>	Albumin 5%, 25%	Hypoproteinemia; burns; volume expansion by 5% to ↑ blood volume; 25% → ↓ hematocrit
<b>Intravenous gamma globulin</b>	IgG antibodies	Hypogammaglobulinemia (in CLL, recurrent infections); ITP; primary immunodeficiency states
<b>Antithrombin III concentrate (AT III)</b>	AT III (trace amounts of other plasma proteins)	ATIII deficiency with or at risk for thrombosis

\*The composition of each type of blood component is described as well as the most common indications for using a given blood component. RBCs, platelets, and fresh frozen plasma are the blood products most commonly used. When transfusing these blood products, it is important to realize that the individual product is always “contaminated” with very small amounts of other blood products (eg, WBCs mixed in a unit of platelets). This contamination can cause some difficulties, particularly isosensitization, in certain patients. AHF, antihemophilic factor; CLL, chronic lymphocytic leukemia; ITP, idiopathic thrombopenic purpura.

VII, IX, and X. It is used primarily for treatment of factor IX deficiency (hemophilia B). Factor IX concentrate is also useful in treating congenital factor VII and factor X deficiencies.

Plasma albumin is a large protein molecule that usually stays within vessels and is a major contributor to plasma oncotic pressure. This protein is used to expand the blood volume of patients in hypovolemic shock and, rarely, to increase the concentration of circulating albumin in patients with hypoalbuminemia.

Immune globulin is a concentrated solution of the antibody IgG; it contains very little IgA or IgM. It is prepared from large pools of plasma. The intravenous form (IVIG) is used in various clinical situations to replace inadequate amounts of IgG in patients who are at risk for recurrent bacterial infection (eg, those with CLL, those receiving BMT or PBSCT). IVIG, in contrast to all other fractions of human blood, cells, or plasma, are able to survive being subjected to heating at 60°C (140°F) for 10 hours to free them of viral contaminants.

## Procuring Blood and Blood Products

### BLOOD DONATION

To protect both the donor and the recipients, all prospective donors are examined and interviewed before they are allowed to donate their blood. The intent of the interview is to assess the general health status of the donor and to identify risk factors that might harm a recipient of the donor's blood. Donors should be in good health and without any of the following:

- A history of viral hepatitis at any time in the past, or a history of close contact with a hepatitis or dialysis patient within 6 months
- A history of receiving a blood transfusion or an infusion of any blood derivative (other than serum albumin) within 6 months
- A history of untreated syphilis or malaria, because these diseases can be transmitted by transfusion even years later. A

person who has been free of symptoms and off therapy for 3 years after malaria may be a donor.

- A history or evidence of drug abuse in which substances were self-injected, because many intravenous/injection drug users are hepatitis carriers and because the risk for human immunodeficiency virus (HIV) is high in this group
- A history of possible exposure to HIV; the population at risk includes people who engage in anal sex, people with multiple sexual partners, intravenous/injection drug users, sexual partners of people at risk for HIV, and people with hemophilia
- A skin infection, because of the possibility of contaminating the phlebotomy needle, and subsequently the blood itself
- A history of recent asthma, urticaria, or allergy to medications, because hypersensitivity can be transferred passively to the recipient
- Pregnancy within 6 months, because of the nutritional demands of pregnancy on the mother
- A history of tooth extraction or oral surgery within 72 hours, because such procedures are frequently associated with transient bacteremia
- A history of exposure to infectious disease within the past 3 weeks, because of the risk of transmission to the recipient
- Recent immunizations, because of the risk of transmitting live organisms (2-week waiting period for live, attenuated organisms; 1 month for rubella; 1 year for rabies)
- A history of recent tattoo, because of the risk of blood-borne infections (eg, hepatitis, HIV)
- Cancer, because of the uncertainty about transmission of the disease
- A history of whole blood donation within the past 56 days

Potential donors should be asked whether they have consumed any aspirin or aspirin-containing medications within the past 3 days. Although aspirin use does not render the donor ineligible, the platelets obtained would be dysfunctional and therefore not useful. Aspirin does not affect the RBCs or plasma obtained from the donor.

All donors are expected to meet the following minimal requirements:

- Body weight should exceed 50 kg (110 pounds) for a standard 450-mL donation. Donors weighing less than 50 kg donate proportionately less blood. People younger than 17 years of age are disqualified from donation.
- The oral temperature should not exceed 37.5°C (99.6°F).
- The pulse rate should be regular and between 50 and 100 beats per minute.
- The systolic arterial pressure should be 90 to 180 mm Hg, and the diastolic pressure should be 50 to 100 mm Hg.
- The hemoglobin level should be at least 12.5 g/dL for women and 13.5 g/dL for men.

### Directed Donation

At times, friends and family of a patient wish to donate blood for that person. These blood donations are termed directed donations. These donations are not any safer than those provided by random donors, because directed donors may not be as willing to identify themselves as having a history of any of the risk factors that disqualify a person from donating blood.

### Standard Donation

Phlebotomy consists of venipuncture and blood withdrawal. Standard precautions are used. Donors are placed in a semi-recumbent position. The skin over the antecubital fossa is carefully cleansed with an antiseptic preparation, a tourniquet is applied, and venipuncture is performed. Withdrawal of 450 mL of blood usually takes less than 15 minutes. After the needle is removed, donors are asked to hold the involved arm straight up, and firm pressure is applied with sterile gauze for 2 or 3 minutes or until bleeding stops. A firm bandage is then applied. Donors remain recumbent until they feel able to sit up, usually within a few minutes. Donors who experience weakness or faintness should rest for a longer period. Donors then receive food and fluids and are asked to remain another 15 minutes.

Donors are instructed to leave the dressing on and to avoid heavy lifting for several hours, to avoid smoking for 1 hour, to avoid drinking alcoholic beverages for 3 hours, to increase fluid intake for 2 days, and to eat a healthy meals for 2 weeks. Specimens from this donated blood are tested to detect infections and to identify the specific blood type (see later discussion).

### Autologous Donation

A patient's own blood may be collected for future transfusion; this method is useful for many elective surgeries where the potential need for transfusion is high (eg, orthopedic surgery). Preoperative donations are ideally collected 4 to 6 weeks before surgery. Iron supplements are prescribed during this period to prevent depletion of iron stores. Occasionally, erythropoietin (epoetin-alfa [Epogen, Procrit]) is given to stimulate erythropoiesis to ensure that the donor's hematocrit remains high enough to be eligible for donation. Typically, 1 unit of blood is drawn each week; the number of units obtained varies with the type of surgical procedure to be performed (ie, the amount of blood anticipated to be transfused). Phlebotomies are not performed within 72 hours of surgery. Individual blood components can also be collected.

The primary advantage of autologous transfusions is the prevention of viral infections from another person's blood. Other advantages include safe transfusion for patients with a history of transfusion reactions, prevention of alloimmunization, and avoidance of complications in patients with alloantibodies. The policy of the American Red Cross requires autologous blood to be transfused only to the donor. If the blood is not required, it can be frozen until the donor needs it in the future (for up to 10 years). The blood is never returned to the general donor supply of blood products to be used by someone else.

The disadvantage of autologous donation is that it may be performed even when the likelihood that the anticipated procedure will necessitate a transfusion is small. Needless autologous donation is expensive, takes time, and uses resources inappropriately. Moreover, in an emergency situation, the autologous units available may be inadequate, and the patient may still require additional units from the general donor supply.

Contraindications to donation of blood for autologous transfusion are acute infection, severely debilitating chronic disease, hemoglobin level less than 11 g/dL, hematocrit less than 33%, unstable angina, and acute cardiovascular or cerebrovascular disease. A history of poorly controlled epilepsy may be considered a contraindication in some centers. Patients with cancer may donate for themselves.

## Intraoperative Blood Salvage

This transfusion method provides replacement for patients who are unable to donate before surgery and for those undergoing vascular, orthopedic, or thoracic surgery. During a surgical procedure, blood lost into a sterile cavity (eg, hip joint) is suctioned into a cell-saver machine. The RBCs are washed, often with saline solution, and then returned to the patient as an intravenous infusion. Salvaged blood cannot be stored, because bacteria cannot be completely removed from the blood.

## Hemodilution

This transfusion method is initiated before or after induction of anesthesia. About 1 or 2 units of blood are removed from the patient through a venous or arterial line and simultaneously replaced with a colloid or crystalloid solution. The blood obtained is then reinfused after surgery (Kreimeier & Messmer, 2002). The advantage of this method is that the patient loses fewer RBCs during surgery, because the added intravenous solutions dilute the concentration of RBCs and lower the hematocrit. Patients who are at risk for myocardial injury, however, should not be further stressed by hemodilution.

## COMPLICATIONS OF BLOOD DONATION

Excessive bleeding at the donor's venipuncture site is sometimes caused by a bleeding disorder in the donor but more often results from a technique error: laceration of the vein, excessive tourniquet pressure, or failure to apply enough pressure after the needle is withdrawn.

Fainting is common after blood donation and may be related to emotional factors, a vasovagal reaction, or prolonged fasting before donation. Because of the loss of blood volume, hypotension and syncope may occur when the donor assumes an erect position. A donor who appears pale or complains of faintness should immediately lie down or sit with head lowered below the knees; he or she should be observed for another 30 minutes.

Anginal chest pain may be precipitated in patients with unsuspected coronary artery disease. Seizures can occur in donors with epilepsy, although the incidence is very low. Both angina and seizures require further medical evaluation.

Many people have the misconception that donating blood can cause AIDS and other infections. Potential donors need to be educated that the equipment used in donation is sterile, a closed system, and not reusable; they are at no risk for acquiring such infections from donating blood.

## BLOOD PROCESSING

Samples of the unit of blood are always taken immediately after donation so that the blood can be typed and tested. Each donation is tested for antibodies to HIV 1 and 2, hepatitis B core antibody (anti-HBc), hepatitis C virus (HCV), and human T-cell lymphotropic virus, type I (anti-HTLV-I/II). The blood is also tested for hepatitis B surface antigen (HbsAG) and for syphilis. Negative reactions are required for the blood to be used, and each unit of blood is labeled to certify the results. A new testing method, using nucleic acid amplification testing (NAT), has increased the ability to detect the presence of HCV and HIV infection, because it directly tests for genomic nucleic acids of the virus itself, rather than for the presence of antibod-

ies to the virus (Korman, Leparc & Benson, 2001). This testing significantly shortens the "window" of inability to detect HIV and HCV from a donated unit, further ensuring the safety of the blood. Blood is also screened for CMV; if it tests positive for CMV, it can still be used, except in recipients who are negative for CMV and who are immunocompromised (eg, BMT or PBSC recipients).

Equally important to viral testing is accurate determination of the blood type. More than 200 antigens have been identified on the surface of RBC membranes. Of these, the most important for safe transfusion are the ABO and Rh systems. The ABO system identifies which sugars are present on the membrane of an individual's RBCs: A, B, both A and B, or neither A nor B (type O). To prevent a significant reaction, the same type of RBCs should be transfused. Previously, it was thought that in an emergency situation in which the patient's blood type was not known, type O blood could be safely transfused. This practice is no longer advised by the American Red Cross.

The Rh antigen (also called D) is present on the surface of RBCs in 85% of the population (Rh-positive). Those who lack the D antigen are called Rh-negative. RBCs are routinely tested for the D antigen as well as ABO. Patients should receive PRBCs with a compatible Rh type.

## TRANSFUSION

Administration of blood and blood components requires knowledge of correct administration techniques and possible complications. It is very important to be familiar with the agency's policies and procedures for transfusion therapy. Methods for transfusing blood components are presented in Charts 33-16 and 33-17. Potential complications of transfusion follow.

### Setting

Although most blood transfusions are performed in the acute care setting, patients with chronic transfusion requirements often can receive transfusions in other settings. Free-standing infusion centers, ambulatory care clinics, a physician's office, and even the home may be appropriate settings for transfusion. Typically, patients who need chronic transfusions but are otherwise stable physically are appropriate candidates for outpatient therapy. Verification and administration of the blood product are performed much as in a hospital setting. Although most blood products can be transfused in the outpatient setting, the home is typically limited to transfusions of PRBCs and factor components (eg, factor VIII for patients with hemophilia).

## Pretransfusion Assessment

### PATIENT HISTORY

Patient history is an important component of the pretransfusion assessment to determine the history of previous transfusions as well as previous reactions to transfusion. The history should include the type of reaction, its manifestations, the interventions required, and whether any preventive interventions were used in subsequent transfusions. It is important to assess the number of pregnancies a woman has had, because an increased number can increase her risk for reaction due to antibodies developed from exposure to fetal circulation. Other concurrent health problems should also be noted, with careful attention to cardiac, pulmonary, and vascular disease.

## Transfusion of Packed Red Blood Cells (PRBCs)

**Preprocedure**

1. Confirm that the transfusion has been prescribed.
2. Check that patient's blood has been typed and cross-matched.
3. Verify that patient has signed a written consent form per institution policy.
4. Explain the procedure to the patient. Instruct patient in signs and symptoms of transfusion reaction (itching, hives, swelling, shortness of breath, fever, chills).
5. Take patient's temperature, pulse, respiration, and blood pressure to establish a baseline for comparing vital signs during transfusion.
6. Use hand hygiene and wear gloves in accordance with Standard Precautions.
7. Use a 20-gauge or larger needle for placement in a large vein. Use special tubing that contains a blood filter to screen out fibrin clots and other particulate matter. Do not vent the blood container.

**Procedure**

1. Obtain the PRBCs from the blood bank *after* the intravenous line is started. (Institution policy may limit release to only 1 unit at a time.)
2. Double-check the labels with another nurse or physician to make sure that the ABO group and Rh type agree with the compatibility record. Check to see that the number and type on the donor blood label and on the patient's chart are correct. Check the patient's identification by asking the patient's name and checking the identification wristband.
3. Check the blood for gas bubbles and any unusual color or cloudiness. (Gas bubbles may indicate bacterial growth. Abnormal color or cloudiness may be a sign of hemolysis.)

*Note:* Never add medications to blood or blood products; if blood is too thick to run freely, normal saline may be added to the unit. If blood must be warmed, use an in-line blood warmer with a monitoring system.

4. Make sure PRBC transfusion is initiated within 30 min after removal of the PRBCs from the blood bank refrigerator.
5. For first 15 minutes, run the transfusion slowly—no faster than 5 mL/min. Observe the patient carefully for adverse effects. If no adverse effects occur during the first 15 min, increase the flow rate unless the patient is at high risk for circulatory overload.
6. Monitor closely for 15–30 min to detect signs of reaction. Monitor vital signs at regular intervals per institution policy; compare results with baseline measurements. Increase frequency of measurements based on patient's condition. Observe the patient frequently throughout the transfusion for any signs of adverse reaction, including restlessness, hives, nausea, vomiting, torso or back pain, shortness of breath, flushing, hematuria, fever, or chills. Should any adverse reaction occur, stop infusion immediately, notify physician, and follow the agency's transfusion reaction standard.
7. Note that administration time does not exceed 4 hr because of the increased risk for bacterial proliferation.
8. Be alert for signs of adverse reactions: circulatory overload, sepsis, febrile reaction, allergic reaction, and acute hemolytic reaction.
9. Change blood tubing after every 2 units transfused, to decrease chance of bacterial contamination.

**Postprocedure**

1. Obtain vital signs and compare with baseline measurements.
2. Dispose of used materials properly.
3. Document procedure in patient's medical record, including patient assessment findings and tolerance to procedure.
4. Monitor patient for response to and effectiveness of the procedure.

## Transfusion of Platelets or Fresh Frozen Plasma (FFP)

**Preprocedure**

1. Confirm that the transfusion has been prescribed.
2. Verify that patient has signed a written consent form per institution policy.
3. Explain the procedure to the patient. Instruct patient in signs and symptoms of transfusion reaction (itching, hives, swelling, shortness of breath, fever, chills).
4. Take patient's temperature, pulse, respiration, and blood pressure to establish a baseline for comparing vital signs during transfusion.
5. Wash hands and wear gloves in accordance with Standard Precautions.
6. Use a 22-gauge or larger needle for placement in a large vein, if possible. Use appropriate tubing per institution policy (platelets often require different tubing from that used for other blood products).

**Procedure**

1. Obtain the platelets or FFP from the blood bank (only *after* the intravenous line is started.)
2. Double-check the labels with another nurse or physician to make sure that the ABO group matches the compatibility record (not usually necessary for platelets; here only if compatible platelets are ordered). Check to see that the number and type on the donor blood label and on the patient's chart are correct. Check the patient's identification by asking the patient's name and checking the identification wristband.
3. Check the blood product for any unusual color or clumps (excessive redness indicates contamination with larger amounts of red blood cells).

4. Make sure platelets or FFP units are administered immediately after they are obtained.
5. Infuse each unit as fast as patient can tolerate to diminish platelet clumping during administration. Observe the patient carefully for adverse effects, including circulatory overload. Decrease rate of infusion if necessary.
6. Observe the patient closely throughout the transfusion for any signs of adverse reaction, including restlessness, hives, nausea, vomiting, torso or back pain, shortness of breath, flushing, hematuria, fever, or chills. Should any adverse reaction occur, stop infusion immediately, notify physician, and follow the agency's transfusion reaction standard.
7. Monitor vital signs at end of transfusion per institution policy; compare results with baseline measurements.
8. Flush line with saline after transfusion to remove blood component from tubing.

**Postprocedure**

1. Obtain vital signs and compare with baseline measurements.
2. Dispose of used materials properly.
3. Document procedure in patient's medical record, including patient assessment findings and tolerance to procedure.
4. Monitor patient for response to and effectiveness of procedure. A platelet count may be ordered 1 hr after platelet transfusion to facilitate this evaluation.

*Note:* FFP requires ABO but not Rh compatibility. Platelets are not typically cross-matched for ABO compatibility. Never add medications to blood or blood products.

## PHYSICAL ASSESSMENT

A systematic physical assessment and measurement of baseline vital signs are important before transfusing any blood product. The respiratory system should be assessed, including careful auscultation of the lungs and for use of accessory muscles. Cardiac system assessment should include careful inspection for any edema as well as other signs of cardiac failure (eg, jugular venous distention). The skin should be observed for rashes, petechiae, and ecchymoses. The sclera should be examined for icterus. In the event of a possible transfusion reaction, a comparison of findings can help differentiate between types of reactions.

## Patient Teaching

Reviewing the signs and symptoms of a potential transfusion reaction is crucial for patients who have not received a transfusion before. Even for those patients who have received prior transfusions, a brief review of signs and symptoms of potential transfusion reactions is advised. Signs and symptoms of a possible reaction include fever, chills, respiratory distress, low back pain, nausea, pain at the intravenous site, or anything “unusual.” Although a thorough review is very important, it is also important to reassure the patient that the blood is carefully tested against the patient’s own blood (cross-matched) to diminish the likelihood of any untoward reaction. Such assurance can be extremely beneficial in allaying anxiety. Similarly, it can be useful to mention again the very low possibility of contracting HIV from the transfusion; this fear persists among many people.

## Transfusion Complications

Any patient who receives a blood transfusion may develop complications from that transfusion. When explaining the reasons for the transfusion, it is important to include the risks and benefits and what to expect during and after the transfusion. Patients must be informed that the supply of blood is not completely risk-free although it has been tested carefully. Nursing management is directed toward preventing complications, promptly recognizing complications if they develop, and promptly initiating measures to control any complications that occur. The following sections describe the most common or potentially severe transfusion-related complications.

## FEBRILE, NONHEMOLYTIC REACTION

The nonhemolytic reaction, caused by antibodies to donor WBCs that are still present in the unit of blood or blood component, is the most common type of transfusion reaction, accounting for more than 90% of reactions. It occurs more frequently in patients who have had previous transfusions (exposure to multiple antigens from previous blood products) and in Rh-negative women who have borne Rh-positive children (exposure to an Rh-positive fetus raises antibody levels in the mother). These reactions occur in 1% of PRBC transfusions and 20% of platelet transfusions. More than 10% of patients with a chronic transfusion requirement develop this type of reaction.

### NURSING RESEARCH PROFILE 33-1

#### Perspectives of Recipients of Blood Transfusions

Fitzgerald, M., Hodgkinson, B., & Thorp, D. (1999). Blood transfusion from the recipient’s perspective. *Journal of Clinical Nursing* 8(5), 593–600.

#### Purpose

The process of informed consent requires that information be provided to the patient before consent and implies that a dialogue between the patient and physicians and nurses occurs during this process. This study stemmed from previous studies examining transfusion practices in a large teaching hospital in Australia; the studies revealed that little is known about how much patients understood about the transfusion process. The purpose of this study was to more closely examine the meaning of patients’ experiences with blood transfusions.

#### Study Sample and Design

The study design employed interpretive phenomenology, a qualitative analysis process that allowed researchers to identify meanings that may have been hidden in common actions. A convenience sample of 19 patients was interviewed; subjects were asked to discuss their experience of receiving a blood transfusion, beginning with the time they were told about it. Subjects received transfusions for a variety of clinical conditions, primarily surgery, cancer, and emergency situations. The interviews were tape recorded and transcribed verbatim. The data were analyzed and themes were identified.

#### Findings

Three broad themes were identified and more closely analyzed: information regarding the transfusion, reaction to receiving a transfusion, and care received during the transfusion. The focus of many of the interviews was on the information process. Physicians’ explanations regarding the purpose of the transfusion were typically brief and were focused on providing factual information, particularly before the

patient’s signing of the consent for the procedure. Nurses’ explanations continued as the procedure progressed but tended to focus only on potential reactions. Neither physicians nor nurses tended to encourage the patient to express his or her concerns, nor sought information from the patient. Few patients could actually recall any of the factual information presented to them. Fear of infection, particularly human immunodeficiency virus (HIV) infection, was present but was not excessive. Subjects verbalized understanding that the risk of acquiring HIV from their transfusion was very remote. Most subjects were told that the transfusion would make them feel better; in reality (and likely due to the severity of their illness/injury) such was not the case. Beyond the initial procedure by the nurse of double-checking the blood product for transfusion against the patient’s identity and hanging the blood, patients did not notice any difference in the nursing care they received during the transfusion.

#### Nursing Implications

Findings from this study have important implications for nurses, particularly concerning the information process. Despite the focus of both physicians and nurses on providing information, patients demonstrated that they did not comprehend it well. Informational needs vary, as do learning styles. It is crucial that nurses assess their patients’ level of understanding about the entire transfusion process. Not having the opportunity to deliberate on the information provided and to express concern was a common theme from the study subjects. Nurses need to make the time for patients to express their concerns and verbalize their feelings. This need exists not only for those receiving their first transfusion but also for those who have long-term transfusion requirements.

The diagnosis of a febrile, nonhemolytic reaction is made by excluding other potential causes, such as a hemolytic reaction or bacterial contamination of the blood product. The signs and symptoms of a febrile, nonhemolytic transfusion reaction are chills (absent to severe) followed by fever (more than 1°C elevation). The fever typically begins within 2 hours after the transfusion is begun. Although not life-threatening, the fever and particularly the chills and muscle stiffness can be frightening to the patient.

These reactions can be diminished, even prevented, by further depleting the blood component of donor WBCs; this is accomplished by a leukocyte reduction filter. The blood product may be filtered during processing, which achieves better results but is more expensive, or during the actual transfusion by adding the filter to the blood administration tubing. Antipyretics can be given to prevent fever, but routine premedication is not advised because it can mask the beginning of a more serious transfusion reaction.

## ACUTE HEMOLYTIC REACTION

The most dangerous, and potentially life threatening, type of transfusion reaction occurs when the donor blood is incompatible with that of the recipient. Antibodies already present in the recipient's plasma rapidly combine with antigens on donor RBCs, and the RBCs are hemolyzed (destroyed) in the circulation (intravascular hemolysis). The most rapid hemolysis occurs in ABO incompatibility. This reaction can occur after transfusion of as little as 10 mL of RBCs. Rh incompatibility often causes a less severe reaction. The most common causes of acute hemolytic reaction are errors in blood component labeling and patient identification that result in the administration of an ABO-incompatible transfusion.

Symptoms consist of fever, chills, low back pain, nausea, chest tightness, dyspnea, and anxiety. As the RBCs are destroyed, the hemoglobin is released from the cells and excreted by the kidneys; therefore, hemoglobin is present in the urine (hemoglobinuria). Hypotension, bronchospasm, and vascular collapse may result. Diminished renal perfusion results in acute renal failure, and DIC may also occur.

The reaction must be recognized promptly and the transfusion discontinued immediately. Blood and urine specimens must be obtained and analyzed for evidence of hemolysis. Treatment goals include maintaining blood volume and renal perfusion and preventing and managing DIC.

Acute hemolytic transfusion reactions are preventable. Meticulous attention to detail in labeling blood samples and blood components and identifying the recipient cannot be overemphasized.

## ALLERGIC REACTION

Some patients may develop urticaria (hives) or generalized itching during a transfusion. The cause of these reactions is thought to be a sensitivity reaction to a plasma protein within the blood component being transfused. Symptoms of an allergic reaction are urticaria, itching, and flushing. The reactions are usually mild and respond to antihistamines. If the symptoms resolve after administration of an antihistamine (eg, diphenhydramine [eg, Benadryl]), the transfusion may be resumed. Rarely, the allergic reaction is severe, with bronchospasm, laryngeal edema, and shock. These reactions are managed with epinephrine, corticosteroids, and pressor support, if necessary.

Giving the patient antihistamines before the transfusion may prevent future reactions. For severe reactions, future blood components are washed to remove any remaining plasma proteins. Leukocyte filters are not useful, because the offending plasma proteins can pass through the filter.

## CIRCULATORY OVERLOAD

If too much blood infuses too quickly, hypervolemia can occur. This condition can be aggravated in patients who already have increased circulatory volume (eg, those with heart failure). PRBCs are safer to use than whole blood. If the administration rate is sufficiently slow, circulatory overload may be prevented. For patients who are at risk for, or already in, circulatory overload, diuretics are administered after the transfusion or between units of PRBCs. Patients receiving fresh frozen plasma or even platelets may also develop circulatory overload. The infusion rate of these blood components must also be titrated to the patient's tolerance.

Signs of circulatory overload include dyspnea, orthopnea, tachycardia, and sudden anxiety. Neck vein distention, crackles at the base of the lungs, and a rise in blood pressure can also occur. If the transfusion is continued, pulmonary edema can develop, as manifested by severe dyspnea and coughing of pink, frothy sputum.

If fluid overload is mild, the transfusion can often be continued after slowing the rate of infusion and administering diuretics. However, if the overload is severe, the patient is placed in an upright position with the feet in a dependent position, the transfusion is discontinued, and the physician is notified. The intravenous line is kept patent with a very slow infusion of normal saline solution or a saline or heparin lock device to maintain access to the vein in case intravenous medications are necessary. Oxygen and morphine may be needed for severe dyspnea.

## BACTERIAL CONTAMINATION

The incidence of bacterial contamination of blood components is very low; however, administration of contaminated products puts the patient at great risk. Contamination can occur at any point during procurement or processing. Many bacteria cannot survive in the cold temperatures used to store PRBCs (platelets are at greater risk for contamination because they are stored at room temperature), but some organisms can survive cold temperatures.

Preventive measures include meticulous care in the procurement and processing of blood components. When PRBCs or whole blood is transfused, it should be administered within a 4-hour period, because warm room temperatures promote bacterial growth. A contaminated unit of blood product may appear normal, or it may have an abnormal color.

The signs of bacterial contamination are fever, chills, and hypotension. These signs may not occur until the transfusion is complete, occasionally not until several hours after the transfusion. If the condition is not treated immediately with fluids and broad-spectrum antibiotics, shock can occur. Even with aggressive management, including vasopressor support, the mortality rate is high.

As soon as the reaction is recognized, any remaining transfusion is discontinued and the intravenous line is kept open with normal saline solution. The physician and the blood bank are notified, and the blood container is returned to the blood bank for testing and culture. Septicemia is treated with intravenous fluids and antibiotics; corticosteroids and vasopressors also may be necessary.

## TRANSFUSION-RELATED ACUTE LUNG INJURY

This is a potentially fatal, idiosyncratic reaction that occurs in fewer than 1 in 5000 transfusions. Plasma antibodies (usually in the donor's plasma) that are present in the blood component stimulate the recipient's WBCs; aggregates of these WBCs form and occlude the microvasculature within the lungs. This lung injury is manifested as pulmonary edema; it can occur within 4 hours after the transfusion.

Signs and symptoms include fever, chills, acute respiratory distress (in the absence of other signs of left ventricular failure, such as elevated central venous pressure), and bilateral pulmonary infiltrates. Aggressive supportive therapy (oxygen, intubation, diuretics) may prevent death.

## DELAYED HEMOLYTIC REACTION

Delayed hemolytic reactions usually occur within 14 days after transfusion, when the level of antibody has been increased to the extent that a reaction can occur. The hemolysis of the RBCs is extravascular, via the RES, and occurs gradually.

Signs and symptoms of a delayed hemolytic reaction are fever, anemia, increased bilirubin level, decreased or absent haptoglobin, and possibly jaundice. Rarely is there hemoglobinuria. Generally, these reactions are not dangerous, but it is useful to recognize them, because subsequent transfusions with blood products containing these antibodies may cause a more severe hemolytic reaction. However, recognition is also difficult, because the patient may not be in a health care setting to be tested for this reaction, and even if the patient is hospitalized, the reaction may be too mild to be recognized clinically. Because the amount of antibody present can be too low to detect, it is difficult to prevent delayed hemolytic reactions. The reaction is usually mild and requires no intervention.

## DISEASES TRANSMITTED BY BLOOD TRANSFUSION

Despite the advances in donor screening and blood testing, certain diseases can still be transmitted by transfusion of blood components. The diseases in Chart 33-18 are examples of this phenomenon.

## COMPLICATIONS OF LONG-TERM TRANSFUSION THERAPY

The complications that have been described represent a real risk for any patient any time a unit of blood is administered. However, patients with long-term transfusion therapy (eg, those with MDS, thalassemia, sickle cell anemia) are at greater risk for infection transmission and for becoming more sensitized to donor antigens, simply because they are exposed to more units of blood and, consequently, more donors. Iron overload is a complication unique to those individuals with long-term PRBC transfusions. A summary of complications associated with long-term transfusion therapy is depicted in Table 33-11.

**Iron Overload.** One unit of PRBCs contains 250 mg of iron. Patients with chronic transfusion requirements can quickly acquire more iron than they can use, leading to iron overload. Over time, the excess iron deposits in the tissues and can cause

Chart  
33-18

## Diseases Transmitted by Blood Transfusion

### Hepatitis (Viral Hepatitis B, C)

- Greater risk from pooled blood products and blood of paid donors than from volunteer donors
- Screening test detects most hepatitis B and C
- Transmittal risk estimated at 1:10,000

### AIDS (HIV and HTLV)

- Donated blood screened for antibodies to HIV
- Transmittal risk estimated at 1:670,000
- People with high-risk behaviors (multiple sex partners, anal sex, intravenous/injection drug use) and people with signs and symptoms that suggest AIDS should not donate blood

### Cytomegalovirus (CMV)

- Transmittal risk greater for premature newborns with CMV antibody-negative mothers and for immunocompromised recipients who are CMV-negative (eg, those with acute leukemia, organ or tissue transplant recipients).
- Blood products rendered "leukocyte-reduced" help reduce transmission of virus.

### Graft-Versus-Host Disease (GVHD)

- Occurs only in severely immunocompromised recipients (eg, Hodgkin's disease, bone marrow transplantation).
- Transfused lymphocytes engraft in recipient and attack host lymphocytes or body tissues; signs and symptoms are fever, diffuse reddened skin rash, nausea, vomiting, diarrhea.
- Preventive measures include irradiating blood products to inactivate donor lymphocytes (no known radiation risks to transfusion recipient) and processing donor blood with leukocyte reduction filters.

### Creutzfeldt-Jakob Disease (CJD)

- Rare, fatal disease causing irreversible brain damage
- No evidence of transmittal by transfusion, but hemophiliacs and others are concerned that transmittal is possible
- All blood donors must be screened for positive family history of CJD.
- Potential donors who spent 6 months or more in the United Kingdom (or Europe) from 1980 to 1996 cannot donate blood; blood products from a donor who develops CJD are recalled.

organ damage, particularly in the liver, heart, testes, and pancreas. Promptly initiating a program of iron chelation therapy (eg, with deferoxamine [Desferal]) can prevent end-organ damage from iron toxicity (Giardina & Grady, 1995).

## NURSING MANAGEMENT FOR TRANSFUSION REACTIONS

If a transfusion reaction is suspected, the transfusion must be immediately stopped and the physician notified. A thorough patient assessment is crucial, because many complications have similar signs and symptoms. The following steps are taken to determine the type and severity of the reaction:

- Stop the transfusion. Maintain the intravenous line with normal saline solution through new intravenous tubing, administered at a slow rate.
- Assess the patient carefully. Compare the vital signs with those from the baseline assessment. Assess the patient's respiratory status carefully. Note the presence of adventitious breath sounds, use of accessory muscles, extent of dyspnea

**Table 33-11 • Common Complications Resulting from Long-Term PRBC Transfusion Therapy\***

	MANIFESTATION	MANAGEMENT
<b>Infection</b>	Hepatitis (B,C)	May immunize against hepatitis B; give alpha-interferon for hepatitis C; monitor hepatic function
	Cytomegalovirus (CMV)	WBC filters to protect against CMV
<b>Iron overload</b>	Heart failure	Prevent by chelation therapy
	Endocrine failure (diabetes, hypothyroidism, hypoparathyroidism, hypogonadism)	
<b>Transfusion reaction</b>	Sensitization	Diminish by RBC phenotyping, using WBC-filtered products
	Febrile reactions	Diminish by using WBC-filtered products

\* Patients with long-term transfusion therapy requirements are at risk not only for the transfusion reactions discussed in the text but also for the complications noted above. In many cases, the use of WBC-filtered (eg, leukocyte-poor) blood products is standard for patients who receive long-term PRBC transfusion therapy. An aggressive chelation program initiated early in the course of therapy can prevent problems with iron overload.  
PRBC, packed red blood cells; WBC, white blood cell; RBC, red blood cell.

(if any), and changes in mental status, including anxiety and confusion. Note any chills, diaphoresis, complaints of back pain, urticaria, and jugular vein distention.

- Notify the physician of the assessment findings, and implement any orders obtained. Continue to monitor the patient's vital signs and respiratory, cardiovascular, and renal status.
- Notify the blood bank that a suspected transfusion reaction has occurred.
- Send the blood container and tubing to the blood bank for repeat typing and culture. The identifying tags and numbers are verified.

If a hemolytic transfusion reaction or bacterial infection is suspected, the nurse should do the following:

- Obtain appropriate blood specimens from the patient.
- Collect a urine sample as soon as possible for a hemoglobin determination.
- Document the reaction, according to the institution's policy.

## PHARMACOLOGIC ALTERNATIVES TO BLOOD TRANSFUSIONS

Pharmacologic agents to stimulate production of one or more types of blood cells by the marrow are commonly used. Chart 33-19 presents examples of such pharmacologic agents.

Researchers continue to seek a blood substitute that is practical and safe. Blood substitutes previously tried have not been successful. However, newer blood substitutes focus solely on oxygen delivery, as an RBC substitute (Rabinovici, 2001). Current blood substitutes in clinical trials have distinct advantages and disadvantages compared with human RBCs. They are manufactured hemoglobin solutions that can be sterilized without destroying the blood substitute. They require no refrigeration and appear to have a long shelf-life (possibly 1 year, versus little more than 1 month for PRBCs). Perhaps more importantly, they require no cross-matching, because there is no RBC membrane to interact with antibodies in the recipient's serum. The most significant disadvantage stems from the blood substitutes extremely short life within human circulation—approximately 1 day, instead of the 30-day life span of a conventionally trans-

fused RBC. Therefore, the use of these products would likely be limited to situations in which the need is short-term (eg, surgery, trauma). Finally, the blood substitutes are likely to be extremely expensive.

## PERIPHERAL BLOOD STEM CELL TRANSPLANTATION (PBSCT) AND BONE MARROW TRANSPLANTATION (BMT)

PBSCT and BMT are therapeutic modalities that offer the possibility of cure for some patients with hematologic disorders such as severe aplastic anemia, some forms of leukemia, and thalassemia. Because most hematologic disease states arise from some form of bone marrow dysfunction, an autologous transplantation (receiving one's own stem cells) is not as common an option as is allogeneic transplantation. A patient receives intensive chemotherapy (sometimes with radiation therapy as well), with the goal being complete ablation of the patient's bone marrow. Stem cells from the donor (ideally, from a matched sibling), or actual marrow from the donor, is then infused into the patient using a process similar to an RBC transfusion. The stem cells travel to the marrow and slowly begin the process of resuming hematopoiesis. The advantage of autotransplantation is the reduced likelihood of complications and mortality; however, the risk of relapse is also higher.

A relatively new strategy is based on transplantation for adoptive cell therapy using certain immune mechanisms derived from the donor's lymphocytes (Slavin et al., 2001; Margolis, Borrello, & Flinn, 2000). In nonmyeloablative stem cell or marrow transplantation, also referred to as a "minitransplant," the conditioning regimen involves much less myelosuppression than in conventional regimens, rendering the patient immunosuppressed but for a shorter period of time. Consequently, the procedure is less toxic to the patient, and there is a significant decrease in morbidity.

After the deconditioning regimen (ie, during the time the patient is immunosuppressed), the allotransplantation is performed, using either marrow or stem cells. The goal is for the donor's lymphocytes to react against any residual malignant cells within the patient and destroy them. This process is typically augmented by

Chart  
33-19

## Pharmacologic Alternatives to Blood Transfusions

### Growth Factors

Recombinant technology has provided a means to produce hematopoietic growth factors necessary for the production of blood cells within the bone marrow. By increasing the body's production of blood cells, transfusions and complications resulting from diminished blood cells (eg, infection from neutropenia or transfusions) may be avoided. However, the successful use of growth factors requires functional bone marrow.

### Erythropoietin

Erythropoietin (epoetin alpha [eg, Epogen, Procrit]) is an effective alternative treatment for patients with chronic anemia secondary to diminished levels of erythropoietin, as in chronic renal disease. This medication stimulates erythropoiesis. It also has been used for patients who are anemic from chemotherapy or zidovudine (AZT) therapy and for those who have diseases involving bone marrow suppression, such as myelodysplastic syndrome (MDS). The use of erythropoietin can also enable a patient to donate several units of blood for future use (eg, preoperative autologous donation). The medication can be administered intravenously or subcutaneously, although plasma levels are better sustained with the subcutaneous route. Side effects are rare, but erythropoietin can cause or exacerbate hypertension. If the anemia is corrected too quickly or is overcorrected, the elevated hematocrit can cause headache and, potentially, seizures. These adverse effects are rare except for patients with renal failure. Serial complete blood counts (CBCs) should be performed to evaluate the response to the medication. The dose and frequency of administration are titrated to the hematocrit.

### Granulocyte-Colony Stimulating Factor (G-CSF)

G-CSF (filgrastim [Neupogen]) is a cytokine that stimulates the proliferation and differentiation of myeloid stem cells; a rapid increase in neutrophils is seen within the circulation. G-CSF is effective in improving transient but severe neutropenia after chemotherapy or in some forms of MDS. It is particularly useful in preventing bacterial infections that would be likely to occur with neutropenia. G-CSF is administered subcutaneously on a daily basis. The primary side effect is bone pain; this probably reflects the increase in hematopoiesis within the marrow. Serial CBCs should be performed to evaluate the response to the medication and to ensure that the rise in white blood cells is not excessive. The effect of G-CSF on myelopoiesis is short; the neutrophil count drops once the medication is stopped.

### Granulocyte-Macrophage Colony Stimulating Factor (GM-CSF)

GM-CSF (sargramostim [Leukine]) is a cytokine that is naturally produced by a variety of cells, including monocytes and endothelial cells. It works either directly or synergistically with other growth factors to stimulate myelopoiesis. GM-CSF is not as specific to neutrophils as is G-CSF; thus, an increase in erythroid (RBC) and megakaryocytic (platelet) production may also be seen. GM-CSF serves the same purpose as G-CSF. However, it may have a greater effect on macrophage function and therefore may be more useful against fungal infections, whereas G-CSF may be better used to fight bacterial infections. GM-CSF is also administered subcutaneously. Side effects include bone pain, fevers, and myalgias.

### Thrombopoietin

Thrombopoietin (TPO) is a cytokine that is necessary for the proliferation of megakaryocytes and subsequent platelet formation. Clinical studies have demonstrated efficacy of TPO in the setting of chemotherapy-induced thrombocytopenia with few side effects (Vadhan-Raj, 2000). Further studies are ongoing to assess the efficacy of TPO in other, more chronic conditions associated with thrombocytopenia (Kuter, 2000).

infusion of the donor's lymphocytes as well (referred to as donor lymphocyte infusion, or DLI). If relapse occurs, repeated DLI has been effective in reestablishing remission in many patients. This approach has great promise, particularly in the setting of hematologic malignancy, and may provide a mechanism to increase the utility of transplantation for more patients than is possible with conventional methods.

Success of transplantation depends on tissue compatibility and the patient's tolerance of the immunosuppression that results from the ablative therapy. Patients require intensive nursing care that is directed toward preventing infection and assessing for early signs and symptoms of complications. One common complication involves the formation of lymphocytes that respond to their new host (ie, the patient) as foreign and mount a reaction against the body. This process, known as graft-versus-host disease (GVHD), can involve the skin, gastrointestinal tract, and liver and can be life-threatening. In hematologic malignancies, some GVHD is actually desirable in that the donor lymphocytes can also mount a reaction against any lingering tumor cells; this process is referred to as graft-versus-malignancy. GVHD is a significant complication in nonmyeloablative transplantation therapy, as well as in conventional allogeneic transplantation. Late complications (occurring more than 100 days after transplantation) are frequent; these patients, particularly those who receive an allogeneic transplant, require careful follow-up for years after transplantation. (See Chap. 16 for further information on GVHD)

## Critical Thinking Exercises

1. You are working in a hematology-oncology clinic. The laboratory reports a critical study result for one of your patients with CLL: the reticulocyte count is 25%. What other laboratory results would be important to review or consider? The patient is profoundly anemic; does this support your original thinking and problem solving? What medical treatment orders would you anticipate? What nursing interventions would be appropriate?
2. You are caring for a young adult patient who has had repeated hospitalizations for sickle cell crisis. What factors should be assessed to determine the patient's education, coping, and pain management needs? What is important for the patient's discharge plan?
3. You are caring for a patient diagnosed with leukemia. The family members are very concerned about the patient's risk for infection at home. What assessments will assist you to determine the patient's risk of developing an infection at home? What instructions should you give about decreasing the risks for infection? How would you alter your interventions if the family members are not fluent in English?
4. You are caring for a patient who is septic and is now receiving a transfusion of 2 units of PRBCs. The patient's temperature spikes to 38.5°C after half of the second unit has been transfused. What are the possible causes of the fever? What are the appropriate nursing interventions?

# ● Assessment of Digestive and Gastrointestinal Function

## **LEARNING OBJECTIVES** ●

*On completion of this chapter, the learner will be able to:*

1. Describe the structure and function of the organs of the gastrointestinal tract.
2. Describe the mechanical and chemical processes involved in digesting and absorbing foods and eliminating waste products.
3. Use assessment parameters appropriate for determining the status of gastrointestinal function.
4. Describe the appropriate preparation, teaching, and follow-up care for patients who are undergoing diagnostic testing of the gastrointestinal tract.

## Anatomic and Physiologic Overview

### ANATOMY OF THE GASTROINTESTINAL TRACT

The GI tract is a 23- to 26-foot-long pathway that extends from the **mouth** through the esophagus, stomach, and intestines to the anus (Fig. 34-1). The **esophagus** is located in the mediastinum in the thoracic cavity, anterior to the spine and posterior to the trachea and heart. This collapsible tube, which is about 25 cm (10 inches) in length, becomes distended when food passes through it. It passes through the diaphragm at an opening called the diaphragmatic hiatus.

The remaining portion of the GI tract is located within the peritoneal cavity. The **stomach** is situated in the upper portion of the abdomen to the left of the midline, just under the left diaphragm. It is a distensible pouch with a capacity of approximately 1500 mL. The inlet to the stomach is called the esophagogastric junction; it is surrounded by a ring of smooth muscle called the lower esophageal sphincter (or cardiac sphincter), which, on contraction, closes off the stomach from the esophagus. The stomach can be divided into four anatomic regions: the cardia (entrance), fundus, body, and pylorus (outlet). Circular smooth muscle in the wall of the pylorus forms the pyloric sphincter and controls the opening between the stomach and the small intestine.

The **small intestine** is the longest segment of the GI tract, accounting for about two thirds of the total length. It folds back and forth on itself, providing approximately 7000 cm of surface area for secretion and **absorption**, the process by which nutrients enter the bloodstream through the intestinal walls. The small intestine is divided into three anatomic parts: the upper part, called the duodenum; the middle part, called the jejunum; and the lower part, called the ileum. The common bile duct, which allows for the passage of both bile and pancreatic secretions, empties into the duodenum at the ampulla of Vater. The junction between the small and large intestine, the cecum, is located in the right lower portion of the abdomen. The ileocecal valve is located at this junction. It controls the passage of intestinal contents into the large intestine and prevents reflux of bacte-

ria into the small intestine. The vermiform appendix is located near this junction.

The **large intestine** consists of an ascending segment on the right side of the abdomen, a transverse segment that extends from right to left in the upper abdomen, and a descending segment on the left side of the abdomen. The terminal portion of the large intestine consists of two parts: the sigmoid colon and the rectum. The rectum is continuous with the **anus**. A network of striated muscle that forms both the internal and the external anal sphincters regulates the anal outlet.

The GI tract receives blood from arteries that originate along the entire length of the thoracic and abdominal aorta. Of particular importance are the gastric artery and the superior and inferior mesenteric arteries. Oxygen and nutrients are supplied to the stomach by the gastric artery and to the intestine by the mesenteric arteries (Fig. 34-2). Blood is drained from these organs by veins that merge with others in the abdomen to form a large vessel called the portal vein. Nutrient-rich blood is then carried to the liver. The blood flow to the GI tract is about 20% of the total cardiac output and increases significantly after eating.

Both the sympathetic and parasympathetic portions of the autonomic nervous system innervate the GI tract. In general, sympathetic nerves exert an inhibitory effect on the GI tract, decreasing gastric secretion and motility and causing the sphincters and blood vessels to constrict. Parasympathetic nerve stimulation causes peristalsis and increases secretory activities. The sphincters relax under the influence of parasympathetic stimulation. The only portions of the tract that are under voluntary control are the upper esophagus and the external anal sphincter.

### FUNCTION OF THE DIGESTIVE SYSTEM

All cells of the body require nutrients. These nutrients are derived from the intake of food that contains proteins, fats, carbohydrates, vitamins and minerals, and cellulose fibers and other vegetable matter of no nutritional value. The primary digestive functions of the GI tract are the following:

- To break down food particles into the molecular form for digestion

## Glossary

**absorption:** phase of the digestive process that occurs when small molecules, vitamins, and minerals pass through the walls of the small and large intestine and into the bloodstream

**amylase:** an enzyme that aids in the digestion of starch

**anus:** last section of the GI tract; outlet for waste products from the system

**chyme:** mixture of food with saliva, salivary enzymes, and gastric secretions that is produced as the food passes through the mouth, esophagus, and stomach

**digestion:** phase of the digestive process that occurs when digestive enzymes and secretions mix with ingested food and when proteins, fats, and sugars are broken down into their component smaller molecules

**elimination:** phase of digestive process that occurs after digestion and absorption, when waste products are evacuated from the body

**esophagus:** collapsible tube connecting the mouth to the stomach, through which food passes as it is ingested

**fibroscopy (gastrointestinal):** intubation of a part of the GI system with a flexible, lighted tube to assist in diagnosis and treatment of diseases of that area

**hydrochloric acid:** acid secreted by the glands in the stomach; mixes with chyme to break it down into absorbable molecules and to aid in the destruction of bacteria

**ingestion:** phase of the digestive process that occurs when food is taken into the GI tract via the mouth and esophagus

**intrinsic factor:** a gastric secretion that combines with vitamin B<sub>12</sub> so that the vitamin can be absorbed

**large intestine:** the portion of the GI tract into which waste material from the small intestine passes as absorption continues and elimination begins; consists of several

parts—ascending segment, transverse segment, descending segment, sigmoid colon, and rectum

**lipase:** an enzyme that aids in the digestion of fats

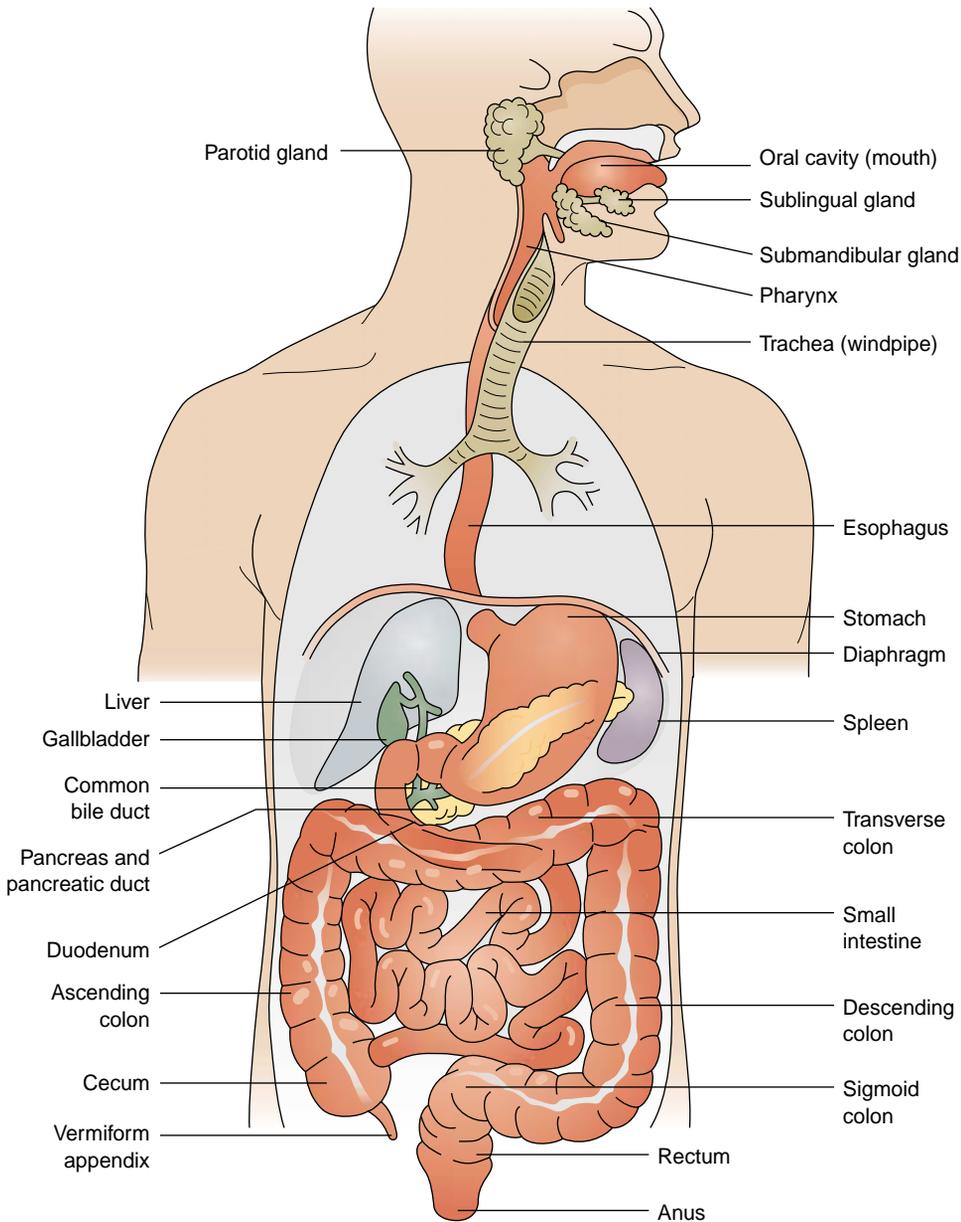

**mouth:** first portion of the GI tract, through which food is ingested

**pepsin:** a gastric enzyme that is important in protein digestion

**small intestine:** longest portion of the GI tract, consisting of three parts—duodenum, jejunum, and ileum—through which food mixed with all secretions and enzymes passes as it continues to be digested and begins to be absorbed into the bloodstream

**stomach:** distensible pouch into which the food bolus passes to be digested by gastric enzymes

**trypsin:** enzyme that aids in the digestion of protein

**FIGURE 34-1** Organs of the digestive system and associated structures.

- To absorb into the bloodstream the small molecules produced by **digestion**
- To eliminate undigested and unabsorbed foodstuffs and other waste products from the body

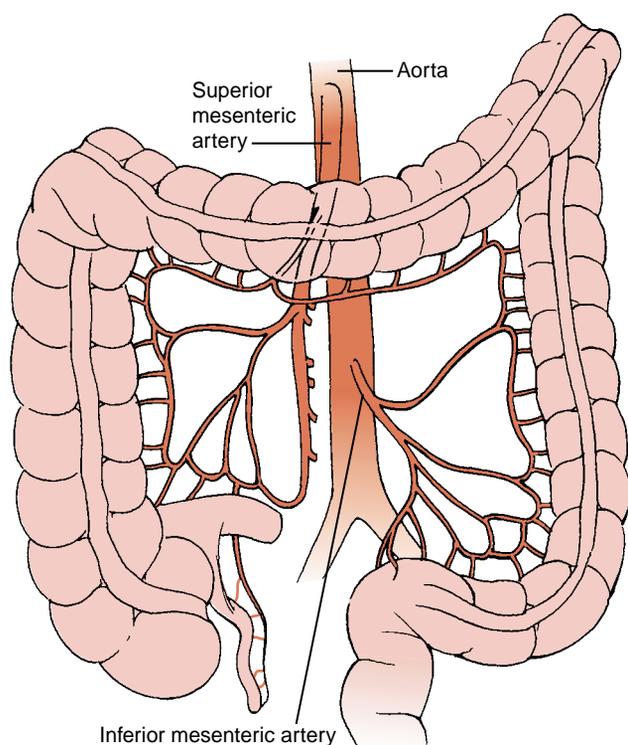

After food is ingested, it is propelled through the GI tract, coming into contact with a wide variety of secretions that aid in its digestion, absorption, or **elimination** from the GI tract.

### Chewing and Swallowing

The process of digestion begins with the act of chewing, in which food is broken down into small particles that can be swallowed and mixed with digestive enzymes. Eating—or even the sight, smell, or taste of food—can cause reflex salivation. Saliva is secreted from three pairs of glands: the parotid, the submaxillary, and the sublingual glands. Approximately 1.5 L of saliva is se-

creted daily. Saliva is the first secretion that comes in contact with food. Saliva contains the enzyme ptyalin, or salivary amylase, which begins the digestion of starches (Table 34-1). Saliva also contains mucus and water, which help to lubricate the food as it is chewed, thereby facilitating swallowing.

Swallowing begins as a voluntary act that is regulated by a swallowing center in the medulla oblongata of the central nervous system. As food is swallowed, the epiglottis moves to cover the tracheal opening and prevent aspiration of food into the lungs. Swallowing, which propels the bolus of food into the upper esophagus, thus ends as a reflex action. The smooth muscle in the wall of the esophagus contracts in a rhythmic sequence from the upper esophagus toward the stomach to propel the bolus of food along the tract. During this process of esophageal peristalsis, the lower esophageal sphincter relaxes and permits the bolus of food to enter the stomach. Subsequently, the lower esophageal sphincter closes tightly to prevent reflux of stomach contents into the esophagus.

**FIGURE 34-2** Anatomy and blood supply of the large intestine.

## Gastric Function

The stomach stores and mixes the food with secretions. It secretes a highly acidic fluid in response to the presence or anticipated **in-gestion** of food. This fluid, which may have a pH as low as 1, derives its acidity from the **hydrochloric acid** (HCl) secreted by the

glands of the stomach. The function of this gastric secretion is two-fold: to break down food into more absorbable components and to aid in the destruction of most ingested bacteria. The stomach can produce about 2.4 L per day of these gastric secretions. Gastric secretions also contain the enzyme **pepsin**, which is important for initiating protein digestion. **Intrinsic factor** is also secreted by the gastric mucosa. This compound combines with dietary vitamin B<sub>12</sub> so that the vitamin can be absorbed in the ileum. In the absence of intrinsic factor, vitamin B<sub>12</sub> cannot be absorbed and pernicious anemia results (see Chapter 33).

Peristaltic contractions in the stomach propel its contents toward the pylorus. Because large food particles cannot pass through the pyloric sphincter, they are churned back into the body of the stomach. In this way, food in the stomach is agitated mechanically and broken down into smaller particles. Food remains in the stomach for a variable length of time, from a half-hour to several hours, depending on the size of food particles, the composition of the meal, and other factors. Peristalsis in the stomach and contractions of the pyloric sphincter allow the partially digested food to enter the small intestine at a rate that permits efficient absorption of nutrients. This food mixed with gastric secretions is called **chyme**. Hormones, neuroregulators, and local regulators found in the gastric secretions control the rate of gastric secretions and influence gastric motility (Table 34-2).

## Small Intestine Function

The digestive process continues in the duodenum. Secretions in the duodenum come from the accessory digestive organs—the pancreas, liver, and gallbladder—and the glands in the wall of the intestine itself. These secretions contain digestive enzymes and bile. Pancreatic secretions have an alkaline pH because of high concentrations of bicarbonate. This neutralizes the acid entering the duodenum from the stomach. The pancreas also secretes digestive enzymes, including **trypsin**, which aids in digesting protein; **amylase**, which aids in digesting starch; and **lipase**, which

**Table 34-1 • The Major Digestive Enzymes and Secretions**

ENZYME/SECRETION	ENZYME SOURCE	DIGESTIVE ACTION
<b>Action of Enzymes That Digest Carbohydrates</b>		
Ptyalin (salivary amylase)	Salivary glands	Starch→dextrin, maltose, glucose
Amylase	Pancreas and intestinal mucosa	Starch→dextrin, maltose, glucose
Maltase	Intestinal mucosa	Dextrin→maltose, glucose
Sucrase	Intestinal mucosa	Maltose→glucose
Lactase	Intestinal mucosa	Sucrose→glucose, fructose
		Lactose→glucose, galactose
<b>Action of Enzymes/Secretions That Digest Protein</b>		
Pepsin	Gastric mucosa	Protein→polypeptides
Trypsin	Pancreas	Proteins and polypeptides→polypeptides, dipeptides, amino acids
Aminopeptidase	Intestinal mucosa	Polypeptides→dipeptides, amino acids
Dipeptidase	Intestinal mucosa	Dipeptides→amino acids
Hydrochloric acid	Gastric mucosa	Protein→polypeptides, amino acids
<b>Action of Enzymes That Digest Fat (Triglyceride)</b>		
Pharyngeal lipase	Pharynx mucosa	Triglycerides→fatty acids, diglycerides, monoglycerides
Steapsin	Gastric mucosa	Triglycerides→fatty acids, diglycerides, monoglycerides
Pancreatic lipase	Pancreas	Triglycerides→fatty acids, diglycerides, monoglycerides
Bile	Liver and gallbladder	Fat emulsification

Table 34-2 • The Major Gastrointestinal Regulatory Substances

SUBSTANCE	STIMULUS FOR PRODUCTION	TARGET TISSUE	EFFECT ON SECRETIONS	EFFECT ON MOTILITY
<b>Neuroregulators</b>				
Acetylcholine	Sight, smell, chewing food, stomach distention	Gastric glands, other secretory glands, gastric and intestinal muscle	Increased gastric acid	Generally increased; decreased sphincter tone
Norepinephrine	Stress, other various stimuli	Secretory glands, gastric and intestinal muscle	Generally inhibitory	Generally decreased; increased sphincter tone
<b>Hormonal Regulators</b>				
Gastrin	Stomach distention with food	Gastric glands	Increased secretion of gastric juice, which is rich in HCl	Increased motility of stomach, decreased time required for gastric emptying Relaxation of ileocecal sphincter Excitation of colon Constriction of gastroesophageal sphincter
Cholecystokinin	Fat in duodenum	Gallbladder Pancreas Stomach	Release of bile into duodenum Increased production of enzyme-rich pancreatic secretions Inhibits gastric secretion somewhat	
Secretin	pH of chyme in duodenum below 4–5	Stomach Pancreas	Inhibits gastric secretion somewhat Increased production of bicarbonate-rich pancreatic juice	Inhibits stomach contractions
<b>Local Regulator</b>				
Histamine	Unclear; substances in food	Gastric glands	Increased gastric acid production	

aids in digesting fats. Bile (secreted by the liver and stored in the gallbladder) aids in emulsifying ingested fats, making them easier to digest and absorb.

The intestinal glands secrete mucus, hormones, electrolytes, and enzymes. The mucus coats the cells and protects the mucosa from injury by HCl. Hormones, neuroregulators, and local regulators found in these intestinal secretions control the rate of intestinal secretions and also influence GI motility. Intestinal secretions total approximately 1 L/day of pancreatic juice, 0.5 L/day of bile, and 3 L/day of secretions from the glands of the small intestine. Tables 34-1 and 34-2 summarize the actions of digestive enzymes and GI regulatory substances.

Two types of contractions occur regularly in the small intestine: segmentation contractions and intestinal peristalsis. *Segmentation contractions* produce mixing waves that move the intestinal contents back and forth in a churning motion. *Intestinal peristalsis* propels the contents of the small intestine toward the colon. Both movements are stimulated by the presence of chyme.

Food, initially ingested in the form of fats, proteins, and carbohydrates, is broken down into absorbable particles (constituent nutrients) by the process of digestion. Carbohydrates are broken down into disaccharides (eg, sucrose, maltose, galactose) and monosaccharides (eg, glucose, fructose). Glucose is the major carbohydrate that the tissue cells use as fuel. Proteins are broken down into amino acids and peptides. Ingested fats are emulsified into monoglycerides and fatty acids. These smaller molecules are then ready to be absorbed. Chyme stays in the small intestine for 3 to 6 hours, allowing for continued breakdown and absorption of nutrients.

Small, finger-like projections called villi are present throughout the entire intestine and function to produce digestive en-

zymes as well as to absorb nutrients. Absorption is the primary function of the small intestine. Vitamins and minerals are not digested but rather absorbed essentially unchanged. Absorption begins in the jejunum and is accomplished by both active transport and diffusion across the intestinal wall into the circulation. Absorption of different nutrients takes place at different locations in the small intestine. Iron and calcium absorption takes place in the duodenum. Fats, proteins, carbohydrates, sodium, and chloride are absorbed in the jejunum. Vitamin B<sub>12</sub> and bile salts are absorbed in the ileum. Magnesium, phosphate, and potassium are absorbed throughout the small intestine (Society of Gastroenterologic Nursing and Associates, 1998).

## Colonic Function

Within 4 hours after eating, residual waste material passes into the terminal ileum and passes slowly into the proximal portion of the colon through the ileocecal valve. This valve, which is normally closed, helps prevent colonic contents from refluxing into the small intestine. With each peristaltic wave of the small intestine, the valve opens briefly and permits some of the contents to pass into the colon.

Bacteria make up a major component of the contents of the large intestine. They assist in completing the breakdown of waste material, especially of undigested or unabsorbed proteins and bile salts. Two types of colonic secretions are added to the residual material: an electrolyte solution and mucus. The electrolyte solution is chiefly a bicarbonate solution that acts to neutralize the end products formed by the colonic bacterial action. The mucus protects the colonic mucosa from the interluminal contents and also provides adherence for the fecal mass.

Slow, weak peristaltic activity moves the colonic contents slowly along the tract. This slow transport allows efficient reabsorption of water and electrolytes, which is the primary purpose of the colon. Intermittent strong peristaltic waves propel the contents for considerable distances. This generally occurs after another meal is eaten, when intestine-stimulating hormones are released. The waste materials from a meal eventually reach and distend the rectum, usually in about 12 hours. As much as one fourth of the waste materials from a meal may still be in the rectum 3 days after the meal was ingested.

### Waste Products of Digestion

Feces consist of undigested foodstuffs, inorganic materials, water, and bacteria. Fecal matter is about 75% fluid and 25% solid material. The composition is relatively unaffected by alterations in diet, because a large portion of the fecal mass is of nondietary origin, derived from the secretions of the GI tract. The brown color of the feces results from the breakdown of bile by the intestinal bacteria. Chemicals formed by intestinal bacteria (especially indole and skatole) are responsible in large part for the fecal odor. Gases formed contain methane, hydrogen sulfide, and ammonia, among others. The GI tract normally contains approximately 150 mL of these gases, which are either absorbed into the portal circulation and detoxified by the liver or expelled from the rectum as flatus.

Elimination of stool begins with distention of the rectum, which reflexively initiates contractions of the rectal musculature and relaxes the normally closed internal anal sphincter. The internal sphincter is controlled by the autonomic nervous system; the external sphincter is under the conscious control of the cerebral cortex. During defecation, the external anal sphincter voluntarily relaxes to allow colonic contents to be expelled. Normally, the external anal sphincter is maintained in a state of tonic contraction. Thus, defecation is seen to be a spinal reflex (involving the parasympathetic nerve fibers) that can be inhibited voluntarily by keeping the external anal sphincter closed. Contracting the abdominal muscles (straining) facilitates emptying of the colon. The average frequency of defecation in humans is once daily, but the frequency varies among individuals.

## Assessment

### HEALTH HISTORY AND CLINICAL MANIFESTATIONS

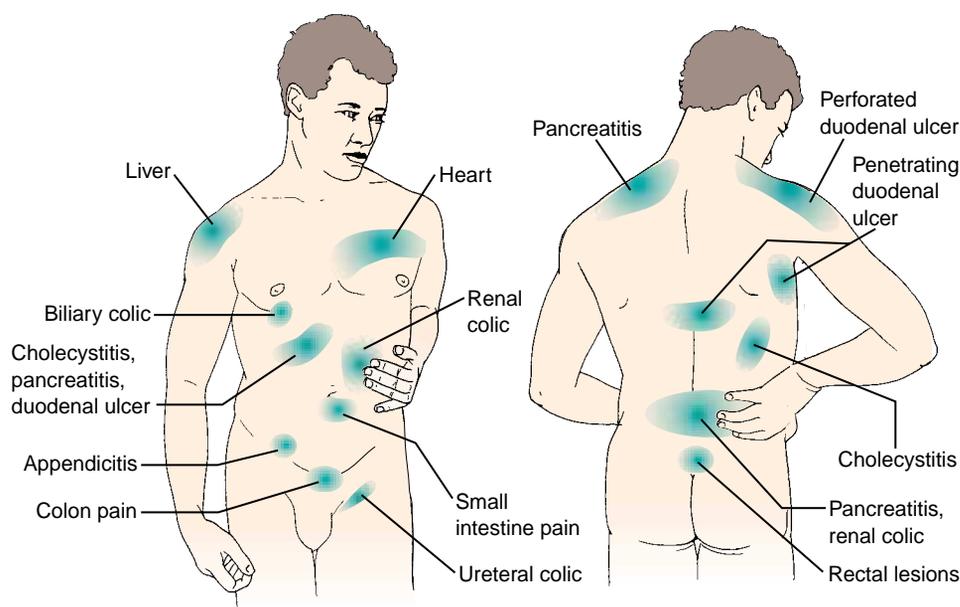

The nurse begins by taking a complete history, focusing on symptoms common to GI dysfunction. These symptoms include pain, indigestion, intestinal gas, nausea and vomiting, hematemesis, and changes in bowel habits and stool characteristics. Information about any previous GI disease is important. The nurse notes past and current medication use and any previous treatment or surgery. Information pertaining to medications is of particular interest because medications are a frequent cause of GI symptoms. The nurse takes a dietary history to assess nutritional status. Questioning about the use of tobacco and alcohol includes details about type and amount. The nurse and patient discuss changes in appetite or eating patterns and any examples of unexplained weight gain or loss over the past year. The nurse also assesses the stool characteristics. The nurse records all abnormal findings and reports them to the physician. It is important to include in the history questions about psychosocial, spiritual, or cultural factors that may be affecting the patient.

### Pain

Pain can be a major symptom of GI disease. The character, duration, pattern, frequency, location, distribution of referred pain (Fig. 34-3), and time of the pain vary greatly depending on the underlying cause. Other factors, such as meals, rest, defecation, and vascular disorders, may directly affect this pain.

### Indigestion

Upper abdominal discomfort or distress associated with eating (commonly called *indigestion*) is the most common symptom of patients with GI dysfunction. The basis for this abdominal distress may be the patient's own gastric peristaltic movements. Bowel movements may or may not relieve the pain. Indigestion can result from disturbed nervous system control of the stomach

**FIGURE 34-3** Common sites of referred abdominal pain.

or from a disorder in the GI tract or elsewhere in the body. Fatty foods tend to cause the most discomfort, because they remain in the stomach longer than proteins or carbohydrates do. Coarse vegetables and highly seasoned foods can also cause considerable distress.

## Intestinal Gas

The accumulation of gas in the GI tract may result in belching (the expulsion of gas from the stomach through the mouth) or flatulence (the expulsion of gas from the rectum). It is through belching that swallowed air is expelled quickly when it reaches the stomach. Usually, gases in the small intestine pass into the colon and are released as flatus. Patients often complain of bloating, distention, or being “full of gas.” Excessive flatulence may be a symptom of gallbladder disease or food intolerance.

## Nausea and Vomiting

Vomiting is another major symptom of GI disease. Vomiting is usually preceded by nausea, which can be triggered by odors, activity, or food intake. The emesis, or vomitus, may vary in color and content. It may contain undigested food particles or blood (hematemesis). When vomiting occurs soon after hemorrhage, the emesis is bright red. If blood has been retained in the stomach, it takes on a coffee-ground appearance because of the action of the digestive enzymes.

## Change in Bowel Habits and Stool Characteristics

Changes in bowel habits may signal colon disease. Diarrhea (an abnormal increase in the frequency and liquidity of the stool or in daily stool weight or volume) commonly occurs when the contents move so rapidly through the intestine and colon that there is inadequate time for the GI secretions to be absorbed. Diarrhea is sometimes associated with abdominal pain or cramping and nausea or vomiting. Constipation (a decrease in the frequency of stool, or stools that are hard, dry, and of smaller volume than normal) may be associated with anal discomfort and rectal bleeding. See Chapter 38 for further discussion of diarrhea and constipation.

The characteristics of the stool can vary greatly. Stool is normally light to dark brown. However, many circumstances, including the ingestion of certain foods and medications, can change the appearance of stool (Table 34-3). Blood in the stool can present in various ways and must be investigated. If blood is shed in sufficient quantities into the upper GI tract, it produces a tarry-black color

(melena). Blood entering the lower portion of the GI tract or passing rapidly through it will appear bright or dark red. Lower rectal or anal bleeding is suspected if there is streaking of blood on the surface of the stool or if blood is noted on toilet tissue. Other common abnormalities in stool characteristics that the patient may describe during the health history include the following:

- Bulky, greasy, foamy stools that are foul in odor; stool color is gray, with a silvery sheen
- Light gray or clay-colored stool, caused by the absence of urobilin
- Stool with mucus threads or pus that may be visible on gross inspection of the stool
- Small, dry, rock-hard masses called scybala; sometimes streaked with blood from rectal trauma as they pass through the rectum
- Loose, watery stool that may or may not be streaked with blood

## PHYSICAL ASSESSMENT

The physical examination includes assessment of the mouth, abdomen, and rectum. The mouth, tongue, buccal mucosa, teeth, and gums are inspected, and ulcers, nodules, swelling, discoloration, and inflammation are noted. People with dentures should remove them during this part of the examination to allow good visualization.

The patient lies supine with knees flexed slightly for inspection, auscultation, palpation, and percussion of the abdomen (Fig. 34-4). The nurse performs inspection first, noting skin changes and scars from previous surgery. It also is important to note the contour and symmetry of the abdomen, to identify any localized bulging, distention, or peristaltic waves.

The nurse performs auscultation before percussion and palpation (which can increase intestinal motility and thereby change bowel sounds) and notes the character, location, and frequency of bowel sounds. The nurse assesses bowel sounds in all four quadrants using the diaphragm of the stethoscope; the high-pitched and gurgling sounds can be heard best in this manner. It is important to document the frequency of the sounds, using the terms *normal* (sounds heard about every 5 to 20 seconds), *hypoactive* (one or two sounds in 2 minutes), *hyperactive* (5 to 6 sounds heard in less than 30 seconds), or *absent* (no sounds in 3 to 5 minutes).

The nurse notes tympany or dullness during percussion. Use of light palpation is appropriate for identifying areas of tenderness or swelling; the nurse may use deep palpation to identify masses in any of the four quadrants. If the patient identifies any area of discomfort, the nurse can assess for rebound tenderness. To elicit rebound tenderness, the nurse exerts pressure over the area and then releases it quickly. It is important to note any pain experienced on withdrawal of the pressure. The nurse notes any abnormal finding in relation to the surface landmarks (xiphoid process, costal margins, anterior iliac spine, and symphysis pubis) or in relation to the four quadrants commonly used to describe the abdomen (right upper quadrant, RUQ; right lower quadrant, RLQ; left upper quadrant, LUQ; and left lower quadrant, LLQ) (Bickley & Hoekelman, 1999).

The final part of the examination is inspection of the anal and perineal area. The nurse should inspect and palpate areas of excoriation or rash, fissures or fistula openings, or external hemorrhoids. A digital rectal examination can be performed to note any areas of tenderness or mass.

**Table 34-3 • Foods and Medications That Alter Stool Color**

ALTERING SUBSTANCE	COLOR
Meat protein	Dark brown
Spinach	Green
Carrots and beets	Red
Cocoa	Dark red or brown
Senna	Yellow
Bismuth, iron, licorice, and charcoal	Black
Barium	Milky white

*Inspecting the abdomen*

*Auscultating the abdomen*

*Palpating the abdomen*

*Percussing the abdomen*

**FIGURE 34-4** Examination of the abdomen includes inspection, auscultation, palpation, and percussion.

## Diagnostic Evaluation

Blood tests are ordered initially. Common blood tests include complete blood count (CBC), carcinoembryonic antigen (CEA), liver function tests, serum cholesterol, and triglycerides. Test findings may reveal alterations in basal metabolic function and may indicate the severity of a disorder.

Many other modalities are available for diagnostic assessment of the GI tract. The majority of these tests and procedures are performed on an outpatient basis in special units designed for this purpose (eg, endoscopy or GI laboratory). The nurse supports and educates patients who are undergoing diagnostic evaluation, whether in an inpatient or an outpatient setting. Patients who require such tests frequently are anxious, elderly, or debilitated. The preparation for many of these studies includes fasting, the use of laxatives or enemas, and ingestion or injection of a contrast agent or a radiopaque dye. These preparatory measures are poorly tolerated by weak and many elderly patients and have the potential to cause fluid and electrolyte imbalances. If further assessment or treatment is needed after any outpatient procedure, the patient may be admitted to the hospital.

Specific nursing interventions for each test are provided later in this chapter. General nursing interventions for the patient who is having GI diagnostic assessment include the following:

- Providing general information about a healthy diet and the nutritional factors that can cause GI disturbances; after a diagnosis has been confirmed, the nurse provides information about specific nutrients that should be included in the diet

- Providing needed information about the test and the activities required of the patient
- Providing instructions about postprocedure care and activity restrictions
- Alleviating anxiety
- Helping the patient cope with discomfort
- Encouraging family members or others to offer emotional support to the patient during the diagnostic testing
- Assessing for adequate hydration before, during, and immediately after the procedure, and providing education about maintenance of hydration

## STOOL TESTS

Basic examination of the stool includes inspecting the specimen for consistency and color and testing for occult (not visible) blood. Special tests, including tests for fecal urobilinogen, fat, nitrogen, parasites, pathogens, food residues, and other substances, require that the specimen be sent to the laboratory.

Stool samples are usually collected on a random basis unless a quantitative study (eg, fecal fat, urobilinogen) is to be performed. Random specimens should be sent promptly to the laboratory for analysis. The quantitative 24- to 72-hour collections must be kept refrigerated until they are taken to the laboratory. Some stool collections require the patient to follow a special diet or to refrain from taking certain medications before the collection. It is important to follow test guidelines closely for accurate results.

Fecal occult blood testing is one of the most commonly performed stool tests. It can be useful in initial screening for several

disorders. It tests only for the presence of blood, so other follow-up testing is required. It is most frequently used in cancer screening programs and for early cancer detection (Chart 34-1). The test can be performed at the bedside, in the laboratory, or at home. It tests for heme, the iron-containing portion of the hemoglobin molecule that is altered during transit through the intestines.

Probably the most widely used occult blood test is the Hematest. It is inexpensive and noninvasive, and it carries no risk to the patient. It should not, however, be performed when there is hemorrhoidal bleeding. The test can be performed at home as well as in the doctor's office. The patient provides a stool specimen, and the physician smears it on a dry, guaiac-impregnated paper slide. If the test is done at home, the patient mails the slide to the physician in an envelope provided for that purpose. The stool specimen is then examined for occult blood. Serial 3- to 6-day testing is recommended. The test is not perfect, because certain factors interfere with its sensitivity and specificity. False-positive results may occur if the patient has eaten rare meat, liver, poultry, turnips, broccoli, cauliflower, melons, salmon, sardines, or horseradish within 7 days before testing. Medications that can cause gastric irritation, such as aspirin, ibuprofen, indomethacin, colchicine, corticosteroids, cancer chemotherapeutic agents, and anticoagulants, may also cause false-positive results. Extensive research has demonstrated that therapeutic doses of iron preparations do not cause false-positive results. Ingestion of vitamin C from supplements or foods can cause false-negative results. Therefore, a careful assessment of the patient's diet and medication regimen is essential to reduce incorrect interpretation of results (Ahmed, 2000).

Other occult blood tests that may yield more specific and more sensitive readings include Hematest II SENSA and HemoQuant. Immunologic tests are more specific to human hemoglobin and decrease the problem of dietary interference. Hemoporphyrin assays detect the broadest range of blood derivatives, but a strict

dietary protocol is essential. Immunochemical tests using anti-human antibodies that are extremely sensitive to human hemoglobin are also available.

## BREATH TESTS

The *hydrogen breath test* was developed to evaluate carbohydrate absorption. It also is used to aid in the diagnosis of bacterial overgrowth in the intestine and short bowel syndrome. This test determines the amount of hydrogen expelled in the breath after it has been produced in the colon (on contact of galactose with fermenting bacteria) and absorbed into the blood.

*Urea breath tests* detect the presence of *Helicobacter pylori*, the bacteria that can live in the mucosal lining of the stomach and cause peptic ulcer disease. The patient takes a capsule of carbon-labeled urea and then provides a breath sample 10 to 20 minutes later. Because *H. pylori* metabolizes urea rapidly, the labeled carbon is absorbed quickly; it can then be measured as carbon dioxide in the expired breath to determine whether *H. pylori* is present. The patient is instructed to avoid antibiotics or loperamide (Pepto-Bismol) for 1 month before the test; sucralfate (Carafate) and omeprazole (Prilosec) for 1 week before the test; and cimetidine (Tagamet), famotidine (Pepcid), ranitidine (Zantac), and nizatidine (Axid) for 24 hours before urea breath testing. *H. pylori* also can be detected by assessing serum antibody levels.

## ABDOMINAL ULTRASONOGRAPHY

Ultrasonography is a noninvasive diagnostic technique in which high-frequency sound waves are passed into internal body structures and the ultrasonic echoes are recorded on an oscilloscope as they strike tissues of different densities. During abdominal ultrasonography, an image of the abdominal organs and structures is produced on the oscilloscope. This procedure is generally used to indicate the size and configuration of abdominal structures. It is particularly useful in the detection of cholelithiasis, cholecystitis, and appendicitis. Most recently this technique has proven useful in diagnosing acute colonic diverticulitis.

Advantages of abdominal ultrasonography are that it requires no ionizing radiation, there are no noticeable side effects, and it is relatively inexpensive. One disadvantage is that it cannot be used to examine structures that lie behind bony tissue, because bone prevents sound waves from passing to deeper structures. Gas and fluid in the abdomen or air in the lungs also prevent transmission of ultrasound.

Endoscopic ultrasonography (EUS) is a specialized enteroscopic procedure that aids in the diagnosis of GI disorders by providing direct imaging of a target area. A small high-frequency ultrasonic transducer is mounted at the tip of the fiberoptic scope so that a transintestinal study can be completed. This procedure gives results with better quality resolution and definition than regular ultrasound imaging. It helps in staging of a tumor, including size, spread, and whether the tumor is operable. It is useful in evaluating transmural changes in the bowel wall that occur in ulcerative colitis. Intestinal gas, bone, and thick layers of adipose tissue (all of which hamper conventional ultrasonography) are not problems when this technique is used.

## Nursing Interventions

The patient fasts for 8 to 12 hours before the test to decrease the amount of gas in the bowel. If gallbladder studies are being performed, the patient should eat a fat-free meal the evening before

Chart 34-1

### Health Promotion: Guidelines for Colorectal Cancer Screening

For adults older than 50 years of age, one of the screening approaches below should be followed:

#### If low-to-average risk (asymptomatic):

- Digital rectal examination annually
  - Fecal occult blood testing annually
- AND
- Flexible sigmoidoscopy every 5 years

#### If moderate risk (colorectal cancer in family members):

- Digital rectal examination annually
  - Fecal occult blood testing annually
- AND
- Colonoscopy every 5–10 years (if there is a history of polypectomy, colonoscopy in 1 year and then every 5 years)

#### If high risk (family history of hereditary disease or inflammatory bowel disease):

- Digital rectal examination annually
  - Fecal occult blood testing annually
  - Flexible sigmoidoscopy every 1–2 years
- OR
- Colonoscopy every 1–2 years
  - Genetic testing

From Pontieri-Lewis, V. (2000). Colorectal cancer. *MedSurg Nursing*, 9, 9–15, 20.

the test. If barium studies are to be performed, the nurse should make sure they are scheduled after this test; otherwise, the barium will interfere with the transmission of the sound waves.

## DNA TESTING

Researchers have refined methods for genetic risk assessment, pre-clinical diagnosis, and prenatal diagnosis to identify persons who are at risk for certain GI disorders (eg, gastric cancer, lactose deficiency, inflammatory bowel disease, colon cancer). In some cases, DNA testing allows practitioners to prevent (or minimize) disease, by intervening before its onset, and to improve therapy. Persons who are identified as at risk for certain GI disorders may choose to undergo genetic counseling to learn about the disease; to understand options for preventing and treating the disease; and to receive support in coping with the situation (Yamada, 1999). Persons at risk for colon cancer often are targeted for DNA testing because it can provide a head start on this preventable cancer.

## IMAGING STUDIES

Imaging studies include x-ray and contrast studies, computed tomography (CT) scans, magnetic resonance imaging (MRI), and scintigraphy (radionuclide imaging).

## Upper Gastrointestinal Tract Study

X-rays can delineate the entire GI tract after the introduction of a contrast agent. A radiopaque liquid (eg, barium sulfate) is commonly used. The patient ingests this tasteless, odorless, nongranular, and completely insoluble (hence, not absorbable) powder in the form of a thick or thin aqueous suspension for the purpose of studying the upper GI tract (upper GI series or barium swallow). The upper GI series enables the examiner to detect or exclude anatomic or functional derangement of the upper GI organs or sphincters. It also aids in the diagnosis of ulcers, varices, tumors, regional enteritis, and malabsorption syndromes. The procedure may be extended to examine the duodenum and small bowel (small bowel follow-through).

The patient swallows barium under direct fluoroscopic examination. As the barium descends into the stomach, the position, patency, and caliber of the esophagus are visualized, enabling the examiner to detect or exclude any anatomic or functional derangement of that organ. Fluoroscopic examination next extends to the stomach as its lumen fills with barium, allowing observation of stomach motility, thickness of the gastric wall, the mucosal pattern, patency of the pyloric valve, and the anatomy of the duodenum. Multiple x-ray films are obtained during the procedure, and additional images may be taken at intervals for up to

### GENETICS IN NURSING PRACTICE—Digestive and Gastrointestinal Disorders

#### SELECTED DIGESTIVE AND GASTROINTESTINAL DISORDERS INFLUENCED BY GENETIC FACTORS

- Cleft lip and/or palate
- Familial adenomatous polyposis
- Hereditary nonpolyposis colorectal cancer (HNPCC)
- Hirschsprung disease (aganglionic megacolon)
- Inflammatory bowel disease (eg, Crohn's disease)
- Pyloric stenosis

#### NURSING ASSESSMENTS

##### FAMILY HISTORY ASSESSMENT

- Careful family history assessment for other family members with a similar condition (eg, cleft lip/palate, pyloric stenosis)
- Assess for other family members in several generations with early-onset colorectal cancer
- Inquire about other family members with inflammatory bowel disease
- Assess family history for other cancers (eg, endometrial, ovarian, renal)

##### PHYSICAL ASSESSMENT

Assess for presence of other clinical symptoms:

- With clefting—congenital heart defect, mental retardation, other birth defects suggestive of a genetic syndrome
- With familial adenomatous polyposis—congenital hyper-trophy of retinal pigment epithelium (CHRPE)

#### MANAGEMENT ISSUES SPECIFIC TO GENETICS

- Inquire whether any affected family member has had DNA mutation testing

- If indicated, refer for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, availability of genetic testing, and gene-based interventions
- Offer appropriate genetics information and resources
- Assess patients' understanding of genetics information
- Provide support to families with newly diagnosed genetics-related digestive disorders
- Participate in management and coordination of care for patients with genetic conditions and for those who are predisposed to develop or pass on a genetic condition

#### GENETICS RESOURCES

Genetic Alliance—a directory of support groups for patients and families with genetic conditions; <http://www.geneticalliance.org>.

American Cancer Society—offers general information about cancer and support resources for families; <http://www.cancer.org>.

Gene Clinics—a listing of common genetic disorders with up-to-date clinical summaries, genetic counseling and testing information; <http://www.geneclinics.org>.

National Organization of Rare Disorders—a directory of support groups and information for patients and families with rare genetic disorders; <http://www.rarediseases.org>.

National Cancer Institute—current information about cancer research, treatment, resources for health providers, individuals, and families; <http://www.nci.nih.gov>.

Online Mendelian Inheritance in Man (OMIM)—a complete listing of inherited genetic conditions; <http://www.ncbi.nlm.nih.gov/omim/stats/html>.

24 hours to evaluate the rate of gastric emptying. Small bowel x-rays taken while the barium is passing through that area allow for observation of the motility of the small bowel. Obstructions, ileitis, and diverticula can be detected if present.

Variations of the upper GI study include double-contrast studies and enteroclysis. The double-contrast method of examining the upper GI tract involves administration of a thick barium suspension to outline the stomach and esophageal wall, after which tablets that release carbon dioxide in the presence of water are given. This technique has the advantage of showing the esophagus and stomach in finer detail, permitting signs of early superficial neoplasms to be noted.

Enteroclysis is a very detailed, double-contrast study of the entire small intestine that involves the continuous infusion, through a duodenal tube, of 500 to 1000 mL of a thin barium sulfate suspension. Methylcellulose is then infused into the small intestine through the tube. The barium and methylcellulose fill the intestinal loops and are observed continuously by fluoroscopy and viewed at frequent intervals as they progress through the jejunum and the ileum. This process (even with normal motility) can take up to 6 hours. The procedure aids in the diagnosis of partial small-bowel obstructions or diverticula.

### NURSING INTERVENTIONS

The patient may need to maintain a low-residue diet for several days before the test. He or she should receive nothing by mouth after midnight before the test. The physician may prescribe a laxative to clean out the intestinal tract. Because smoking can stimulate gastric motility, the nurse discourages the patient from smoking on the morning before the examination. In addition, the nurse withholds all medications.

Follow-up care is needed after any of the upper GI procedures to ensure that the patient has completely eliminated the ingested barium. Fluids must be increased to facilitate evacuation of stool and barium. The nurse monitors the patient's stools until they return to their normal color (the barium will look like clay). A laxative or enema may be needed.

## Lower Gastrointestinal Tract Study

When barium is instilled rectally to visualize the lower GI tract, the procedure is called a barium enema. The purpose of a barium enema is to detect the presence of polyps, tumors, and other lesions of the large intestine and to demonstrate any abnormal anatomy or malfunction of the bowel.

The radiopaque substance is instilled rectally in the radiology department during fluoroscopy. If the patient has been prepared adequately and the colon has been evacuated completely, the contour of the entire colon, including the cecum and appendix (if patent), is clearly visible and the motility of each portion may be observed readily. The procedure usually takes about 15 to 30 minutes, during which time x-ray images are taken.

Other means for visualizing the colon include double-contrast studies and a water-soluble contrast study. A double-contrast or air-contrast barium enema involves the instillation of a thicker barium solution, followed by the instillation of air. The patient may feel some cramping or discomfort with this process. This test provides a contrast between the air-filled lumen and the barium-coated mucosa, allowing easier detection of smaller lesions.

If active inflammatory disease, fistulas, or perforation of the colon is suspected, a water-soluble iodinated contrast agent (eg, Gastrografin) can be used. The procedure is the same as for a bar-

ium enema; however, the patient must be assessed for allergy to iodine or contrast agent. The contrast agent is eliminated readily after the procedure, so there is no need for postprocedure laxatives. Some diarrhea may occur in a few patients until the contrast agent has been totally eliminated.

### NURSING INTERVENTIONS

Preparing the patient includes emptying and cleansing the lower bowel. This often necessitates a low-residue diet 1 to 2 days before the test (the preparation required by different radiology departments may vary); a clear liquid diet and a laxative the evening before; nothing by mouth after midnight; and cleansing enemas until returns are clear the following morning. The nurse should make sure that barium enemas are scheduled before any upper GI studies. If the patient has active inflammatory disease of the colon, enemas are contraindicated. Barium enema also is contraindicated in patients with signs of perforation or obstruction; instead, a water-soluble contrast study may be performed in these situations. Active GI bleeding may prohibit the use of laxatives and enemas.

The nurse administers an enema or laxative after these tests to facilitate barium removal. Increasing fluid intake also will assist in eliminating the barium. As with any barium study, the nurse monitors the patient for complete elimination of the barium.

## Computed Tomography

CT provides cross-sectional images of abdominal organs and structures. Multiple x-ray images are taken from many different angles, digitized in the computer, reconstructed, and then viewed on a computer monitor. Indications for abdominal CT scanning are diseases of the liver, spleen, kidney, pancreas, and pelvic organs. CT is a valuable tool for detecting and localizing many inflammatory conditions in the colon, such as appendicitis, diverticulitis, regional enteritis, and ulcerative colitis. Because the adequacy of detail in the test depends on the presence of fat, this diagnostic tool is not useful for very thin, cachectic patients. The procedure is completely painless, but radiation doses are considerable. Because a scanning time of 5 seconds is required, motion artifacts produced by heart-beat and respiration cannot be avoided, resulting in pictures that are less than clear.

New, continuous-motion (helical or spiral), three-dimensional CT scans have been developed that provide very detailed pictures of the GI organs and vasculature (Yamada, 1999). Colonography can be completed in minutes. It involves inserting a thin, straw-like tube into the colon and inflating the bowel with air to generate a computer image of the intestine. There is little discomfort, and sedation is not needed.

### NURSING INTERVENTIONS

The patient should not eat or drink for 6 to 8 hours before the test. The practitioner may prescribe an intravenous or oral contrast agent. Therefore, the nurse should question the patient about contrast dye allergies. If barium studies are to be performed, it is important to schedule them after CT scanning, so as not to interfere with imaging.

## Magnetic Resonance Imaging

MRI is used in gastroenterology to supplement ultrasonography and CT scanning. It is a noninvasive technique that uses magnetic fields and radio waves to produce an image of the area being

studied. The use of oral contrast agents to enhance the image has increased the application of this technique for the diagnosis of GI diseases. It is useful in evaluating abdominal soft tissues as well as blood vessels, abscesses, fistulas, neoplasms, and other sources of bleeding.

The physiologic artifacts of heartbeat, respiration, and peristalsis may create a less-than-clear image. Newer, fast-imaging MRI techniques help to eliminate these physiologic motion artifacts. MRI is contraindicated for patients with permanent pacemakers, artificial heart valves and defibrillators, implanted insulin pumps, or implanted transcutaneous electrical nerve stimulation devices, because the magnetic field could cause malfunction. MRI is also contraindicated for patients with internal metal devices (eg, aneurysm clips) or intraocular metallic fragments.

### NURSING INTERVENTIONS

The patient should not eat or drink for 6 to 8 hours before the test. Before the test, the patient must remove all jewelry and other metals. The patient lies in a machine that constructs an image based on the magnetic field created between the machine and the structures scanned. The entire procedure takes 30 to 90 minutes.

It is important to warn patients that the close-fitting scanners used in many MRI facilities may induce feelings of claustrophobia and that the machine will make a knocking sound during the procedure. Open MRIs that are less close-fitting eliminate the claustrophobia that many patients experience.

### Scintigraphy

Scintigraphy (radionuclide testing) relies on the use of radioactive isotopes (ie, technetium, iodine, and indium) to reveal displaced anatomic structures, changes in organ size, and the presence of neoplasms or other focal lesions, such as cysts or abscesses.

Scintigraphic scanning is also used to measure the uptake of tagged red blood cells and leukocytes. Tagging of red blood cells and leukocytes by injection of a radionuclide is performed to define areas of inflammation, abscess, blood loss, or neoplasm. A sample of blood is removed, mixed with a radioactive substance, and reinjected into the patient. Abnormal concentrations of blood cells are then detected at 24- and 48-hour intervals.

## Gastrointestinal Motility Studies

Radionuclide testing also is used to assess gastric emptying and colonic transit time. For gastric emptying studies, the liquid and solid components of a meal are tagged with radionuclide markers. After the patient ingests the meal, the patient is positioned under a scintiscanner, which measures the rate of passage of the radioactive substance out of the stomach. This is useful in diagnosing disorders of gastric motility. Radionuclide evaluation of gastric emptying is now preferred over intubation methods because it gives more defined results (Phillips & Wingate, 1998). This procedure is helpful for evaluating any functional cause of gastric emptying, but its most common clinical uses at this time are in the evaluation of diabetic gastroparesis and of the rapid emptying process in the dumping syndrome.

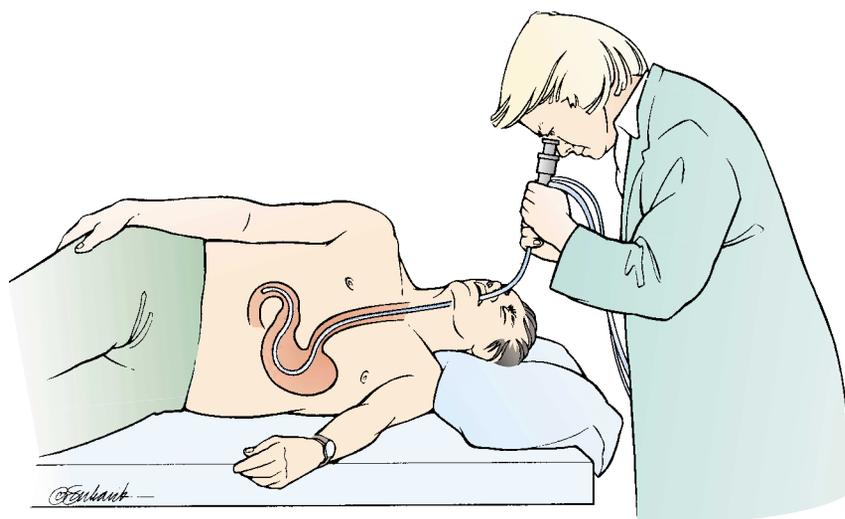

Colonic transit studies are used to evaluate colonic motility instances of chronic constipation and obstructive defecation syndromes. This is usually an outpatient study. The patient is given a capsule containing 20 radionuclide markers and instructions to follow a regular diet and normal daily activities. Abdominal x-rays are taken every 24 hours until all markers are passed. This process usually takes 4 to 5 days, but in the presence of severe constipation it may take as long as 10 days. People with chronic diarrhea may be evaluated at 8-hour intervals. The amount of time it takes for the radioactive material to move through the colon indicates colonic motility.

## ENDOSCOPIC PROCEDURES

Endoscopic procedures used in GI tract assessment include fibroscopy/esophagogastroduodenoscopy, anoscopy, proctoscopy, sigmoidoscopy, colonoscopy, small-bowel enteroscopy, and endoscopy through ostomy.

### Upper Gastrointestinal Fibroscopy/ Esophagogastroduodenoscopy

Fiberscopes are flexible scopes equipped with fiberoptic lenses. **Fibroscopy** of the upper GI tract allows direct visualization of the esophageal, gastric, and duodenal mucosa through a lighted endoscope (gastroscope) (Fig. 34-5). This procedure,

**FIGURE 34-5** Patient undergoing gastroscopy.

called esophagogastroduodenoscopy (EGD), is especially valuable when esophageal, gastric, or duodenal abnormalities or inflammatory, neoplastic, or infectious processes are suspected. This procedure also can be used to evaluate esophageal and gastric motility and to collect secretions and tissue specimens for further analysis.

The gastroenterologist views the GI tract through a viewing lens and can take still or video photographs through the scope to document findings. Electronic video endoscopes also are available that attach directly to a video processor, converting the electronic signals into pictures on a television screen. This allows larger and continuous viewing capabilities, as well as the simultaneous recording of the procedure.

Side-viewing flexible scopes are used to visualize the common bile duct and the pancreatic and hepatic ducts through the ampulla of Vater in the duodenum. This procedure, called endoscopic retrograde cholangiopancreatography (ERCP), uses the endoscope in combination with radiographic techniques to view the ductal structures of the biliary tract. ERCP is helpful in evaluating jaundice, pancreatitis, pancreatic tumors, common duct stones, and biliary tract disease. ERCP is described further in Chapter 40.

Upper GI fibroscopy also can be a therapeutic procedure when it is combined with other procedures. Therapeutic endoscopy can be used to remove common bile duct stones, dilate strictures, and treat gastric bleeding and esophageal varices. Laser-compatible scopes can be used to provide laser therapy for upper GI neoplasms. Sclerosing solutions can be injected through the scope in an attempt to control upper GI bleeding.

After the patient is sedated, the endoscope is lubricated with a water-soluble lubricant and passed smoothly and slowly along the back of the mouth and down into the esophagus. The gastroenterologist views the gastric wall and the sphincters, and then advances the endoscope into the duodenum for further examination. Biopsy forceps to obtain tissue specimens or cytology brushes to obtain cells for microscopic study can be passed through the scope. The procedure usually takes about 30 minutes.

The patient may experience nausea, gagging, or choking. Use of topical anesthetics and moderate sedation makes it important to monitor and maintain the oral airway during and after the procedure. Finger or ear oximeters are used to monitor oxygen saturation, and supplemental oxygen may be used if needed. Emergency equipment must be readily available. Precautions must be taken to protect the scope, because the fiberoptic bundles can be broken if the scope is bent at an acute angle. The patient wears a mouth guard to keep from biting the scope.

### NURSING INTERVENTIONS

The patient should not eat or drink for 6 to 12 hours before the examination. Patient preparation includes helping the patient spray or gargle with a local anesthetic, and administering midazolam (Versed) intravenously just before the scope is introduced. Midazolam is a sedative that provides moderate sedation and relieves anxiety during the procedure. The nurse also may administer atropine to reduce secretions, and may give glucagon, if needed and prescribed, to relax smooth muscle. The nurse positions the patient on the left side to facilitate saliva drainage and to provide easy access for the endoscope. After the procedure, the nurse instructs the patient not to eat or drink until the gag reflex returns (in 1 to 2 hours), to prevent aspiration of food or fluids into the lungs. The nurse places the patient in the Simms position until he or she is awake and then places the patient in the semi-Fowler's position until ready for discharge. After gastroscopy,

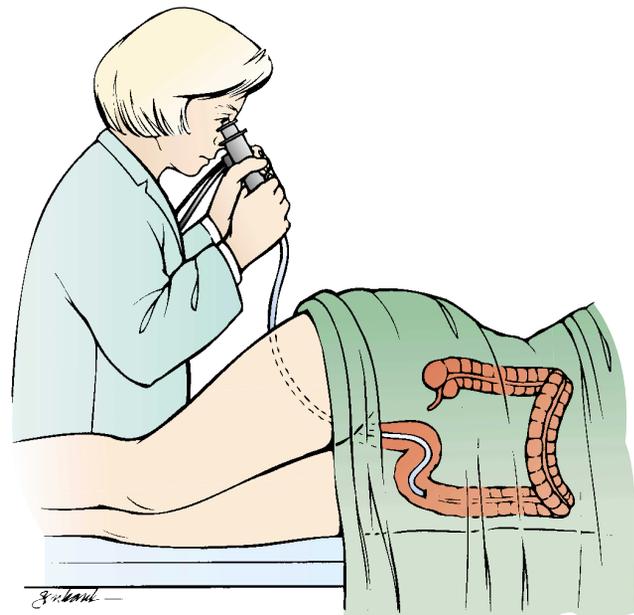

assessment by the nurse includes observing for signs of perforation, such as pain, bleeding, unusual difficulty swallowing, and an elevated temperature. The nurse monitors the pulse and blood pressure for changes that can occur with sedation. The nurse can test the gag reflex by placing a tongue blade onto the back of the throat to see whether gagging occurs. After the patient's gag reflex has returned, the nurse can offer lozenges, saline gargle, and oral analgesics to relieve minor throat discomfort. Patients who were sedated for the procedure must stay on bed rest until fully alert. After moderate sedation, the patient must be accompanied and transported home if the procedure was performed on an outpatient basis. The nurse instructs the patient not to drive for 10 to 12 hours if sedation was used.

### Anoscopy, Proctoscopy, and Sigmoidoscopy

The lower portion of the colon also can be viewed directly to evaluate rectal bleeding, acute or chronic diarrhea, or change in bowel patterns and to observe for ulceration, fissures, abscesses, tumors, polyps, or other pathologic processes. Rigid or flexible fiberoptic scopes can be used. The anoscope is a rigid scope that is used to examine the anus and lower rectum. Proctoscopes and sigmoidoscopes are rigid scopes that are used to inspect the rectum and the sigmoid colon.

Flexible scopes have largely replaced the rigid scopes for routine examinations. The flexible fiberoptic sigmoidoscope (Fig. 34-6) permits the colon to be examined up to 40 to 50 cm (16 to 20 inches) from the anus, much more than the 25 cm (10 inches) that can be visualized with the rigid sigmoidoscope. The flexible scope has many of the same capabilities as the scopes used for the upper GI study, including the use of still or video images to document findings.

For rigid scope procedures, the patient assumes the knee-chest position at the edge of the bed or the examining table. With the back inclined at about a 45-degree angle, the patient is properly positioned for the introduction of an anoscope, proctoscope, or

**FIGURE 34-6** Flexible fiberoptic sigmoidoscopy. The flexible scope is advanced past the proximal sigmoid and then into the descending colon.

sigmoidoscope. During the examination, it is important to keep the patient informed about the progress of the examination and to explain that the pressure exerted by the instrument will create the urge to have a bowel movement.

For flexible scope procedures, the patient assumes a comfortable position on the left side with the right leg bent and placed anteriorly. Again, it is important to keep the patient informed throughout the examination and to explain the sensations associated with the examination. Biopsies and polypectomies can be performed during this procedure. Biopsy is performed with small biting forceps introduced through the endoscope; one or more small pieces of tissue may be removed. If rectal or sigmoid polyps are present, they may be removed with a wire snare, which is used to grasp the pedicle, or stalk. An electrocoagulating current is then used to sever the polyp and prevent bleeding. It is extremely important that all excised tissue be placed immediately in moist gauze or in an appropriate receptacle, labeled correctly, and delivered without delay to the pathology laboratory for examination.

### NURSING INTERVENTIONS

These examinations require only limited bowel preparation, including a warm tap water or Fleet's enema until returns are clear. Dietary restrictions usually are not necessary, and sedation usually is not required. During the procedure, the nurse monitors vital signs, skin color and temperature, pain tolerance, and vagal response (Society of Gastroenterologic Nursing and Associates, 2000). After the procedure, the nurse monitors the patient for rectal bleeding and signs of intestinal perforation (ie, fever, rectal drainage, abdominal distention, and pain). On completion of the examination, the patient can resume regular activities and dietary practices.

### Fiberoptic Colonoscopy

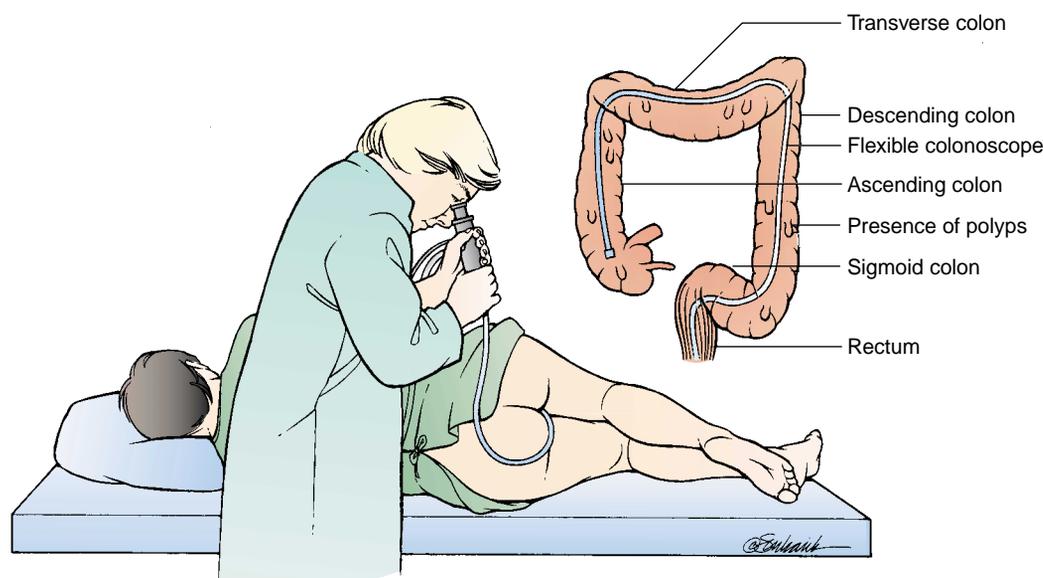

Direct visual inspection of the colon to the cecum is possible by means of a flexible fiberoptic colonoscope (Fig. 34-7). These scopes have the same capabilities as those used for esophagogastro-

duodenoscopy; however, they are larger in diameter and longer. Still and video recordings can be used to document the procedure and findings.

This procedure is used commonly as a diagnostic aid and screening device. It is most frequently used for cancer screening (see Chart 34-1) and for surveillance in patients with previous colon cancer or polyps. In addition, tissue biopsies can be obtained as needed, and polyps can be removed and evaluated. Other uses of colonoscopy include the evaluation of patients with diarrhea of unknown cause, occult bleeding, or anemia; further study of abnormalities detected on barium enema; and diagnosis, clarification, and determination of the extent of inflammatory or other bowel disease.

Therapeutically, the procedure can be used to remove all visible polyps with a special snare and cautery through the colonoscope. Many colon cancers begin with adenomatous polyps of the colon; therefore, one goal of colonoscopic polypectomy is early detection and prevention of colorectal cancer. This procedure also can be used to treat areas of bleeding or stricture. Use of bipolar and unipolar coagulators, use of heater probes, and injections of sclerosing agents or vasoconstrictors are all possible during this procedure. Laser-compatible scopes provide laser therapy for bleeding lesions or colonic neoplasms. Bowel decompression can also be completed during the procedure.

Colonoscopy is performed while the patient is lying on the left side with the legs drawn up toward the chest. The patient's position may be changed during the test to facilitate advancement of the scope. The procedure usually takes about 1 hour. Discomfort may result from instillation of air to expand the colon or from insertion and moving of the scope. Biopsy forceps or a cytology brush may be passed through the scope to obtain specimens for histology and cytology examinations. Potential complications of colonoscopy include cardiac dysrhythmias and respiratory depression resulting from the medications administered, vasovagal reactions, and circulatory overload or hypotension resulting from overhydration or underhydration during bowel preparation. Therefore, it is important to monitor the patient's cardiac and respiratory function continuously. Oxygen saturation is monitored with a

**FIGURE 34-7** Colonoscopy. The flexible scope is passed through the rectum and sigmoid colon into the descending, transverse, and ascending colon.

finger or ear oximeter. Supplemental oxygen should be used as necessary.

### NURSING INTERVENTIONS

The success of the procedure depends on how well the colon is prepared. Adequate colon cleansing provides optimal visualization and decreases the time needed for the procedure. First, the patient should limit the intake of liquids for 24 to 72 hours before the examination. Then, cleansing of the colon can be accomplished in various ways. The physician may prescribe a laxative for two nights before the examination and a Fleet's or saline enema until the return runs clear the morning of the test. More frequently, however, polyethylene glycol electrolyte lavage solutions (Golytely, Colyte, NuLytely) are used as intestinal lavages for effective cleansing of the bowel. The patient maintains a clear liquid diet starting at noon the day before the procedure. Then the patient ingests lavage solutions orally at intervals over 3 to 4 hours. If necessary, the nurse can give this solution through a feeding tube if the patient is unable to swallow. Patients with a colostomy can receive this same bowel preparation. With the use of lavage solutions, bowel cleansing is fast (rectal effluent is clear in about 4 hours) and is tolerated fairly well by most patients. Side effects of the electrolyte solutions include nausea, bloating, cramps or abdominal fullness, fluid and electrolyte imbalance, and hypothermia (patients are often told to drink the preparation as cold as possible to make it more palatable). The side effects are especially problematic for elderly patients, and sometimes they have difficulty ingesting the required volume of solution. The use of lavage solutions is contraindicated in patients with intestinal obstruction or inflammatory bowel disease.

Additional nursing actions include the following:

- Instructing the patient not to take routine medications when the lavage solution is ingested; the medications will not be digested and therefore will be ineffective
- Advising the diabetic patient to consult with his or her physician about medication adjustment to prevent hyperglycemia or hypoglycemia resulting from dietary modifications required in preparation for the test
- Instructing all patients, especially the elderly, to maintain adequate fluid, electrolyte, and caloric intake while undergoing bowel cleansing

Special precautions must be taken for some patients. Implantable defibrillators and pacemakers are at high risk for malfunction if electrosurgical procedures (ie, polypectomy) are performed in conjunction with colonoscopy. A cardiologist should be consulted before the test is performed, and the defibrillator should be turned off. These patients require careful cardiac monitoring during the procedure. Colonoscopy cannot be performed if there is a suspected or documented colon perforation, acute severe diverticulitis, or fulminant colitis. Therapeutic colonoscopy may be contraindicated in patients with coagulopathies and in those receiving anticoagulation therapy, because of the high risk for excessive bleeding during and after the procedure. Nonsteroidal anti-inflammatory agents (NSAIDs), aspirin, ticlopidine, and pentoxifylline must be discontinued before the test and for 2 weeks after the procedure. Patients taking coumadin or heparin must consult the physician for specific instructions. Those with prosthetic heart valves or a history of endocarditis require prophylactic antibiotics before the procedure.

Informed consent is obtained before the test. The patient receives nothing by mouth (NPO) after midnight before the test,

but most medications can be taken with a small amount of water; the physician should be consulted about medication use. Before the examination, the nurse may administer intravenously an opioid analgesic or a sedative (eg, midazolam) to provide moderate sedation and relieve anxiety during the procedure. Glucagon may be used, if needed, to relax the colonic musculature and to reduce spasm during the test. Elderly or debilitated patients may require a reduced dosage of these medications to decrease the risks of over-sedation and cardiopulmonary complications.

During the procedure, the nurse monitors for changes in oxygen saturation, vital signs, color and temperature of the skin, level of consciousness, abdominal distention, vagal response, and pain intensity. After the procedure, patients who were sedated are maintained on bed rest until fully alert. Some will have abdominal cramps caused by increased peristalsis stimulated by the air insufflated into the bowel during the procedure. Immediately after the test, the nurse observes the patient for signs and symptoms of bowel perforation (eg, rectal bleeding, abdominal pain or distention, fever, focal peritoneal signs). If midazolam was used, the nurse explains its amnesic effects. It is important to provide written instructions, because the patient may be unable to recall verbal information. If the procedure is performed on an outpatient basis, someone must accompany and transport the patient home. After a therapeutic procedure, the nurse instructs the patient to report any bleeding to the physician.

### Small-Bowel Enteroscopy

Technology for the use of the small-caliber transnasal endoscope to allow direct inspection of the wall of the small intestine continues to be developed. Two methods are being used at this time: the "push" and the "pull" endoscope methods. The "pull" endoscope is very long and flexible and has a balloon at its tip. When inflated, the balloon tip advances the scope by peristalsis through the small intestine. Reglan may be administered intravenously to assist passage. This procedure takes up to 10 hours to complete. The patient may be kept in the recovery area or sent home during this period. Once the scope has entered the distal ileum, the balloon is deflated and the tube is retracted slowly while the endoscopist examines the intestinal wall. "Push" endoscopes have been designed to be smaller in caliber and longer in length, while still allowing the use of biopsy forceps and probes (Lightdale, 2000). These two methods are especially useful in the evaluation of patients who have continued bleeding even after extensive diagnostic testing has identified no other problem area. They can also be used when biopsy of the small bowel is needed to diagnose malabsorption syndromes.

### Endoscopy Through Ostomy

Endoscopy using a flexible endoscope through an ostomy stoma is useful for visualizing a segment of the small or large intestine. It may be indicated to evaluate an anastomosis, to screen for recurrent disease, or to visualize and treat bleeding in a segment of the bowel. Nursing interventions are similar to those for other endoscopic procedures.

## MANOMETRY AND ELECTROPHYSIOLOGIC STUDIES

Manometry and electrophysiologic studies are methods for evaluating patients with GI motility disorders. The manometry test measures changes in intraluminal pressures and the coordination

of muscle activity in the GI tract. The pressures can be recorded manually, on a physiograph, or on a computer.

Esophageal manometry is used to detect motility disorders of the esophagus and the lower esophageal sphincter. Patients must refrain from eating or drinking for 8 to 12 hours before the test. Medications that could have a direct affect on motility (eg, calcium channel blockers, anticholinergic agents, sedatives) are withheld for 24 to 48 hours. A pressure-sensitive catheter is inserted through the nose and is connected to a transducer and a video recorder. The patient then swallows small amounts of water while the resultant pressure changes are recorded.

Gastroduodenal, small-intestine, and colonic manometry are used to evaluate delayed gastric emptying and gastric and intestinal motility disorders such as irritable bowel syndrome or atonic colon. This is often an ambulatory outpatient procedure lasting 24 to 72 hours. Anorectal manometry measures the resting tone of the internal anal sphincter and the contractibility of the external anal sphincter. It is helpful in evaluating patients with chronic constipation or fecal incontinence and is useful in biofeedback for the treatment of fecal incontinence. It can be performed in conjunction with rectal sensory functioning tests. Phospho-Soda or a saline cleansing enema is administered 1 hour before the test. Positioning for the test is either the prone or the lateral position.

A rectal sensory function test is used to evaluate rectal sensory function and neuropathy. A catheter and balloon are passed into the rectum, and the balloon is inflated until the patient feels distention. Then the tone and pressure of the rectum and anal sphincter are measured. The results are especially helpful in the evaluation of patients with chronic constipation, diarrhea, or incontinence.

Electrogastrography, an electrophysiologic study, also may be performed to assess gastric motility disturbances. Electrodes are placed over the abdomen, and gastric electrical activity is recorded for up to 24 hours. Patients may exhibit rapid, slow, or irregular waveform activity. Electrogastrography can be useful in detecting motor or nerve dysfunction in the stomach.

## Defecography

Defecography measures anorectal function. Very thick barium paste is instilled into the rectum, and then fluoroscopy is performed to assess the function of the rectum and anal sphincter while the patient attempts to expel the barium. The test requires no preparation. The use of scintigraphic techniques to measure rectal emptying of radioisotope-labeled artificial stool can provide more quantitative information.

Electromyographic (EMG) studies can supplement anorectal manometry to measure the integrity and function of the anal sphincters in an effort to treat functional bowel incontinence and constipation.

## GASTRIC ANALYSIS, GASTRIC ACID STIMULATION TEST, AND pH MONITORING

Analysis of the gastric juice yields information about the secretory activity of the gastric mucosa and the presence or degree of gastric retention in patients thought to have pyloric or duodenal obstruction. It is also useful for diagnosing diseases such as Zollinger-Ellison syndrome.

The patient is kept NPO for 8 to 12 hours before the procedure. Any medications that affect gastric secretions are withheld for 24 to 48 hours before the test. Smoking is not allowed on the morning before the test, because it increases gastric secretions. A small nasogastric tube with a catheter tip marked at various points is inserted through the nose. When the tube is at a point slightly less than 50 cm (21 inches) distant, it should be within the stomach, lying along the greater curvature. Once in place, the tube is secured to the patient's cheek and the patient is placed in a semi-reclining position. The entire stomach contents are aspirated by gentle suction into a syringe, and gastric samples are collected every 15 minutes for the next hour.

The gastric acid stimulation test usually is performed in conjunction with gastric analysis. Histamine or pentagastrin is administered subcutaneously to stimulate gastric secretions. It is important to inform the patient that this injection may produce a flushed feeling. The nurse monitors blood pressure and pulse frequently to detect hypotension. Gastric specimens are collected after the injection every 15 minutes for 1 hour and are labeled to indicate the time of specimen collection after histamine injection. The volume and pH of the specimen are measured. In certain instances, cytologic study by the Papanicolaou technique may be used to determine the presence or absence of malignant cells. Enzyme analysis of the gastric juice may be indicated.

Important diagnostic information to be gained from gastric analysis includes the ability of the mucosa to secrete HCl. This ability is altered in various disease states, including

- Pernicious anemia—patients with this disease secrete no acid under basal conditions or after stimulation
- Severe chronic atrophic gastritis or gastric cancer—patients with these diseases secrete little or no acid
- Peptic ulcer—patients with peptic ulcers secrete some acid
- Duodenal ulcers—patients with duodenal ulcers usually secrete an excess amount of acid

Esophageal reflux of gastric acid may be diagnosed by ambulatory pH monitoring. The patient is NPO for 6 hours before the test, and all medications affecting gastric secretions are withheld for 24 to 36 hours before the test. A probe that measures pH is placed through the nose and into position about 5 inches above the lower esophageal sphincter. It is connected to an external recording device and is worn for 24 hours while the patient continues his or her normal daily activities. The end result is a computer analysis and graphic display of the results. This test allows for the direct correlation between chest pain and reflux episodes (Wolfe, 2000).

A Bernstein test may be performed to evaluate complaints of acid-related chest or epigastric pain. HCl is instilled through a small feeding tube positioned in the esophagus. This is done to try to elicit reported chest pain. Resultant signs and symptoms are compared with the usual symptoms the patient reports. However, since the advent of ambulatory pH monitoring, this previously popular evaluation tool is used infrequently (Wolfe, 2000).

## LAPAROSCOPY (PERITONEOSCOPY)

Laparoscopy can be used for the diagnosis of GI disease. This procedure is performed through a small incision in the abdominal wall. Special fiberoptic laparoscopes allow direct visualization of the organs and structures within the abdomen, permitting visualization and identification of any growths, anomalies, and inflammatory processes. In addition, biopsy samples can be taken from the structures and organs as necessary. This procedure can

be used to evaluate peritoneal disease, chronic abdominal pain, abdominal masses, and gallbladder and liver disease. However, laparoscopy has not become an important diagnostic modality in patients with acute abdominal pain, because less invasive tools (ie, CT and MRI) are readily available (Wolfe, 2000). Laparoscopy usually requires general anesthesia and sometimes requires that the stomach and bowel be decompressed. Gas (usually carbon dioxide) is insufflated into the peritoneal cavity to create a working space for visualization. One of the most positive benefits of this procedure is that after visualization of a problem, excision (eg, removal of the gallbladder) can then be performed at the same time, if appropriate.

## Pathophysiologic and Psychological Considerations

Abnormalities of the GI tract are numerous and represent every type of major pathology that can affect other organ systems, including bleeding, perforation, obstruction, inflammation, and cancer. Congenital, inflammatory, infectious, traumatic, and neoplastic lesions have been encountered in every portion, and at every site, along the length of the GI tract. As with all other organ systems, the GI tract is subject to circulatory disturbances, faulty nervous system control, and aging.

Apart from the many organic diseases to which the GI tract is susceptible, there are many extrinsic factors that can interfere with its normal function and produce symptoms. Stress and anxiety, for example, often find their chief expression in indigestion, anorexia, or motor disturbances of the intestines, sometimes producing constipation or diarrhea. In addition to the state of mental health, physical factors such as fatigue and an inadequate or abruptly changed dietary intake can markedly affect the GI tract. When assessing and instructing the patient, the nurse should consider the variety of mental and physical factors that affect the function of the GI tract.

### Gerontologic Considerations

Normal physiologic changes of the GI system that occur with aging are identified in the accompanying Gerontologic Considerations box. The nurse should carefully assess and monitor signs and symptoms related to these changes. Age-related changes in the mouth include loss of teeth, diminished number of taste buds, decreased production of saliva, and atrophy of gingival tissue. These changes cause difficulty in chewing and swallowing. Changes in the esophagus include decreased muscle tone and weakness in the lower esophageal sphincter, leading to reflux and heartburn.

Decreased gastric motility leads to delayed gastric emptying. Atrophy of the mucosa causes a decrease in HCl production, and this can lead to food intolerances, malabsorption, or decrease in vitamin B<sub>12</sub> absorption. Changes in the small and large intestine are evidenced largely by decreased motility and decreased transit time, which lead to complaints of indigestion and constipation. Other changes lead to decreased absorption of nutrients (dextrose, fats, calcium, and iron) in the large intestine. The nerve supply to the anal sphincter is sometimes impaired, causing fecal incontinence (Luekenotte, 2000).

## Gerontologic Considerations

### Age-Related Changes of the Gastrointestinal System

#### Oral Cavity and Pharynx

- Injury/loss or decay of teeth
- Atrophy of taste buds
- Decreased saliva production
- Reduced ptyalin and amylase in saliva

#### Esophagus

- Decreased motility and emptying
- Weakened gag reflex
- Decreased resting pressure of lower esophageal sphincter

#### Stomach

- Degeneration and atrophy of gastric mucosal surfaces with decreased production of HCl
- Decreased secretion of gastric acids and most digestive enzymes
- Decreased motility and emptying

#### Small Intestine

- Atrophy of muscle and mucosal surfaces
- Thinning of villi and epithelial cells

#### Large Intestine

- Decrease in mucus secretion
- Decrease in elasticity of rectal wall
- Decreased tone of internal anal sphincter
- Slower and duller nerve impulses in rectal area

## Critical Thinking Exercises

1. You are caring for a 24-year-old male patient who was admitted for acute abdominal pain. He has just arrived from the emergency room and is being scheduled for tests this afternoon. What laboratory tests would you expect to be ordered? He is scheduled for a CT and ultrasound in 2 hours. What preparation is needed for these tests? What preprocedure education is needed?

2. A 58-year-old patient assigned to you this morning has just left to go to the Endoscopy Suite, where she will undergo a colonoscopy. You know that your patient will receive moderate sedation during the procedure and that she will be returned to your care once she is fully alert. What should you anticipate in the course of recovery for your patient after the colonoscopy? What medications might be used for the moderate sedation, and what effects of those medications would you expect to see during the recovery period? Describe the potential complications that could occur and what you will monitor. What are the goals for care during this period?

# ● Management of Patients With Oral and Esophageal Disorders

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Use the nursing process as a framework for care of patients with conditions of the oral cavity.
2. Describe the relationship of dental hygiene and dental problems to nutrition.
3. Describe the nursing management of patients with abnormalities of the lips, gums, teeth, mouth, and salivary glands.
4. Use the nursing process as a framework for care of patients with cancer of the oral cavity.
5. Identify the physical and psychosocial long-term needs of patients with oral cancer.
6. Use the nursing process as a framework for care of patients undergoing neck dissection.
7. Use the nursing process as a framework for care of patients with conditions of the esophagus.
8. Describe the various conditions of the esophagus and their clinical manifestations and management.

**B**ecause digestion normally begins in the mouth, adequate nutrition is related to good dental health and the general condition of the mouth. Any discomfort or adverse condition in the oral cavity can affect a person's nutritional status. Changes in the oral cavity may influence the type and amount of food ingested as well as the degree to which food particles are properly mixed with salivary enzymes. Disease of the mouth or tongue can interfere with speech and thus affect communication and self-image. Esophageal problems related to swallowing can also adversely affect food and fluid intake, thereby jeopardizing general health and well-being. Given the close relationship between adequate nutritional intake and the structures of the upper gastrointestinal tract (lips, mouth, teeth, pharynx, esophagus), health teaching can help prevent disorders associated with these structures.

The oral cavity, which includes the lips, mouth, and gums, is subject to many disorders and diseases. Table 35-1 reviews common abnormalities, their possible causes, and nursing management. As identified in a report by the U.S. Surgeon General in 2000, oral health is a very important component of a person's physical and psychological sense of well-being. Severe periodontal disease affects approximately 14% of adults 45 to 64 years of age and 23% of adults 65 to 74 years of age (US Department of Health and Human Services, 2000).

## Disorders of the Teeth

### DENTAL PLAQUE AND CARIES

Tooth decay is an erosive process that begins with the action of bacteria on fermentable carbohydrates in the mouth, which produces acids that dissolve tooth enamel. The extent of damage to the teeth depends on the following:

- The presence of dental plaque
- The strength of the acids and the ability of the saliva to neutralize them
- The length of time the acids are in contact with the teeth
- The susceptibility of the teeth to decay

Dental plaque is a gluey, gelatin-like substance that adheres to the teeth. The initial action that causes damage to a tooth occurs under dental plaque.

Dental decay begins with a small hole, usually in a fissure (a break in the tooth's enamel) or in an area that is hard to clean. Left unchecked, the affected area penetrates the enamel into the dentin. Because dentin is not as hard as enamel, decay progresses more rapidly and in time reaches the pulp. When the blood, lymph vessels, and nerves are exposed, they become infected and an abscess may form, either within the tooth or at the tip of the root. Soreness and pain usually occur with an abscess. As the in-

fection continues, the patient's face may swell, and there may be pulsating pain. The dentist can determine by x-ray studies the extent of damage and the type of treatment needed. Treatment for dental caries includes fillings, dental implants, and extractions. If treatment is not successful, the tooth may need to be extracted. In general, dental decay is associated with young people, but older adults are subject to decay as well, particularly from drug-induced or age-related oral dryness (see the accompanying Gerontologic Considerations box).

### Prevention

Measures used to prevent and control dental caries include practicing effective mouth care, reducing the intake of starches and sugars (refined carbohydrates), applying fluoride to the teeth or drinking fluoridated water, refraining from smoking, controlling diabetes, and using pit and fissure sealants (Chart 35-1).

### MOUTH CARE

Healthy teeth must be conscientiously and effectively cleaned on a daily basis. Brushing and flossing are particularly effective in mechanically breaking up the bacterial plaque that collects around teeth.

Normal mastication (chewing) and the normal flow of saliva also aid greatly in keeping the teeth clean. Because many ill patients do not eat adequate amounts of food, they produce less saliva, which in turn reduces this natural tooth cleaning process. The nurse may need to assume the responsibility for brushing the patient's teeth. In any case, merely wiping the patient's mouth and teeth with a swab is ineffective. The most effective method is mechanical cleansing (brushing). If brushing is impossible, it is better to wipe the teeth with a gauze pad, then have the patient swish an antiseptic mouthwash several times before expectorating into an emesis basin. A soft-bristled toothbrush is more effective than a sponge or foam stick. The lips may be coated with a water-soluble gel to prevent drying.

### DIET

Dental caries may be prevented by decreasing the amount of sugar and starch in the diet. Patients who snack should be encouraged to choose less cariogenic alternatives, such as fruits, vegetables, nuts, cheeses, or plain yogurt.

### FLUORIDATION

Fluoridation of public water supplies has been found to decrease dental caries. Some areas of the country have natural fluoridation; other communities have added fluoride to public water supplies. Fluoridation may be achieved also by having a dentist apply a concentrated gel or solution to the teeth, adding fluoride to home

## Glossary

**achalasia:** absent or ineffective peristalsis (wavelike contraction) of the distal esophagus accompanied by failure of the esophageal sphincter to relax in response to swallowing

**dysphagia:** difficulty swallowing

**gastroesophageal reflux:** back-flow of gastric or duodenal contents into the esophagus

**hernia:** protrusion of an organ or part of an organ through the wall of the cavity that normally contains it

**lithotripsy:** use of shock waves to break up or disintegrate stones

**odynophagia:** pain on swallowing

**parotitis:** inflammation of the parotid gland

**pyrosis:** heartburn

**periapical abscess:** abscessed tooth

**sialadenitis:** inflammation of the salivary glands

**stomatitis:** inflammation of the oral mucosa

**temporomandibular disorders:** a group of conditions that cause pain or dysfunction of the temporomandibular joint (TMJ) and surrounding structures

**xerostomia:** dry mouth

Table 35-1 • Disorders of the Lips, Mouth, and Gums

CONDITION	SIGNS AND SYMPTOMS	POSSIBLE CAUSES AND SEQUELAE	NURSING CONSIDERATIONS
<b>Abnormalities of the Lips</b>			
Actinic cheilitis	Irritation of lips associated with scaling, crusty, fissure; white overgrowth of horny layer of epidermis (hyperkeratosis) Considered a premalignant squamous cell skin cancer	Exposure to sun; more common in fair-skinned people and in those whose occupations involve sun exposure, such as farmers May lead to squamous cell cancer	Teach patient importance of protecting lips from the sun by using protective ointment such as sun block Instruct patient to have a periodic checkup by physician
Herpes simplex 1 (cold sore or fever blister)	Symptoms may be delayed up to 20 days after exposure; singular or clustered painful vesicles that may rupture	An opportunistic infection; frequently seen in immunosuppressed patients; very contagious May recur with menstruation, fever, or sun exposure	Use acyclovir or zovirax ointment or systemic medications as prescribed Administer analgesics as prescribed Instruct patient to avoid irritating foods
Chancre	Reddened circumscribed lesion that ulcerates and becomes crusted	Primary lesion of syphilis; very contagious	Comfort measures: cold soaks to lip, mouth care Administer antibiotics as prescribed Instruct patient regarding contagion
Contact dermatitis	Red area or rash; itching	Allergic reaction to lipstick, cosmetic ointments, or toothpaste	Instruct patient to avoid possible causes Administer corticosteroids as prescribed
<b>Abnormalities of the Mouth</b>			
Leukoplakia	White patches; may be hyperkeratotic; usually in buccal mucosa; usually painless	Fewer than 2% are malignant, but may progress to cancer Common among tobacco users	Instruct patient to see a physician if leukoplakia persists longer than 2 weeks Eliminate risk factors, such as tobacco
Hairy leukoplakia	White patches with rough hair-like projections; typically found on lateral border of the tongue	Possibly viral; smoking and use of tobacco Often seen in people who are HIV positive	Instruct patient to see a physician if condition persists longer than 2 weeks
Lichen planus	White papules at the intersection of a network of interlacing lesions; usually ulcerated and painful	Recurrences are common May lead to a malignant process Unknown cause	Apply topical corticosteroids such as fluocinolone acetonide oral base gel Avoid foods that irritate Administer corticosteroids systemically or intralesionally as prescribed Instruct the patient of need for follow-up if condition is chronic
Candidiasis (moniliasis/thrush)	Cheesy white plaque that looks like milk curds; when rubbed off, it leaves an erythematous and often bleeding base	<i>Candida albicans</i> fungus; predisposing factors include diabetes, antibiotic therapy, and immunosuppression	Antifungal medications such as nystatin (Mycostatin), Amphotericin B, clotrimazole, or ketoconazole may be prescribed; these may be taken in pill form or as a suspension; when used as a suspension, instruct the patient to swish vigorously for at least 1 minute and then swallow
Aphthous stomatitis (canker sore)	Shallow ulcer with a white or yellow center and red border; seen on the inner side of the lip and cheek or on the tongue; it begins with a burning or tingling sensation and slight swelling; painful; usually lasts 7–10 days and heals without a scar	Associated with emotional or mental stress, fatigue, hormonal factors, minor trauma (such as biting), allergies, acidic foods and juices, and dietary deficiencies Associated with HIV infection May recur	Instruct the patient in comfort measures, such as saline rinses, and a soft or bland diet Antibiotics or corticosteroids may be prescribed
Nicotine stomatitis (smoker's patch)	Two stages—begins as a red stomatitis; over time the tongue and mouth become covered with a creamy, thick, white mucous membrane, which may slough, leaving a beefy red base	Chronic irritation by tobacco	Cessation of tobacco use; if condition exists for longer than 2 weeks a physician should be consulted and a biopsy may be needed

(continued)

**Table 35-1 • Disorders of the Lips, Mouth, and Gums (Continued)**

CONDITION	SIGNS AND SYMPTOMS	POSSIBLE CAUSES AND SEQUELAE	NURSING CONSIDERATIONS
Krythoplakia	Red patch on the oral mucous membrane	Nonspecific inflammation; more frequently seen in the elderly	
Kaposi's sarcoma	Appears first on the oral mucosa as a red, purple, or blue lesion; may be singular or multiple; may be flat or raised	HIV infection	Instruct patient regarding side effects of planned treatment
<b>Abnormalities of the Gums</b>			
Gingivitis	Painful, inflamed, swollen gums; usually the gums bleed in response to light contact	Poor oral hygiene: food debris, bacterial plaque, and calculus (tartar) accumulate; the gums may also swell in response to normal processes such as puberty and pregnancy	Teach patient proper oral hygiene; see Preventive Oral Hygiene chart
Necrotizing gingivitis (trench mouth)	Gray-white pseudomembranous ulcerations affecting the edges of the gums, mucosa of the mouth, tonsils, and pharynx; foul breath; painful, bleeding gums; swallowing and talking are painful	Poor oral hygiene; bacterial infection, inadequate rest, overwork, emotional stress, smoking, and poor nutrition may contribute to development	Teach patient proper oral hygiene; see Preventive Oral Hygiene chart Irrigate with 2% to 3% hydrogen peroxide or normal saline solution Avoid irritants such as smoking and spicy foods
Herpetic gingivostomatitis	Burning sensation with the appearance of small vesicles 24–48 hours later; vesicles may rupture, forming sore, shallow ulcers covered with a gray membrane	Herpes simplex virus; occurs most frequently in people who are immunosuppressed; may occur in other infectious processes such as streptococcal pneumonia, meningococcal meningitis, and malaria	Apply topical anesthetics as prescribed; may need opioids if pain is severe Saline or 2% to 3% hydrogen peroxide irrigations Antiviral agents such as acyclovir may be prescribed
Periodontitis	Little discomfort at onset; may have bleeding, infection, gum recession, and loosening of teeth; later in the disease tooth loss may occur	May result from untreated gingivitis Poor or inadequate dental hygiene and inadequate diet contribute to development	Instruct patient in proper oral hygiene Instruct patient to consult a dentist

water supplies, using fluoridated toothpaste or mouth rinse, or using sodium fluoride tablets, drops, or lozenges.

### PIT AND FISSURE SEALANTS

The occlusal surfaces of the teeth have pits and fissures, areas that are prone to caries. Some dentists apply a special coating to fill and

seal these areas from potential exposure to cariogenic processes. These sealants last up to 7 years.

### DENTOALVEOLAR ABSCESS OR PERIAPICAL ABSCESS

**Periapical abscess**, more commonly referred to as an abscessed tooth, involves the collection of pus in the apical dental periosteum (fibrous membrane supporting the tooth structure) and

## Gerontologic Considerations

### Oral Problems

Many medications taken by the elderly cause dry mouth, which is uncomfortable, impairs communication, and increases the risk of oral infection. These medications include the following:

- Diuretics
- Antihypertensive medications
- Anti-inflammatory agents
- Antidepressant medications

Poor dentition can exacerbate problems of aging, such as

- Decreased food intake
- Loss of appetite
- Social isolation
- Increased susceptibility to systemic infection (from periodontal disease)
- Trauma to the oral cavity secondary to thinner, less vascular oral mucous membranes

### Chart 35-1 • PATIENT EDUCATION

#### Preventive Oral Hygiene

- Brush teeth using a soft toothbrush at least two times daily. Hold toothbrush at a 45-degree angle between the brush and the gums and teeth. A small brush is better than a large brush. Gums and tongue surface should be brushed.
- Floss at least once daily.
- Use an antiplaque mouth rinse.
- Visit a dentist at least every 6 months, or when you have a chipped tooth, a lost filling, an oral sore that persists longer than 2 weeks, or a toothache.
- Avoid alcohol and tobacco products, including smokeless tobacco.
- Maintain adequate nutrition and avoid sweets.
- Replace toothbrush at first signs of wear, usually every 2 months.

the tissue surrounding the apex of the tooth (where it is suspended in the jaw bone). The abscess has two forms: acute and chronic. Acute periapical abscess is usually secondary to a suppurative pulpitis (a pus-producing inflammation of the dental pulp) that arises from an infection extending from dental caries. The infection of the dental pulp extends through the apical foramen of the tooth to form an abscess around the apex.

Chronic dentoalveolar abscess is a slowly progressive infectious process. It differs from the acute form in that the process may progress to a fully formed abscess without the patient's knowing it. The infection eventually leads to a "blind dental abscess," which is really a periapical granuloma. It may enlarge to as much as 1 cm in diameter. It is often discovered on x-ray films and is treated by extraction or root canal therapy, often with apicectomy (excision of the apex of the tooth root).

### Clinical Manifestations

The abscess produces a dull, gnawing, continuous pain, often with a surrounding cellulitis and edema of the adjacent facial structures, and mobility of the involved tooth. The gum opposite the apex of the tooth is usually swollen on the cheek side. Swelling and cellulitis of the facial structures may make it difficult for the patient to open the mouth. In well-developed abscesses, there may be a systemic reaction, fever, and malaise.

### Management

In the early stages of an infection, a dentist or dental surgeon may perform a needle aspiration or drill an opening into the pulp chamber to relieve tension and pain and to provide drainage. Usually, the infection will have progressed to a periapical abscess. Drainage is provided by an incision through the gingiva down to the jawbone. Pus (purulent material) escapes under pressure. This procedure is commonly performed in the dentist's office, but it may be performed in an outpatient surgery center or a same-day surgery department. After the inflammatory reaction has subsided, the tooth may be extracted or root canal therapy performed. Antibiotics may be prescribed.

### Nursing Management

The nurse assesses the patient for bleeding after treatment and instructs the patient to use a warm saline or warm water mouth rinse to keep the area clean. The patient is also instructed to take antibiotics and analgesics as prescribed, to advance from a liquid diet to a soft diet as tolerated, and to keep follow-up appointments.

## MALOCCLUSION

Malocclusion is a misalignment of the teeth of the upper and lower dental arcs when the jaws are closed. Malocclusion can be inherited or acquired (from thumb-sucking, trauma, or some medical conditions). Malocclusion makes the teeth difficult to clean and can lead to decay, gum disease, and excess wear on supporting bone and gum tissues. About 50% of the population has some form of malocclusion. Correction of malocclusion requires an orthodontist with special training, a patient who is motivated and cooperative, and adequate time. Most treatments begin when the patient has shed the last primary tooth and the last permanent successor has erupted, usually at about 12 or 13 years of age, but treatment may occur in adulthood. Preventive orthodontics may be started at age 5 years if malocclusion is diagnosed early. The need for teeth

straightening in adolescence is reduced if preventive orthodontics is started with the primary teeth.

### Management

People with malocclusion have an obviously misaligned bite or crooked, crowded, widely spaced, or protruding teeth. To realign the teeth, the orthodontist gradually forces the teeth into a new location by using wires or plastic bands (braces). These devices may be unattractive, but this psychological burden must be overcome if good results are to be achieved. In the final phase of treatment, a retaining device is worn for several hours each day to support the tissues as they adjust to the new alignment of the teeth.

### Nursing Management

The patient must practice meticulous oral hygiene, and the nurse encourages the patient to persist in this important part of the treatment. An adolescent undergoing orthodontic correction who is admitted to the hospital for some other problem may have to be reminded to continue wearing the retainer (if it does not interfere with the problem requiring hospitalization).

## Disorders of the Jaw

Abnormal conditions affecting the mandible (jaw) and of the temporomandibular joint (which connects the mandible to the temporal bone at the side of the head in front of the ear) include congenital malformation, fracture, chronic dislocation, cancer, and syndromes characterized by pain and limited motion. Temporomandibular disorders and jaw surgery (a treatment common in many structural abnormalities or cancer of the jaw) are presented in this section.

## TEMPOROMANDIBULAR DISORDERS

**Temporomandibular disorders** are categorized as follows (National Oral Health Information Clearinghouse, 2000):

- Myofascial pain—a discomfort in the muscles controlling jaw function and in neck and shoulder muscles
- Internal derangement of the joint—a dislocated jaw, a displaced disc, or an injured condyle
- Degenerative joint disease—rheumatoid arthritis or osteoarthritis in the jaw joint

Diagnosis and treatment of temporomandibular disorders remain somewhat ambiguous, but the condition is thought to affect about 10 million people in the United States. Misalignment of the joints in the jaw and other problems associated with the ligaments and muscles of mastication are thought to result in tissue damage and muscle tenderness. Suggested causes include arthritis of the jaw, head injury, trauma or injury to the jaw or joint, stress, and malocclusion (although research does not support malocclusion as a cause).

### Clinical Manifestations

Patients have pain ranging from a dull ache to throbbing, debilitating pain that can radiate to the ears, teeth, neck muscles, and facial sinuses. They often have restricted jaw motion and locking of

the jaw. They may hear clicking and grating noises, and chewing and swallowing may be difficult. Depression may occur in response to these symptoms.

### Assessment and Diagnostic Findings

Diagnosis is based on the patient's subjective symptoms of pain, limitations in range of motion, dysphagia, difficulty chewing, difficulty with speech, or hearing difficulties. Magnetic resonance imaging, x-ray studies, and an arthrogram may be performed.

### Management

Although some practitioners think the role of stress in temporomandibular joint (TMJ) disorders is overrated, patient education in stress management may be helpful (to reduce grinding and clenching of teeth). Patients may also benefit from range-of-motion exercises. Pain management measures may include nonsteroidal anti-inflammatory drugs (NSAIDs), with the possible addition of opioids, muscle relaxants, or mild antidepressants. Occasionally, a bite plate or splint (plastic guard worn over the upper and lower teeth) may be worn to protect teeth from grinding; however, this is a short-term therapy. Conservative and reversible treatment is recommended. If irreversible surgical options are recommended, the patient is encouraged to seek a second opinion.

### SURGICAL MANAGEMENT

Correction of mandibular structural abnormalities may require surgery involving repositioning or reconstruction of the jaw. Simple fractures of the mandible without displacement, resulting from a blow on the chin, and planned surgical interventions, as in the correction of long or short jaw syndrome, may require treatment by these means. Jaw reconstruction may be necessary in the aftermath of trauma from a severe injury or cancer, both of which can cause tissue and bone loss.

Mandibular fractures are usually closed fractures. Rigid plate fixation (insertion of metal plates and screws into the bone to approximate and stabilize the bone) is the current treatment of choice in many cases of mandibular fracture and in some mandibular reconstructive surgery procedures. Bone grafting may be performed to replace structural defects using bones from the patient's own ilium, ribs, or cranial sites. Rib tissue may also be harvested from cadaver donors.

### Nursing Management

The patient who has had rigid fixation should be instructed not to chew food in the first 1 to 4 weeks after surgery. A liquid diet is recommended, and dietary counseling should be obtained to ensure optimal caloric and protein intake.

### PROMOTING HOME AND COMMUNITY-BASED CARE

The patient needs specific guidelines for mouth care and feeding. Any irritated areas in the mouth should be reported to the physician. The importance of keeping scheduled appointments for assessing the stability of the fixation appliance is emphasized.

Consultation with a dietitian may be indicated so that the patient and family can learn about foods that are high in essential nutrients and ways in which these foods can be prepared so that they can be consumed through a straw or spoon, while remaining palatable. Nutritional supplements may be recommended.

## Disorders of the Salivary Glands

The salivary glands consist of the parotid glands, one on each side of the face below the ear; the submandibular and sublingual glands, both in the floor of the mouth; and the buccal gland, beneath the lips. About 1200 mL of saliva are produced daily. The glands' primary functions are lubrication, protection against harmful bacteria, and digestion.

### PAROTITIS

**Parotitis** (inflammation of the parotid gland) is the most common inflammatory condition of the salivary glands, although inflammation can occur in the other salivary glands as well. Mumps (epidemic parotitis), a communicable disease caused by viral infection and most commonly affecting children, is an inflammation of a salivary gland, usually the parotid.

Elderly, acutely ill, or debilitated people with decreased salivary flow from general dehydration or medications are at high risk for parotitis. The infecting organisms travel from the mouth through the salivary duct. The organism is usually *Staphylococcus aureus* (except in mumps). The onset of this complication is sudden, with an exacerbation of both the fever and the symptoms of the primary condition. The gland swells and becomes tense and tender. The patient feels pain in the ear, and swollen glands interfere with swallowing. The swelling increases rapidly, and the overlying skin soon becomes red and shiny.

Preventive measures are essential and include advising the patient to have necessary dental work performed before surgery. In addition, maintaining adequate nutritional and fluid intake, good oral hygiene, and discontinuing medications (eg, tranquilizers, diuretics) that can diminish salivation may help prevent the condition. If parotitis occurs, antibiotic therapy is necessary. Analgesics may also be prescribed to control pain. If antibiotic therapy is not effective, the gland may need to be drained by a surgical procedure known as parotidectomy. This procedure may be necessary to treat chronic parotitis.

### SIALADENITIS

**Sialadenitis** (inflammation of the salivary glands) may be caused by dehydration, radiation therapy, stress, malnutrition, salivary gland calculi (stones), or improper oral hygiene. The inflammation is associated with infection by *S. aureus*, *Streptococcus viridans*, or pneumococcus. In hospitalized or institutionalized patients the infecting organism may be methicillin-resistant *S. aureus* (MRSA) (McQuone, 1999). Symptoms include pain, swelling, and purulent discharge. Antibiotics are used to treat infections. Massage, hydration, and corticosteroids frequently cure the problem. Chronic sialadenitis with uncontrolled pain is treated by surgical drainage of the gland or excision of the gland and its duct.

### SALIVARY CALCULUS (SIALOLITHIASIS)

Sialolithiasis, or salivary calculi (stones), usually occurs in the submandibular gland. Salivary gland ultrasonography or sialography (x-ray studies filmed after the injection of a radiopaque substance into the duct) may be required to demonstrate obstruction of the duct by stenosis. Salivary calculi are formed mainly from calcium phosphate. If located within the gland, the calculi are irregular and vary in diameter from 3 to 30 mm. Calculi in the duct are small and oval.

Calculi within the salivary gland itself cause no symptoms unless infection arises; however, a calculus that obstructs the gland's duct causes sudden, local, and often colicky pain, which is abruptly relieved by a gush of saliva. This characteristic symptom is often disclosed in the patient's health history. On physical assessment, the gland is swollen and quite tender, the stone itself can be palpable, and its shadow may be seen on x-ray films.

The calculus can be extracted fairly easily from the duct in the mouth. Sometimes, enlargement of the ductal orifice permits the stone to pass spontaneously. Occasionally **lithotripsy**, a procedure that uses shock waves to disintegrate the stone, may be used instead of surgical extraction for parotid stones and smaller submandibular stones. Lithotripsy requires no anesthesia, sedation, or analgesia. Side effects can include local hemorrhage and swelling. Surgery may be necessary to remove the gland if symptoms and calculi recur repeatedly.

## NEOPLASMS

Although they are uncommon, neoplasms (tumors or growths) of almost any type may develop in the salivary gland. Tumors occur more often in the parotid gland. The incidence of salivary gland tumors is similar in men and women. Risk factors include prior exposure to radiation to the head and neck. Diagnosis is based on the health history and physical examination and the results of fine needle aspiration biopsy.

Management of salivary gland tumors evokes controversy, but the common procedure involves partial excision of the gland, along with all of the tumor and a wide margin of surrounding tissue. Dissection is carefully performed to preserve the seventh cranial nerve (facial nerve), although it may not be possible to preserve the nerve if the tumor is extensive. If the tumor is malignant, radiation therapy may follow surgery. Radiation therapy alone may be a treatment choice for tumors that are thought to be contained or if there is risk of facial nerve damage from surgical intervention. Chemotherapy is usually used for palliative purposes. Local recurrences are common, and the recurrent growth usually is more aggressive than the original. It has also been observed that patients with salivary gland tumors have an increased incidence of second primary cancers (Bull, 2001).

## Cancer of the Oral Cavity

Cancers of the oral cavity, which can occur in any part of the mouth or throat, are curable if discovered early. These cancers are associated with the use of alcohol and tobacco. The combination of alcohol and tobacco seems to have a synergistic carcinogenic effect. About 95% of cases of oral cancer occur in people older than 40 years of age, but the incidence is increasing in men younger than age 30 because of the use of smokeless tobacco, especially snuff (Centers for Disease Control and Prevention, 2002).

Cancer of the oral cavity accounts for less than 2% of all cancer deaths in the United States. Men are afflicted more often than women; however, the incidence of oral cancer in women is increasing, possibly because they use tobacco and alcohol more frequently than they did in the past. The 5-year survival rate for cancer of the oral cavity and pharynx is 55% for whites and 33% for African Americans. Of the 7400 annual deaths from oral cancer, the distribution by site is estimated as follows: tongue, 1700; mouth, 2000; pharynx, 2100; other, 1600 (American Cancer Society, Cancer Facts and Figures, 2002).

Chronic irritation by a warm pipestem or prolonged exposure to the sun and wind may predispose a person to lip cancer. Predisposing factors for other oral cancers are exposure to tobacco (including smokeless tobacco), ingestion of alcohol, dietary deficiency, and ingestion of smoked meats.

## Pathophysiology

Malignancies of the oral cavity are usually squamous cell cancers. Any area of the oropharynx can be a site for malignant growths, but the lips, the lateral aspects of the tongue, and the floor of the mouth are most commonly affected.

## Clinical Manifestations

Many oral cancers produce few or no symptoms in the early stages. Later, the most frequent symptom is a painless sore or mass that will not heal. A typical lesion in oral cancer is a painless indurated (hardened) ulcer with raised edges. Tissue from any ulcer of the oral cavity that does not heal in 2 weeks should be examined through biopsy. As the cancer progresses, the patient may complain of tenderness; difficulty in chewing, swallowing, or speaking; coughing of blood-tinged sputum; or enlarged cervical lymph nodes.

## Assessment and Diagnostic Findings

Diagnostic evaluation consists of an oral examination as well as an assessment of the cervical lymph nodes to detect possible metastases. Biopsies are performed on suspicious lesions (those that have not healed in 2 weeks). High-risk areas include the buccal mucosa and gingiva for people who use snuff or smoke cigars or pipes. For those who smoke cigarettes and drink alcohol, high-risk areas include the floor of the mouth, the ventrolateral tongue, and the soft palate complex (soft palate, anterior and posterior tonsillar area, uvula, and the area behind the molar and tongue junction).

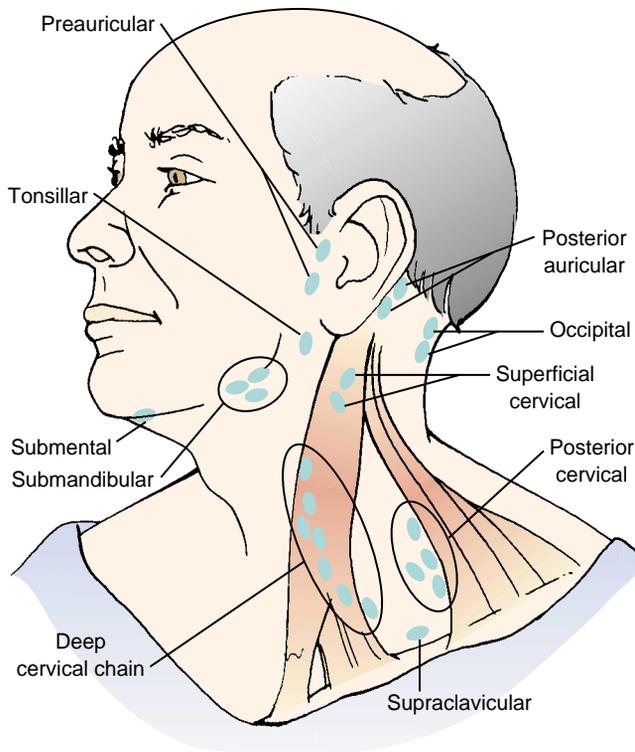

## Medical Management

Management varies with the nature of the lesion, the preference of the physician, and patient choice. Surgical resection, radiation therapy, chemotherapy, or a combination of these therapies may be effective.

In cancer of the lip, small lesions are usually excised liberally; larger lesions involving more than one third of the lip may be more appropriately treated by radiation therapy because of superior cosmetic results. The choice depends on the extent of the lesion and what is necessary to cure the patient while preserving the best appearance. Tumors larger than 4 cm often recur.

Cancer of the tongue may be treated with radiation therapy and chemotherapy to preserve organ function and maintain quality of life. A combination of radioactive interstitial implants (surgical implantation of a radioactive source into the tissue adjacent to or at the tumor site) and external beam radiation may be used. If the cancer has spread to the lymph nodes, the surgeon may perform a neck dissection. Surgical treatments leave a less functional tongue; surgical procedures include hemiglossectomy (surgical removal of half of the tongue) and total glossectomy (removal of the tongue).

Often cancer of the oral cavity has metastasized through the extensive lymphatic channel in the neck region (Fig. 35-1), requiring a neck dissection and reconstructive surgery of the oral

**FIGURE 35-1** Lymphatic drainage of the head and neck.

cavity. A common reconstructive technique involves use of a radial forearm free flap (a thin layer of skin from the forearm along with the radial artery).

## Nursing Management

The nurse assesses the patient's nutritional status preoperatively, and a dietary consultation may be necessary. The patient may require enteral (through the intestine) or parenteral (intravenous) feedings before and after surgery to maintain adequate nutrition. If a radial graft is to be performed, an Allen test on the donor arm must be performed to ensure that the ulnar artery is patent and can provide blood flow to the hand after removal of the radial artery. The Allen test is performed by asking the patient to make a fist and then manually compressing the ulnar artery. The patient is then asked to open the hand into a relaxed, slightly flexed position. The palm will be pale. Pressure on the ulnar artery is released. If the ulnar artery is patent, the palm will flush within about 3 to 5 seconds.

Postoperatively, the nurse assesses for a patent airway. The patient may be unable to manage oral secretions, making suctioning necessary. If grafting was included in the surgery, suctioning must be performed with care to prevent damage to the graft. The graft is assessed postoperatively for viability. Although color should be assessed (white may indicate arterial occlusion, and blue mottling may indicate venous congestion), it can be difficult to assess the graft by looking into the mouth. A Doppler ultrasound device may be used to locate the radial pulse at the graft site and to assess graft perfusion.

## NURSING PROCESS: THE PATIENT WITH CONDITIONS OF THE ORAL CAVITY

### Assessment

Obtaining a health history allows the nurse to determine the patient's learning needs concerning preventive oral hygiene and to identify symptoms requiring medical evaluation. The history includes questions about the patient's normal brushing and flossing routine; frequency of dental visits; awareness of any lesions or irritated areas in the mouth, tongue, or throat; recent history of sore throat or bloody sputum; discomfort caused by certain foods; daily food intake; use of alcohol and tobacco, including smokeless chewing tobacco; and the need to wear dentures or a partial plate. For more information about dentures, see the accompanying Gerontologic Considerations box.

A careful physical assessment follows the health history. Both the internal and the external structures of the mouth and throat are inspected and palpated. Dentures and partial plates are removed to ensure a thorough inspection of the mouth. In general, the examination can be accomplished by using a bright light source (penlight) and a tongue depressor. Gloves are worn to palpate the tongue and any abnormalities.

### LIPS

The examination begins with inspection of the lips for moisture, hydration, color, texture, symmetry, and the presence of ulcerations or fissures. The lips should be moist, pink, smooth, and symmetric. The patient is instructed to open the mouth wide; a tongue blade is then inserted to expose the buccal mucosa for an assessment of color and lesions. Stensen's duct of each parotid gland is visible as a small red dot in the buccal mucosa next to the upper molars.

### GUMS

The gums are inspected for inflammation, bleeding, retraction, and discoloration. The odor of the breath is also noted. The hard palate is examined for color and shape.

### TONGUE

The dorsum (back) of the tongue is inspected for texture, color, and lesions. A thin white coat and large, vallate papillae in a "V" formation on the distal portion of the dorsum of the tongue are

## Gerontologic Considerations

### Denture Care

Many older adults wear dentures. Mouth care and regular checkups remain part of the denture-wearing older adult's health promotion activities.

- Brush dentures twice a day.
- Remove dentures at night and soak them in water or a denture product. (Never put dentures in hot water, because they may warp.)
- Rinse mouth with warm salt water in the morning, after meals, and at bedtime.
- Clean well under partial dentures, where food particles tend to get caught.
- Consume nonsticky foods that have been cut into small pieces; chew slowly.
- See dentist regularly to assess and readjust fit.

normal findings. The patient is instructed to protrude the tongue and move it laterally. This provides the examiner with an opportunity to estimate the tongue's size as well as its symmetry and strength (to assess the integrity of the 12th cranial nerve [hypoglossal]).

Further inspection of the ventral surface of the tongue and the floor of the mouth is accomplished by asking the patient to touch the roof of the mouth with the tip of the tongue. Any lesions of the mucosa or any abnormalities involving the frenulum or superficial veins on the undersurface of the tongue are assessed for location, size, color, and pain. This is a common area for oral cancer, which presents as a white or red plaque, an indurated ulcer, or a warty growth.

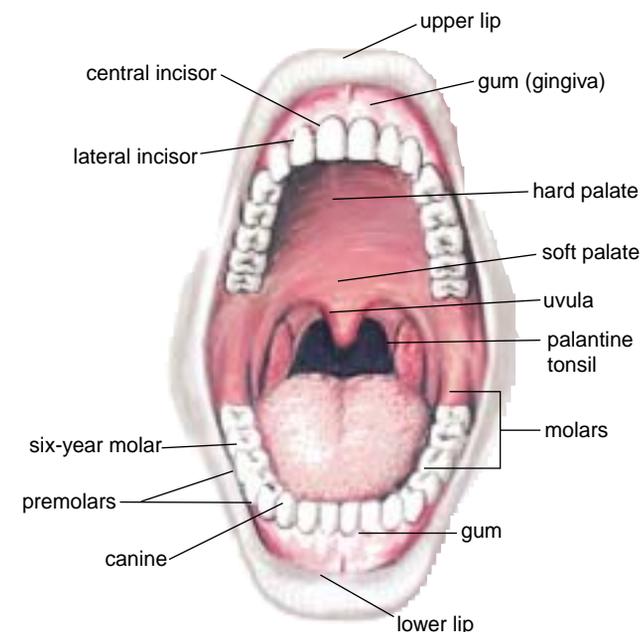

A tongue blade is used to depress the tongue for adequate visualization of the pharynx. It is pressed firmly beyond the midpoint of the tongue; proper placement avoids a gagging response. The patient is told to tip the head back, open the mouth wide, take a deep breath, and say "ah." Often this flattens the posterior tongue and briefly allows a full view of the tonsils, uvula, and posterior pharynx (Fig. 35-2). These structures are inspected for color, symmetry, and evidence of exudate, ulceration, or enlargement. Normally, the uvula and soft palate rise symmetrically with a deep inspiration or "ah"; this indicates an intact vagus nerve (10th cranial nerve).

A complete assessment of the oral cavity is essential because many disorders, such as cancer, diabetes, and immunosuppressive conditions resulting from medication therapy or AIDS, may be manifested by changes in the oral cavity. The neck is examined for enlarged lymph nodes (adenopathy).

## Nursing Diagnoses

Based on all the assessment data, major nursing diagnoses may include the following:

- Impaired oral mucous membrane related to a pathologic condition, infection, or chemical or mechanical trauma (eg, medications, ill-fitting dentures)

**FIGURE 35-2** Structures of the mouth, including the tongue and palate.

- Imbalanced nutrition, less than body requirements, related to inability to ingest adequate nutrients secondary to oral or dental conditions
- Disturbed body image related to a physical change in appearance resulting from a disease condition or its treatment
- Fear of pain and social isolation related to disease or change in physical appearance
- Pain related to oral lesion or treatment
- Impaired verbal communication related to treatment
- Risk for infection related to disease or treatment
- Deficient knowledge about disease process and treatment plan

## Planning and Goals

The major goals for the patient may include improved condition of the oral mucous membrane, improved nutritional intake, attainment of a positive self-image, relief of pain, identification of alternative communication methods, prevention of infection, and understanding of the disease and its treatment.

## Nursing Interventions

### PROMOTING MOUTH CARE

The nurse instructs the patient in the importance and techniques of preventive mouth care. If a patient cannot tolerate brushing or flossing, an irrigating solution of 1 teaspoon of baking soda to 8 ounces of warm water, half-strength hydrogen peroxide, or normal saline solution is recommended. The nurse reinforces the need to perform oral care and provides such care to patients who are unable to provide it for themselves.

If a bacterial or fungal infection is present, the nurse administers the appropriate medications and instructs the patient in how to administer the medications at home. The nurse monitors the patient's physical and psychological response to treatment.

**Xerostomia**, dryness of the mouth, is a frequent sequela of oral cancer, particularly when the salivary glands have been exposed to radiation or major surgery. It is also seen in patients who are receiving psychopharmacologic agents, patients with HIV infection, and patients who cannot close the mouth and as a result become mouth-breathers. To minimize this problem, the patient is advised to avoid dry, bulky, and irritating foods and fluids, as well as alcohol and tobacco. The patient is also encouraged to increase intake of fluids (when not contraindicated) and to use a humidifier during sleep. The use of synthetic saliva, a moisturizing antibacterial gel such as Oral Balance, or a saliva production stimulant such as Salagen may be helpful.

**Stomatitis**, or mucositis, which involves inflammation and breakdown of the oral mucosa, is often a side effect of chemotherapy or radiation therapy. Prophylactic mouth care is started when the patient begins receiving treatment; however, mucositis may become so severe that a break in treatment is necessary. If a patient receiving radiation therapy has poor dentition, extraction of the teeth before radiation treatment in the oral cavity is often initiated to prevent infection. Many radiation therapy centers recommend the use of fluoride treatments for patients receiving radiation to the head and neck.

### ENSURING ADEQUATE FOOD AND FLUID INTAKE

The patient's weight, age, and level of activity are recorded to determine whether nutritional intake is adequate. A daily calorie count may be necessary to determine the exact quantity of food and fluid ingested. The frequency and pattern of eating are recorded to determine whether any psychosocial or physiologic factors are

Chart 35-2

## Home Care Checklist • The Patient With an Oral Condition

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Demonstrate use of suction equipment if indicated.	✓	✓
• State rationale for humidification.	✓	✓
• State foods necessary to meet caloric needs and dietary needs (ie, change in consistency, seasoning limitations, supplements).	✓	✓
• Demonstrate oral hygiene.	✓	✓
• Demonstrate care of incision.	✓	✓
• State when next medical/dental follow-up appointment will be scheduled.	✓	✓

affecting ingestion. The nurse recommends changes in the consistency of foods and the frequency of eating, based on the disorder and the patient's preferences. Consultation with a dietitian can be helpful. The goal is to help the patient attain and maintain desirable body weight and level of energy, as well as to promote the healing of tissue.

### SUPPORTING A POSITIVE SELF-IMAGE

A patient who has a disfiguring oral condition or has undergone disfiguring surgery may experience an alteration in self-image. The patient is encouraged to verbalize the perceived change in body appearance and to realistically discuss actual changes or losses. The nurse offers support while the patient verbalizes fears and negative feelings (withdrawal, depression, anger). The nurse listens attentively and determines whether the patient's needs are primarily psychosocial or cognitive-perceptual. This determination will help the nurse to individualize a plan of care. The patient's strengths, achievements, and positive attributes are reinforced.

The nurse should determine the patient's anxieties concerning relationships with others. Referral to support groups, a psychiatric liaison nurse, a social worker, or a spiritual advisor may be useful in helping the patient to cope with anxieties and fears. Emphasizing that the patient's worth is not diminished by a physical change in a body part can be a helpful approach. The patient's progress toward development of positive self-esteem is documented. The nurse should be alert to signs of grieving and should record emotional changes. By providing acceptance and support, the nurse encourages the patient to verbalize feelings.

### MINIMIZING PAIN AND DISCOMFORT

Oral lesions can be painful. Strategies to reduce pain and discomfort include avoiding foods that are spicy, hot, or hard (eg, pretzels, nuts). The patient is instructed about mouth care. It may be necessary to provide the patient with an analgesic such as viscous lidocaine (Xylocaine Viscous 2%) or opioids, as prescribed. The nurse can reduce the patient's fear of pain by providing information about pain control methods.

### PROMOTING EFFECTIVE COMMUNICATION

Verbal communication may be impaired by radical surgery for oral cancer. It is therefore vital to assess the patient's ability to communicate in writing before surgery. Pen and paper are provided postoperatively to patients who can use them to communicate. A communication board with commonly used words or pictures is obtained preoperatively and given after surgery to patients who cannot write so that they may point to needed items. A speech therapist is also consulted postoperatively.

### PREVENTING INFECTION

Leukopenia (a decrease in white blood cells) may result from radiation, chemotherapy, AIDS, and some medications used to treat HIV infection. Leukopenia reduces defense mechanisms, increasing the risk for infections. Malnutrition, which is also common among these patients, may further decrease resistance to infection. If the patient has diabetes, the risk of infection is further increased.

Laboratory results should be evaluated frequently and the patient's temperature checked every 4 to 8 hours for an elevation that may indicate infection. Visitors who might transmit microorganisms are prohibited because the patient's immunologic system is depressed. Sensitive skin tissues are protected from trauma to maintain skin integrity and prevent infection. Aseptic technique is necessary when changing dressings. Desquamation (shedding of the epidermis) is a reaction to radiation therapy that causes dryness and itching and can lead to a break in skin integrity and subsequent infection.

As described earlier, adequate nutrition is helpful in preventing infection. Signs of wound infection (redness, swelling, drainage, tenderness) are reported to the physician. Antibiotics may be prescribed prophylactically.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

The patient who is recovering from treatment of an oral condition is instructed about mouth care, nutrition, prevention of infection, and signs and symptoms of complications (Chart 35-2). Methods of preparing nutritious foods that are seasoned according to the patient's preference and at the preferred temperature are explained. For some patients, it may be more convenient to use commercial baby foods than to prepare liquid and soft diets. The patient who cannot take foods orally may receive enteral or parenteral nutrition; the administration of these feedings is explained and demonstrated to the patient and the care provider.

For patients with cancer, instructions are provided in the use and care of any prostheses. The importance of keeping dressings clean is emphasized, as is the need for conscientious oral hygiene.

#### Continuing Care

The need for ongoing care in the home depends on the patient's condition. The patient, the family members or others responsible for home care, the nurse, and other health care professionals (eg, speech therapist, nutritionist, psychologist) work together to prepare an individual plan of care.

If suctioning of the mouth or tracheostomy tube is required, the necessary equipment is obtained and the patient and care providers

are taught how to use it. Considerations include the control of odors and humidification of the home to keep secretions moist. The patient and the care providers are taught how to assess for obstruction, hemorrhage, and infection and what actions to take if they occur. The home care nurse may provide physical care, monitor for changes in the patient's physical status (eg, skin integrity, nutritional status, respiratory function), and assess the adequacy of pain control measures. The nurse also assesses the patient's and family's ability to manage incisions, drains, and feeding tubes and the use of recommended strategies for communication. The ability of the patient and family to accept physical, psychological, and role changes is assessed and addressed.

Follow-up visits to the physician are important to monitor the patient's condition and to determine the need for modifications in treatment and general care. The nurse reinforces instructions in an effort to promote the patient's self-care and comfort.

Because patients and their family members and health care providers tend to focus on the most obvious needs and issues, the nurse reminds the patient and family about the importance of continuing health promotion and screening practices. Those patients who have not been involved in these practices in the past are educated about their importance and are referred to appropriate health care providers.

## Evaluation

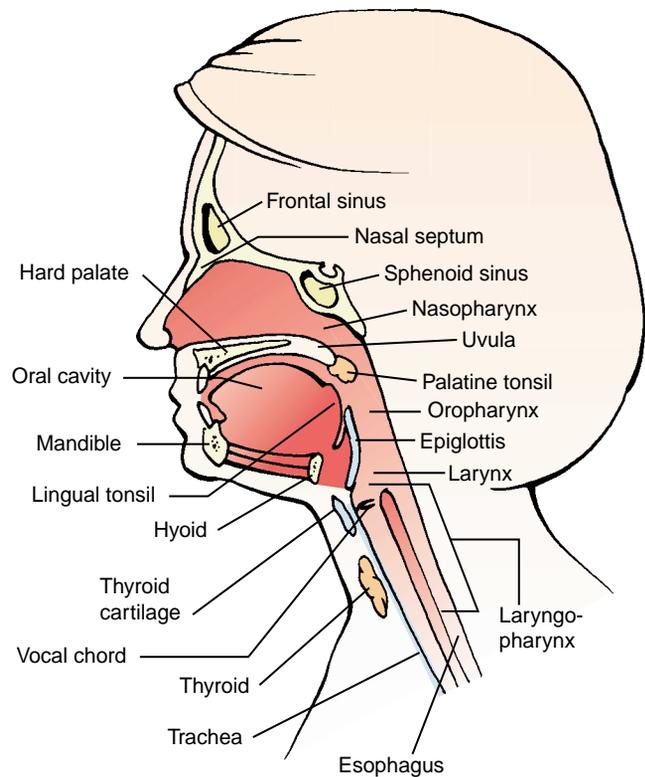

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Shows evidence of intact oral mucous membranes
  - a. Is free of pain and discomfort in the oral cavity
  - b. Has no visible alteration in membrane integrity
  - c. Identifies and avoids foods that are irritating (eg, nuts, pretzels, spicy foods)
  - d. Describes measures that are necessary for preventive mouth care
  - e. Complies with medication regimen
  - f. Limits or avoids use of alcohol and tobacco (including smokeless tobacco)
2. Attains and maintains desirable body weight
3. Has a positive self-image
  - a. Verbalizes anxieties
  - b. Is able to accept change in appearance and modify self-concept accordingly
4. Attains an acceptable level of comfort
  - a. Verbalizes that pain is absent or under control
  - b. Avoids foods and liquids that cause discomfort
  - c. Adheres to medication regimen
5. Has decreased fears related to pain, isolation, and the inability to cope
  - a. Accepts that pain will be managed if not eliminated
  - b. Freely expresses fears and concerns
6. Is free of infection
  - a. Exhibits normal laboratory values
  - b. Is afebrile
  - c. Performs oral hygiene after every meal and at bedtime
7. Acquires information about disease process and course of treatment

## Neck Dissection

Malignancies of the head and neck include those of the oral cavity, oropharynx, hypopharynx, nasopharynx, nasal cavity, paranasal sinus, and larynx (Fig. 35-3). (Laryngeal cancer is

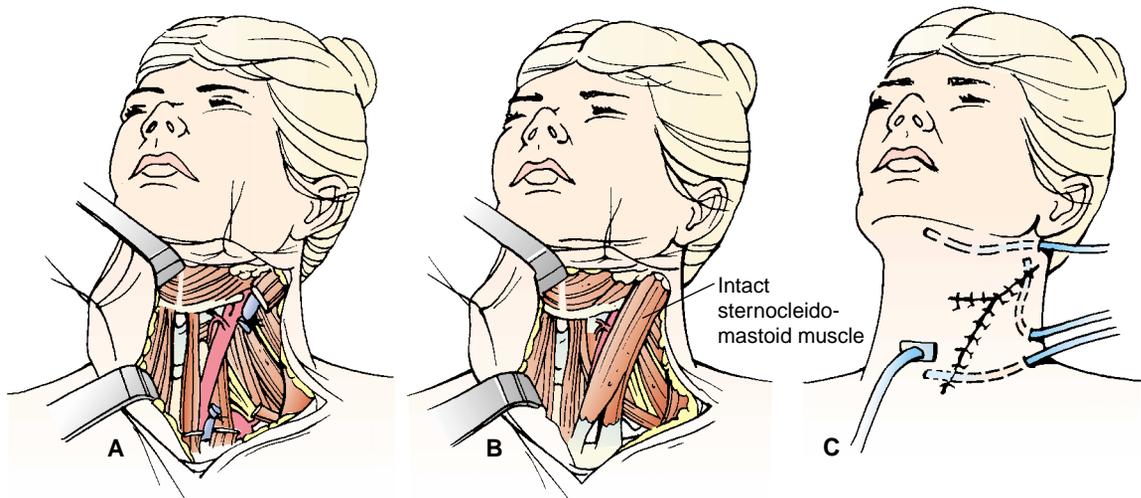

**FIGURE 35-3** Anatomy of the head and neck.

presented in Chapter 22.) These cancers account for fewer than 5% of all cancers. Depending on the location and stage, treatment may consist of radiation therapy, chemotherapy, surgery, or a combination of these modalities. Deaths from malignancies of the head and neck are primarily attributable not to recurrence at the primary site but to local-regional metastasis to the cervical lymph nodes in the neck. This often occurs by way of the lymphatics before the primary lesion has been treated. This local-regional metastasis is not amenable to surgical resection and responds poorly to chemotherapy and radiation therapy.

A radical neck dissection involves removal of all cervical lymph nodes from the mandible to the clavicle and removal of the sternocleidomastoid muscle, internal jugular vein, and spinal accessory muscle on one side of the neck. The associated morbidities include shoulder drop and poor cosmesis (visible neck depression). Modified radical neck dissection, which preserves one or more of the nonlymphatic structures, is used more often. A selective neck dissection (in comparison to a radical dissection) preserves one or more of the lymph node groups, the internal jugular vein, the sternocleidomastoid muscle, and the spinal accessory nerve (Fig. 35-4).

Reconstructive techniques may be performed with a variety of grafts. A cutaneous flap (skin and subcutaneous tissue), such as the deltopectoral flap, may be used. A more frequently used graft for head and neck reconstruction is a myocutaneous flap (subcutaneous tissue, muscle and skin). The pectoralis major muscle is usually used. A microvascular free flap may be used for large defects. This involves the transfer of muscle, skin, or bone with an artery and vein to the area of reconstruction, using microinstrumentation. Areas used for a free flap include the scapula, the radial area of the forearm, or the fibula. The fibula, which provides a larger bone area, may be used if mandibular reconstruction is involved.

**FIGURE 35-4** (A) A classic radical neck dissection in which the sternocleidomastoid and smaller muscles are removed. All tissue is removed, from the ramus of the jaw to the clavicle. The jugular vein has also been removed. The selective neck dissection (B) is similar but preserves the sternocleidomastoid muscle, internal jugular vein, and spinal accessory nerve. The wound is closed (C), and portable suction drainage tubes are in place.

## NURSING PROCESS: THE PATIENT UNDERGOING A NECK DISSECTION

### Assessment

Preoperatively, the patient's physical and psychological preparation for major surgery is assessed, along with his or her knowledge of the preoperative and postoperative procedures. Postoperatively, the patient is assessed for complications such as altered respiratory status, wound infection, and hemorrhage. As healing occurs, neck range of motion is assessed to determine whether there has been a decrease in range of motion due to nerve or muscle damage.

### Diagnosis

#### NURSING DIAGNOSES

Based on all the assessment data, major nursing diagnoses may include the following:

- Deficient knowledge about preoperative and postoperative procedures
- Ineffective airway clearance related to obstruction by mucus, hemorrhage, or edema
- Acute pain related to surgical incision
- Risk for infection related to surgical intervention secondary to decreased nutritional status, or immunosuppression from chemotherapy or radiation therapy
- Impaired tissue integrity secondary to surgery and grafting
- Imbalanced nutrition, less than body requirements, related to disease process or treatment
- Situational low self-esteem related to diagnosis or prognosis
- Impaired verbal communication secondary to surgical resection
- Impaired physical mobility secondary to nerve injury

#### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Potential postoperative complications that may develop include the following:

- Hemorrhage
- Chyle fistula
- Nerve injury

### Planning and Goals

The major goals for the patient include participation in the treatment plan, maintenance of respiratory status, absence of infection, viability of the graft, maintenance of adequate intake of food and fluids, effective coping strategies, attainment of comfort, effective communication, and absence of complications.

### Nursing Interventions

#### PROVIDING PREOPERATIVE PATIENT EDUCATION

Before surgery, the patient should be informed about the nature and extent of the surgery, and what the postoperative period will be like. The patient is encouraged to ask questions and to express concerns about the upcoming surgery and the expected results. During this exchange, the nurse has an opportunity to assess the patient's coping abilities, answer questions, and develop a plan for offering assistance. A sense of mutual understanding and rapport will make the postoperative experience less traumatic for the patient. The patient's expressions of concern, anxieties, and fears can guide the nurse in providing support postoperatively.

#### PROVIDING GENERAL POSTOPERATIVE CARE

The general postoperative nursing interventions are similar to those presented in Chapter 20. For the patient who has had extensive neck surgery, specific postoperative interventions include maintenance of a patent airway and continuous assessment of respiratory status, wound care and oral hygiene, maintenance of adequate nutrition, and observation for hemorrhage or nerve injury.

#### MAINTAINING THE AIRWAY

After the endotracheal tube or airway has been removed and the effects of the anesthesia have worn off, the patient may be placed in Fowler's position to facilitate breathing and promote comfort. This position also increases lymphatic and venous drainage, facilitates swallowing, and decreases venous pressure on the skin flaps.

In the immediate postoperative period, the nurse assesses for stridor (coarse, high-pitched sound on inspiration) by listening frequently over the trachea with a stethoscope. This finding must be reported immediately because it indicates obstruction of the airway. Signs of respiratory distress, such as dyspnea, cyanosis, changes in mental status, and changes in vital signs, are assessed because they may suggest edema, hemorrhage, inadequate oxygenation, or inadequate drainage.

Pneumonia may occur in the postoperative phase if pulmonary secretions are not removed. Coughing and deep breathing are encouraged to aid in the removal of secretions. The patient should assume a sitting position, with the nurse supporting the neck so that the patient can bring up excessive secretions. If this is ineffective, the patient's respiratory tract may have to be suctioned. Care is taken to protect the suture lines during suctioning. If a tracheostomy tube is in place, suctioning is performed through the tube. The patient may also be instructed on use of Yankauer suction (tonsil tip suction) to remove oral secretions. Temperature should not be taken orally.

### RELIEVING PAIN

Pain and the patient's fear of pain are assessed and managed. Patients with head and neck cancer often report less pain than patients with other types of cancer; however, the nurse needs to be aware that each person's pain experience is individual. The nurse administers analgesics as prescribed and assesses their effectiveness.

### PROVIDING WOUND CARE

Wound drainage tubes are usually inserted during surgery to prevent the collection of fluid subcutaneously. The drainage tubes are connected to portable suction device (eg, Jackson-Pratt), and the container is emptied periodically. Between 80 and 120 mL of serosanguineous secretions may drain over the first 24 hours. Excessive drainage may be indicative of a chyle fistula or hemorrhage (see later discussion). If dressings are present, they may need to be reinforced from time to time. Dressings are observed for evidence of hemorrhage and constriction, which impairs respiration and perfusion of the graft. The graft is assessed for color and temperature, and for the presence of a pulse if applicable, to determine viability. The graft should be pale pink and warm to the touch. The surgical incisions are also assessed for infection, which is reported immediately. Prophylactic antibiotics may be prescribed.

### MAINTAINING ADEQUATE NUTRITION

Nutritional status is assessed preoperatively; early intervention to correct nutritional imbalances may decrease the risk of postoperative complications. Frequently, nutrition is less than optimal because of inadequate intake, and the patient often requires enteral or parenteral supplements preoperatively to attain a positive nitrogen balance. This therapy may need to be continued postoperatively if the patient cannot take enough nutrients by mouth. Supplements (eg, Ensure, Sustacal) that are nutritionally dense may help reestablish a positive nitrogen balance. They may be taken enterally by mouth, by nasogastric feeding tube, or by gastrostomy feeding tube. (See the Plan of Nursing Care for further discussion.)

The patient who is able to chew may take food by mouth; the level of the patient's chewing ability will determine whether some diet modification (eg, soft, pureed, or liquid foods) is necessary. Food preferences should also be discussed with the patient. Oral care before eating may enhance the patient's appetite, and oral care after eating is important to prevent infection and dental caries. Most patients are able to maintain and gain weight.

### SUPPORTING COPING MEASURES

Preoperatively, information about the planned surgery is given to the patient and family. The psychological postoperative nursing intervention is aimed at supporting the patient who has had a change in body image or who has major concerns regarding the prognosis. The patient may have difficulty communicating and may be concerned about his or her ability to breathe and swallow normally. The nurse enlists the support of family or friends in encouraging and reassuring the patient that adjusting to the results of this surgery will take time.

The person who has had extensive neck surgery often is sensitive about his or her appearance. This can occur when the operative area is covered by bulky dressings, when the incision line is visible, or later after healing has occurred but the appearance of the neck and possibly the lower face has been significantly altered. If the nurse accepts the patient's appearance and expresses a positive, optimistic attitude, the patient is more likely to be encouraged. The patient also needs an opportunity to express concerns regarding the success of the surgery and the prognosis. The American Cancer Society may be a resource to provide a volunteer to meet with the patient either preoperatively or postoperatively.

People with cancer of the head and neck frequently have used alcohol or tobacco before surgery; postoperatively, the patient is encouraged to abstain from these substances. Alternative methods of coping need to be explored. A referral to Alcoholics Anonymous may be appropriate.

### PROMOTING EFFECTIVE COMMUNICATION

If a laryngectomy was performed, the nurse explores other methods of communicating with the patient and obtains a consultation with a speech/language therapist. Alternatives to verbal communication may include use of a pencil and paper or pointing to needed items on a picture pad. Alternative speech techniques, such as an electrolarynx (a mechanical device held against the neck) or esophageal speech, may be taught by a speech/language therapist.

### MAINTAINING PHYSICAL MOBILITY

Excision of muscles and nerves results in weakness at the shoulder that can cause shoulder drop, a forward curvature of the shoulder. Many problems can be avoided with a conscientious exercise program. These exercises are usually begun after the drains have been removed and the neck incision is sufficiently healed. The purpose of the exercises depicted in Figure 35-5 is to promote maximal shoulder function and neck motion after surgery. Physical therapists and occupational therapists can assist patients in performing these exercises.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

#### Hemorrhage

Hemorrhage may occur from carotid artery rupture as a result of necrosis of the graft or damage to the artery itself from tumor or infection. The following measures are indicated:

- Vital signs are assessed. Tachycardia, tachypnea, and hypotension may indicate hemorrhage and impending hypovolemic shock.
- The patient is instructed to avoid the Valsalva maneuver to prevent stress on the graft and carotid artery.
- Signs of impending rupture, such as high epigastric pain or discomfort, are reported.

**FIGURE 35-5** Three rehabilitation exercises after head and neck surgery. The objective is to regain maximum shoulder function and neck motion after neck surgery. From *Exercise for Radical Neck Surgery Patients*. Head and Neck Service, Department of Surgery, Memorial Hospital, New York, NY.

- Dressings and wound drainage are observed for excessive bleeding.
- If hemorrhage occurs, assistance is summoned immediately.
- Hemorrhage requires the continuous application of pressure to the bleeding site or major associated vessel.
- Although some advocate placing the patient in modified Trendelenburg position to maintain blood pressure, others recommend that the head of the patient's bed be elevated to maintain airway patency and prevent aspiration.
- A controlled, calm manner will allay the patient's anxiety.
- The surgeon is notified immediately, because a vascular or ligature tear requires surgical intervention.

### Chyle Fistula

A chyle fistula (milk-like drainage from the thoracic duct into the thoracic cavity) may develop as a result of damage to the thoracic duct during surgery. The diagnosis is made if there is excess drainage which has a 3% fat content and a specific gravity of 1.012 or greater. Treatment of a small leak (500 mL or less) includes application of a pressure dressing and a diet of medium-chain fatty acids or parenteral nutrition. Surgical intervention to repair the damaged duct is necessary for larger leaks.

### Nerve Injury

Nerve injury can occur if the cervical plexus or spinal accessory nerves are severed during surgery. Because lower facial paralysis may occur as a result of injury to the facial nerve, this complication is observed for and reported. Likewise, if the superior laryngeal nerve is damaged, the patient may have difficulty swallowing liquids and food because of the partial lack of sensation of the glottis. Speech therapy may be indicated to assist with the problems related to nerve injury.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

The patient and care provider will require instructions about management of the wound, the dressing, and any drains that remain in place. Patients who require oral suctioning or who have a tracheostomy may be very anxious about their care at home; the transition to home can be eased if the care provider is given several opportunities to demonstrate the ability to meet the patient's needs (Chart 35-3).

If the patient cannot take food by mouth, detailed instructions and demonstration of enteral or parenteral feedings will be required. Education in techniques of effective oral hygiene is also important.

Chart 35-3

## Home Care Checklist • Recovering From Neck Surgery

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Demonstrate use of suction equipment.	✓	✓
• State rationale for humidification.	✓	✓
• State dietary modifications needed to meet caloric needs.	✓	✓
• Demonstrate enteral or parenteral feeding techniques.	✓	✓
• Demonstrate care of incision and drains.	✓	✓
• State when next checkup is needed.	✓	✓
• Demonstrate exercises.	✓	✓
• Identify available support groups.	✓	✓

### Continuing Care

A referral for home care nursing may be necessary in the early period after discharge. The nurse will assess healing, ensure that feedings are being administered properly, and detect any complications. The home care nurse assesses the patient's adjustment to changes in physical appearance and status, ability to communicate, and ability to eat normally. Physical and speech therapy also may be continued at home.

The patient is given information regarding local support groups such as "I Can Cope" or "New Voice Club," if indicated. The local chapter of the American Cancer Society may be contacted for information and equipment needed for the patient.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Discusses expected course of treatment
2. Demonstrates good respiratory exchange
  - a. Lungs are clear to auscultation
  - b. Breathes easily with no shortness of breath
  - c. Demonstrates ability to use suction effectively
3. Remains free of infection
  - a. Maintains normal laboratory values
  - b. Is afebrile
4. Graft is pink and warm to touch
5. Maintains adequate intake of foods and fluids
  - a. Accepts altered route of feeding
  - b. Is well hydrated
  - c. Maintains or gains weight
6. Demonstrates ability to cope
  - a. Discusses emotional responses to the diagnosis
  - b. Attends support group meetings
7. Verbalizes comfort
8. Attains maximal mobility
  - a. Adheres to physical therapy exercises
  - b. Attains maximal range of motion

The Plan of Nursing Care presents an overview of the care of a patient undergoing a neck dissection.

## Disorders of the Esophagus

The esophagus is a mucus-lined, muscular tube that carries food from the mouth to the stomach. It begins at the base of the pharynx and ends about 4 cm below the diaphragm. Its ability to transport food and fluid is facilitated by two sphincters. The upper esophageal sphincter, also called the hypopharyngeal sphincter, is located at the

junction of the pharynx and the esophagus. The lower esophageal sphincter, also called the gastroesophageal sphincter, is located at the junction of the esophagus and the stomach. An incompetent lower esophageal sphincter allows reflux (backward flow) of gastric contents. There is no serosal layer of the esophagus; therefore, if surgery is necessary, it is more difficult to perform suturing or anastomosis.

### DYSPHAGIA

**Dysphagia** (difficulty swallowing) is the most common symptom of esophageal disease. This symptom may vary from an uncomfortable feeling that a bolus of food is caught in the upper esophagus (before it eventually passes into the stomach) to acute pain on swallowing (**odynophagia**). Obstruction of food (solid and soft) and even liquids may occur anywhere along the esophagus. Often the patient can indicate that the problem is located in the upper, middle, or lower third of the esophagus.

There are many pathologic conditions of the esophagus, including motility disorders (achalasia, diffuse spasm), gastroesophageal reflux, hiatal hernias, diverticula, perforation, foreign bodies, chemical burns, benign tumors, and carcinoma.

### ACHALASIA

**Achalasia** is absent or ineffective peristalsis of the distal esophagus, accompanied by failure of the esophageal sphincter to relax in response to swallowing. Narrowing of the esophagus just above the stomach results in a gradually increasing dilation of the esophagus in the upper chest. Achalasia may progress slowly and occurs most often in people 40 years of age or older.

### Clinical Manifestations

The primary symptom of achalasia is difficulty in swallowing both liquids and solids. The patient has a sensation of food sticking in the lower portion of the esophagus. As the condition progresses, food is commonly regurgitated, either spontaneously or intentionally by the patient to relieve the discomfort produced by prolonged distention of the esophagus by food that will not pass into the stomach. The patient may also complain of chest pain and heartburn (**pyrosis**). Pain may or may not be associated with eating. There may be secondary pulmonary complications from aspiration of gastric contents.

### Assessment and Diagnostic Findings

X-ray studies show esophageal dilation above the narrowing at the gastroesophageal junction. Barium swallow, computed tomography  
(text continues on page 975)

## Plan of Nursing Care

### The Patient Who Has Undergone Neck Dissection

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Ineffective airway clearance related to obstruction secondary to edema, hemorrhage, or inadequate wound drainage

**Goal:** Maintenance of normal respiratory function

- |   |   |   |
|---|---|---|
| <ol style="list-style-type: none"> <li>1. Place the patient in Fowler's position.</li> <li>2. Monitor vital signs according to postoperative routine.</li> <li>3. Auscultate breath sounds as needed. In the immediate postoperative period, place the stethoscope over the trachea to assess for stridor.</li> <li>4. Encourage deep breathing and coughing. Place the patient in a sitting position and support the neck area with both hands.</li> <li>5. Suction the airway as needed using sterile technique and a soft catheter.</li> <li>6. Provide humidified air or oxygen if the patient has a tracheostomy.</li> </ol> | <ol style="list-style-type: none"> <li>1. Fowler's position facilitates expansion of the lungs because the diaphragm is pulled downward and the abdominal viscera are pulled away from the lungs. Breathing is promoted. This position also increases lymphatic and venous drainage, decreases swallowing, and decreases venous pressure on the graft. Regurgitation and aspiration of stomach contents are prevented postoperatively.</li> <li>2. Edema, hemorrhage, or inadequate drainage will alter heart rate and respirations. Tachypnea and restlessness may indicate respiratory distress.</li> <li>3. Abnormal breath sounds may indicate ineffective ventilation, decreased perfusion, and fluid accumulation. Stridor, a harsh, high-pitched sound primarily heard on inspiration, indicates airway obstruction.</li> <li>4. Deep breathing before coughing promotes expansion of the airways and a more forceful cough. The coughing mechanism assists airway cilia with removal of secretions. Splinting the incision during coughing reduces strain and promotes the expulsion of secretions by allowing deeper inspirations.</li> <li>5. Suctioning assists in removal of secretions that the patient may be unable to cough up, thereby assisting with maintaining a patent airway.</li> <li>6. Keeps secretions thin.</li> </ol> | <ul style="list-style-type: none"> <li>• Achieves a normal respiratory rate</li> <li>• Breathes comfortably</li> <li>• Avoids use of accessory muscles of respiration</li> <li>• Maintains vital signs within normal range</li> <li>• Shows evidence of normal breath sounds</li> <li>• Coughs effectively</li> <li>• Maintains a patent airway</li> <li>• Does not develop a mucus plug</li> </ul> |
|---|---|---|

**Nursing Diagnosis:** Risk for infection

**Goal:** Absence of infection

- |  |  |   |
|--|--|---|
| <ol style="list-style-type: none"> <li>1. Instruct the patient in preoperative and postoperative oral hygiene using slightly alkaline solutions such as 8 oz of water mixed with 1 teaspoon of baking soda, or normal saline solution, every 4 hours.</li> <li>2. Monitor wound suction drainage.</li> </ol> | <ol style="list-style-type: none"> <li>1. Oral care decreases oral bacteria, thereby decreasing the risk of bacterial infection postoperatively. Hydrogen peroxide should not be used, because it may break down fresh granulation tissue.</li> <li>2. Suction drainage negates the need for pressure dressings because the skin flaps are pulled down tightly. Drainage should be 80–120 mL of serosanguineous secretions for the first 24 hours; then the secretions should decrease daily. Continuous bloody drainage indicates small vessel oozing.</li> </ol> | <ul style="list-style-type: none"> <li>• Patient performs oral hygiene preoperatively and postoperatively every 4 hours</li> <li>• Mouth remains clean</li> <li>• Wound drains less than 200 mL of serosanguineous drainage on the first postoperative day</li> <li>• No hematoma at skin graft</li> <li>• Serosanguineous drainage is within normal limits</li> <li>• Dressing remains intact with no constriction of airway or blood flow</li> <li>• Wound and surrounding skin remain clean and free of infection</li> <li>• Patient is afebrile with normal respirations and a normal heart rate</li> <li>• Patient is alert and aware of surroundings</li> </ul> |
|--|--|---|

(continued)

## Plan of Nursing Care

### The Patient Who Has Undergone Neck Dissection (Continued)

Nursing Interventions	Rationale	Expected Outcomes
-----------------------	-----------	-------------------

- |   |   |  |
|---|---|--|
| 3. Note drainage quantity and odor.   | 3. Purulent, malodorous drainage indicates an infection. Drainage greater than 300 mL in the first 24 hours is considered abnormal.   |  |
| 4. Assess condition of dressing and reinforce pressure dressings as needed. Assess for any possible constrictions that would affect respirations or decrease blood flow to graft. | 4. If portable wound suction is not used, pressure dressings may be applied to obliterate dead spaces and provide immobilization. These dressings are reinforced, not changed, as needed. |  |
| 5. Use aseptic technique to cleanse skin around the drains; change the dressings as ordered by surgeon (usually the second through fifth postoperative days).                     | 5. Aseptic technique prevents wound contamination. Sterile saline effectively cleans the skin around the drains.  |  |
| 6. Monitor vital signs. Assess for symptoms of infection: chills, diaphoresis, altered level of consciousness.  | 6. An elevated temperature, tachypnea, and tachycardia may indicate an infection.   |  |

#### Nursing Diagnosis: Impaired skin integrity

##### Goal: Maintenance of intact skin and viability of graft

- |  |  |   |
|--|--|---|
| 1. Assess condition of graft for viability.          | 1. Cyanotic, cool graft indicates possible necrosis. (Pale graft indicates arterial thrombosis; purple graft indicates venous congestion.) | <ul style="list-style-type: none"> <li>• Graft is pale pink in color and warm to touch</li> <li>• Tissue blanches to gentle touch</li> <li>• Graft has pulse via Doppler ultrasound</li> <li>• Patient does not have wound infection</li> </ul> |
| 2. Assess wound for signs and symptoms of infection. | 2. Infected wound interferes with healing and threatens the viability of the graft.  |   |

#### Nursing Diagnosis: Imbalanced nutrition, less than body requirements, related to anorexia and dysphagia

##### Goal: Attainment/maintenance of adequate nutrition

- |   |   |  |
|---|---|--|
| 1. Assess nutritional status preoperatively, consult with dietitian.  | 1. Poor nutritional status preoperatively impairs wound healing and increases potential for infection.  | <ul style="list-style-type: none"> <li>• Does not have weight loss greater than 10% of body weight. (If weight loss is greater than 10%, supplements are given to maintain/increase weight and obtain positive nitrogen balance.)</li> <li>• Tolerates tube feedings</li> <li>• No signs of aspiration</li> <li>• No sign of fistula</li> <li>• Expresses a desire for food</li> <li>• Swallows food easily</li> <li>• Is comfortable eating alone or with others</li> </ul> |
| 2. Administer tube feedings as prescribed. Keep head of bed elevated during feeding to prevent aspiration. Monitor for signs of tracheoesophageal fistula (feeding in tracheal secretions).   | 2. A nasogastric tube may be in place for several days to administer enteral feedings.  |  |
| 3. Provide oral hygiene before and after meals.   | 3. Oral hygiene enhances appetite.  |  |
| 4. Assist with oral intake: <ol style="list-style-type: none"> <li>Offer easily chewed foods; mash or blenderize if necessary.</li> <li>Suggest that the head be tilted to the unaffected side when swallowing.</li> <li>Inquire whether privacy is desired when eating.</li> <li>Provide altered eating utensils as needed.</li> </ol> | 4. Soft-textured foods facilitate swallowing. Passage of food may be tolerated better when the head is tilted to the unaffected side. Self-feeding difficulties may cause embarrassment and interfere with intake quantity. |  |

(continued)

## Plan of Nursing Care

### The Patient Who Has Undergone Neck Dissection (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Situational low self-esteem and body image related to changes in appearance and alterations in communication

**Goal:** Attainment of positive self-image

1. Assist the patient to communicate effectively: <ol style="list-style-type: none"> <li>Provide materials for writing messages.</li> <li>Make certain that the call bell is readily accessible.</li> <li>Develop nonverbal ways to communicate (eg, finger-tapping, sign language, sign board).</li> <li>Consult speech/language therapist.</li> </ol>	1. Temporary hoarseness is common after neck surgery. A tracheostomy may be performed, and verbal communication may not be possible. Communication with head movement may be impossible because of incisional pain and need to maintain position of neck for graft. A speech/language therapist may assist with other forms of communication, such as esophageal speech or electrolarynx.	<ul style="list-style-type: none"> <li>Recognizes that hoarseness is temporary</li> <li>Develops alternative forms of communication</li> <li>Willingly conveys fears and concerns</li> <li>Accepts prognosis with realistic limitations</li> <li>Accepts support as offered</li> <li>Absence of facial paralysis</li> <li>Absence of drooling and dysphagia</li> <li>Maintains normal shoulder function</li> <li>Verbalizes methods to enhance physical appearance</li> </ul>
2. Encourage verbalization of fears: <ol style="list-style-type: none"> <li>Provide time to listen.</li> <li>Project a positive, optimistic attitude.</li> <li>Reinforce reality.</li> <li>Collaborate with family members to elicit their support and encouragement.</li> <li>Consult support groups such as New Voice Club through the American Cancer Society.</li> </ol>	2. Listening conveys acceptance and encourages further verbalization. An optimistic approach conveys interest and hope. Honesty will promote a trusting relationship. This includes confirming cosmetic and functional limitations. Family members or significant others can provide valuable support to the patient.	
3. Observe for facial paralysis.	3. Injury to facial nerve will cause lower facial paralysis.	
4. Observe for excessive drooling.	4. Damage to the hypoglossal nerve will result in excessive drooling and decreased ability to swallow.	
5. Check for normal shoulder position and function.	5. Damage to the spinal accessory nerve will result in drooping of the shoulder. Rehabilitation exercises are begun after the incision is healed.	
6. Provide information on clothing/cosmetics to deemphasize physical defects (offer information on “Look Good, Feel Better” program through American Cancer Society).	6. Physical appearance may be enhanced through use of cosmetics or clothing.	

(CT) of the esophagus, and endoscopy may be used for diagnosis; however, the diagnosis is confirmed by manometry, a process in which the esophageal pressure is measured by a radiologist or gastroenterologist.

## Management

The patient should be instructed to eat slowly and to drink fluids with meals. As a temporary measure, calcium channel blockers and nitrates have been used to decrease esophageal pressure and improve swallowing. Injection of botulinum toxin (Botox) to quadrants of the esophagus via endoscopy has been helpful because it inhibits the contraction of smooth muscle. Periodic injections are required to maintain remission. If these methods are unsuccessful, pneumatic (forceful) dilation or surgical separation of the muscle fibers may be recommended (Streeter, 1999; Anness et al., 2000).

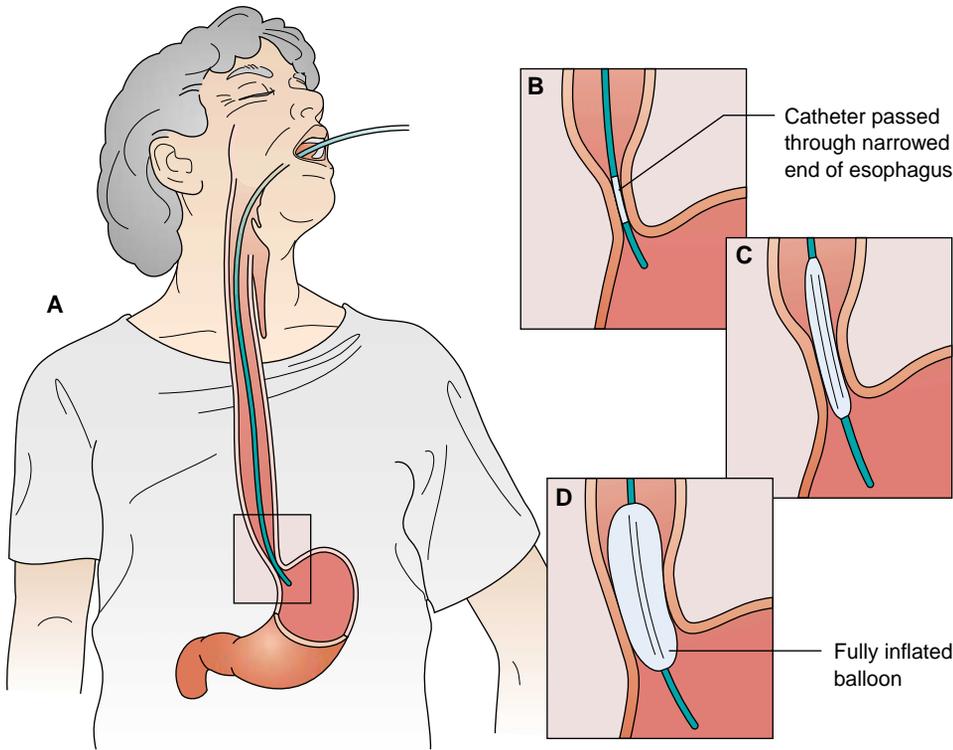

Achalasia may be treated conservatively by pneumatic dilation to stretch the narrowed area of the esophagus (Fig. 35-6). Pneumatic dilation has a high success rate. Although perforation is a

potential complication, its incidence is low. The procedure can be painful; therefore, moderate sedation in the form of an analgesic or tranquilizer, or both, is administered for the treatment. The patient is monitored for perforation. Complaints of abdominal tenderness and fever may be indications of perforation (see later discussion).

Achalasia may be treated surgically by esophagomyotomy (Fig. 35-7). The procedure usually is performed laparoscopically, either with a complete lower esophageal sphincter myotomy and an antireflux procedure (see later discussion of fundoplasty), or without an antireflux procedure. The esophageal muscle fibers are separated to relieve the lower esophageal stricture. Although patients with a history of achalasia have a slightly higher incidence of esophageal cancer, long-term follow-up with esophagoscopy for early detection has not proved beneficial.

## DIFFUSE SPASM

Diffuse spasm is a motor disorder of the esophagus. The cause is unknown, but stressful situations can produce contractions of the

**FIGURE 35-6** Treatment of achalasia by the conservative approach. (A–C) The dilator is passed, guided by a previously inserted guidewire. (D) When the balloon is in proper position, it is distended by pressure sufficient to dilate the narrowed area of the esophagus.

esophagus. It is more common in women and usually manifests in middle age.

### Clinical Manifestations

Diffuse spasm is characterized by difficulty or pain on swallowing (dysphagia, odynophagia) and by chest pain similar to that of coronary artery spasm.

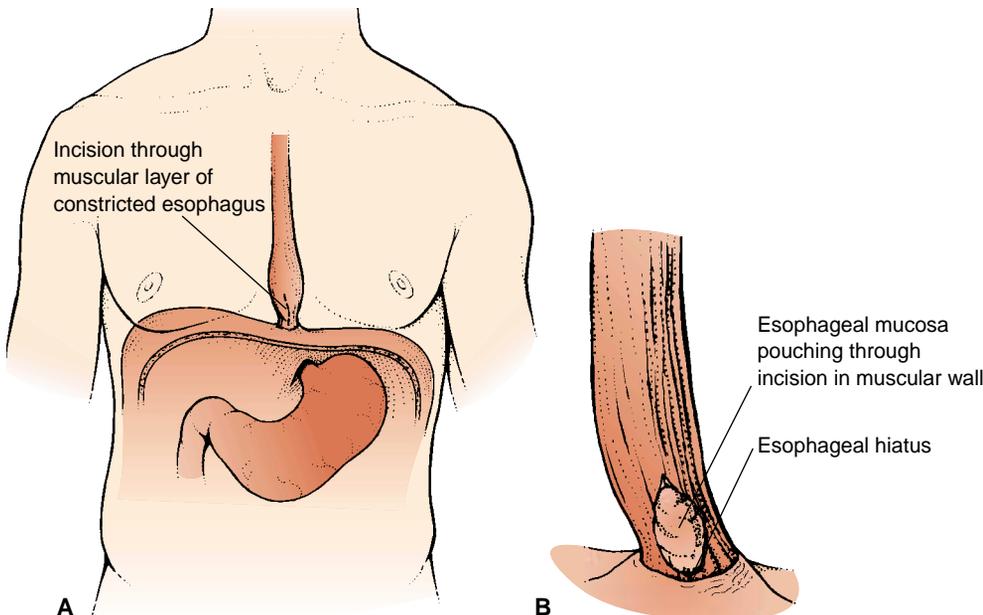

### Assessment and Diagnostic Findings

Esophageal manometry, which measures the motility of the esophagus and the pressure within the esophagus, indicates that

simultaneous contractions of the esophagus occur irregularly. Diagnostic x-ray studies after ingestion of barium show separate areas of spasm.

### Management

Conservative therapy includes administration of sedatives and long-acting nitrates to relieve pain. Calcium channel blockers have also been used to manage diffuse spasm. Small, frequent feedings and a soft diet are usually recommended to decrease the esophageal pressure and irritation that lead to spasm. Dilation performed by bougienage (use of progressively sized flexible dilators), pneumatic dilation, or esophagomyotomy may be necessary if the pain becomes intolerable.

**FIGURE 35-7** Treatment of achalasia: esophagomyotomy. (A) The esophagus is approached via thoracotomy from the front, on the left side. An incision is made through the muscularis of the esophagus extending about 1 cm into the gastric area. (B) The incision is large enough to allow a pouching of the esophageal mucosa. Separation of the muscular fibers relieves the narrowing at the lower end of the esophagus and permits the patient to swallow normally again.

## HIATAL HERNIA

The esophagus enters the abdomen through an opening in the diaphragm and empties at its lower end into the upper part of the stomach. Normally, the opening in the diaphragm encircles the esophagus tightly, and the stomach lies completely within the abdomen. In a condition known as hiatus (or hiatal) **hernia**, the opening in the diaphragm through which the esophagus passes becomes enlarged, and part of the upper stomach tends to move up into the lower portion of the thorax. Hiatal hernia occurs more often in women than men. There are two types of hiatal hernias: sliding and paraesophageal. Sliding, or type I, hiatal hernia occurs when the upper stomach and the gastroesophageal junction (GEJ) are displaced upward and slide in and out of the thorax (Fig. 35-8A). About 90% of patients with esophageal hiatal hernia have a sliding hernia. A paraesophageal hernia occurs when all or part of the stomach pushes through the diaphragm beside the esophagus (see Fig. 35-8B). Paraesophageal hernias may be further classified as types II, III, or IV, depending on the extent of herniation, with type IV having the greatest herniation.

### Clinical Manifestations

The patient with a sliding hernia may have heartburn, regurgitation, and dysphagia, but at least 50% of patients are asymptomatic. Sliding hiatal hernia is often implicated in reflux. The patient with a paraesophageal hernia usually feels a sense of fullness after eating or may be asymptomatic. Reflux usually does not occur, because the gastroesophageal sphincter is intact. The complications of hemorrhage, obstruction, and strangulation can occur with any type of hernia.

### Assessment and Diagnostic Findings

Diagnosis is confirmed by x-ray studies, barium swallow, and fluoroscopy.

### Management

Management for an axial hernia includes frequent, small feedings that can pass easily through the esophagus. The patient is advised

not to recline for 1 hour after eating, to prevent reflux or movement of the hernia, and to elevate the head of the bed on 4- to 8-inch (10- to 20-cm) blocks to prevent the hernia from sliding upward. Surgery is indicated in about 15% of patients. Medical and surgical management of a paraesophageal hernia is similar to that for gastroesophageal reflux; however, paraesophageal hernias may require emergency surgery to correct torsion (twisting) of the stomach or other body organ that leads to restriction of blood flow to that area.

## DIVERTICULUM

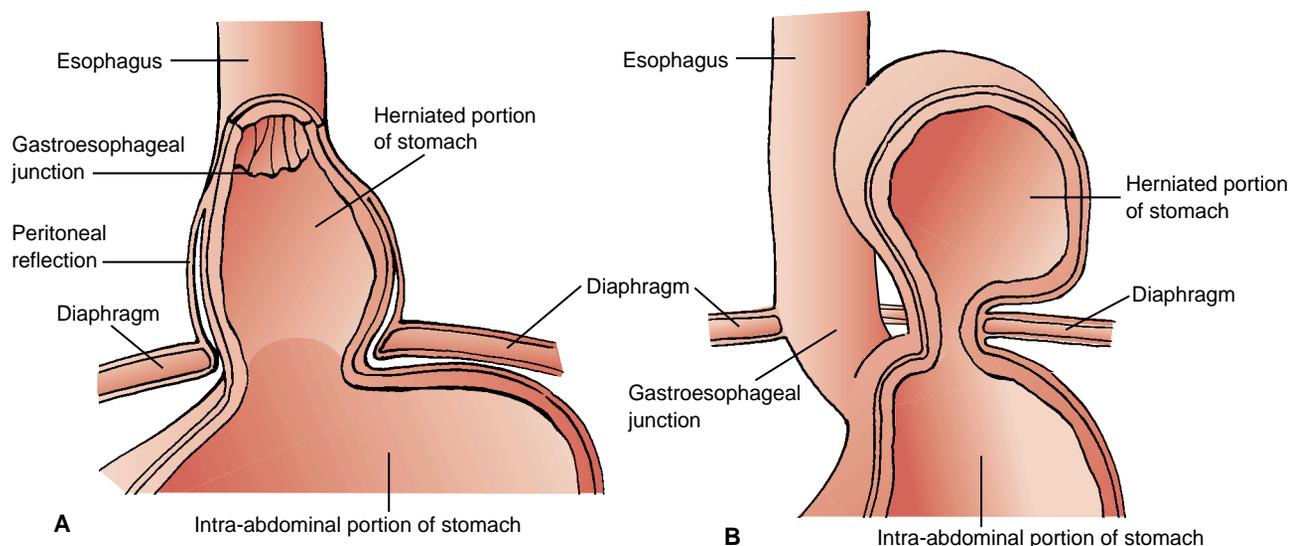

A diverticulum is an outpouching of mucosa and submucosa that protrudes through a weak portion of the musculature. Diverticula may occur in one of the three areas of the esophagus—the pharyngoesophageal or upper area of the esophagus, the midesophageal area, or the epiphrenic or lower area of the esophagus—or they may occur along the border of the esophagus intramurally.

The most common type of diverticulum, which is found three times more frequently in men than in women, is Zenker's diverticulum (also known as pharyngoesophageal pulsion diverticulum or a pharyngeal pouch). It occurs posteriorly through the cricopharyngeal muscle in the midline of the neck. It is usually seen in people older than 60 years of age. Other types of diverticula include midesophageal, epiphrenic, and intramural diverticula.

Midesophageal diverticula are uncommon. Symptoms are less acute, and usually the condition does not require surgery. Epiphrenic diverticula are usually larger diverticula in the lower esophagus just above the diaphragm. They are thought to be related to the improper functioning of the lower esophageal sphincter or to motor disorders of the esophagus. Intramural diverticulosis is the occurrence of numerous small diverticula associated with a stricture in the upper esophagus.

### Clinical Manifestations

Symptoms experienced by the patient with a pharyngoesophageal pulsion diverticulum include difficulty swallowing, fullness in the neck, belching, regurgitation of undigested food, and gurgling

**FIGURE 35-8** Sliding esophageal and paraesophageal hernias. (A) Sliding esophageal hernia. The upper stomach and cardioesophageal junction have moved upward and slide in and out of the thorax. (B) Paraesophageal hernia. All or part of the stomach pushes through the diaphragm next to the gastroesophageal junction.

noises after eating. The diverticulum, or pouch, becomes filled with food or liquid. When the patient assumes a recumbent position, undigested food is regurgitated, and coughing may be caused by irritation of the trachea. Halitosis and a sour taste in the mouth are also common because of the decomposition of food retained in the diverticulum.

Symptoms produced by midesophageal diverticula are less acute. One third of patients with epiphrenic diverticula are asymptomatic, and the remaining two thirds complain of dysphagia and chest pain. Dysphagia is the most common complaint of patients with intramural diverticulosis.

### Assessment and Diagnostic Findings

A barium swallow may be performed to determine the exact nature and location of a diverticulum. Manometric studies are often performed for patients with epiphrenic diverticula to rule out a motor disorder. Esophagoscopy usually is contraindicated because of the danger of perforation of the diverticulum, with resulting mediastinitis (inflammation of the organs and tissues that separate the lungs). Blind insertion of a nasogastric tube should be avoided.

### Management

Because pharyngoesophageal pulsion diverticulum is progressive, the only means of cure is surgical removal of the diverticulum. During surgery, care is taken to avoid trauma to the common carotid artery and internal jugular veins. The sac is dissected free and amputated flush with the esophageal wall. In addition to a diverticulectomy, a myotomy of the cricopharyngeal muscle is often performed to relieve spasticity of the musculature, which otherwise seems to contribute to a continuation of the previous symptoms. Postoperatively, the patient may have a nasogastric tube inserted at the time of surgery. The surgical incision must be observed for evidence of leakage from the esophagus and a developing fistula. Food and fluids are withheld until x-ray studies show no leakage at the surgical site. The diet begins with liquids and progresses as tolerated.

Surgery is indicated for epiphrenic and midesophageal diverticula only if the symptoms are troublesome and becoming worse. Treatment consists of a diverticulectomy and long myotomy. Intramural diverticula usually regress after the esophageal stricture is dilated.

### PERFORATION

The esophagus is not an uncommon site of injury. Perforation may result from stab or bullet wounds of the neck or chest, trauma from motor vehicle crash, caustic injury from a chemical burn (described later), or inadvertent puncture by a surgical instrument during examination or dilation.

### Clinical Manifestations

The patient has persistent pain followed by dysphagia. Infection, fever, leukocytosis, and severe hypotension may be noted. In some instances, signs of pneumothorax are observed.

### Assessment and Diagnostic Findings

Diagnostic x-ray studies and fluoroscopy are used to identify the site of the injury.

### Management

Because of the high risk of infection, broad-spectrum antibiotic therapy is initiated. A nasogastric tube is inserted to provide suction and to reduce the amount of gastric juice that can reflux into the esophagus and mediastinum. Nothing is given by mouth; nutritional needs are met by parenteral nutrition. Parenteral nutrition is preferred to gastrostomy because the latter might cause reflux into the esophagus.

Surgery may be necessary to close the wound, and postoperative nutritional support then becomes a primary concern. Depending on the incision site and the nature of surgery, the postoperative nursing management is similar to that for patients who have had thoracic or abdominal surgery.

### FOREIGN BODIES

Many swallowed foreign bodies pass through the gastrointestinal tract without the need for medical intervention. However, some swallowed foreign bodies (eg, dentures, fish bones, pins, small batteries, items containing mercury or lead) may injure the esophagus or obstruct its lumen and must be removed. Pain and dysphagia may be present, and dyspnea may occur as a result of pressure on the trachea. The foreign body may be identified by x-ray film. Perforation may have occurred (see earlier discussion).

Glucagon, because of its relaxing effect on the esophageal muscle, may be injected intramuscularly. An endoscope (with a covered hood or overtube) may be used to remove the impacting food or object from the esophagus. A mixture consisting of sodium bicarbonate and tartaric acid may be used to increase intraluminal pressure by the formation of a gas. Caution must be used with this treatment because there is risk of perforation.

### CHEMICAL BURNS

Chemical burns of the esophagus may be caused by undissolved medications in the esophagus. This occurs more frequently in the elderly than it does among the general adult population. A chemical burn may also occur after swallowing of a battery, which may release caustic alkaline. Chemical burns of the esophagus occur most often when a patient, either intentionally or unintentionally, swallows a strong acid or base (eg, lye). This patient is emotionally distraught as well as in acute physical pain. An acute chemical burn of the esophagus may be accompanied by severe burns of the lips, mouth, and pharynx, with pain on swallowing. There may be difficulty in breathing due to either edema of the throat or a collection of mucus in the pharynx.

The patient, who may be profoundly toxic, febrile, and in shock, is treated immediately for shock, pain, and respiratory distress. Esophagoscopy and barium swallow are performed as soon as possible to determine the extent and severity of damage. The patient is given nothing by mouth, and intravenous fluids are administered. A nasogastric tube may be inserted by the physician. Vomiting and gastric lavage are avoided to prevent further exposure of the esophagus to the caustic agent. The use of corticosteroids to reduce inflammation and minimize subsequent scarring and stricture formation is of questionable value. The value of the prophylactic use of antibiotics for these patients has also been questioned; however, these treatments continue to be prescribed (Schaffer & Herbert, 2000).

After the acute phase has subsided, the patient may need nutritional support via enteral or parenteral feedings. The patient may require further treatment to prevent or manage strictures of the esophagus. Dilation by bougienage may be sufficient, but dilation treatment may need to be repeated periodically. (In bougienage,

cylindrical rubber tubes of different sizes, called bougies, are advanced into the esophagus via the oral cavity. Progressively larger bougies are used to dilate the esophagus. The procedure usually is performed in the endoscopy suite or clinic by the gastroenterologist.) For strictures that do not respond to dilation, surgical management is necessary. Reconstruction may be accomplished by esophagectomy and colon interposition to replace the portion of esophagus removed.

## GASTROESOPHAGEAL REFLUX DISEASE

Some degree of **gastroesophageal reflux** (back-flow of gastric or duodenal contents into the esophagus) is normal in both adults and children. Excessive reflux may occur because of an incompetent lower esophageal sphincter, pyloric stenosis, or a motility disorder. The incidence of reflux seems to increase with aging.

### Clinical Manifestations

Symptoms of gastroesophageal reflux disease (GERD) may include pyrosis (burning sensation in the esophagus), dyspepsia (indigestion), regurgitation, dysphagia or odynophagia (difficulty swallowing, pain on swallowing), hypersalivation, and esophagitis. The symptoms may mimic those of a heart attack. The patient's history aids in obtaining an accurate diagnosis.

### Assessment and Diagnostic Findings

Diagnostic testing may include an endoscopy or barium swallow to evaluate damage to the esophageal mucosa. Ambulatory 12- to 36-hour esophageal pH monitoring is used to evaluate the degree of acid reflux. Bilirubin monitoring (Bilitec) is used to measure bile reflux patterns. Exposure to bile can cause mucosal damage (Aronson, 2000; Stein et al., 1999).

### Management

Management begins with teaching the patient to avoid situations that decrease lower esophageal sphincter pressure or cause esophageal irritation. The patient is instructed to eat a low-fat diet; to avoid caffeine, tobacco, beer, milk, foods containing peppermint or spearmint, and carbonated beverages; to avoid eating or drinking 2 hours before bedtime; to maintain normal body weight; to avoid tight-fitting clothes; to elevate the head of the bed on 6- to 8-inch (15- to 20-cm) blocks; and to elevate the upper body on pillows. If reflux persists, the patient may be given medications such as antacids or histamine receptor blockers. Proton pump inhibitors (medications that decrease the release of gastric acid, such as lansoprazole [Prevacid] or rabeprazole [Aciphex]) may be used; however, there is concern that these products may increase intragastric bacterial growth and the risk for infection. In addition, the patient may receive prokinetic agents, which accelerate gastric emptying. These agents include bethanechol (Urecholine), domperidone (Motilium), and metoclopramide (Reglan). Metoclopramide has central nervous system complications with long-term use. The use of pectin-based products is now being studied (Aronson, 2000).

If medical management is unsuccessful, surgical intervention may be necessary. Surgical management involves a fundoplication (wrapping of a portion of the gastric fundus around the sphincter area of the esophagus). Fundoplication may be performed by laparoscopy.

## BARRETT'S ESOPHAGUS

It is believed that long-standing untreated GERD may result in a condition known as Barrett's esophagus. This has been identi-

fied as a precancerous condition that, if left untreated, can result in adenocarcinoma of the esophagus, which has a poor prognosis. It is more common among middle-aged white men; however, the incidence is increasing among women and among African Americans.

### Clinical Manifestations

The patient complains of symptoms of GERD, notably frequent heartburn. The heartburn is a result of reflux, which eventually causes changes in the cells lining the lower esophagus. The patient may also complain of symptoms related to peptic ulcers or esophageal stricture, or both.

### Assessment and Diagnostic Findings

An esophagogastroduodenoscopy (EGD) is performed. This usually reveals an esophageal lining that is red rather than pink. Biopsies are taken, and the cells resemble those of the intestine.

### Management

Monitoring varies depending on the amount of cell changes. Some physicians may recommend a repeat EGD in 6 to 12 months if there are minor cell changes. Medical and surgical management is similar to that for GERD. Because this is a condition that is increasing in incidence, research is underway to determine the best monitoring and surgical interventions (Mueller et al., 2000; Stein et al., 1999).

## BENIGN TUMORS OF THE ESOPHAGUS

Benign tumors can arise anywhere along the esophagus. The most common lesion is a leiomyoma (tumor of the smooth muscle), which can occlude the lumen of the esophagus. Most benign tumors are asymptomatic and are distinguished from cancerous lesions by a biopsy. Small lesions are excised during esophagoscopy; lesions that occur within the wall of the esophagus may require treatment via a thoracotomy.

## CANCER OF THE ESOPHAGUS

In the United States, carcinoma of the esophagus occurs more than three times as often in men as in women. It is seen more frequently in African Americans than in Caucasians and usually occurs in the fifth decade of life. Cancer of the esophagus has a much higher incidence in other parts of the world, including China and northern Iran (Greenlee, 2001; Castell & Richter, 1999).

Chronic irritation is a risk factor for esophageal cancer. In the United States, cancer of the esophagus has been associated with ingestion of alcohol and with the use of tobacco. There seems to be an association between GERD and adenocarcinoma of the esophagus. People with Barrett's esophagus (which is caused by chronic irritation of mucous membranes due to reflux of gastric and duodenal contents) have a higher incidence of esophageal cancer (Stein, 1999).

### Pathophysiology

Esophageal cancer is usually of the squamous cell epidermoid type; however, the incidence of adenocarcinoma of the esophagus is increasing in the United States. Tumor cells may spread beneath the esophageal mucosa or directly into, through, and beyond the muscle layers into the lymphatics. In the latter stages,

obstruction of the esophagus is noted, with possible perforation into the mediastinum and erosion into the great vessels.

## Clinical Manifestations

Many patients have an advanced ulcerated lesion of the esophagus before symptoms are manifested. Symptoms include dysphagia, initially with solid foods and eventually with liquids; a sensation of a mass in the throat; painful swallowing; substernal pain or fullness; and, later, regurgitation of undigested food with foul breath and hiccups. The patient first becomes aware of intermittent and increasing difficulty in swallowing. As the tumor progresses and the obstruction becomes more complete, even liquids cannot pass into the stomach. Regurgitation of food and saliva occurs, hemorrhage may take place, and progressive loss of weight and strength occurs from starvation. Later symptoms include substernal pain, persistent hiccup, respiratory difficulty, and foul breath. The delay between the onset of early symptoms and the time when the patient seeks medical advice is often 12 to 18 months. Anyone with swallowing difficulties should be encouraged to consult a physician immediately.

## Assessment and Diagnostic Findings

Although new endoscopic techniques are being studied for screening and diagnosis of esophageal cancer, currently diagnosis is confirmed most often by EGD with biopsy and brushings. Bronchoscopy usually is performed, especially in tumors of the middle and the upper third of the esophagus, to determine whether the trachea has been affected and to help determine whether the lesion can be removed. Endoscopic ultrasound or mediastinoscopy is used to determine whether the cancer has spread to the nodes and other mediastinal structures. Cancer of the lower end of the esophagus may be caused by adenocarcinoma of the stomach that extends upward into the esophagus.

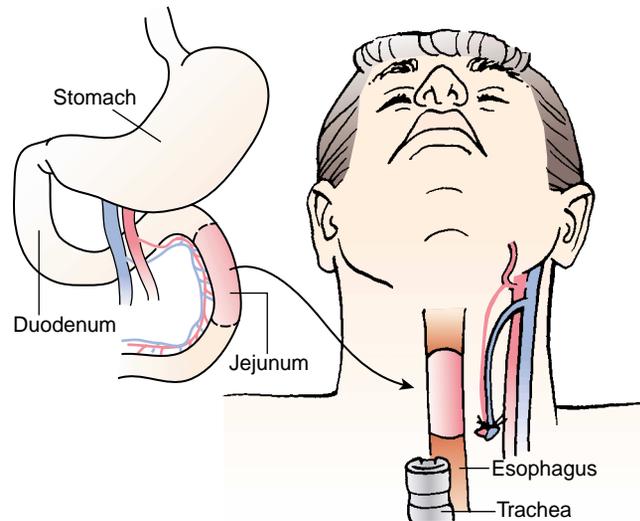

## Medical Management

If esophageal cancer is found at an early stage, treatment goals may be directed toward cure; however, it is often found in late stages, making relief of symptoms the only reasonable goal of therapy. Treatment may include surgery, radiation, chemotherapy, or a combination of these modalities, depending on the extent of the disease.

Standard surgical management includes a total resection of the esophagus (esophagectomy) with removal of the tumor plus a wide tumor-free margin of the esophagus and the lymph nodes in the area. The surgical approach may be through the thorax or the abdomen, depending on the location of the tumor. When tumors occur in the cervical or upper thoracic area, esophageal continuity may be maintained by free jejunal graft transfer, in which the tumor is removed and the area is replaced with a portion of the jejunum (Fig. 35-9). A segment of the colon may be used, or the stomach can be elevated into the chest and the proximal section of the esophagus anastomosed to the stomach.

Tumors of the lower thoracic esophagus are more amenable to surgery than are tumors located higher in the esophagus, and gastrointestinal tract integrity is maintained by anastomosing the lower esophagus to the stomach.

Surgical resection of the esophagus has a relatively high mortality rate because of infection, pulmonary complications, or leakage through the anastomosis. Postoperatively, the patient will have a nasogastric tube in place that should not be manipulated. The patient is given nothing by mouth until x-ray studies confirm that the anastomosis is secure and not leaking.

**FIGURE 35-9** Esophageal reconstruction with free jejunal transfer. A portion of the jejunum is grafted between the esophagus and pharynx to replace the abnormal portion of the esophagus. The vascular structures are also anastomosed. A portion of the graft may be externalized through the neck wound to evaluate graft viability.

Preoperative radiation therapy or chemotherapy, or both, may be used; however, treatment is based on type of cell, tumor spread, and patient condition.

Palliative treatment may be necessary to keep the esophagus open, to assist with nutrition, and to control saliva. Palliation may be accomplished with dilation of the esophagus, laser therapy, placement of an endoprosthesis (stent), radiation, or chemotherapy. Because the ideal method of treating esophageal cancer has not yet been found, treatment is individually determined.

## Nursing Management

Intervention is directed toward improving the patient's nutritional and physical condition in preparation for surgery, radiation therapy, or chemotherapy. A program to promote weight gain based on a high-calorie and high-protein diet, in liquid or soft form, is provided if adequate food can be taken by mouth. If this is not possible, parenteral or enteral nutrition is initiated. Nutritional status is monitored throughout treatment. The patient is informed about the nature of the postoperative equipment that will be used, including that required for closed chest drainage, nasogastric suction, parenteral fluid therapy, and gastric intubation. Immediate postoperative care is similar to that provided for patients undergoing thoracic surgery. After recovering from the effects of anesthesia, the patient is placed in a low Fowler's position, and later in a Fowler's position, to assist in preventing reflux of gastric secretions. The patient is observed carefully for regurgitation and dyspnea. A common postoperative complication is aspiration pneumonia. The patient's temperature is monitored to detect any elevation that may indicate aspiration or seepage of fluid through the operative site into the mediastinum.

If jejunal grafting has been performed, the nurse checks for graft viability hourly for at least the first 12 hours. To make the graft visible, the surgeon usually brings a portion of the jejunum to the exterior neck by way of a small incision. Moist gauze covers the external portion of the graft. The gauze is removed briefly to assess the graft for color and to assess for the presence of a pulse by means of Doppler ultrasonography.

If an endoprosthesis has been placed or an anastomosis has been performed, a functioning continuum will exist between the throat and the stomach. Immediately after surgery, the nasogastric tube should be marked for position, and the physician is notified if displacement occurs. The nurse does not attempt to reinsert a displaced nasogastric tube, because damage to the anastomosis may occur. The nasogastric tube is removed 5 to 7 days after surgery, and a barium swallow is performed to assess for any anastomotic leak before the patient is allowed to eat.

Once feeding begins, the nurse encourages the patient to swallow small sips of water and, later, small amounts of pureed food. When the patient is able to increase food intake to an adequate amount, parenteral fluids are discontinued. If an endoprosthesis is used, it may easily become obstructed if food is not chewed sufficiently. After each meal, the patient remains upright for at least 2 hours to allow the food to move through the gastrointestinal tract. It is a challenge to encourage the patient to eat, because appetite is usually poor. Family involvement and home-cooked favorite foods may help the patient to eat. Antacids may help those with gastric distress.

If radiation is part of the therapy, the patient's appetite is further depressed and esophagitis may occur, causing pain when food is eaten. Liquid supplements may be more easily tolerated.

Often, in either the preoperative or the postoperative period, an obstructed or nearly obstructed esophagus causes difficulty with excess saliva, so that drooling becomes a problem. Oral suction may be used if the patient is unable to handle oral secretions, or a wick-type gauze may be placed at the corner of the mouth to direct secretions to a dressing or emesis basin. The possibility that the patient may aspirate saliva into the tracheobronchial tree and develop pneumonia is of great concern.

When the patient is ready to go home, the family is instructed about how to promote nutrition, what observations to make, what measures to take if complications occur, how to keep the patient comfortable, and how to obtain needed physical and emotional support.

## NURSING PROCESS: THE PATIENT WITH A CONDITION OF THE ESOPHAGUS

### Assessment

Emergency conditions of the esophagus (perforation, chemical burns) usually occur in the home or away from medical help and require emergency medical care. The patient is treated for shock and respiratory distress and transported as quickly as possible to a medical facility. Foreign bodies in the esophagus do not pose an immediate threat to life unless pressure is exerted on the trachea, resulting in dyspnea or interfering with respiration, or unless there is leakage of caustic alkali from a battery. Educating the public to prevent inadvertent swallowing of foreign bodies or corrosive agents is a major health issue.

For nonemergency symptoms, a complete health history may reveal the nature of the esophageal disorder. The nurse asks about the patient's appetite. Has it remained the same, increased, or decreased? Is there any discomfort with swallowing? If so, does it occur only with certain foods? Is it associated with pain? Does a change in position affect the discomfort? The patient is asked to describe the pain. Does anything aggravate it? Are there any other symptoms that occur regularly, such as regurgitation, nocturnal regurgitation, eructation (belching), heartburn, substernal pressure, a sensation that food is sticking in the throat, a feeling of becoming full after eating a small amount of food, nausea, vom-

iting, or weight loss? Are the symptoms aggravated by emotional upset? If the patient reports any of these symptoms, the nurse asks about the time of their occurrence, their relationship to eating, and factors that relieve or aggravate them (eg, position change, belching, antacids, vomiting).

This history also includes questions about past or present causative factors, such as infections and chemical, mechanical, or physical irritants; the degree to which alcohol and tobacco are used; and the amount of daily food intake. The nurse determines whether the patient appears emaciated and auscultates the patient's chest to determine whether pulmonary complications exist.

### Nursing Diagnosis

Based on the assessment data, the nursing diagnoses may include the following:

- Imbalanced nutrition, less than body requirements, related to difficulty swallowing
- Risk for aspiration related to difficulty swallowing or to tube feeding
- Acute pain related to difficulty swallowing, ingestion of an abrasive agent, tumor, or frequent episodes of gastric reflux
- Deficient knowledge about the esophageal disorder, diagnostic studies, medical management, surgical intervention, and rehabilitation

### Planning and Goals

The major goals for the patient may include attainment of adequate nutritional intake, avoidance of respiratory compromise from aspiration, relief of pain, and increased knowledge level.

### Nursing Interventions

#### ENCOURAGING ADEQUATE NUTRITIONAL INTAKE

The patient is encouraged to eat slowly and to chew all food thoroughly so that it can pass easily into the stomach. Small, frequent feedings of nonirritating foods are recommended to promote digestion and to prevent tissue irritation. Sometimes liquid swallowed with food helps the food pass through the esophagus. Food should be prepared in an appealing manner to help stimulate the appetite. Irritants such as tobacco and alcohol should be avoided. A baseline weight is obtained, and daily weights are recorded. The patient's intake of nutrients is assessed.

#### DECREASING RISK OF ASPIRATION

The patient who has difficulty swallowing or difficulty handling secretions should be kept in at least a semi-Fowler's position to decrease the risk of aspiration. The patient can be instructed in the use of oral suction to decrease the risk of aspiration further.

#### RELIEVING PAIN

Small, frequent feedings are recommended, because large quantities of food overload the stomach and promote gastric reflux. The patient is advised to avoid any activities that increase pain, and to remain upright for 1 to 4 hours after each meal to prevent reflux. The head of the bed should be placed on 4- to 8-inch (10- to 20-cm) blocks. Eating before bedtime is discouraged.

The patient is advised that excessive use of over-the-counter antacids can cause rebound acidity. Antacid use should be directed by the primary care provider, who can recommend the daily, safe dose needed to neutralize gastric juices and prevent esophageal

Chart 35-4

## Home Care Checklist • The Patient With an Esophageal Condition

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Demonstrate use of suction equipment.	✓	✓
• State dietary modifications needed to meet caloric needs.	✓	✓
• Demonstrate enteral or parenteral feeding techniques.	✓	✓
• Demonstrate care of incision if indicated.	✓	✓
• State when next checkup is needed.	✓	✓
• Identify available support groups.	✓	✓

irritation. Histamine<sub>2</sub> antagonists are administered as prescribed to decrease gastric acid irritation.

### PROVIDING PATIENT EDUCATION

The patient is prepared physically and psychologically for diagnostic tests, treatments, and possible surgical intervention. The principal nursing interventions include reassuring the patient and discussing the procedures and their purposes. Some disorders of the esophagus evolve over time, whereas others are the result of trauma (eg, chemical burns, perforation). In instances of trauma, the emotional and physical preparation for treatment is more difficult because of the short time available and the circumstances of the injury. Treatment interventions must be evaluated continually; the patient is given sufficient information to participate in care and diagnostic tests. If endoscopic diagnostic methods are used, the patient is instructed regarding the moderate sedation that will be used during the procedure. If procedures are being performed on an outpatient basis with the use of moderate sedation, the patient is instructed to have someone available to drive him or her home after the procedure. If surgery is required, immediate and long-term evaluation is similar to that for a patient undergoing thoracic surgery.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

The self-care required of the patient depends on the nature of the disorder and on the surgery or treatment measures used (eg, diet, positioning, medications). If an ongoing condition exists, the nurse helps the patient plan for needed physical and psychological adjustments and for follow-up care (Chart 35-4).

Special equipment, such as suction or enteral or parenteral feeding devices, may be required. The patient may need assistance in planning meals, using medications as prescribed, and resuming activities. Education about nutritional requirements and how to measure the adequacy of nutrition is important. Elderly and debilitated patients in particular often need assistance and education in ways to adjust to their limitations and to resume activities that are important to them.

#### Continuing Care

Patients with chronic esophageal conditions require an individualized approach to their management at home. Foods may need to be prepared in a special way (blenderized foods, soft foods), and the patient may need to eat more frequently (eg, four to six small servings per day). The medication schedule is adjusted to the patient's daily activities as much as possible. Analgesic medications and antacids can usually be taken as needed every 3 to 4 hours.

Postoperative home health care focuses on nutritional support, management of pain, and respiratory function. Some patients are discharged from the hospital with enteral feeding by means of a gastrostomy or jejunostomy tube or parenteral nutrition. The patient and care provider need specific instructions regarding management of the equipment and treatments. Home care visits by a nurse may be necessary to assess the patient's care and the care provider's ability to provide the necessary care. (See Chapter 36 for more information about parenteral nutrition and management of the patient with a gastrostomy.) For some patients, a multidisciplinary team comprising a dietitian, a social worker, and family members is helpful. Hospice care is appropriate for some patients.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

- Achieves an adequate nutritional intake
  - Eats small, frequent meals
  - Drinks water with small servings of food
  - Avoids irritants (alcohol, tobacco, very hot beverages)
  - Maintains desired weight
- Does not aspirate or develop pneumonia
  - Maintains upright position during feeding
  - Uses oral suction equipment effectively
- Is free of pain or able to control pain within a tolerable level
  - Avoids large meals and irritating foods
  - Takes medications as prescribed and with adequate fluids (at least 4 ounces), and remains upright for at least 10 minutes after taking medications
  - Maintains an upright position after meals for 1 to 4 hours
  - Reports that there is less eructation and chest pain
- Increases knowledge level of esophageal condition, treatment, and prognosis
  - States cause of condition
  - Discusses rationale for medical or surgical management and diet or medication regimen
  - Describes treatment program
  - Practices preventive measures so injuries are avoided

### Critical Thinking Exercises

- You are interviewing a patient in the medical clinic. The patient is complaining of difficulty swallowing as well as indigestion. Describe how you would continue to assess this patient to obtain the additional information that is

needed. Identify the various factors that may be causing this patient's symptoms.

**2.** You are caring for two postoperative patients. One patient is being treated for cancer of the mouth, the other for cancer of the esophagus. How will the nutritional care of these two patients differ? Describe the communication needs and psychosocial needs of these patients.

# ● Gastrointestinal Intubation and Special Nutritional Modalities

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Describe the purposes and types of GI intubation.
2. Discuss nursing management of the patient who has a nasogastric or nasoenteric tube.
3. Use the nursing process as a framework for care of the patient receiving an enteral feeding.
4. Explain the preoperative and postoperative care of the patient with a gastrostomy.
5. Use the nursing process as a framework for care of the patient with a gastrostomy.
6. Identify the purposes and uses of parenteral nutrition.
7. Use the nursing process as a framework for care of the patient receiving parenteral nutrition.
8. Describe the nursing measures used to prevent complications from parenteral nutrition.

This chapter presents several topics related to gastrointestinal (GI) intubation. Nursing management topics relate to managing the care of patients with nasogastric (NG) and nasoenteric tubes and gastrostomies, providing tube feedings, and teaching points related to home health care and nutritional therapy. In addition, parenteral nutrition is presented, including general indications for this nutritional modality and nursing care of patients receiving these support measures.

## Gastrointestinal Intubation

GI intubation is the insertion of a rubber or plastic tube into the stomach, the **duodenum** (first section of the small intestine), or the intestine. The tube may be inserted through the mouth, the nose, or the abdominal wall. The tubes can be short, medium, or long, depending on their intended use; **nasogastric (NG) tubes** are short, **nasoduodenal tubes** are of medium length, and nasoenteric tubes are long. GI intubation may be performed for the following reasons:

- To decompress the stomach and remove gas and fluid
- To lavage the stomach and remove ingested toxins
- To diagnose disorders of GI motility and other disorders
- To administer medications and feedings
- To treat an obstruction
- To compress a bleeding site
- To aspirate gastric contents for analysis

A variety of tubes are used for decompression, aspiration, and lavage. The Sengstaken-Blakemore tube is a type of NG tube used to treat bleeding esophageal varices (see Chapter 39). Orogastric tubes are large-bore tubes with wide proximal outlets for removal of particles of ingested substances (eg, pills); they are primarily used in emergency departments. Various other tubes are used to administer feedings and medications. The tubes are made of various materials (rubber, polyurethane, silicone), and they vary in length

(90 cm to 3 m [3 to 10 ft]), in size (6 to 18 French [Fr]), in purpose, and in placement in the GI tract (stomach, duodenum, jejunum) (Table 36-1). Any solution administered through a tube is either poured through a syringe or delivered by a drip mechanism regulated by gravity or by an electric pump. **Aspiration** (suctioning) to remove gas and fluids is accomplished with the use of a syringe, an electric suction machine, or a wall suction outlet.

## SHORT TUBES

An NG tube or short tube is introduced through the nose into the stomach, often before or during esophageal or stomach surgery. Commonly used short tubes include the Levin tube and the gastric sump tube. Short tubes are used in adults primarily to remove fluid and gas from the upper GI tract or to obtain a specimen of gastric contents for laboratory studies. They are occasionally used for the short-term (3 to 4 weeks) administration of medications or feedings.

### Levin Tube

The Levin tube has a single lumen (the hollow part of the tube), ranges from 14 to 18 Fr in size, and is made of plastic or rubber with openings near its tip. It is 125 cm (50 in) long. Circular markings at specific points on the tube serve as guides for insertion. A marking is made on the tube to indicate the midpoint. The tube is advanced cautiously until this marking reaches the patient's nostril, suggesting that the tube is in the stomach. Placement is checked by observing the characteristics of the aspirate and by testing the **pH** (which varies according to the source of the aspirate). Seeing the tube on an x-ray study is the only sure way to verify its location. The Levin tube is connected to low intermittent suction (30 to 40 mm Hg). Intermittent suction is used to avoid erosion or tearing of the stomach lining, which can result from constant adherence of the tube's lumen to the mucosal lining of the stomach.

## Glossary

**antireflux valve:** valve that prevents return or backward flow of fluid

**aspiration:** breathing of fluids or foods into the trachea and lungs; removal of substance by suction

**bolus:** a feeding administered into the stomach in large amounts and at designated intervals

**central venous access device (CVAD):** a device designed and used for long-term administration of medications and fluids into central veins

**cyclic feeding:** periodic feeding/infusion given over a short period (8 to 12 hours)

**decompression (intestinal):** removal of intestinal contents to prevent gas and fluid from distending the coils of the intestine

**dumping syndrome:** rapid emptying of the stomach contents into the small intestine; characterized by sweating and weakness

**duodenum:** the first part of the small intestine, which connects with the pylorus of the stomach and extends to the jejunum

**feeding tube:** tube through which nutritional products, water, and other fluids can be introduced into the GI tract

**gastrostomy:** surgical creation of an opening into the stomach for the purpose of administering foods and fluids

**irrigation:** flushing of the tube with water or other fluids to clear it

**jejunum:** second portion of the small intestine, extending from the duodenum to the ileum

**low-profile gastrostomy device (LPGD, G-button):** an enteral feeding access device that is flush with the skin and is used for long-term feeding

**nasoduodenal tube:** tube inserted through the nose into the beginning of the small intestine (duodenum)

**nasogastric (NG) tube:** tube inserted through the nose into the stomach

**nasojejunal tube:** tube inserted through the nose into the second portion of the small intestine (jejunum)

**osmolality:** ionic concentration of fluid

**osmosis:** passage of solvent through a semi-permeable membrane; the solvent, usually water, passes through the membrane from a region of low concentration of solute to that of a higher concentration of solute

**parenteral nutrition:** method of supplying nutrients to the body by an intravenous route

**percutaneous endoscopic gastrostomy (PEG):** an endoscopic procedure for placing a permanent feeding tube into the stomach

**peristalsis:** wavelike movement that occurs involuntarily in the alimentary canal

**pH:** the degree of acidity or alkalinity of a substance or solution

**peripherally inserted central catheter (PICC):** a device used for intermediate-term intravenous therapy

**stoma:** artificially created opening between a body cavity (eg, intestine) and the body surface

**total nutrient admixture:** an admixture of lipid emulsions, proteins, carbohydrates, electrolytes, vitamins, trace minerals, and water

**Table 36-1 • Nasogastric, Nasoenteric, and Feeding Tubes**

TUBE TYPE	LENGTH (CM)	SIZE (FRENCH)	LUMEN	OTHER CHARACTERISTICS
<b>Nasogastric Tubes</b>				
Levin (plastic or rubber)	125	14–18	Single	Circular markings at intervals along the tube serve as guidelines for insertion
Gastric sump or Salem (plastic)	120	12–18	Double	Smaller lumen acts as a vent
Moss	90	12–16	Triple	Contains both a gastric decompression lumen and a duodenal lumen for postoperative feedings
Sengstaken-Blakemore (rubber)			Triple	Two lumens are used to inflate the gastric and esophageal balloons
<b>Nasoenteric Decompression Tubes</b>				
Miller-Abbott (rubber)	300	12–18	Double	One lumen uses mercury, water, saline, or air for balloon inflation
Harris	180	14, 16	Single	Mercury-weighted tip (or may use water as a weight)
Cantor (rubber)	300	16	Single	Mercury-weighted bag (or may use water as a weight)
Baker (plastic)	270	16	Double	One lumen is used for balloon inflation
<b>Nasoenteric Feeding Tubes</b>				
Dobbhoff or EnteraFlo (polyurethane or silicone rubber)	160–175	8–12	Single	Tungsten-weighted tip, radiopaque, stylet

## Gastric Sump

The gastric sump (Salem) tube is a radiopaque, clear plastic, double-lumen NG tube used to decompress the stomach and keep it empty. It is 120 cm (48 in) long and is passed into the stomach in the same way as the Levin tube. The inner, smaller tube vents the larger suction-drainage tube to the atmosphere by means of an opening at the distal end of the tube. The sump tube can protect gastric suture lines because, when used properly, it maintains the force of suction at the drainage openings, or outlets, at less than 25 mm Hg, the level of capillary fragility. The small vent tube (known as the blue pigtail) controls this action. These tubes are connected to low continuous suction. The suction lumen is irrigated as prescribed to maintain patency.

To prevent reflux of gastric contents through the vent lumen (blue pigtail), the vent lumen is kept above the patient's waist; otherwise it will act as a siphon. A one-way **antireflux valve** seated in the blue pigtail prevents the reflux of gastric contents out the vent lumen (Fig. 36-1). The valve is removed after irrigation of the suction lumen, and 20 mL of air is injected to reestablish a buffer of air between the gastric contents and the valve.

## MEDIUM TUBES

Medium-length nasoenteric tubes are used for feeding. Feeding tubes placed in the duodenum are 160 cm (60 in) long; feeding tubes placed in the **jejunum** (portion of the small intestine adjacent to the duodenum) are 175 cm (66 in) long. They can be inserted at the time of surgery or before surgery, by interventional radiologists assisted by fluoroscopy or at the bedside. If the tube is inserted at the bedside, placement is verified by radiography.

After insertion, the tip of the tube will initially be in the stomach; it usually takes 24 hours for the tube to pass through the stomach and into the intestines.

**NURSING ALERT** Having the patient lie on the right side facilitates passage, because gravity and peristaltic motion will move the weighted tube into the duodenum.

Polyurethane or silicone rubber feeding tubes have narrow diameters (6 to 12 Fr) and tungsten tips (rather than mercury-filled bags); some have a water-activated lubricant that makes it easier to insert the tube. The tubing may kink when a stylet is not used, particularly if the patient is uncooperative or unable to swallow. Feeding tubes with a stylet are inserted with caution in patients who are predisposed to esophageal puncture, such as elderly and frail patients with thin tissues. These tubes are advanced in the same way as an NG tube; that is, with the patient in Fowler's position. If this is not feasible, the patient is placed on the right side.

## LONG TUBES

A long nasoenteric tube is introduced through the nose and passed through the esophagus and stomach into the intestinal tract. It is used to aspirate intestinal contents so that gas and fluid do not distend the intestine; this is called **decompression**. Three major nasoenteric tubes used for aspiration and decompression are the Miller-Abbott tube, the Harris tube, and the Cantor tube. These tubes are used to relieve obstruction of the small intestine. They are also used prophylactically; they may be inserted the night before GI surgery to prevent postoperative obstruction.

**FIGURE 36-1** Gastric sump tube (Salem) equipped with a one-way anti-reflux valve that allows air to enter and prevents gastric contents from escaping. The antireflux valve is designed with a pressure activated air buffer (PAAB). The buffer is activated (1) and the valve closes (2) when pressure from gastric contents enters the tubing. Argyle Silicone Salem Sump Tube with preattached Argyle Salem Sump Anti-Reflux Valve courtesy of Sherwood Medical, St. Louis, Missouri.

Because **peristalsis** is either stopped or slowed for 24 to 48 hours after surgery as a result of anesthesia and visceral manipulation, NG or nasogastric suction is used to evacuate fluids and flatus so that vomiting is prevented, tension is reduced along the incision line, and obstruction is prevented. Usually, the tube remains in place until peristalsis returns, as evidenced by the resumption of bowel sounds and the passage of flatus.

### Miller-Abbott Tube

The Miller-Abbott tube is a double-lumen rubber tube that is 300 cm (10 ft) long and 12, 14, 16, or 18 Fr in size. One lumen is used to introduce mercury, water, or saline into the balloon at the end of the tube for weighting of the tube; the other lumen is used for aspiration. Before the tube is inserted, the balloon should be tested and its capacity measured; then it should be deflated completely. The tube should be lubricated sparingly and chilled well (chilling causes the tube to become stiff and facilitates its passage) before the tip is inserted through the patient's nose. Markings on the tube indicate the distance it has been passed. Before removal, the balloon at the end of the lumen must be completely deflated.

### Harris Tube

The Harris tube is a single-lumen (14 Fr), mercury-weighted tube of about 180 cm (6 ft). This tube has a metal tip that is lu-

bricated and introduced through the nose. The mercury-weighted bag follows. The weight of the mercury promotes the passage of the bag by gravity. This tube is used solely for suction and **irrigation**. Usually, a Y-tube is attached to the end of the Harris tube. The suction is applied to one side of the Y and the other side is clamped, except when irrigation of the tube is being performed.

### Cantor Tube

The Cantor tube is 300 cm (10 ft) long and has a 16-Fr lumen. Its distinguishing feature is that it is larger than the other long tubes. It has a 4- or 5-mL bag at the extreme end of the rubber tubing; mercury, water or saline is introduced into this bag to weight the tube. Before the tube is inserted, the bag is wrapped around the tube. After the tube is lubricated, it is advanced through the nose and into the esophagus (Fig. 36-2). The patient assumes a sitting position and may be offered sips of water to facilitate passage of the tube. Fluoroscopy helps to verify that the tube has passed into the duodenum.

## NURSING MANAGEMENT OF PATIENTS UNDERGOING NASOGASTRIC OR NASOENTERIC INTUBATION

Nursing interventions include the following:

- Instructing the patient about the purpose of the tube and the procedure required for inserting and advancing it
- Describing the sensations to be expected during tube insertion
- Inserting the NG tube and assisting with insertion of the nasoenteric tube
- Confirming the placement of the NG tube
- Advancing the nasoenteric tube
- Monitoring the patient and maintaining tube function
- Providing oral and nasal hygiene and care
- Monitoring for potential complications
- Removing the tube

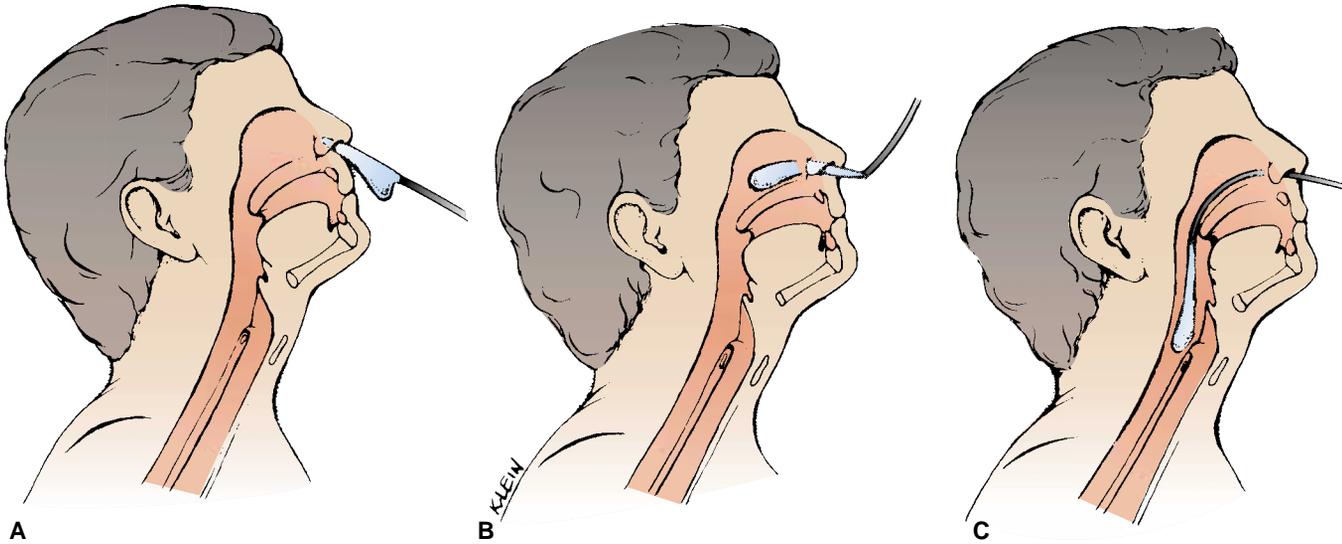

### Providing Instruction

Before the patient is intubated, the nurse explains the purpose of the tube; this information may assist the patient to be cooperative and tolerant of what is often an unpleasant procedure. The general activities related to inserting the tube are then reviewed, including the fact that the patient may have to breathe through the mouth and that the procedure may cause gagging until the tube has passed the area of the gag reflex.

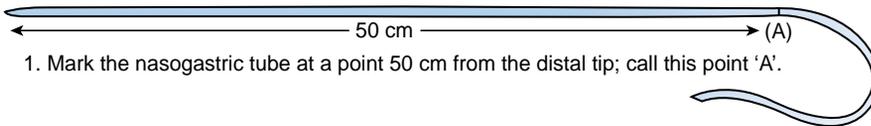

### Inserting the Tube

Before inserting the tube, the clinician determines how much tubing will be needed to reach the stomach or the small intestine. A mark is made on the tube to indicate the desired length. This length is determined by measuring the distance from the tip of the nose to the earlobe, and from the earlobe to the xiphoid process, then adding 6 inches for NG placement or 8 to 10 inches for intestinal placement (Fig. 36-3).

While the tube is being inserted, the patient usually sits upright with a towel spread bib-fashion over the chest. Tissue wipes are made available. Privacy and adequate light are provided. The physician may swab the nostril and spray the oropharynx with

**FIGURE 36-2** Passage of Cantor tube. (A) Tube with weighted bag (mercury, water, normal saline solution) is introduced through the nose. (B) After the weighted bag has entered the nostril, the catheter is tilted upward (head can also be tilted slightly upward) to facilitate gravity pull on the weighted bag. (C) The weight of the mercury (or water or normal saline solution) pulls the bag downward.

1. Mark the nasogastric tube at a point 50 cm from the distal tip; call this point 'A'.

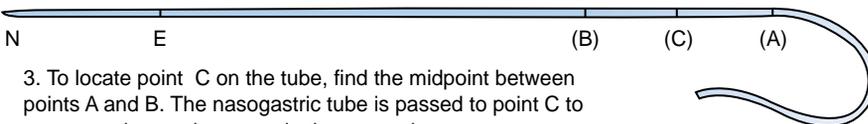

Measuring distance from nostril to tip of earlobe.

Measuring distance from earlobe to tip of xiphoid process.

2. Have the patient sit in a neutral position with head facing forward. Place the distal tip of the tubing at the tip of the patient's nose (N); extend tube to the tragus (tip) of the ear (E), and then extend the tube straight down to the tip of the xiphoid (X). Mark this point 'B' on the tubing.

3. To locate point C on the tube, find the midpoint between points A and B. The nasogastric tube is passed to point C to ensure optimum placement in the stomach.

**FIGURE 36-3** Measuring length of nasogastric tube for placement into stomach.

Cetacaine (tetracaine/benzocaine) to numb the nasal passage and suppress the gag reflex. This makes the entire procedure more tolerable. Having the patient gargle with a liquid anesthetic or hold ice chips in the mouth for a few minutes can have the same effect. Encouraging the patient to breathe through the mouth or to pant often helps, as does swallowing water, if permitted.

A polyurethane tube may need to be warmed to make it more pliable. To make the tube easier to insert, it should be lubricated with a water-soluble substance (K-Y jelly) unless it has a dry coating called hydromer, which, when moistened, provides its own lubrication. The nurse wears gloves during the procedure.

The patient is placed in Fowler's position, and the nostrils are inspected for any obstruction. The more patent nostril is selected for use. The tip of the patient's nose is tilted, and the tube is aligned to enter the nostril. When the tube reaches the nasopharynx, the patient is instructed to lower the head slightly and to begin to swallow as the tube is advanced. The patient may also sip water through a straw to facilitate advancement of the tube. The oropharynx is inspected to ensure that the tube has not coiled in the pharynx or mouth.

### Confirming Placement

To ensure patient safety, it is essential to confirm that the tube has been placed correctly, particularly because tubes may be accidentally inserted in the lungs, which may be undetected in high-risk patients. Examples of high-risk patients are those with a decreased level of consciousness, confused mental state, poor or absent cough and gag reflexes, or agitation during insertion. Presence of an endotracheal tube and recent removal of an endotracheal tube also increase the risk for inadvertent placement of the tube in the lung (Metheny, 1998). Initially, an x-ray study should confirm tube placement. However, each time liquids or medications are administered, and once a shift for continuous feedings, the tube must be checked to ensure that it remains properly placed. The traditional recommendation has been to inject air through the tube while auscultating the epigastric area with a stethoscope to detect air insufflations. However, studies indicate that this auscultatory method is not accurate in determining whether the tube has been inserted into the stomach, intestines, or respiratory tract (Metheny et al., 1999). Instead of the auscultation method, a combination of three methods is recommended:

- Measurement of tube length
- Visual assessment of aspirate
- pH measurement of aspirate

After the tube is inserted, the exposed portion of the tube is measured and the length is documented. The nurse measures the exposed tube length every shift and compares it with the original measurement. An increase in the length of exposed tube may indicate dislodgement, or a leaking or ruptured balloon if the tube has a balloon.

Visual assessment of the color of the aspirate may help identify tube placement. Metheny et al. (1994) found that gastric aspirate is most frequently cloudy and green, tan or off-white, or bloody or brown. Intestinal aspirate is primarily clear and yellow to bile-colored. Pleural fluid is usually pale yellow and serous, and tracheobronchial secretions are usually tan or off-white mucus. Researchers suggest that the appearance of the aspirate may be helpful in distinguishing between gastric and intestinal placement but is of little value in ruling out respiratory placement. This method is less helpful when the patient is receiving continuous

feedings, because aspirate often looks like the formula that is used for the feeding (Metheny & Titler, 2001).

Determining the pH of the tube aspirate is a more accurate method of confirming tube placement. The pH method can also be used to monitor the advancement of the tube into the small intestines. The pH of gastric aspirate is acidic (1 to 5). The pH of intestinal aspirate is approximately 6 or greater, and the pH of respiratory aspirate is more alkaline (7 or greater). pH testing is best suited for distinguishing between gastric and intestinal placement. A pH sensor enteral tube is available which does not require fluid aspirate to obtain pH values; it can be useful in distinguishing gastric from small bowel placement of the tube. The pH method is less helpful with continuous feedings, because tube feedings have a pH value of 6.6 and neutralize the GI pH (Metheny & Titler, 2001). For more information, see Nursing Research Profile 36-1.

Using gastric aspiration as a means of verifying that the NG tube has been placed correctly may be a problem because of the characteristic properties and diameter of the tubes. Studies suggest that aspiration may be performed more easily with polyurethane tubes and tubes with a size 10 Fr diameter. Metheny et al. (1993) recommended the following steps if problems occur with aspiration of fluid from small-bore feeding tubes:

1. Insufflate 20 mL of air through the tube with a large syringe (30 to 60 mL).
2. Pull back on the plunger.
3. If step 2 is ineffective, insufflate another 20 mL of air and replace the large syringe with a smaller one (12 mL); attempt to aspirate.
4. If the measure is still ineffective, repeat step 3.
5. Change the patient's position and attempt to aspirate.

### Securing the Tube

After the correct position of the tip has been confirmed, the NG tube is secured to the nose (Fig. 36-4). A liquid skin barrier should be applied to the skin where the NG tube will be secured. The prepared area is covered with a strip of hypoallergenic tape or Op-site; the tube is then placed over the tape and secured with a second piece of tape. The nasoenteric tube can be secured by taping it to the forehead (see Fig. 36-4). This keeps the tube from dislodging when the patient moves but still allows it to pass into the intestine. Instead of tape, a feeding tube attachment device (Hollister) can be used to secure the tube. This device adheres to the nose and uses an adjustable clip to hold the tube in place (Fig. 36-5). After the nasoenteric tube has progressed into the intestine (after approximately 24 hours), the tube may be taped in place.

### Advancing the Nasoenteric Decompression Tube

After the tube has passed through the pyloric sphincter, it may be advanced 5 to 7.5 cm (2 to 3 in) every hour. To enable gravity and peristalsis to assist in the passage of the tube, the patient is generally asked to lie in the following positions in this order: on the right side for 2 hours, on the back for 2 hours, and then on the left side for 2 hours. Ambulation, if possible, also helps advance the tube. If the tube is advanced too rapidly, it will curl and kink in the stomach. The tube is irrigated with normal saline solution every 6 to 8 hours to prevent blockage.

### NURSING RESEARCH PROFILE 36-1

#### Assessment of Feeding Tube Location

Metheny, N. A., Smith, L., & Stewart, B. J. (2000). Development of a reliable and valid bedside test for bilirubin and its utility for improving prediction of feeding tube location. *Nursing Research*, 49, 302–309.

#### Purpose

Although a wide variety of methods have been used to assess feeding tube location at the bedside, pH testing of aspirate has been found to be the most reliable in differentiating between gastric and respiratory placement of the tube and between gastric and intestinal placement of the tube. However, it is not reliable in distinguishing intestinal from respiratory fluids, because both of these fluids are alkaline. One new method that is being studied to distinguish these fluids is testing the tube aspirate for bilirubin, which is normally found in intestinal fluids but not in respiratory fluids.

The purposes of this study were (1) to assess the validity of a visual bilirubin teststrip used with a colorimetric visual bilirubin (VBIL) scale to predict laboratory bilirubin values, (2) to evaluate the interrater reliability of staff nurses using the visual bilirubin test strip and VBIL scale, and (3) to evaluate the ability of the visual bilirubin test strip and VBIL scale in combination with pH testing to predict feeding tube placement in the respiratory tract, stomach, or intestine.

#### Study Sample and Design

Concurrent pH and bilirubin testing was conducted on 631 GI specimens obtained from adult, acutely ill patients with newly inserted feeding tubes; the testing was done within 5 minutes of x-ray studies obtained to confirm tube placement. Also, 225 respiratory specimens were tested. A teststrip and VBIL scale as well as laboratory assay were used to measure bilirubin. A pH meter and pH teststrips were used to

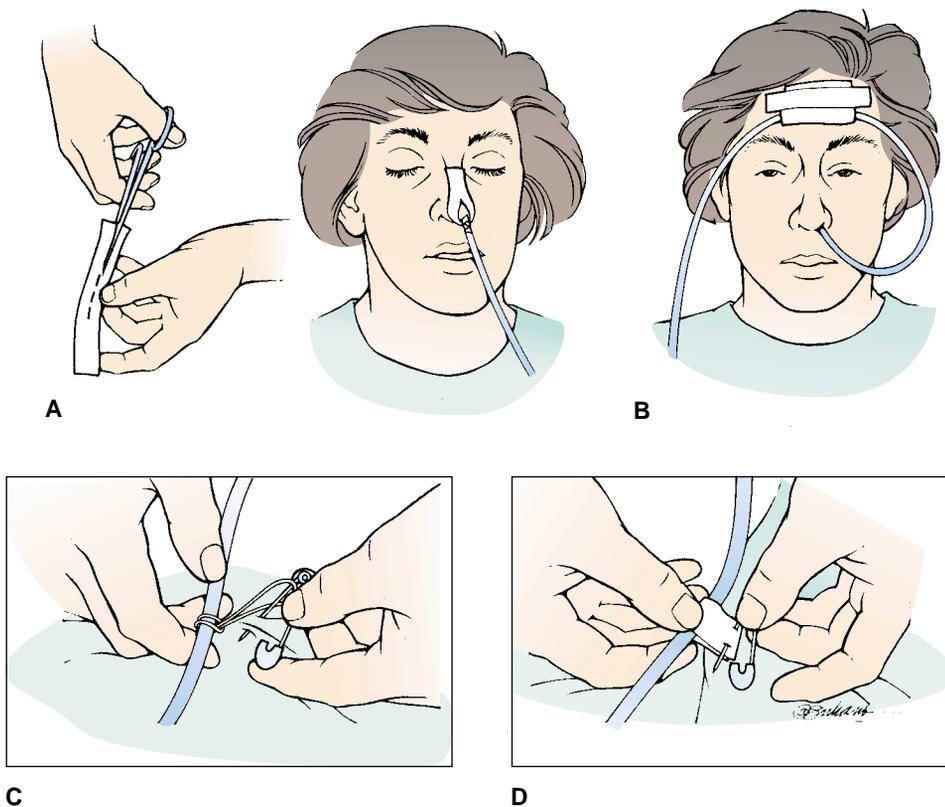

measure pH. Results were read by research assistants and staff nurses, who were blinded to (unaware of) the source or type of specimens. These readings were compared with the x-ray results.

#### Findings

There was a high correlation (0.93) between the readings made from the VBIL scale and the laboratory bilirubin assay. A pH reading greater than 5 and a bilirubin reading lower than 5 mg/dL accurately identified 100% of the respiratory specimens. A pH of 5 or less and a bilirubin concentration lower than 5 mg/dL accurately identified 98% of the gastric specimens. Approximately 88% of the specimens with a pH greater than 5 and a bilirubin value of 5 mg/dL or higher were intestinal specimens.

#### Nursing Implications

Use of the VBIL scale and bilirubin test strip has the potential for greatly improving the accuracy of determining feeding tube placement at the bedside. However, before its approval by the U.S. Food and Drug Administration for this purpose, further refinements are required to make sure that the most accurate readings can be made. Until such approval, nurses must rely on the auscultatory method, pH measurements, and observations of the patient's physical status to determine tube placement. Any question about correct tube placement should be investigated, and placement should be confirmed by x-ray studies whenever indicated.

**FIGURE 36-4** Securing NG and nasoenteric tubes. (A) The NG tube is secured to the nose with tape to prevent injury to the nasopharyngeal passages. (B) Tape is placed on the forehead and the nasoenteric tube is taped to it, thereby allowing the tube to be advanced until desired placement is achieved. (C, D) Secure tubing to the patient's gown with either an elastic band or tape attached to a safety pin to prevent tension on the line during movement of the patient.

**FIGURE 36-5** Feeding tube attachment device. Courtesy of Hollister, Incorporated.

### Monitoring the Patient and Maintaining Tube Function

If the NG tube is used for decompression, it is attached to intermittent low suction. If it is used for enteral nutrition, the end of the tube is plugged between feedings. The nurse confirms tube placement before any fluids or medications are instilled and once a shift for continuous feedings. Displacement of the tube may be caused by tension on the tube (when the patient moves around in the bed or room), coughing, tracheal or nasotracheal suctioning, or airway intubation. If the NG tube is removed inadvertently in a patient who has undergone esophageal or gastric surgery, it is replaced by the physician, usually under fluoroscopy to avoid trauma to the suture line.

It is important to keep an accurate record of all fluid intake, feedings, and irrigation. To maintain patency, the tube is irrigated every 4 to 6 hours with normal saline to avoid electrolyte loss through gastric drainage. If an automatic flush enteral pump is used, the flushing schedule may be altered. The nurse records the amount, color, and type of all drainage every 8 hours.

When double- or triple-lumen tubes are used, each lumen is labeled according to its intended use: aspiration, feeding, or balloon inflation. To avoid tension on the tube, the portion of the tube from the nose to the drainage unit is fixed in position, either with a safety pin or with adhesive tape loops that are pinned to the patient's pajamas or gown. The tube must be looped loosely to prevent tension and dislodgement (see Fig. 36-4).

### Providing Oral and Nasal Hygiene

Regular and conscientious oral and nasal hygiene is a vital part of patient care, because the tube causes discomfort and pressure and may be in place for several days. Moistened cotton-tipped swabs can be used to clean the nose, followed by cleansing with a water-soluble lubricant. Frequent mouth care is comforting for the patient. The nasal tape is changed every 2 to 3 days, and the nose is inspected for skin irritation. If the nasal and pharyngeal mucosa are

excessively dry, steam or cool vapor inhalations may be beneficial. Throat lozenges, an ice collar, chewing gum, or sucking on hard candies (if permitted), and frequent movement also assist in relieving patient discomfort. These activities keep the mucous membranes moist and help prevent inflammation of the parotid glands.

### Monitoring and Managing Potential Complications

Patients with NG or nasogastric intubation are susceptible to a variety of problems, including fluid volume deficit, pulmonary complications, and tube-related irritations. These potential complications require careful ongoing assessment.

Symptoms of fluid volume deficit include dry skin and mucous membranes, decreased urinary output, lethargy, and decreased body temperature. Assessment of fluid volume deficit involves maintaining an accurate record of intake and output. This includes measuring NG drainage, fluid instilled by irrigation of the NG tube, water taken by mouth, vomitus, water administered with tube feedings, and intravenous (IV) fluids. Laboratory values, particularly blood urea nitrogen and creatinine, are monitored. The nurse assesses 24-hour fluid balance and reports negative fluid balance, increased NG output, interruption of IV therapy, or any other disturbance in fluid intake or output.

Pulmonary complications from NG intubation occur because coughing and clearing of the pharynx are impaired, because gas buildup can irritate the phrenic nerve, and because tubes may become dislodged, retracting the distal end above the esophagogastric sphincter. Medications (antacids, simethicone, and metoclopramide) are administered to decrease potential problems. Signs and symptoms of complications include coughing during the administration of foods or medications, difficulty clearing the airway, tachypnea, and fever. Assessment includes regular auscultation of lung sounds and routine assessment of vital signs. It is important to encourage the patient to cough and to take deep breaths regularly. The nurse also carefully confirms the proper placement of the tube before instilling any fluids or medications.

Irritation of the mucous membranes is a common complication of NG intubation. The nostrils, oral mucosa, esophagus, and trachea are susceptible to irritation and necrosis. Visible areas are inspected frequently, and the adequacy of hydration is assessed. When providing oral hygiene, the nurse carefully inspects the mucous membranes for signs of irritation or excessive dryness. The nurse palpates the area around the parotid glands to detect any tenderness or enlarged nodes, indicating parotitis, and observes for any skin or mucous membrane irritation or necrosis. In addition, it is important to assess the patient for esophagitis and tracheitis; symptoms include sore throat and hoarseness.

### Removing the Tube

Before removing a tube, the nurse may intermittently clamp and unclamp the NG tube for a trial period of 24 hours to ensure that the patient does not experience nausea, vomiting, or distention. Before the tube is removed, it is flushed with 10 mL of normal saline to ensure that it is free of debris and away from the gastric lining; then the balloon (if present) is deflated. Gloves are worn to remove the tube. The tube is withdrawn gently and slowly for 15 to 20 cm (6 to 8 in) until the tip reaches the esophagus; the

remainder is withdrawn rapidly from the nostril. A nasointestinal tube is withdrawn at intervals of 10 minutes until the end reaches the esophagus. If the tube does not come out easily, force should not be used, and the problem should be reported to the physician. As the tube is withdrawn, it is concealed in a towel, because the sight of it may be unpleasant to the patient. After the tube is removed, the nurse provides oral hygiene.

## Tube Feedings With Nasogastric and Nasoenteric Devices

Tube feedings are given to meet nutritional requirements when oral intake is inadequate or not possible and the GI tract is functioning normally. Tube feedings have several advantages over parenteral nutrition: they are low in cost, safe, well tolerated by the patient, and easy to use both in extended care facilities and in the patient's home. Tube feedings have other advantages:

- They preserve GI integrity by delivery of nutrients and medications (antacids, simethicone, and metoclopramide) intraluminally
- They preserve the normal sequence of intestinal and hepatic metabolism
- They maintain fat metabolism and lipoprotein synthesis
- They maintain normal insulin/glucagon ratios

Tube feedings are delivered to the stomach (in the case of NG intubation or gastrostomy) or to the distal duodenum or proximal jejunum (in the case of nasoduodenal or **nasojejunal tube** feeding). Nasoduodenal or nasojejunal feeding is indicated when the esophagus and stomach need to be bypassed or when the patient is at risk for **aspiration** (breathing fluids or foods into the trachea and lungs). For long-term feedings (longer than 4 weeks), nasoduodenal, gastrostomy, or jejunostomy tubes are preferred for administration of medications or food. The numerous conditions requiring enteral nutrition are summarized in Table 36-2.

## OSMOSIS AND OSMOLALITY

Osmolality is an important consideration for patients receiving tube feedings through the duodenum or jejunum, because feeding formulas with a high osmolality may lead to undesirable effects, such as dumping syndrome (described below).

Fluid balance is maintained by **osmosis**, the process by which water moves through membranes from a dilute solution of lower **osmolality** (ionic concentration) to a more concentrated solution of higher osmolality until both solutions are of nearly equal osmolality. The osmolality of normal body fluids is approximately 300 mOsm/kg. The body attempts to keep the osmolality of the contents of the stomach and intestines at approximately this level.

Highly concentrated solutions and certain foods can upset the normal fluid balance in the body. Individual amino acids and carbohydrates are small particles that have great osmotic effect. Proteins are extremely large particles and therefore have less osmotic effect. Fats are not water-soluble and do not enter into a solution in water; thus, they have no osmotic effect. Electrolytes, such as sodium and potassium, are comparatively small particles; they have a great effect on osmolality and consequently on the patient's ability to tolerate a given solution.

When a concentrated solution of high osmolality is taken in large amounts, water will move to the stomach and intestines from fluid surrounding the organs and the vascular compartment. The patient has a feeling of fullness, nausea, and diarrhea; this causes dehydration, hypotension, and tachycardia, collectively termed the **dumping syndrome**. Starting with a more dilute solution and increasing the concentration over several days can generally alleviate this problem. Patients vary in the degree to which they tolerate the effects of high osmolality; usually debilitated patients are more sensitive. The nurse needs to be knowledgeable about the osmolality of the patient's formula and needs to observe for and take steps to prevent undesired effects.

## TUBE FEEDING FORMULAS

The choice of formula to be delivered by tube feeding is influenced by the status of the GI tract and the nutritional needs of

**Table 36-2 • Conditions Requiring Enteral Therapy**

CONDITION OR NEED	EXAMPLES
Preoperative bowel preparation	—
Gastrointestinal problems	Fistula, short-bowel syndrome, mild pancreatitis, Crohn's disease, ulcerative colitis, nonspecific maldigestion or malabsorption
Cancer therapy	Radiation, chemotherapy
Convalescent care	Surgery, injury, severe illness
Coma, semiconsciousness*	Stroke, head injury, neurologic disorder, neoplasm
Hypermetabolic conditions	Burns, trauma, multiple fractures, sepsis, AIDS, organ transplantation
Alcoholism, chronic depression, anorexia nervosa*	Chronic illness, psychiatric or neurologic disorder
Debilitation*	Disease or injury
Maxillofacial or cervical surgery	Disease or injury
Oropharyngeal or esophageal paralysis*	Disease or injury, neoplasm, inflammation, trauma, respiratory failure

\*Because some of these patients are at risk for regurgitating or vomiting and aspirating administered formula, each condition must be considered individually.

the patient. The formula characteristics evaluated include chemical composition of the nutrient source (protein, carbohydrates, fat), caloric density, osmolality, residue, bacteriologic safety, vitamins, minerals, and cost.

Various major formula types for tube feedings are available commercially. Blenderized formulas can be made by the patient's family or obtained in a ready-to-use form that is carefully prepared according to directions. Commercially prepared polymeric formulas (formulas with high molecular weight) are composed of protein, carbohydrates, and fats in a high-molecular-weight form (Boost Plus, TwoCal HN, Isosource). Chemically defined formulas contain predigested and easy-to-absorb nutrients (Osmolite HN). Modular products contain only one major nutrient, such as protein (Promote). Disease-specific formulas are available for various conditions, such as renal failure (Nepro), severe chronic obstructive pulmonary disease (Pulmocare). Nepro is high in calories and low in electrolytes. It is ideal for patients who require electrolyte and fluid restriction. Pulmocare is high in fat and low in carbohydrates. Its high density (1.5 calories/mL) is ideal for patients who require fluid restriction, and it is also designed to reduce carbon dioxide production. Fiber has also been added to formulas (Jevity) in an attempt to decrease the occurrence of diarrhea. Some feedings are given as supplements, and others are designed to meet the patient's total nutritional needs. Dietitians collaborate with physicians and nurses in determining the best formula for the individual patient.

**NURSING ALERT** Commercial formulas frequently present problems because the composition is fixed and some patients are not able to tolerate certain ingredients, such as sodium, protein, or potassium. Modular products may be substituted, and the critical constituents of sodium, potassium, and fat can be added. Attention is given to including all essential minerals and vitamins. Total intake of calories, nutrients, and fluids must be assessed when there is a reduction in total intake or excessive dilution of feedings.

## TUBE FEEDING ADMINISTRATION METHODS

Many patients do not tolerate NG and nasogastric tube feedings well. Often a medium- or fine-bore Silastic nasogastric tube is tolerated better than a plastic or rubber tube. The finer-bore tube requires a finely dispersed formula to ensure that the patency of the tube is maintained. For long-term tube feeding therapy, a gastrostomy or jejunostomy tube is used (see later discussion).

The tube feeding method chosen depends on the location of the tube, patient tolerance, convenience, and cost. Intermittent bolus feedings are administered into the stomach (usually by gastrostomy tube) in large amounts at designated intervals and may be given 4 to 8 times per day. The intermittent gravity drip is another method for administering tube feedings into the stomach and is commonly used when the patient is at home. In this instance, the tube feeding is administered over 30 minutes at designated intervals. Both of these tube-feeding methods are practical and inexpensive. However, the feedings delivered at variable rates may be poorly tolerated and time-consuming.

The continuous infusion method is used when feedings are administered into the small intestine. This method is preferred for patients who are at risk for aspiration or who tolerate the tube feedings poorly. The feedings are given continuously at a constant rate by means of a pump. The continuous tube feeding method, which requires a pump device, decreases abdominal dis-

tion, gastric residuals, and the risk of aspiration. However, pumps are expensive, and they permit the patient less flexibility than intermittent feedings do.

An alternative to the continuous infusion method is **cyclic feeding**. The infusion is given at a faster rate over a shorter time (usually 8 to 12 hours). Feeding may be infused at night to avoid interrupting the patient's lifestyle. Cyclic continuous infusions may be appropriate for patients who are being weaned from tube feedings to an oral diet, as a supplement for a patient who cannot eat enough, and for patients at home who need daytime hours free from the pump.

Tube feeding solutions vary in terms of required preparation, consistency, and the number of calories and supplemental vitamins they contain. The choice of solution depends on the size and location of the tube, the patient's nutrient needs, the type of nutritional supplement, the method of delivery, and the convenience for the patient at home. A wide variety of containers, feeding tubes and catheters, delivery systems, and pumps are available for use with tube feedings.

## NURSING PROCESS: THE PATIENT RECEIVING A TUBE FEEDING

### Assessment

A preliminary assessment of the patient who requires a tube feeding includes several considerations, as well as the family's need for information:

- What is the patient's nutritional status, as judged by current physical appearance, dietary history, and recent weight loss?
- Are there any existing chronic illnesses or factors that will increase metabolic demands on the body (eg, surgical stress, fever)?
- What is the patient's hydration status? What are the electrolyte levels?
- Is the patient's digestive tract functioning?
- Are the kidneys functioning normally?
- Are fluid requirements (ie, 30 to 40 mL/kg body weight) being met?
- What medications and other therapies is the patient receiving that may affect digestive intake and function of the digestive system?
- Does the dietary prescription fulfill the patient's needs?

In addition, a more elaborate assessment is performed for patients who require extensive nutritional therapy. A team that includes the nurse, physician, and dietitian conducts this assessment. In addition to the history and physical examination (which includes anthropometric measurements), nutritional assessment consists of recording any weight change; determining albumin, prealbumin, and transferrin levels and total lymphocyte count; testing for the delayed hypersensitivity reaction; and evaluating muscle function. (See Chapter 5 for a detailed description of nutritional assessment.)

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the major nursing diagnoses may include the following:

- Imbalanced nutrition, less than body requirements, related to inadequate intake of nutrients
- Risk for diarrhea related to the dumping syndrome or to tube feeding intolerance
- Risk for ineffective airway clearance related to aspiration of tube feeding
- Risk for deficient fluid volume related to hypertonic dehydration
- Risk for ineffective coping related to discomfort imposed by the presence of the NG or nasogastric tube
- Risk for ineffective therapeutic regimen management
- Deficient knowledge about home tube feeding regimen

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Complications of NG and nasogastric tube feeding therapy are classified into three types—GI, mechanical, and metabolic. Table 36-3 lists complications, possible causes, and appropriate interventions.

### Planning and Goals

The major goals for the patient may include nutritional balance, normal bowel elimination pattern, reduced risk of aspiration, adequate hydration, individual coping, knowledge and skill in self-care, and prevention of complications.

### Nursing Interventions

#### MAINTAINING FEEDING EQUIPMENT AND NUTRITIONAL BALANCE

The temperature and volume of the feeding, the flow rate, and the total fluid intake are important factors to be considered when tube feedings are administered. The schedule of tube feedings, including the correct quantity and frequency, is maintained. The nurse must carefully monitor the drip rate and avoid administering fluids too rapidly.

Feedings are administered by gravity (drip), bolus, or continuous controlled pump (mL/hour or drops/hour). Gravity feedings are placed above the level of the stomach, with the speed of administration determined by gravity. **Bolus** feedings are given in large volumes (300 to 400 mL every 4 to 6 hours). Continuous feeding is the preferred method; delivery of the feeding in small amounts over long periods reduces the incidence of aspiration, distention, nausea, vomiting, and diarrhea. Continuous administration rates of about 100 to 150 mL/hour (2400 to 3600 calories/day) are effective in inducing positive nitrogen balance and progressive weight gain without producing abdominal cramps and diarrhea. If the feeding is intermittent, 200 to 350 mL is given in 10 to 15 minutes. Enteral pumps are mechanical devices that control the delivery rate of feeding formula (Fig. 36-6). Pumps allow for a constant flow rate and can infuse a viscous formula through a small-diameter feeding tube. These pumps are relatively heavy and must be attached to an IV pole. For home use, there are portable lightweight enteral pumps available that weigh about 4 pounds and are easy to handle. An enteral pump is available with an automatic water flush system. In addition to administering the feeding formula, these pumps provide hourly water flushes that are designed to prevent clogged feeding tubes (Petnicki, 1998).

Residual gastric content is measured before each intermittent feeding and every 4 to 8 hours during continuous feedings. (This aspirated fluid is readministered to the patient.) The research findings of McClave et al. (1992) indicated that, if the amount of aspirated gastric content is greater than or equal to 200 mL for NG tubes or if residual volumes are greater than or equal to 100 mL for gastrostomy tubes, tube feeding intolerance should be considered. Tube feedings may be continued with close monitoring of gastric residual volume, radiographic studies, and the patient's physical status. If excessive residual volumes occur twice, the nurse notifies the physician.

Maintaining tube function is an ongoing responsibility of the nurse, patient, or primary caregiver. To ensure patency and to decrease the chance of bacterial growth, crusting, or occlusion of the tube, 20 to 30 mL of water is administered in each of the following instances:

- Before and after each dose of medication and each tube feeding
- After checking for gastric residuals and gastric pH
- Every 4 to 6 hours with continuous feedings
- If the tube feeding is discontinued for any reason

#### PROVIDING MEDICATIONS BY TUBE

When different types of medications are administered, each type is given separately, using a bolus method that is compatible with the medication's preparation (Table 36-4). The tube is flushed with 20 to 30 mL of water after each dose. If a liquid form of a medication is not available and the medication can be crushed, it must first be reduced to a fine powder or the tube will become clogged. Devices are available (eg, Handicrush Irrigation Syringe by Nestle) that crush and dissolve tablets with water (Fig. 36-7). Medications are not mixed with each other or with the feeding formula. When small-bore feeding tubes for continuous infusion are irrigated after medication administration, a 30-mL or larger syringe is used, because the pressure generated by smaller syringes could rupture the tube.

#### MAINTAINING FEEDING REGIMENS AND DELIVERY SYSTEMS

Tube feeding formula is delivered to patients by either an open or a closed system. The open system comes in cans or as a powder and may be mixed with water. The feeding container (which is hung on a pole) and the tubing used with the open system are changed—usually every 24 to 72 hours. To avoid bacterial contamination, the amount of feeding formula in the bag should never exceed what is expected to be infused in 4 hours.

Closed delivery systems use a prefilled, sterile container that is spiked with enteral tubing. The bag holding the feeding formula for the closed system can be hung safely for 24 to 48 hours.

The tube-feeding regimen must be assessed frequently to evaluate its effectiveness and avoid complications (Chart 36-1).

#### MAINTAINING NORMAL BOWEL ELIMINATION PATTERN

Patients receiving NG or nasogastric tube feedings commonly have diarrhea (watery stools occurring three or more times in 24 hours). Pasty, unformed stool is expected with enteral therapy, because many formulas have little or no residue. The dumping syndrome also leads to diarrhea, but to confirm dumping syndrome as the cause of diarrhea other possible causes must be ruled out, among them the following:

**Table 36-3 • Complications of Enteral Therapy**

COMPLICATIONS	CAUSES	SELECTED NURSING INTERVENTIONS
<b>Gastrointestinal</b>		
Diarrhea (most common)	Hyperosmolar feedings Rapid infusion/bolus feedings Bacteria-contaminated feedings Lactase deficiency Medications/antibiotic therapy Decreased serum osmolality level Food allergies Cold formula	Assess fluid balance and electrolyte levels; report findings Assess rate of infusion and temperature of formula Implement changes in tube feeding formula or rate Replace formula every 4 hours; change tube feeding container and tubing daily
Nausea/vomiting	Change in rate Hyperosmolar formula Inadequate gastric emptying	Check residuals; if $\geq 200$ mL for NG or $>100$ mL for gastrostomy, continue feeding and recheck; report if residual is still high Review medications
Gas/bloating/cramping	Air in tube	Keep tubing free of air
Dumping syndrome	Bolus feedings/rapid rate Cold formula	Check fiber and water content; report findings Check rate and temperature of formula
Constipation	High milk (lactose) content Lack of fiber Inadequate fluid intake/dehydration	Check fiber and water content; report findings
<b>Mechanical</b>		
Aspiration pneumonia	Improper tube placement Vomiting and aspirated tube feeding Flat in bed Use of large tube	Implement reliable method for checking small-bore enteral tube placement (ie, measuring length of exposed tube) Keep head of bed elevated 30 degrees continuously
Tube displacement	Excessive coughing/vomitus Tension on the tube or unsecured tube Tracheal suctioning Airway intubation	Check tube placement before administering feeding
Tube obstruction	Inadequate flushing/formula rate	Follow policy for flushing of tube and for crushing medications
Residue	Inadequate crushing of medications and flushing after administration	Obtain liquid medications when possible Flush feeding tube before and after medication administration
Nasopharyngeal irritation	Tube position/improper taping Use of large tubes	Tape tube to prevent pressure on nares Assess nasopharyngeal mucous membranes every 4 hours
<b>Metabolic</b>		
Hyperglycemia	Glucose intolerance High carbohydrate content of the feeding	Check blood glucose levels periodically
Dehydration and azotemia (excessive urea in the blood)	Hyperosmolar feedings with insufficient fluid intake	Report signs and symptoms of dehydration Implement changes in tube feeding formula, rate, or ratio to water
Tube feeding syndrome	Excessive urea from high-protein mixture and formulas lacking fat Dehydration	Implement changes in tube feeding formula, rate, or ratio to water

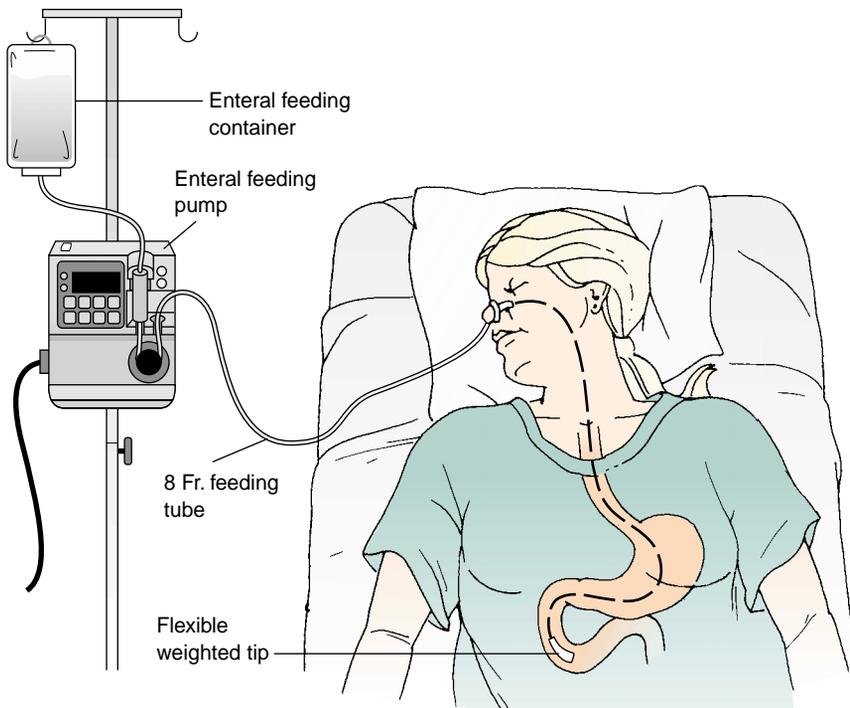

- Zinc deficiency—Adding 15 mg of zinc to the tube feeding every 24 hours is recommended to maintain a normal serum level of 50 to 150  $\mu\text{g/dL}$  (7.65 to 22.95  $\text{fmol/L}$ )
- Contaminated formula
- Malnutrition—A decrease in the intestinal absorptive area resulting from malnutrition can cause diarrhea
- Medication therapy—Antibiotics, such as clindamycin (Cleocin) and lincomycin (Lincocin); antiarrhythmics, such as quinidine and propranolol (Inderal); and aminophylline, theophylline, and digitalis have been found to increase the frequency of diarrhea in some patients

The dumping syndrome results from rapid distention of the jejunum when hypertonic solutions are administered quickly

(over 10 to 20 minutes). Foods high in carbohydrates and electrolytes draw extracellular fluid from the vascular system into the jejunum so that dilution and absorption can occur. Measures for managing the GI symptoms (diarrhea, nausea) associated with the dumping syndrome are presented in Chart 36-2.

#### REDUCING THE RISK OF ASPIRATION

Aspiration pneumonia occurs when stomach contents or enteral feedings are regurgitated and aspirated, or when an NG tube is improperly positioned and feedings are instilled into the pharynx or the trachea. Nasoenteric tubes, especially those that provide for gastric and esophageal or duodenal decompression, have helped decrease the frequency of regurgitation and aspiration.

**FIGURE 36-6** Nasoenteric tube feeding by continuous controlled pump.

To prevent aspiration, the nurse must establish the correct tube feeding placement before every feeding, each time medications are administered, and once every shift if the tube feeding is continuous. Feedings and medications should always be given with the patient in the proper position to prevent regurgitation. To reduce the risk of reflux and pulmonary aspiration, the semi-Fowler's position is necessary for an NG feeding, with the patient's head elevated at least 30 to 45 degrees. This position is maintained at least 1 hour after completion of an intermittent tube feeding and is maintained at all times for patients receiving continuous tube feedings. Another prevention strategy is to monitor residual volumes (Edwards & Metheny, 2000).

If aspiration is suspected, the feeding is stopped immediately, the pharynx and trachea are suctioned, and the patient is placed on the right side with the head of the bed down. The physician is notified immediately.

#### MAINTAINING ADEQUATE HYDRATION

The nurse carefully monitors hydration because, in many cases, the patient cannot communicate the need for water. Water (at least 2 L/day) is given every 4 to 6 hours and after feedings to prevent hypertonic dehydration. At the beginning of administration, the feeding is diluted to at least half-strength and not more than 50 to 100 mL is given at a time, or 40 to 60 mL/hour is given in continuous drip administration. This gradual administration helps the patient to develop tolerance, especially for hyperosmolar solutions. Key nursing interventions include observing for signs of dehydration (dry mucous membranes, thirst, decreased urine output); administering water routinely and as needed; and monitoring intake, output, and fluid balance (24-hour intake versus output).

**Table 36-4 • Preparing Medication for Delivery by Feeding Tube**

MEDICATION FORM	PREPARATION
Liquid	None
Simple compressed tablets	Crush and dissolve in water
Buccal or sublingual tablets	Administer as prescribed
Soft gelatin capsules filled with liquid	Make an opening in capsule and squeeze out contents
Enteric-coated tablets	Do not crush; change in form is required
Timed-release tablets	Do not crush tablets because doing so may release too much drug too quickly (overdose); check with pharmacist for alternative formulation
Timed-release capsules or sustained-release capsules	Some can be opened and contents added to tube-feeding formula; <i>always</i> check with pharmacist before doing this

Chart  
36-2

## Preventing Symptoms of Dumping Syndrome

The following strategies may help prevent some of the uncomfortable symptoms of dumping syndrome related to tube feeding:

- Slow the formula instillation rate to provide time for carbohydrates and electrolytes to be diluted.
- Administer feedings at room temperature, because temperature extremes stimulate peristalsis.
- Administer feeding by continuous drip (if tolerated) rather than by bolus, to prevent sudden distention of the intestine.
- Advise the patient to remain in semi-Fowler's position for 1 hour after the feeding; this position prolongs intestinal transit time by decreasing the effect of gravity.
- Instill the minimal amount of water needed to flush the tubing before and after a feeding, because fluid given with a feeding increases intestinal transit time.

**FIGURE 36-7** The Pill Crusher™ Syringe (from Welcon, Inc.) crushes medications to a fine powder and then allows them to be administered to persons with feeding tubes. The Pill Crusher™ is also used to irrigate the feeding tube and assists in hydrating the patient. Courtesy of Welcon, Inc., Fort Worth, TX (www.welcon.com).

### PROMOTING COPING ABILITY

The psychosocial goal of nursing care is to support and encourage the patient to accept physical changes and to convey hope that daily progressive improvement is possible. If the patient is having difficulty adjusting to the treatment, the nurse intervenes

by encouraging self-care (eg, recording daily weight and intake and output), within the parameters of the patient's activity level. In addition, the nurse reinforces an optimistic approach by identifying signs and symptoms that indicate progress (daily weight gain, electrolyte balance, absence of nausea and diarrhea).

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

Patients who require long-term tube feedings in the home care setting have conditions such as obstruction of the upper GI tract, malabsorption syndrome, surgery of the GI tract or of the head or neck region, or decreased level of consciousness. For a patient to be considered for tube feeding at home, the following criteria must be met: The patient must be medically stable and must have successfully completed a tube feeding trial (tolerated 70% of feeding). In addition, the patient must be capable of self-care or have a caregiver who is willing to assume the responsibility, and the patient or caregiver must have access to supplies and interest in learning how to administer tube feedings at home.

Preparation of the patient for home administration of enteral feedings begins while the patient is still hospitalized. Ideally, the nurse teaches while administering the feedings so that the patient can observe the mechanics of the procedure, participate in the procedure, ask questions, and express any concerns. Before discharge, the nurse provides information about the equipment needed, formula purchase and storage, and administration of the feedings (frequency, quantity, rate of instillation).

Family members who will be active in the patient's home care are encouraged to participate in all teaching sessions. Available printed information about the equipment, the formula, and the procedure is reviewed. The nurse encourages the patient and caregiver to learn to use the equipment with the supervision of the nurse. Arrangements are made for the caregiver to obtain the equipment and formula and have it ready for use before the patient's discharge.

#### Continuing Care

Referral to a home care agency is important so that a nurse can arrange to be present to supervise and provide support during the first feeding at home. Further visits will depend on the skill and comfort of the patient or caregiver in administering the feedings.

### Chart 36-1 • ASSESSMENT

#### Measures for Assessing Tube Feeding Regimens

The following nursing measures may be implemented when assessing the effectiveness and safety of tube feeding:

1. Assess tube placement, patient's position (head of bed elevated 30 to 45 degrees), and formula flow rate.
2. Determine the patient's ability to tolerate the formula. Observe for fullness, bloating, distention, urticaria, nausea, vomiting, and stool pattern and character.
3. Check clinical responses, as noted in laboratory findings (blood urea nitrogen, serum protein, prealbumin, electrolytes, renal function, hemoglobin, hematocrit).
4. Observe for signs of dehydration (dry mucous membranes, thirst, decreased urine output).
5. Record the amount of formula actually taken in by the patient.
6. Report an elevated blood glucose level, decreased urinary output, sudden weight gain, and periorbital or dependent edema.
7. Replace any formula administered by an open system every 4 hours with fresh formula. Formula should be at room temperature or cool (not cold).
8. Change tube feeding container and tubing every 24 to 72 hours.
9. Assess residual volume before each feeding or, in the case of continuous feedings, every 4 hours. Return the aspirate to the stomach.
10. Monitor intake and output.
11. Weigh the patient twice weekly.
12. Consult the dietitian regularly.

During all visits, the nurse monitors the patient's physical status (weight, vital signs, activity level) and the ability of the patient and family to administer the tube feedings correctly. In addition, the nurse assesses for any complications (dumping syndrome, nausea or vomiting, weight loss, lethargy, confusion, excessive thirst). The patient or caregiver is encouraged to keep a diary to record times and amounts of feedings and any symptoms that occur. The nurse reviews the diary with the patient and caregiver during home visits.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

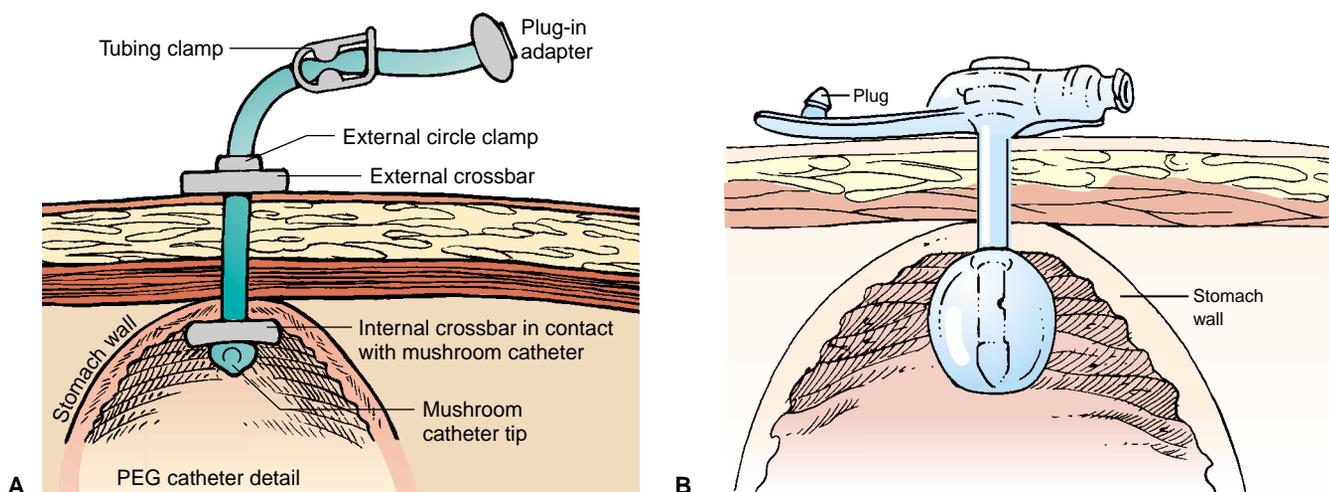

1. Attains or maintains nutritional balance
  - a. Has a positive nitrogen balance
  - b. Maintains laboratory values within normal limits (ie, blood urea nitrogen, hemoglobin, hematocrit, prealbumin, serum protein)
  - c. Attains or maintains hydration of body tissue
  - d. Attains or maintains desired body weight
2. Is free of episodes of diarrhea
  - a. Has fewer than three watery stools a day
  - b. Does not have a bowel movement after a bolus feeding
  - c. States that there is no intestinal cramping
  - d. Has normal bowel sounds
3. Avoids aspiration
  - a. Lungs are clear to auscultation
  - b. Exhibits normal heart rate and respirations
4. Attains or maintains hydration of body tissue
  - a. Has a balanced intake and output every 24 hours
  - b. Does not have dry skin or dry mucous membranes
5. Copes effectively with tube feeding regimen
6. Demonstrates skill in managing tube feeding regimen
7. Experiences no complications
  - a. Has no GI disturbances
  - b. Tube remains intact and patent for duration of therapy
  - c. Maintains metabolic balance within normal limits

## Gastrostomy

A **gastrostomy** is a surgical procedure in which an opening is created into the stomach for the purpose of administering foods and fluids. In some instances, a gastrostomy is preferred for prolonged nutrition (greater than 3 to 4 weeks)—for example, in the elderly or debilitated patient. Gastrostomy is also preferred over NG feedings in the comatose patient because the gastroesophageal sphincter remains intact. Regurgitation and aspiration are less likely to occur with a gastrostomy than with NG feedings.

Different types of feeding gastrostomies may be used, including the Stamm (temporary and permanent), Janeway (permanent), and percutaneous endoscopic gastrostomy (temporary) systems. The Stamm and Janeway gastrostomies require either an upper abdominal midline incision or a left upper quadrant transverse incision. The Stamm procedure requires the use of concentric purse-string sutures to secure the tube to the anterior gastric wall. To create the gastrostomy, an exit wound is created in the left upper abdomen. The Janeway procedure necessitates the creation of a tunnel (called a gastric tube) that is brought out through the abdomen to form a permanent **stoma**.

A **percutaneous endoscopic gastrostomy (PEG)** is a procedure that requires the services of two physicians (or a physician and a nurse with specialty skills). After administering a local anesthetic, one physician inserts a cannula into the stomach through an abdominal incision and then threads a nonabsorbable suture through the cannula; the second physician looks through an endoscope that has been passed into the upper GI tract and uses the endoscopic snare to grasp the end of the suture and guide it up through the patient's mouth. The suture is knotted to the dilator tip at the end of the PEG tube. The endoscopist then advances the dilator tip through the patient's mouth while the first physician pulls the suture through the cannula site. The attached PEG tube is guided down the esophagus, into the stomach, and out through the abdominal incision (Fig. 36-8A). The mushroom catheter tip and internal crossbar secure the tube against the stomach wall. An external crossbar or bumper keeps the catheter

**FIGURE 36-8** (A) A detail of the abdomen and the PEG tube, showing catheter fixation. (B) A detail of the abdomen and the nonobturated LPGD, showing balloon fixation.

in place. A tubing adaptor is in place between feedings, and a clamp or plug is used to close or open the tubing. If an endoscope is unable to pass through the esophagus, then the gastrostomy can be performed under x-ray guidance through the abdominal wall. This procedure is known as fluoroscopically guided percutaneous gastrostomy, or FPG (Johnson, 1997).

The initial PEG device can be removed and replaced once the tract is well established (10 to 14 days after insertion). Replacement of the PEG device is indicated to provide long-term nutritional support, to replace a clotted or migrated tube, or to enhance patient comfort. The PEG replacement device should be fitted securely to the stoma to prevent leakage of gastric acid and is maintained in place through traction between the internal and anchoring devices.

An alternative to the PEG device is a **low-profile gastrostomy device (LPGD)** (see Fig. 36-8B). The LPGD may be inserted 3 to 6 months after initial gastrostomy tube placement. These devices are inserted flush with the skin; they eliminate the possibility of tube migration and obstruction and have antireflux valves to prevent gastric reflux. Two types of devices may be used—obtured or nonobtured. The obtured devices (G-button) have a dome tip that acts as an internal stabilizer. A major drawback is the need for a physician to obturate (insert a tube that is larger than the actual stoma). The nonobtured device (MIC-KEY) has an external skin disk and is inserted into the stoma without force; a balloon is inflated to secure placement. A nurse in the home setting can insert these devices easily. The drawbacks of both types of LPGDs are the inability to check residual volumes (one-way valve) and the need for a special adaptor to connect the device to the feeding container.

Patients with severe gastroesophageal reflux are at risk for aspiration pneumonia and therefore are not candidates for a gastrostomy. A jejunostomy is preferred, or jejunal feeding through a nasojejunal tube may be recommended.

## NURSING PROCESS: THE PATIENT WITH A GASTROSTOMY

### Assessment

The focus of the preoperative assessment is to determine the patient's ability both to understand and to cope with the impending surgical experience. The nurse evaluates the patient's ability to adjust to a change in body image and to participate in self-care, along with the patient's and the family's psychological status.

The purpose of the operative procedure is explained so that the patient will have a better understanding of the expected postoperative course. The patient needs to know that the result of this surgery is to bypass the mouth and esophagus so that liquid feedings can be administered directly into the stomach by means of a rubber or plastic tube or a prosthesis. If the prosthesis is to be permanent, the patient should be made aware of this. Psychologically, this is often difficult for the patient to accept. If the procedure is being performed to relieve discomfort, prolonged vomiting, debilitation, or an inability to eat, the patient may find it more acceptable.

The nurse evaluates the patient's skin condition and determines whether a delay in healing may be anticipated because of a systemic disorder (eg, diabetes mellitus, cancer).

In the postoperative period, the patient's fluid and nutritional needs are assessed to ensure proper intake of food and fluids. The nurse inspects the tube for proper maintenance and the incision for signs of infection. At the same time, the nurse evaluates the

patient's response to the change in body image and the patient's understanding of the feeding methods. Interventions are identified to help the patient cope with the tube and learn self-care measures.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the major nursing diagnoses in the postoperative period may include the following:

- Imbalanced nutrition, less than body requirements, related to enteral feeding problems
- Risk for infection related to presence of wound and tube
- Risk for impaired skin integrity at tube site
- Ineffective coping related to inability to eat normally
- Disturbed body image related to presence of tube
- Risk for ineffective therapeutic regimen management related to knowledge deficit about home care and the feeding procedure

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Potential complications that may develop include the following:

- Wound infection, cellulitis, and abdominal wall abscess
- GI bleeding
- Premature removal of the tube

## Planning and Goals

The major goals for the patient may include attaining an optimal level of nutrition, preventing infection, maintaining skin integrity, enhancing coping, adjusting to changes in body image, acquiring knowledge of and skill in self-care, and preventing complications.

## Nursing Interventions

### MEETING NUTRITIONAL NEEDS

The first fluid nourishment is administered soon after surgery and usually consists of tap water and 10% glucose. At first, only 30 to 60 mL (1 to 2 oz) is given at one time, but the amount is increased gradually. By the second day, 180 to 240 mL (6 to 8 oz) may be given at one time, provided it is tolerated and no leakage of fluid occurs around the tube. Water and milk can be instilled after 24 hours for a permanent gastrostomy. High-calorie liquids are added gradually. In some settings, during the early postoperative period the nurse aspirates gastric secretions and reinstills them after adding enough feeding solution to bring the volume to the desired total. By this method, gastric dilation is avoided.

Blenderized foods are added gradually to clear liquids until a full diet is achieved. Powdered feedings that are easily liquefied are commercially available. The patient who receives blenderized tube feedings typically is not forced to give up usual dietary patterns, which may prove to be psychologically more acceptable. In addition, near-normal bowel function is promoted because the fiber and residue are similar to that of a normal diet. Intake of milk is avoided in patients with lactase deficiency.

### PROVIDING TUBE CARE AND PREVENTING INFECTION

A small dressing can be applied over the tube outlet, and the gastrostomy tube can be held in place by a thin strip of adhesive tape that is first placed around the tube and then firmly attached to

the abdomen. The dressing protects the skin around the incision from seepage of gastric acid and spillage of feedings.

The nurse verifies the tube's placement, assesses residuals, and rotates the tube or stabilizing disk once daily to prevent skin breakdown. Some gastrostomy tubes have balloons that are inflated with water to anchor the tube in the stomach. The adequacy of balloon inflation is checked weekly by deflating the balloon using a Luer-tip syringe.

### PROVIDING SKIN CARE

The skin surrounding a gastrostomy requires special care because it may become irritated from the enzymatic action of gastric juices that leak around the tube. Left untreated, the skin becomes macerated, red, raw, and painful. The nurse washes the area around the tube with soap and water daily, removes any encrustation with saline solution, rinses the area well with water, and pats it dry. Once the stoma heals and drainage ceases, a dressing is not required. A long-term gastrostomy may require a special dressing or stabilization device to protect the skin around the tube from gastric secretions and to help secure the tube in place (Fig. 36-9).

Skin at the exit site is evaluated daily for signs of breakdown, irritation, excoriation, and the presence of drainage or gastric leakage. The nurse encourages the patient and family members to participate in this inspection and in hygiene activities. If skin problems do occur, an enterostomal therapist or wound care specialist can be of assistance.

### ENHANCING BODY IMAGE

The patient with a gastrostomy has experienced a major assault to body image. Eating, a physiologic and social function, can no longer be taken for granted. The patient is also aware that gastrostomy as a therapeutic intervention is performed only in the presence of a major, chronic, or perhaps terminal illness.

Calm discussion of the purposes and routines of gastrostomy feeding can help keep the patient from feeling overwhelmed. Talking with a person who has had a gastrostomy can also help the patient to accept the expected changes. Adjusting to a change in body image takes time and requires family support and acceptance. Evaluating the existing family support system is necessary. One family member may emerge as the primary support person.

**FIGURE 36-9** Protection at the gastrostomy site. A PEG tube may be protected by a dressing that allows access to the tube but covers the exit site. Typically the tube is stabilized with tape over the dressing. From Craven, R., & Hirnle, C. (2002). *Fundamentals of nursing: Human health and function* (4th ed.). Philadelphia: Lippincott Williams & Wilkins.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

During the postoperative course, the nurse monitors the patient for potential complications. The most common complications are wound infection and other wound problems, including cellulitis at the wound site and abscesses in the abdominal wall. Because many patients who receive tube feedings are debilitated and have compromised nutritional status, any signs of infections are promptly reported to the physician so that appropriate antibiotic therapy can be instituted.

Bleeding from the insertion site in the stomach may also occur. The nurse closely monitors the patient's vital signs and observes all drainage from the operative site, vomitus, and stool for evidence of bleeding. Any signs of bleeding are reported promptly.

Premature removal of the tube, whether it is done inadvertently by the patient or by the caregiver, is another complication. If the tube is removed prematurely, the skin is cleansed and a sterile dressing is applied; the nurse immediately notifies the physician. The tract will close within 4 to 6 hours if the tube is not replaced promptly.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

The patient who is to receive gastrostomy tube feedings in the home setting must be capable of, and responsible for, administering the tube feedings or have a caregiver who is able to do so. There must also be the physical, financial, and social resources to maintain care.

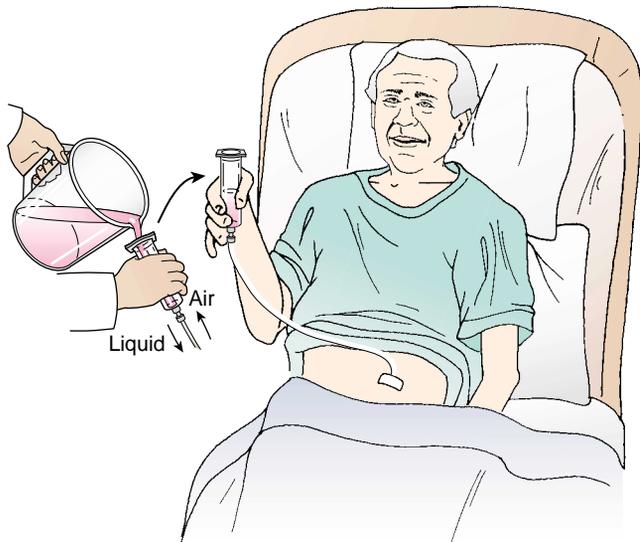

The nurse assesses the patient's level of knowledge, interest in learning about the tube feeding, and ability to understand and apply the information before providing detailed instructions about how to prepare the formula and manage the tube feeding. Written materials for patients and caregivers are designed to outline the care instructions. To facilitate self-care, the nurse encourages the patient to participate in the tube feedings during hospitalization and to establish as normal a routine as possible.

Demonstration of the tube feeding begins by showing the patient how to check for residual gastric contents before the feeding. The patient then learns how to check and maintain the patency of the tube by administering room-temperature water before and after the feeding. This will establish patency before the feeding and then clear the tube of food particles, which could decompose if allowed to remain in the tube. All feedings are given at room temperature or near body temperature.

For a bolus feeding, the nurse shows the patient how to introduce the liquid into the catheter by using a funnel or the barrel of a syringe. The receptacle is tilted to allow air to escape while the liquid is being instilled initially. As the funnel or syringe fills with liquid, the feeding is allowed to flow into the stomach by gravity by holding the barrel or syringe perpendicular to the abdomen (Fig. 36-10). Raising or lowering the receptacle to no higher than 45 cm (18 in) above the abdominal wall regulates the rate of flow.

A bolus feeding of 300 to 500 mL usually is given for each meal and requires 10 to 15 minutes to complete. The amount is often determined by the patient's reaction. If the patient feels full, it may be desirable to give smaller amounts more frequently.

The patient and caregiver must understand that keeping the head of the bed elevated for at least 1 hour after feeding facilitates digestion and decreases the risk for aspiration. Any obstruction requires that the feeding be stopped and the physician notified.

**FIGURE 36-10** Bolus gastrostomy feeding by gravity. (A) Feeding is instilled at an angle so that air does not enter the stomach. (B) Syringe is raised perpendicular to the abdomen so that feeding can enter by gravity.

The patient or caregiver is instructed to flush the tube with 30 mL of water after each bolus or medication administration, and otherwise to flush the tube daily to keep it patent. Adaptors are available that can be secured to the end of the tube to create a “Y” site for ease of flushing or medication delivery. The flushing equipment is cleaned with warm, soapy water and rinsed after each use.

The patient and caregiver are made aware that the tube is marked at skin level to provide the patient a baseline for later comparison. They are advised to monitor the tube’s length and to notify the physician or home care nurse if the segment of the tube outside the body becomes shorter or longer.

If the patient is to use an intermittent or continuous-pressure feeding pump at home, instruction in the use of the particular type of pump is essential. Most feeding pumps have built-in alarms that signal when the bag is empty, when the battery is low, or when an occlusion is present. The patient and caregiver need to be aware of these alarms and how to troubleshoot the pump.

### Continuing Care

Referral to a home care agency is important to ensure initial supervision and support for the patient and caregiver. The home care nurse assesses the patient’s status and progress and evaluates the techniques that are used in administering the tube feeding. Further instruction and supervision in the home setting may be required to help the patient and caregiver adapt to a physical environment and equipment that are different from the hospital setting. The nurse also reviews with the patient and caregiver information about complications to report (eg, dumping syndrome, nausea and vomiting, infection of the skin at the insertion site of the tube).

The home care nurse assists the patient and family in establishing as normal a routine as possible. Some patients will want to experience a sensation of normal eating and are advised that they can try smelling, tasting, and chewing small amounts of food before taking their tube feedings. This stimulates the flow of salivary and gastric secretions and may give some sensation of a normal meal. The chewed food can then be deposited by the patient into a funnel or syringe attached to the gastrostomy tube for ad-

ministration into the stomach. The patient or caregiver is encouraged to keep a diary to record the times and amounts of feedings and any symptoms that occur. The nurse reviews the diary during home visits. When the tube is to be replaced, the patient or caregiver must be taught how to do this.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Achieves an adequate intake of nutrients
  - a. Tolerates quantity and frequency of tube feedings
  - b. Has 50 mL or less of residual gastric content before each feeding
  - c. Has no diarrhea
  - d. Maintains or gains weight
  - e. Has normal electrolyte values
2. Is free from infection and skin breakdown
  - a. Is afebrile
  - b. Has no drainage from the incision
  - c. Demonstrates intact skin surrounding the exit site
  - d. Inspects exit site twice a day
3. Adjusts to change in body image
  - a. Is able to discuss expected changes
  - b. Verbalizes concerns
  - c. Asks to speak with someone who has experienced this procedure
4. Demonstrates skill in managing feeding regimen
  - a. Helps prepare prescribed formula or blenderized food
  - b. Handles equipment competently
  - c. Helps administer the feeding or does so independently
  - d. Demonstrates how to maintain tube patency
  - e. Cleans tubing as needed
  - f. Keeps an accurate record of intake
  - g. Can remove and reinsert the tube as appropriate and needed for feedings
5. Avoids complications
  - a. Exhibits adequate wound healing
  - b. Has no abnormal bleeding from puncture site
  - c. Tube remains intact for the duration of therapy

## Parenteral Nutrition

**Parenteral nutrition (PN)** is a method of providing nutrients to the body by an IV route. It is a very complex admixture of individual chemicals combined in a single container. The components of a PN admixture are proteins, carbohydrates, fats, electrolytes, vitamins, trace minerals, and sterile water. The goals of PN are to improve nutritional status, establish a positive nitrogen balance, maintain muscle mass, promote weight gain, and enhance the healing process.

### ESTABLISHING POSITIVE NITROGEN BALANCE

When a patient’s intake of protein and nutrients is significantly less than that required by the body to meet energy expenditures, a state of negative nitrogen balance results. In response, the body begins to convert the protein found in muscles into carbohydrates to be used to meet energy needs. The result is muscle wasting, weight loss, fatigue, and, if left uncorrected, death.

The average postoperative adult patient requires approximately 1500 calories per day to keep the body from using its own store of

protein. Traditional IV fluids do not provide sufficient calories or nitrogen to meet the body's daily requirements. PN solutions, which supply nutrients such as dextrose, amino acids, electrolytes, vitamins, minerals, and fat emulsions, provide enough calories and nitrogen to meet the patient's daily nutritional needs. In general, PN can provide 30 to 35 kcal/kg of body weight and 1.0 to 1.5 g of protein/kg of body weight (Rombeau & Rolandelli, 2000).

The patient with fever, trauma, burns, major surgery, or hypermetabolic disease may require up to 10,000 additional calories daily. The volume of fluid necessary to provide these calories would surpass fluid tolerance and lead to pulmonary edema or heart failure. To provide the required calories in small volume, it is necessary to increase the concentration of nutrients and use a route of administration (ie, a large, high-flow vein [subclavian vein]) that will rapidly dilute incoming nutrients to the proper levels of body tolerance.

When highly concentrated glucose is administered, caloric requirements are satisfied and the body uses amino acids for protein synthesis rather than for energy. Additional potassium is added to the solution to maintain proper electrolyte balance and to transport glucose and amino acids across cell membranes. To prevent deficiencies and fulfill requirements for tissue synthesis, other elements, such as calcium, phosphorus, magnesium, and sodium chloride, are added (Rombeau & Rolandelli, 2000).

## CLINICAL INDICATIONS

The indications for PN include a 10% deficit in body weight (compared with preillness weight), an inability to take oral food or fluids within 7 days after surgery, and hypercatabolic situations such as major infection with fever. In both the home and hospital setting, PN is indicated in the following situations:

- The patient's intake is insufficient to maintain an anabolic state (eg, severe burns, malnutrition, short bowel syndrome, AIDS, sepsis, cancer).
- The patient's ability to ingest food orally or by tube is impaired (eg, paralytic ileus, Crohn's disease with obstruction, postradiation enteritis, severe hyperemesis gravidarum in pregnancy).
- The patient is not interested in or is unwilling to ingest adequate nutrients (eg, anorexia nervosa, postoperative elderly patients).
- The underlying medical condition precludes being fed orally or by tube (eg, acute pancreatitis, high enterocutaneous fistula).
- Preoperative and postoperative nutritional needs are prolonged (eg, extensive bowel surgery).

## FORMULAS

A total of 2 to 3 L of solution is administered over a 24-hour period using a filter (1.2-micron particulate filter). Before administration, the PN infusion must be inspected for clarity and any precipitate. The label is compared with the physician's order, noting the expiration date. Fat emulsions (Intralipid) may be infused simultaneously with PN through a Y-connector close to the infusion site. Fat emulsions should not be filtered. Before administration, the fat emulsion solution is inspected for frothiness, separation, or oily appearance. Usually 500 mL of a 10% emulsion is administered over 4 to 6 hours, one to three times a week. Fat emulsions can provide up to 30% of the total daily calorie intake.

Lipid emulsions can be admixed with other components of PN to create a **total nutrient admixture** (TNA). TNA is commonly called a "three-in-one" formulation. All the parenteral nutrient components are mixed in one container and administered to the patient over a 24-hour period. A special final filter (1.5 micron filter) is used with this solution. Before administration, the solution is observed for oil droplets that have separated from the solution, forming a noticeable layer (cracking of lipid emulsion); such a solution should be discarded. Advantages of the TNA over PN are cost savings in preparation and equipment, decreased risk of contamination, decreased risk of catheter contamination, decreased pharmacy preparation time, less nursing time, and increased patient convenience and satisfaction. Ideally, the pharmacist, nutritionist, and physician collaborate to determine the specific formula needed.

## INITIATING THERAPY

PN solutions are initiated slowly and advanced gradually each day to the desired rate, as the patient's fluid and glucose tolerance permits. The patient's laboratory test results and response to PN therapy are monitored on an ongoing basis by the nutritional support team. Standing orders are initiated for weighing the patient; monitoring intake, output, and blood glucose; and baseline and periodic monitoring of complete blood count, platelet count, and chemistry panel, including serum carbon dioxide, magnesium, phosphorus, triglycerides, and prealbumin. A 24-hour urine nitrogen determination may be performed for analysis of nitrogen balance. In most hospitals, the physician prescribes PN solutions on a daily standard PN order form. The formulation of the PN solutions is calculated carefully each day to meet the complete nutritional needs of the individual patient.

## ADMINISTRATION METHODS

Various vascular access devices are used to administer PN solutions in clinical practice. PN may be administered by either peripheral or central IV lines, depending on the patient's condition and the anticipated length of therapy.

### Peripheral Method

To supplement oral intake when complete bowel rest is not indicated and NG or nasogastric suction is not required, a peripheral parenteral nutrition (PPN) formula may be prescribed. PPN is administered through a peripheral vein; this is possible because the solution is less hypertonic than PN solution. PPN formulas are not nutritionally complete. Protein and dextrose are limited. Dextrose concentrations of more than 10% should not be administered through peripheral veins because they irritate the intima (innermost walls) of small veins, causing chemical phlebitis. Lipids are administered simultaneously to buffer the PPN and to protect the peripheral vein from irritation. The usual length of therapy using PPN is 5 to 7 days (Hamilton, 2000).

### Central Method

Because PN solutions have five or six times the solute concentration of blood (and exert an osmotic pressure of about 2000 mOsm/L), they are injurious to the intima of peripheral veins. Therefore, to prevent phlebitis and other venous complications, these solutions are administered into the vascular system through a catheter inserted into a high-flow, large blood vessel (the

subclavian vein). Concentrated solutions are then very rapidly diluted to isotonic levels by the blood in this vessel.

Four types of **central venous access devices (CVAD)** are available—nontunneled (or percutaneous) central catheters, peripherally inserted central catheters, tunneled catheters, and implanted ports. Whenever one of these catheters is inserted, catheter tip placement should be confirmed by x-ray studies before PN therapy is initiated. The optimal position is the midproximal third of the superior vena cava.

### NONTUNNELED CENTRAL CATHETERS

Nontunneled central catheters are used for short-term (less than 30 days) IV therapy in the acute care, long-term care, and home care settings. The physician inserts these catheters. Examples of nontunneled central catheters are Vas Cath, Percutaneous Subclavian, and Hohn catheters. The subclavian vein is the most common vessel used, because the subclavian area provides a stable insertion site to which the catheter can be anchored, allows the patient freedom of movement, and provides easy access to the dressing site. The jugular or femoral vein also may be used. Single-, double-, and triple-lumen central catheters are available for central lines. To ensure accessibility, a triple-lumen subclavian catheter should be used, because it offers three ports for various uses (Fig. 36-11). The 16-gauge distal lumen can be used to infuse blood or other viscous fluids. The 18-gauge middle lumen is reserved for PN infusion. The 18-gauge proximal port can be used for administration of blood or medications. A port not being used for fluid administration can be used for obtaining blood specimens if indicated.

If a single-lumen central catheter is used for administering PN, various restrictions apply. Blood cannot be drawn from the catheter and medications cannot be administered through it, because the medication may be incompatible with the components of the nutritional solution (insulin is an exception). If medications must be given, they must be infused through a separate peripheral IV line,

not by piggyback into the PN line. Transfusions of blood products also cannot be given through the main line, because red cells may possibly coat the lumen of the catheter, thereby reducing the flow of the nutritional solution.

### PERIPHERALLY INSERTED CENTRAL CATHETERS

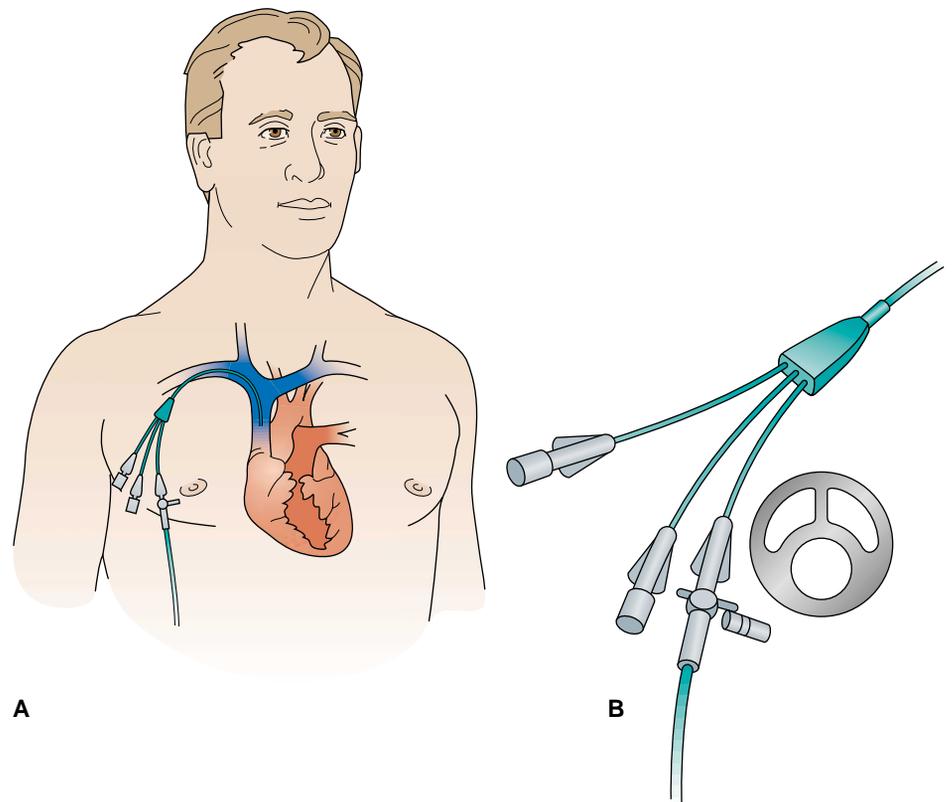

**Peripherally inserted central catheters (PICC)** are used for intermediate-term (3 to 12 months) IV therapy in the hospital, long-term care, or home setting. These catheters may be inserted at the bedside or in the outpatient setting by a specially trained nurse. The basilic or cephalic vein is accessed through the antecubital space, and the catheter is threaded to a designated location, depending on the type of solution to be infused (superior vena cava for PN). Taking of blood pressure and blood specimens from the extremity with the PICC is avoided (see Chapter 14).

### TUNNELED CENTRAL CATHETERS

Tunneled central catheters are for long-term use and may remain in place for many years. These catheters are cuffed and can have single or double lumens; examples are the Hickman, Goshong, and Permacath. These catheters are inserted surgically. They are threaded under the skin (reducing the risk of ascending infection) to the subclavian vein, and the distal end of the catheter is advanced into the superior vena cava 2 to 3 cm above the junction with the right atrium (see Chapter 16).

### IMPLANTED PORTS

Implanted ports are also used for long-term home IV therapy; examples include the Port-A-Cath, Mediport, Hickman Port, and P.A.S. Port. Instead of exiting from the skin, as do the Hickman and Goshong catheters, the end of the catheter is attached to a small chamber that is placed in a subcutaneous pocket, either on the anterior chest wall or on the forearm. The subcutaneous port requires minimal care and allows the patient complete freedom

**FIGURE 36-11** Subclavian triple-lumen catheter used for parenteral nutrition and other adjunctive therapy. **(A)** The catheter is threaded through the subclavian vein into the vena cava. **(B)** Each lumen is an avenue for solution administration. The lumens are secured with threaded needleless adapters or Luer-lock caps when the device is not in use.

of activity. Implanted ports are more expensive than the external catheters, and access requires passing a special needle (Huber-tipped) through the skin into the chamber to initiate IV therapy (see Chapter 16). Taking of blood pressure and blood specimens from the extremity with the port system is avoided.

### NONTUNNELED CENTRAL CATHETER INSERTION

The procedure is explained so that the patient understands the importance of not touching the catheter insertion site and is aware of what to expect during the insertion procedure. To insert the catheter, the patient is placed supine, in head-low position (to produce dilation of neck and shoulder vessels, which makes entry easier and prevents air embolus). The area is shaved if necessary, and the skin is prepared with acetone and alcohol to remove surface oils. Final skin preparation includes cleaning with tincture of 2% iodine or chlorhexidine. To afford maximal accuracy in the placement of the catheter, the patient is instructed to turn the head away from the site of venipuncture and to remain motionless while the catheter is inserted and the wound is dressed.

The preferred insertion route is the subclavian vein, which leads into the superior vena cava. The external jugular route can be used, but usually only in emergency situations. Because a nontunneled central catheter is always a potential source of serious infection, the site should be changed every 4 weeks or as recommended by the Centers for Disease Control and Prevention.

Sterile drapes are applied to the upper chest. The patient may be asked to wear a facemask to prevent the spread of microorganisms. Procaine or lidocaine is injected to anesthetize the skin and underlying tissues. The target area is the inferior border at the midpoint of the clavicle. A large-bore needle on a syringe is inserted and moved parallel to and beneath the clavicle until it enters the vein. The syringe is then detached and a radiopaque catheter is inserted through the needle into the vein.

When the catheter is positioned, the needle is withdrawn and the hub of the catheter is attached to the IV tubing. Until the syringe is detached from the needle and the catheter is inserted, the patient may be asked to perform the Valsalva maneuver. (To do this, the patient is instructed to take a deep breath, hold it, and bear down with mouth closed. Compression of the abdomen may also accomplish the maneuver.) The Valsalva maneuver is performed to produce a positive phase in central venous pressure, to lessen the possibility of air being drawn into the circulatory system (air embolism). The physician sutures the catheter to the skin to avoid inadvertent removal.

The catheter insertion site is swabbed with either tincture of 2% iodine or a chlorhexidine solution. A gauze or transparent dressing is applied using strict sterile technique. An isotonic IV solution, such as dextrose 5% in water (D<sub>5</sub>W), is administered to keep the vein patent.

The position of the tip of the catheter is checked with fluoroscopy to confirm its location in the superior vena cava and to rule out a pneumothorax resulting from puncture of the pleura. Once the catheter position is confirmed, the prescribed PN solution is started. The initial rate of infusion is usually 50 mL/hour, and the rate is gradually increased to the maintenance rate or predetermined dose (eg, 100 to 125 mL/hour). An infusion pump is always used for administration of PN or PPN.

An injection site cap is attached to the end of each central catheter lumen, creating a closed system. IV infusion tubing is connected to the insertion site cap of the central catheter with a threaded needleless adapter or Luer-lock device. Each lumen is labeled according to location (proximal, middle, distal). To ensure patency, all lumens are flushed with a diluted heparin flush ini-

tially, daily when not in use, after each intermittent infusion, after blood drawing, and whenever an infusion is disconnected. Force is never used to flush the catheter. If resistance is met, aspiration may be effective in cleansing the lumen; if this is not effective, the physician is notified. Low-dose t-PA (alteplase) may be prescribed to dissolve a clot or fibrin sheath. If attempts to clear the lumen are ineffective, the lumen is labeled as “clotted off.”

### DISCONTINUING PARENTERAL NUTRITION

The PN solution is discontinued gradually to allow the patient to adjust to decreased levels of glucose. After administration of the PN solution is terminated, isotonic glucose is administered for several hours to protect against rebound hypoglycemia. Providing oral carbohydrates will shorten the tapering time. Specific symptoms of rebound hypoglycemia include weakness, faintness, sweating, shakiness, feeling cold, confusion, and increased heart rate. Once all IV therapy is completed, the nurse (with a physician's order) removes the nontunneled central venous catheter or PICC and applies an occlusive dressing to the exit site. Tunneled catheters and implanted ports are removed by the physician.

In cases of serious illness when death is imminent, some patients or families may request that PN be discontinued. This difficult issue poses many ethical questions, some of which are discussed in Chart 36-3.

### NURSING PROCESS: THE PATIENT RECEIVING PARENTERAL NUTRITION

#### Assessment

The nurse assists in identifying patients who may be candidates for PN. Indicators include any significant weight loss (10% or more of usual weight), a decrease in oral food intake for more than 1 week, any significant sign of protein loss (serum albumin levels less than 3.2 g/dL [32 g/L], muscle wasting, decreased tissue healing, or abnormal urea nitrogen excretion), and persistent vomiting and diarrhea. The nurse carefully monitors the patient's hydration, electrolyte levels, and calorie intake.

#### Diagnosis

#### NURSING DIAGNOSES

Based on the assessment data, the major nursing diagnoses may include the following:

- Imbalanced nutrition, less than body requirements, related to inadequate oral intake of nutrients
- Risk for infection related to contamination of the central catheter site or infusion line
- Risk for excess or deficient fluid volume related to altered infusion rate
- Risk for immobility related to fear that the catheter will become dislodged or occluded
- Risk for ineffective therapeutic regimen management related to knowledge deficit about home PN therapy

#### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

The most common complications are pneumothorax, air embolism, a clotted or displaced catheter, sepsis, hyperglycemia, rebound hypoglycemia, and fluid overload. These problems

### Chart 36-3 • Ethics and Related Issues

#### Is It Ethical to Withhold or Withdraw Nutrition and Hydration?

##### Situation

It is generally agreed that patients (or their designated decision makers) can refuse life-saving treatment, particularly if the means of treatment are extraordinary (eg, ventilators, dialysis machines, extracorporeal oxygenators). Extraordinary means include medications, treatments, and procedures that can be obtained only at excessive cost, pain, or inconvenience and offer no reasonable hope of benefit. Nutrition and hydration therapy, however, are perceived as ordinary means by many.

Ordinary means are those medications, treatments, and procedures that offer a reasonable hope of benefit and can be obtained without excessive expense, pain, or inconvenience. Additionally, withdrawing or withholding nutrition and hydration can in and of itself cause death. Thus, some have argued that nutrition and hydration should always be provided to every patient, regardless of the patient's preference or condition.

##### Dilemma

The patient's desire to have nutrition or hydration withdrawn or withheld may conflict with the reluctance of others to harm the patient by withdrawing the food and water needed for survival (autonomy versus nonmaleficence).

##### Discussion

- What arguments would you offer against the withholding and withdrawing of nutrition and hydration?
- What arguments would you offer in favor of withholding and withdrawing of nutrition and hydration?
- Are foods and fluids always "ordinary means," or are there instances in which they might be considered "extraordinary"? Support your answer.

Answer the above questions using as an example a patient in a persistent vegetative state (ie, unable to express his or her wishes).

and the associated collaborative interventions are described in Table 36-5.

## Planning and Goals

The major goals for the patient may include optimal level of nutrition, absence of infection, adequate fluid volume, optimal level of activity (within individual limitations), knowledge of and skill in self-care, and prevention of complications.

## Nursing Interventions

### MAINTAINING OPTIMAL NUTRITION

A continuous, uniform infusion of PN solution over a 24-hour period is desired. In some cases, however (eg, home care patients), cyclic PN may be appropriate. With cyclic PN, there is a set time during a 24-hour period when PN is infused and a set time when it is not. The time periods for infusion are sufficient to meet the patient's nutritional and pharmacologic needs. Ideally, cyclic PN is infused over an 8- to 10-hour period during the night.

The patient is weighed daily (this may be decreased to two or three times per week), at the same time of the day under the same conditions for accurate comparison. Under the PN regimen (without additional energy expenditure), a satisfactory weight

gain is usually achieved. It is important to keep accurate intake and output records and calculations of fluid balance. A calorie count is kept of any oral nutrients. Trace elements (copper, zinc, chromium, manganese, and selenium) are included in PN solutions and are individualized for each patient. The PN solutions are prescribed daily by the physician on a standard PN order form based on laboratory values and patient tolerance.

### PREVENTING INFECTION

The high glucose content of PN solutions makes these solutions ideal culture media for bacterial and fungal growth, and CVADs provide a port of entry. *Candida albicans* is the most common infectious organism. Other infectious organisms include *Staphylococcus aureus*, *Staphylococcus epidermidis*, and *Klebsiella pneumoniae*. Meticulous technique is essential to prevent infection.

The primary sources of microorganisms for catheter-related infections are the skin and the catheter hub. The catheter site is covered with an occlusive gauze dressing that is usually changed every other day. Alternatively, a transparent dressing may be used and changed weekly. The Centers for Disease Control and Prevention recommends changing dressings for CVADs only if they are damp, bloody, loose, or soiled. The dressings are changed using sterile technique. The nurse and patient wear masks during dressing changes to reduce the possibility of airborne contamination. The area is checked for leakage, bloody drainage, a kinked catheter, and skin reactions such as inflammation, redness, swelling, tenderness, or purulent drainage. The nurse puts on sterile gloves and cleanses the area with tincture of 2% iodine or a chlorhexidine solution on a sterile gauze. The site is cleaned thoroughly using circular motion from the site outward approximately 3 inches. This is repeated two times. This is followed with the same cleaning procedure using 2 × 2-inch gauze pads moistened with sterile water or saline solution (alcohol is used to remove iodine). Next the catheter lumens are cleaned from the exit site to the distal end with an alcohol wipe. The insertion site is covered with an occlusive gauze pad or transparent dressing centered over the area.

The advantages of using a transparent dressing over the gauze pad are that it allows frequent examination of the catheter site without changing the dressing, it adheres well, and it is more comfortable for the patient. When an extension set is used with a central catheter, it is considered an extension of the catheter itself. It is not routinely changed with dressing or tubing changes. The connection (hub) between the catheter and extension tubing is secured with adhesive tape to prevent separation and exposure to air. Main-line IV tubing and filters are changed every 72 to 96 hours, and all connections are taped securely to avoid breaks in the integrity of the system. The dressing and tubing are labeled with the date, time of insertion, time of dressing change, and initials of the person who carried out the procedure; this information is also documented in the medical record.

The catheter is another major source of colonization and infection. Antiseptic-impregnated central venous catheters are new devices that reduce catheter colonization by coating of the catheter surfaces with antimicrobial agents. Two types are available, one coated with chlorhexidine/silver sulfadiazine and the other with minocycline/rifampin (Hanna et al., 2001).

### MAINTAINING FLUID BALANCE

An infusion pump is necessary for PN to maintain an accurate rate of administration. A designated rate is set in milliliters per hour, and the rate checked every 30 to 60 minutes. An alarm signals a problem. The infusion rate should not be increased or decreased

Table 36-5 • Complications of Parenteral Nutrition

COMPLICATION	CAUSE	NURSING ACTIONS AND COLLABORATIVE INTERVENTIONS
Pneumothorax	Improper catheter placement and inadvertent puncture of the pleura	Place patient in Fowler's position. Offer reassurance. Monitor vital signs. Prepare for thoracentesis or chest tube insertion.
Air embolism	Disconnected tubing Cap missing from port Blocked segment of vascular system	Tape all tubing connection sites securely. Replace tubing immediately and notify physician. Replace cap and notify physician. Turn patient on left side and place in the head-low position. Notify physician.
Clotted catheter line	Inadequate/infrequent heparin flushes Disruption of infusion	Administer heparin flush in unused lines twice a day. Monitor infusion rate hourly and inspect the integrity of the line. On <i>rare</i> occasions, flush with urokinase as prescribed.
Catheter displacement and contamination	Excessive movement, possibly with a nonsecured catheter Separation of tubing and contamination	Stop the infusion and notify the physician. Tape all tubing connection sites. Avoid interrupting the main line or piggybacking other lines.
Sepsis	Separation of dressings Contaminated solution Infection at insertion site of catheter	Reinforce or change dressing quickly using aseptic technique. Discard. Notify pharmacist. Notify physician. Monitor vital signs every 4 hours. Catheter site is changed every 4 weeks.
Hyperglycemia	Glucose intolerance	Monitor glucose levels (blood and urine). Monitor urine output. Observe for stupor, confusion, lethargy. Notify physician; the addition of insulin to the PN solution may be prescribed.
Fluid overload	Fluid infusing rapidly	Decrease infusion rate, use infusion pump. Monitor vital signs. Notify physician. Treat respiratory distress by sitting patient upright and administering oxygen as needed, if prescribed.
Rebound hypoglycemia	Feedings stopped too abruptly	Monitor for symptoms (weakness, tremors, diaphoresis, headache, hunger, and apprehension); notify physician. Gradually wean patient from PN.

to compensate for fluids that have infused too quickly or too slowly. If the solution runs out, 10% dextrose and water is infused until the next PN solution is available from the pharmacy.

If the rate is too rapid, hyperosmolar diuresis occurs (excess sugar will be excreted), which, if severe enough, can cause intractable seizures, coma, and death. Symptoms of rapid hypertonic fluid intake include headache, nausea, fever, chills, and increasing lethargy.

If the flow rate is too slow, the patient does not get the maximal benefit of calories and nitrogen. Intake and output are recorded every 8 hours so that fluid imbalance can be readily detected. The patient is weighed two or three times a week; in ideal situations, the patient will show neither weight loss nor significant weight gain. The nurse assesses for signs of dehydration (eg, thirst, decreased skin turgor, decreased central venous pressure) and reports these findings to the physician immediately. It is es-

sential to monitor blood glucose levels, because hyperglycemia can cause diuresis and excessive fluid loss.

### ENCOURAGING ACTIVITY

Activities and ambulation are encouraged when the patient is physically capable. With a catheter in the subclavian vein, the patient is free to move the extremities and should be encouraged to maintain good muscle tone. If applicable, the teaching and exercise program initiated in the occupational and physical therapy departments should be reinforced.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

Successful home PN requires teaching the patient and family specialized skills using an intensive training program and follow-up

### Chart 36-4 • PATIENT EDUCATION

#### Teaching Patients About Home Parenteral Nutrition

An effective home care teaching program prepares the patient to manage the appropriate form of PN: how to store solutions, set up the infusion, flush the line with heparin, change the dressings, and troubleshoot for problems. The most common complication is sepsis. Strict aseptic technique is taught for hand hygiene, handling equipment, changing the dressing, and preparing the solution.

#### Troubleshooting Mechanical Difficulties

Mechanical problems usually arise from technical complications in the infusion pump or catheter site. The patient needs to know how to measure the length of the external portion of the catheter; this measurement is used as a comparison if the line is pulled or if dislodgement is suspected. The patient also needs to know how to recognize catheter problems (eg, leakage, loose cap, blood clot, dislodgement) and should receive a list of instructions explaining what to do for each problem.

#### Recognizing Metabolic Complications

The patient is given a list of symptoms that indicate metabolic complications (neuropathies, mentation changes, diarrhea, nausea, skin

changes, decreased urine output) and directions on how to contact the home health care nurse or physician if any of these complications occurs. The patient is instructed to have weekly serum chemistry and hematology tests as well.

#### Obtaining Psychosocial Support

The psychosocial aspects of home PN are as important as the physiologic and technical concerns. Patients must cope with the loss of eating and with changes in lifestyle brought on by sleep disturbances (frequent urination during infusions, usually two or three times during the night).

Major psychosocial reactions include depression, anger, withdrawal, anxiety, and impaired self-image. A successful home parenteral nutrition program depends on the patient's and family's motivation, emotional stability, and technical competence. Patients and families need to know which support groups are available in the community to help them cope with the transition and to minimize disruption of lifestyle.

supervision in the home. This is accomplished through a team effort. The financial costs of such programs, although high, are less than those incurred in a hospital. Initiation of a home program may be the only way the patient can be discharged from the hospital.

Ideal candidates for home PN are those patients who have a reasonable life expectancy after return home, have only a limited number of medical illnesses other than the one that has resulted in the need for PN, and are highly motivated and fairly self-sufficient. In addition, ability to learn, availability of family interest and support, adequate finances, and the physical plan of the home are factors that must be assessed when the decision for home PN is made.

Home health care agencies sponsoring home PN programs have developed teaching brochures for every aspect of the treatment, including catheter and dressing care, use of an infusion pump, administration of fat emulsions, and instillation of heparin flushes. Teaching begins in the hospital and continues in the home or in an ambulatory infusion center.

#### Continuing Care

The home care nurse should be aware that the average patient needs about 2 weeks of instruction and reinforcement. For more information about home patient education, see Charts 36-4 and 36-5.

#### Evaluation

##### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Attains or maintains nutritional balance
2. Is free of infection at the catheter site
  - a. Is afebrile
  - b. Has no purulent drainage from the catheter insertion site
  - c. Has intact IV line
3. Is hydrated, as evidenced by good skin turgor
4. Achieves an optimal level of activity, within limitations
5. Demonstrates skill in managing PN regimen

### Chart 36-5

#### Home Care Checklist • The Patient Receiving Parenteral Nutrition

*At the completion of the home care instruction, the patient or caregiver will be able to:*

	Patient	Caregiver
• Discuss goal and purpose of PN therapy	✓	✓
• Discuss basic components of PN solution.	✓	✓
• List emergency phone numbers.	✓	✓
• Demonstrate how to handle PN solutions and medications correctly.	✓	✓
• Demonstrate how to operate infusion pump.	✓	✓
• Demonstrate how to prime tubing and filter.	✓	✓
• Demonstrate how to connect and disconnect PN infusion.	✓	✓
• Demonstrate how to perform catheter dressing changes.	✓	✓
• Demonstrate how to heparinize central line.	✓	✓
• Identify possible PN complications and interventions.	✓	✓

6. Prevents complications
  - a. Maintains proper catheter and equipment function
  - b. Has no symptoms of sepsis
  - c. Maintains metabolic balance within normal limits
  - d. Shows improved and stabilized nutritional status

### Critical Thinking Exercises

1. You are caring for a patient with an NG feeding tube. Before administering the patient's tube feeding, you explain to the patient that you will be checking to make sure the tube is placed correctly. The patient responds that she is accustomed to this and that the other nurses "check the tube by placing the end of it in a cup of water;" the patient also states that the nurses then "put air in the tube and use a stethoscope to listen for bubbles in my stomach." How would you respond to the patient? What research findings guide your actions in confirming the placement of the tube? What follow-up actions would you take to ensure that there is consistency among the nursing staff in the procedure used for confirmation of tube placement?
2. A patient who is receiving gastrostomy tube feedings is to be discharged from the hospital to return home within the next few days. Several family members are to be taught how to administer the tube feedings. What are the learning priorities that should be accomplished before the patient is discharged? What assessment parameters should be used to determine whether the family has the necessary resources for providing care for the patient at home?
3. A patient who had major abdominal surgery 1 week ago and who has developed a paralytic ileus is to begin receiving PN. What explanation would you give to this patient about the benefits of PN and the procedure for its administration? How would you alter your plan of care to include assessment for complications of PN? What assessment would you conduct to determine whether the patient is a candidate for home PN therapy?

# ● Management of Patients With Gastric and Duodenal Disorders

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Compare the etiology, clinical manifestations, and management of acute gastritis, chronic gastritis, and peptic ulcer.
2. Use the nursing process as a framework for care of patients with gastritis.
3. Use the nursing process as a framework for care of patients with peptic ulcer.
4. Describe the dietary, pharmacologic, and surgical treatment of peptic ulcer.
5. Describe the nursing management of patients who undergo surgical procedures to treat obesity.
6. Use the nursing process as a framework for care of patients with gastric cancer.
7. Use the nursing process as a framework for care of patients undergoing gastric surgery.
8. Identify the complications of gastric surgery and their prevention and management.
9. Describe the home health care needs of the patient who has had gastric surgery.

An individual's nutritional status depends not only on the type and amount of intake but also on the functioning of the gastric and intestinal portions of the gastrointestinal (GI) system. This chapter describes disorders of the stomach and duodenum and their treatment.

## Gastritis

**Gastritis** (inflammation of the **gastric** or stomach mucosa) is a common GI problem. Gastritis may be acute, lasting several hours to a few days, or chronic, resulting from repeated exposure to irritating agents or recurring episodes of acute gastritis.

Acute gastritis is often caused by dietary indiscretion—the person eats food that is contaminated with disease-causing microorganisms or that is irritating or too highly seasoned. Other causes of acute gastritis include overuse of aspirin and other nonsteroidal anti-inflammatory drugs (NSAIDs), excessive alcohol intake, bile reflux, and radiation therapy. A more severe form of acute gastritis is caused by the ingestion of strong acid or alkali, which may cause the mucosa to become gangrenous or to perforate. Scarring can occur, resulting in pyloric obstruction. Gastritis also may be the first sign of an acute systemic infection.

Chronic gastritis and prolonged inflammation of the stomach may be caused by either benign or malignant ulcers of the stomach or by the bacteria *Helicobacter pylori*. Chronic gastritis is sometimes associated with autoimmune diseases such as pernicious anemia; dietary factors such as caffeine; the use of medications, especially NSAIDs; alcohol; smoking; or reflux of intestinal contents into the stomach.

## Pathophysiology

In gastritis, the gastric mucous membrane becomes edematous and hyperemic (congested with fluid and blood) and undergoes superficial erosion (Fig. 37-1). It secretes a scanty amount of gastric juice, containing very little acid but much mucus. Superficial ulceration may occur and can lead to hemorrhage.

## Clinical Manifestations

The patient with acute gastritis may have abdominal discomfort, headache, lassitude, nausea, anorexia, vomiting, and hiccups. Some patients, however, have no symptoms. The patient with chronic gastritis may complain of anorexia, heartburn after eating, belching, a sour taste in the mouth, or nausea and vomiting. Patients with chronic gastritis from vitamin B<sub>12</sub> deficiency usually have evidence of malabsorption of vitamin B<sub>12</sub> caused by antibodies against intrinsic factor.

## Assessment and Diagnostic Findings

Gastritis is sometimes associated with achlorhydria or hypochlorhydria (absence or low levels of hydrochloric acid [HCl]) or with hyperchlorhydria (high levels of HCl). Diagnosis can be determined by endoscopy, upper GI radiographic studies, and histologic examination of a tissue specimen obtained by biopsy. In addition to biopsy, other diagnostic measures for detecting *H. pylori* include serologic testing for antibodies against the *H. pylori* antigen, a 1-minute ultrarapid urease test, and a breath test.

## Medical Management

The gastric mucosa is capable of repairing itself after a bout of gastritis. As a rule, the patient recovers in about 1 day, although the appetite may be diminished for an additional 2 or 3 days. Acute gastritis is also managed by instructing the patient to refrain from alcohol and food until symptoms subside. After the patient can take nourishment by mouth, a nonirritating diet is recommended. If the symptoms persist, fluids may need to be administered parenterally. If bleeding is present, management is similar to the procedures used for upper GI tract hemorrhage (discussed later in this chapter).

If gastritis is caused by ingestion of strong acids or alkalis, treatment consists of diluting and neutralizing the offending agent. To neutralize acids, common antacids (eg, aluminum hydroxide) are used; to neutralize an alkali, diluted lemon juice or diluted vinegar is used. If corrosion is extensive or severe, emetics and lavage are avoided because of the danger of perforation and damage to the esophagus.

Therapy is supportive and may include nasogastric (NG) intubation, analgesic agents and sedatives, antacids, and intravenous (IV) fluids. Fiberoptic endoscopy may be necessary. In extreme cases, emergency surgery may be required to remove gangrenous or perforated tissue. Gastrojejunostomy or gastric resection may be necessary to treat pyloric obstruction, a narrowing of the pyloric orifice.

Chronic gastritis is managed by modifying the patient's diet, promoting rest, reducing stress, and initiating pharmacotherapy. *H. pylori* may be treated with antibiotics (eg, tetracycline or amoxicillin, combined with clarithromycin) and a proton pump inhibitor (eg, lansoprazole [Prevacid]), and possibly bismuth salts (Pepto-Bismol) (Table 37-1). Research is being conducted to develop a vaccine against *H. pylori* (Alsahli et al., 2001).

## NURSING PROCESS: THE PATIENT WITH GASTRITIS

### Assessment

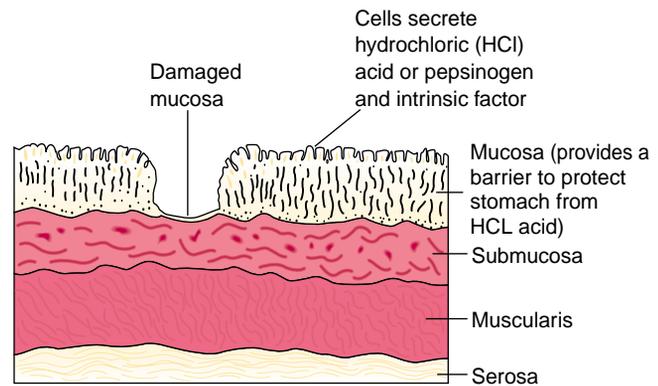

When obtaining the history, the nurse asks about the patient's presenting signs and symptoms. Does the patient have heartburn, indigestion, nausea, or vomiting? Do the symptoms occur

## Glossary

**antrectomy:** removal of the pyloric (antrum) portion of the stomach with anastomosis (surgical connection) to the duodenum (gastroduodenostomy or Billroth I) or anastomosis to the jejunum (gastrojejunostomy or Billroth II)  
**dumping syndrome:** physiologic response to rapid emptying of gastric contents into the jejunum, manifested by nausea, weak-

ness, sweating, palpitations, syncope, and possibly diarrhea; occurs in patients who have had partial gastrectomy and gastrojejunostomy  
**duodenum:** first portion of the small intestine, between the stomach and the jejunum  
**gastric:** refers to the stomach  
**gastritis:** inflammation of the stomach  
**hematemesis:** vomiting of blood

**melena:** tarry or black stools; indicative of blood in stools  
**morbid obesity:** 100 pounds or more over ideal body weight  
**pyloroplasty:** surgical procedure to increase the opening of the pyloric orifice  
**pylorus:** opening between the stomach and the duodenum  
**pyrosis:** heartburn

**FIGURE 37-1** Endoscopic view of erosive gastritis (*left*). Damage from irritants (*right*) results in increased intracellular pH, impaired enzyme function, disrupted cellular structures, ischemia, vascular stasis, and tissue death. From Porth, C. (2002). *Pathophysiology: Concepts of altered health states* (6th ed.). Philadelphia: Lippincott Williams & Wilkins.

at any specific time of the day, before or after meals, after ingesting spicy or irritating foods, or after the ingestion of certain drugs or alcohol? Has there been recent weight gain or loss? Are the symptoms related to anxiety, stress, allergies, eating or drinking too much, or eating too quickly? How are the symptoms relieved? Is there a history of previous gastric disease or surgery? A diet history plus a 72-hour dietary recall (a list of everything the patient ate and drank in the last 72 hours) may be helpful.

A thorough history is important because it helps the nurse to identify whether known dietary excesses or other indiscretions are associated with the current symptoms, whether others in the patient's environment have similar symptoms, whether the patient is vomiting blood, and whether any known caustic element has been ingested. The nurse also identifies the duration of the current symptoms, any methods used by the patient to treat these symptoms, and whether the methods are effective. Signs to note during the physical examination include abdominal tenderness, dehydration, and evidence of any systemic disorder that might be responsible for the symptoms of gastritis.

## Nursing Diagnoses

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Anxiety related to treatment
- Imbalanced nutrition, less than body requirements, related to inadequate intake of nutrients
- Risk for imbalanced fluid volume related to insufficient fluid intake and excessive fluid loss subsequent to vomiting
- Deficient knowledge about dietary management and disease process
- Acute pain related to irritated stomach mucosa

## Planning and Goals

The major goals for the patient may include reduced anxiety, avoidance of irritating foods, adequate intake of nutrients, maintenance of fluid balance, increased awareness of dietary management, and relief of pain.

## Nursing Interventions

### REDUCING ANXIETY

If the patient has ingested acids or alkalis, emergency measures may be needed. The nurse offers supportive therapy to the patient and family during treatment and after the ingested acid or alkali has been neutralized or diluted. In some cases, the nurse may need to prepare the patient for additional diagnostic studies (endoscopy) or surgery. The patient usually feels anxious about the pain and the treatment modalities. The nurse uses a calm approach to assess the patient and to answer all questions as completely as possible. It is important to explain all procedures and treatments according to the patient's level of understanding.

### PROMOTING OPTIMAL NUTRITION

For acute gastritis, the nurse provides physical and emotional support and helps the patient manage the symptoms, which may include nausea, vomiting, heartburn, and fatigue. The patient should take no foods or fluids by mouth—possibly for days—until the acute symptoms subside, thus allowing the gastric mucosa to heal. If IV therapy is necessary, the nurse monitors it regularly, along with serum electrolyte values. After the symptoms subside, the nurse can offer the patient ice chips followed by clear liquids. Introducing solid food as soon as possible will provide oral nutrition, decrease the need for IV therapy, and minimize irritation to the gastric mucosa. As food is introduced, the nurse evaluates and reports any symptoms that suggest a repeat episode of gastritis.

Table 37-1 • Pharmacologic Therapy for Peptic Ulcer Disease and Gastritis

PHARMACOLOGIC AGENT	MAJOR ACTION	NURSING CONSIDERATIONS
<b>Antibiotics and Bismuth Salts</b>		
Tetracycline (plus metronidazole, proton pump inhibitor, and bismuth salts)	Exerts bacteriostatic effects to eradicate <i>Helicobacter pylori</i> bacteria in the gastric mucosa	May cause photosensitivity reaction; warn patient to use sunscreen. Use with caution in patients with renal or hepatic impairment. Milk or dairy products may reduce medication effectiveness.
Amoxicillin (plus clarithromycin and proton pump inhibitor such as omeprazole [Prilosec])	A bactericidal antibiotic that assists with eradicating <i>H. pylori</i> bacteria in the gastric mucosa	May cause diarrhea. Do not use in patients allergic to penicillin.
Metronidazole (Flagyl); use with clarithromycin and proton pump inhibitor	An amebocide that assists with eradicating <i>H. pylori</i> bacteria in the gastric mucosa	Administer with meals to decrease GI distress. Administer with other antibiotics and proton pump inhibitors.
Clarithromycin (Biaxin); use with proton pump inhibitor and amoxicillin	Exerts bactericidal effects to eradicate <i>H. pylori</i> bacteria in the gastric mucosa	May cause GI upset.
Bismuth subsalicylate (Pepto-Bismol); use with antibiotics	Suppresses <i>H. pylori</i> bacteria in the gastric mucosa and assists with healing of mucosal lesions	Given concurrently with antibiotics to cure <i>H. pylori</i> infection. Should be taken on an empty stomach.
<b>Histamine 2 (H<sub>2</sub>) Receptor Antagonists</b>		
Cimetidine (Tagamet)	Inhibits acid secretion by blocking the action of histamine on the histamine receptors of the parietal cells in the stomach	Least expensive of the H <sub>2</sub> receptor antagonists. May cause confusion, agitation, or coma in the elderly or those with renal or hepatic insufficiency. Long-term use may cause gynecomastia, impotence, and diarrhea.
Ranitidine (Zantac)	Inhibits acid secretion by blocking the action of the histamine on the histamine receptors of the parietal cells in the stomach	Prolonged drug half-life in patients with renal and hepatic insufficiency. Causes fewer side effects than cimetidine. Rarely causes constipation, diarrhea, dizziness, and depression.
Famotidine (Pepcid)	Inhibits acid secretion by blocking the action of histamine on the histamine receptors on the parietal cells in the stomach	Best choice for critically ill patient because it is known to have least risk of interaction with other medications. (It is unclear whether other H <sub>2</sub> receptor antagonists are as safe as famotidine.) Does not alter medication metabolism in the liver. Prolonged half-life in patients with renal insufficiency. Short-term relief for gastroesophageal reflux. Dilute before IV injection. Rarely causes constipation or diarrhea.
Nizatidine (Axid)	Inhibits acid secretion by blocking the action of histamine on the histamine receptors on the parietal cells in the stomach	Used for duodenal ulcers. Prolonged half-life in patients with renal insufficiency. Rarely causes sweating, increased liver enzymes, nausea, urticaria.
<b>Proton (Gastric Acid) Pump Inhibitor</b>		
Omeprazole (Prilosec)	Decreases gastric acid secretion by slowing the hydrogen-potassium adenosine triphosphatase (H <sup>+</sup> , K <sup>+</sup> -ATPase) pump on the surface of the parietal cells	Long-term use may cause gastric tumors and bacterial invasion. May cause diarrhea, additional pain, and nausea.
Lansoprazole (Prevacid)	Decreases gastric acid secretion by slowing the H <sup>+</sup> , K <sup>+</sup> -ATPase pump on the surface of the parietal cells.	A delayed-release capsule that is to be swallowed whole and taken before meals.
Rabeprazole (Aciphex)	Decreases gastric acid secretion by slowing the H <sup>+</sup> , K <sup>+</sup> -ATPase pump on the surface of the parietal cells	A delayed-release tablet; swallow whole.

(continued)

**Table 37-1 • Pharmacologic Therapy for Peptic Ulcer Disease and Gastritis (Continued)**

PHARMACOLOGIC AGENT	MAJOR ACTION	NURSING CONSIDERATIONS
<b>Cytoprotective Medications</b>		
Misoprostol (Cytotec)	A synthetic prostaglandin; protects the gastric mucosa from ulcerogenic agents; also increases mucus production and bicarbonate levels	Used as a preventive medication (to prevent ulceration in patients using NSAIDs). Administer with food. May cause diarrhea and cramping (including uterine cramping).
Sucralfate (Carafate)	In the presence of gastric acid, sucralfate creates a viscous substance that forms a protective layer at the site of the ulcer and prevents digestion by pepsin	May cause constipation or nausea. Approved for duodenal— <i>not gastric</i> —ulcers.

The nurse discourages the intake of caffeinated beverages, because caffeine is a central nervous system stimulant that increases gastric activity and pepsin secretion. It also is important to discourage alcohol use. Discouraging cigarette smoking is important because nicotine reduces the secretion of pancreatic bicarbonate and thus inhibits the neutralization of gastric acid in the duodenum (Eastwood, 1997). When appropriate, the nurse refers the patient for alcohol counseling and smoking cessation programs.

### PROMOTING FLUID BALANCE

Daily fluid intake and output are monitored to detect early signs of dehydration (minimal urine output of 30 mL/hour, minimal intake of 1.5 L/day). If food and fluids are withheld, IV fluids (3 L/day) usually are prescribed and a record of fluid intake plus caloric value (1 L of 5% dextrose in water = 170 calories of carbohydrate) needs to be maintained. Electrolyte values (sodium, potassium, chloride) are assessed every 24 hours to detect imbalance.

The nurse must always be alert for any indicators of hemorrhagic gastritis, which include **hematemesis** (vomiting of blood), tachycardia, and hypotension. If these occur, the physician is notified and the patient's vital signs are monitored as the patient's condition warrants. Guidelines for managing upper GI tract bleeding are discussed later in this chapter.

### RELIEVING PAIN

Measures to help relieve pain include instructing the patient to avoid foods and beverages that may be irritating to the gastric mucosa (described earlier) and instructing the patient about using medications to relieve chronic gastritis. To follow up, the nurse assesses the patient's level of pain and the extent of comfort attained from the use of medications and avoidance of irritating substances.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

The nurse evaluates the patient's knowledge about gastritis and develops an individualized teaching plan that includes information about stress management, diet, and medications (Chart 37-1). Dietary instructions take into account the patient's daily caloric needs, food preferences, and pattern of eating. The nurse and patient review foods and other substances to be avoided (eg, spicy, irritating, or highly seasoned foods; caffeine; nicotine; alcohol). Consultation with a dietitian may be recommended.

Providing information about prescribed antibiotics, bismuth salts, medications to decrease gastric secretion, and medications to protect mucosal cells from gastric secretions can help the patient recover and prevent recurrence. Patients with pernicious anemia need information about long-term vitamin B<sub>12</sub> injections; the nurse may instruct a family member about administering these injections or make arrangements for the patient to receive the injections from a health care provider. Finally, the nurse emphasizes the importance of keeping follow-up appointments with health care providers.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Exhibits less anxiety
2. Avoids eating irritating foods or drinking caffeinated beverages or alcohol
3. Maintains fluid balance
  - a. Has intake of at least 1.5 L daily
  - b. Drinks six to eight glasses of water daily

**Chart 37-1**

#### Home Care Checklist • The Patient With Gastritis

At the completion of the home care instruction, the patient or caregiver will be able to:

- Identify foods and other substances that may cause gastritis.
- Describe medication regimen to follow.
- State need for vitamin B<sub>12</sub> injections if patient has pernicious anemia.

	Patient	Caregiver
• Identify foods and other substances that may cause gastritis.	✓	✓
• Describe medication regimen to follow.	✓	✓
• State need for vitamin B <sub>12</sub> injections if patient has pernicious anemia.	✓	✓

- c. Has a urinary output of about 1 L daily
- d. Displays adequate skin turgor
4. Adheres to medical regimen
  - a. Selects nonirritating foods and beverages
  - b. Takes medications as prescribed
5. Maintains appropriate weight
6. Reports less pain

## Gastric and Duodenal Ulcers

A peptic ulcer is an excavation (hollowed-out area) that forms in the mucosal wall of the stomach, in the **pylorus** (opening between stomach and duodenum), in the **duodenum** (first part of small intestine), or in the esophagus. A peptic ulcer is frequently referred to as a gastric, duodenal, or esophageal ulcer, depending on its location, or as peptic ulcer disease. Erosion of a circumscribed area of mucous membrane is the cause (Fig. 37-2). This erosion may extend as deeply as the muscle layers or through the muscle to the peritoneum. Peptic ulcers are more likely to be in the duodenum than in the stomach. As a rule they occur alone, but they may occur in multiples. Chronic gastric ulcers tend to occur in the lesser curvature of the stomach, near the pylorus. Table 37-2 compares the features of gastric and duodenal ulcers.

Peptic ulcer disease occurs with the greatest frequency in people between the ages of 40 and 60 years. It is relatively uncommon in women of childbearing age, but it has been observed in children and even in infants. After menopause, the incidence of peptic ulcers in women is almost equal to that in men. Peptic ulcers in the body of the stomach can occur without excessive acid secretion.

**FIGURE 37-2** Deep peptic ulcer. From Porth, C. (2002). *Pathophysiology: Concepts of altered health states* (6th ed). Philadelphia: Lippincott Williams & Wilkins.

**Table 37-2 • Comparing Duodenal and Gastric Ulcers**

DUODENAL ULCER	GASTRIC ULCER
<b>Incidence</b>	
Age 30–60	Usually 50 and over
Male: female = 2–3:1	Male: female = 1:1
80% of peptic ulcers are duodenal	15% of peptic ulcers are gastric
<b>Signs, Symptoms, and Clinical Findings</b>	
Hypersecretion of stomach acid (HCl)	Normal—hyposecretion of stomach acid (HCl)
May have weight gain	Weight loss may occur
Pain occurs 2–3 hours after a meal; often awakened between 1–2 AM; ingestion of food relieves pain	Pain occurs ½ to 1 hour after a meal; rarely occurs at night; may be relieved by vomiting; ingestion of food does not help, sometimes increases pain
Vomiting uncommon	Vomiting common
Hemorrhage less likely than with gastric ulcer, but if present melena more common than hematemesis	Hemorrhage more likely to occur than with duodenal ulcer; hematemesis more common than melena
More likely to perforate than gastric ulcers	
<b>Malignancy Possibility</b>	
Rare	Occasionally
<b>Risk Factors</b>	
<i>H. pylori</i> , alcohol, smoking, cirrhosis, stress	<i>H. pylori</i> , gastritis, alcohol, smoking, use of NSAIDs, stress

In the past, stress and anxiety were thought to be causes of ulcers. Research has identified that peptic ulcers result from infection with the gram-negative bacteria *H. pylori* (Tytgat, 2000). However, ulcers do seem to develop more commonly in people who are tense; whether this is a contributing factor to the condition is uncertain. In addition, excessive secretion of HCl in the stomach may contribute to the formation of gastric ulcers, and stress may be associated with its increased secretion. The ingestion of milk and caffeinated beverages, smoking, and alcohol also may increase HCl secretion.

Familial tendency may be a significant predisposing factor. A further genetic link is noted in the finding that people with blood type O are more susceptible to peptic ulcers than are those with blood type A, B, or AB. There also is an association between duodenal ulcers and chronic pulmonary disease or chronic renal disease. Other predisposing factors associated with peptic ulcer include chronic use of NSAIDs, alcohol ingestion, and excessive smoking.

Rarely, ulcers are caused by excessive amounts of the hormone gastrin, produced by tumors. This Zollinger-Ellison syndrome (ZES) consists of severe peptic ulcers, extreme gastric hyperacidity, and gastrin-secreting benign or malignant tumors of the pancreas. Stress ulcers, which are clinically different from peptic ulcers, are ulcerations in the mucosa that can occur in the gastroduodenal area. Stress ulcers may occur in patients who are exposed to stressful conditions. Esophageal ulcers occur as a result of the backward flow of HCl from the stomach into the esophagus (gastroesophageal reflux disease [GERD]).

## Pathophysiology

Peptic ulcers occur mainly in the gastroduodenal mucosa because this tissue cannot withstand the digestive action of gastric acid (HCl) and pepsin. The erosion is caused by the increased concentration or activity of acid-pepsin, or by decreased resistance of the mucosa. A damaged mucosa cannot secrete enough mucus to act as a barrier against HCl. The use of NSAIDs inhibits the secretion of mucus that protects the mucosa. Patients with duodenal ulcer disease secrete more acid than normal, whereas patients with gastric ulcer tend to secrete normal or decreased levels of acid.

ZES is suspected when a patient has several peptic ulcers or an ulcer that is resistant to standard medical therapy. It is identified by the following findings: hypersecretion of gastric juice, duodenal ulcers, and gastrinomas (islet cell tumors) in the pancreas. Ninety percent of tumors are found in the “gastric triangle,” which encompasses the cystic and common bile ducts, the second and third portions of the duodenum, and the neck and body of the pancreas. Approximately one third of gastrinomas are malignant. Diarrhea and steatorrhea (unabsorbed fat in the stool) may be evident. The patient may have coexisting parathyroid adenomas or hyperplasia and may therefore exhibit signs of hypercalcemia. The most common complaint is epigastric pain. *H. pylori* is not a risk factor for ZES.

*Stress ulcer* is the term given to the acute mucosal ulceration of the duodenal or gastric area that occurs after physiologically stressful events, such as burns, shock, severe sepsis, and multiple organ traumas. These ulcers are most common in ventilator-dependent patients after trauma or surgery. Fiberoptic endoscopy within 24 hours after injury reveals shallow erosions of the stomach wall; by 72 hours, multiple gastric erosions are observed. As the stressful condition continues, the ulcers spread. When the patient recovers, the lesions are reversed. This pattern is typical of stress ulceration.

Differences of opinion exist as to the actual cause of mucosal ulceration in stress ulcers. Usually, it is preceded by shock; this leads to decreased gastric mucosal blood flow and to reflux of duodenal contents into the stomach. In addition, large quantities of pepsin are released. The combination of ischemia, acid, and pepsin creates an ideal climate for ulceration.

Stress ulcers should be distinguished from Cushing’s ulcers and Curling’s ulcers, two other types of gastric ulcers. Cushing’s ulcers are common in patients with trauma to the brain. They may occur in the esophagus, stomach, or duodenum and are usually deeper and more penetrating than stress ulcers. Curling’s ulcer is frequently observed about 72 hours after extensive burns and involves the antrum of the stomach or the duodenum.

## Clinical Manifestations

Symptoms of an ulcer may last for a few days, weeks, or months and may disappear only to reappear, often without an identifiable cause. Many people have symptomless ulcers, and in 20% to 30% perforation or hemorrhage may occur without any preceding manifestations.

As a rule, the patient with an ulcer complains of dull, gnawing pain or a burning sensation in the midepigastrium or in the back. It is believed that the pain occurs when the increased acid content of the stomach and duodenum erodes the lesion and stimulates the exposed nerve endings. Another theory suggests that contact of the lesion with acid stimulates a local reflex mechanism that initiates contraction of the adjacent smooth muscle. Pain is usually relieved by eating, because food neutralizes the

acid, or by taking alkali; however, once the stomach has emptied or the alkali’s effect has decreased, the pain returns. Sharply localized tenderness can be elicited by applying gentle pressure to the epigastrium at or slightly to the right of the midline.

Other symptoms include **pyrosis** (heartburn), vomiting, constipation or diarrhea, and bleeding. Pyrosis is a burning sensation in the esophagus and stomach that moves up to the mouth. Heartburn is often accompanied by sour eructation, or burping, which is common when the patient’s stomach is empty.

Although vomiting is rare in uncomplicated duodenal ulcer, it may be a symptom of a peptic ulcer complication. It results from obstruction of the pyloric orifice, caused by either muscular spasm of the pylorus or mechanical obstruction from scarring or acute swelling of the inflamed mucous membrane adjacent to the ulcer. Vomiting may or may not be preceded by nausea; usually it follows a bout of severe pain and bloating, which is relieved by ejection of the gastric contents. Emesis often contains undigested food eaten many hours earlier. Constipation or diarrhea can occur, probably as a result of diet and medications.

Fifteen percent of patients with gastric ulcers experience bleeding. Patients may present with GI bleeding as evidenced by the passage of tarry stools. A small portion of patients who bleed from an acute ulcer have had no previous digestive complaints, but they develop symptoms thereafter (Yamada, 1999).

## Assessment and Diagnostic Findings

A physical examination may reveal pain, epigastric tenderness, or abdominal distention. A barium study of the upper GI tract may show an ulcer; however, endoscopy is the preferred diagnostic procedure because it allows direct visualization of inflammatory changes, ulcers, and lesions. Through endoscopy, a biopsy of the gastric mucosa and of any suspicious lesions can be obtained. Endoscopy may reveal lesions that are not evident on x-ray studies because of their size or location.

Stools may be tested periodically until they are negative for occult blood. Gastric secretory studies are of value in diagnosing achlorhydria and ZES. *H. pylori* infection may be determined by biopsy and histology with culture. There is also a breath test that detects *H. pylori*, as well as a serologic test for antibodies to the *H. pylori* antigen. Pain that is relieved by ingesting food or antacids and absence of pain on arising are also highly suggestive of an ulcer.

## Medical Management

Once the diagnosis is established, the patient is informed that the problem can be controlled. Recurrence may develop; however, peptic ulcers treated with antibiotics to eradicate *H. pylori* have a lower recurrence rate than those not treated with antibiotics. The goals are to eradicate *H. pylori* and to manage gastric acidity. Methods used include medications, lifestyle changes, and surgical intervention.

## PHARMACOLOGIC THERAPY

Currently, the most commonly used therapy in the treatment of ulcers is a combination of antibiotics, proton pump inhibitors, and bismuth salts that suppresses or eradicates *H. pylori*; histamine 2 (H<sub>2</sub>) receptor antagonists and proton pump inhibitors are used to treat NSAID-induced and other ulcers not associated with *H. pylori* ulcers. Table 37-1 provides details about pharmacologic treatment.

The patient is advised to adhere to the medication regimen to ensure complete healing of the ulcer. Because most patients become symptom-free within a week, it becomes a nursing responsibility to stress the importance of following the prescribed regimen so that the healing process can continue uninterrupted and the return of chronic ulcer symptoms can be prevented. Rest, sedatives, and tranquilizers may add to the patient's comfort and are prescribed as needed. Maintenance dosages of H<sub>2</sub> receptor antagonists are usually recommended for 1 year.

For patients with ZES, hypersecretion of acid may be controlled with high doses of H<sub>2</sub> receptor antagonists. These patients may require twice the normal dose, and dosages usually need to be increased with prolonged use. Octreotide (Sandostatin), a medication that suppresses gastrin levels, also may be prescribed.

Patients at risk for stress ulcers may be treated prophylactically with IV H<sub>2</sub> receptor antagonists and cytoprotective agents (e.g., misoprostol, sucralfate) because of the risk for upper GI tract hemorrhage. Frequent gastric aspiration is performed to allow monitoring of gastric secretion pH.

### STRESS REDUCTION AND REST

Reducing environmental stress requires physical and psychological modifications on the patient's part as well as the aid and cooperation of family members and significant others. The patient may need help in identifying situations that are stressful or exhausting. A rushed lifestyle and an irregular schedule may aggravate symptoms and interfere with regular meals taken in relaxed settings and with the regular administration of medications. The patient may benefit from regular rest periods during the day, at least during the acute phase of the disease. Biofeedback, hypnosis, or behavior modification may be helpful.

### SMOKING CESSATION

Studies have shown that smoking decreases the secretion of bicarbonate from the pancreas into the duodenum, resulting in increased acidity of the duodenum. Research indicates that continuing to smoke cigarettes may significantly inhibit ulcer repair. Therefore, the patient is strongly encouraged to stop smoking. Smoking cessation support groups and other smoking cessation approaches are helpful for many patients (Eastwood, 1997).

### DIETARY MODIFICATION

The intent of dietary modification for patients with peptic ulcers is to avoid oversecretion of acid and hypermotility in the GI tract. These can be minimized by avoiding extremes of temperature and overstimulation from consumption of meat extracts, alcohol, coffee (including decaffeinated coffee, which also stimulates acid secretion) and other caffeinated beverages, and diets rich in milk and cream (which stimulate acid secretion). In addition, an effort is made to neutralize acid by eating three regular meals a day. Small, frequent feedings are not necessary as long as an antacid or a histamine blocker is taken. Diet compatibility becomes an individual matter: the patient eats foods that can be tolerated and avoids those that produce pain.

### SURGICAL MANAGEMENT

The introduction of antibiotics to eradicate *H. pylori* and of H<sub>2</sub> receptor antagonists as treatment for ulcers has greatly reduced the need for surgical interventions. However, surgery is usually recommended for patients with intractable ulcers (those that fail to heal after 12 to 16 weeks of medical treatment), life-threatening hemorrhage, perforation, or obstruction, and for those with ZES not responding to medications (Yamada, 1999). Surgical procedures

include vagotomy, with or without pyloroplasty, and the Billroth I and Billroth II procedures (Table 37-3; see also the section on gastric surgery later in this chapter). Patients who need ulcer surgery may have had a long illness. They may be discouraged and have had interruptions in their work role and pressures in their family life.

### FOLLOW-UP CARE

Recurrence within 1 year may be prevented with the prophylactic use of H<sub>2</sub> receptor antagonists given at a reduced dose. Not all patients require maintenance therapy; it may be prescribed only for those with two or three recurrences per year, those who have had a complication such as bleeding or outlet obstruction, or those who are candidates for gastric surgery but are at too high a risk for surgery. The likelihood of recurrence is reduced if the patient avoids smoking, coffee (including decaffeinated coffee) and other caffeinated beverages, alcohol, and ulcerogenic medications (eg, NSAIDs).

## NURSING PROCESS: THE PATIENT WITH ULCER DISEASE

### Assessment

The nurse asks the patient to describe the pain and the methods used to relieve it (e.g., food, antacids). The patient usually describes peptic ulcer pain as burning or gnawing; it occurs about 2 hours after a meal and frequently awakens the patient between midnight and 3 AM. Taking antacids, eating, or vomiting often relieves the pain. If the patient reports a recent history of vomiting, the nurse determines how often emesis has occurred and notes important characteristics of the vomitus: Is it bright red, does it resemble coffee grounds, or is there undigested food from previous meals? Has the patient noted any bloody or tarry stools?

The nurse also asks the patient to list his or her usual food intake for a 72-hour period and to describe food habits (e.g., speed of eating, regularity of meals, preference for spicy foods, use of seasonings, use of caffeinated beverages and decaffeinated coffee). Lifestyle and habits are a concern as well. Does the patient use irritating substances? For example, does he or she smoke cigarettes? If yes, how many? Does the patient ingest alcohol? If yes, how much and how often? Are NSAIDs used? The nurse inquires about the patient's level of anxiety and his or her perception of current stressors. How does the patient express anger or cope with stressful situations? Is the patient experiencing occupational stress or problems within the family? Is there a family history of ulcer disease?

The nurse assesses vital signs and reports tachycardia and hypotension, which may indicate anemia from GI bleeding. The stool is tested for occult blood, and a physical examination, including palpation of the abdomen for localized tenderness, is performed as well.

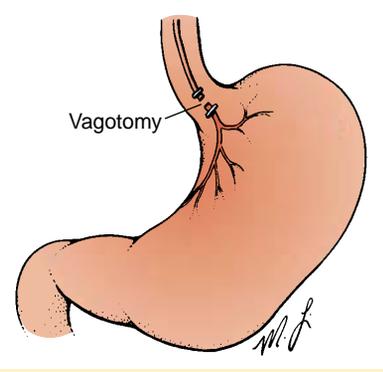

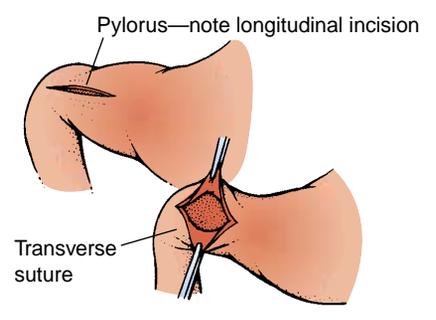

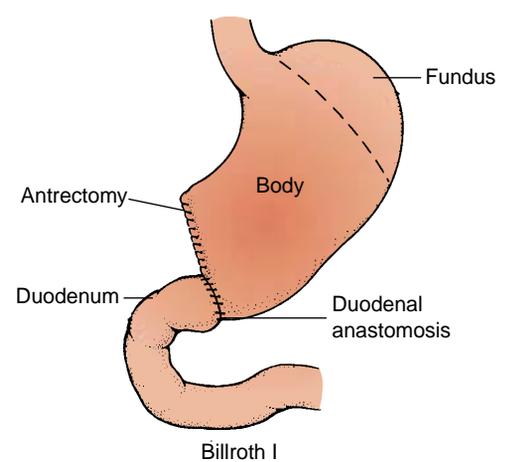

### Diagnosis

#### NURSING DIAGNOSES

Based on the assessment data, the patient's nursing diagnoses may include the following:

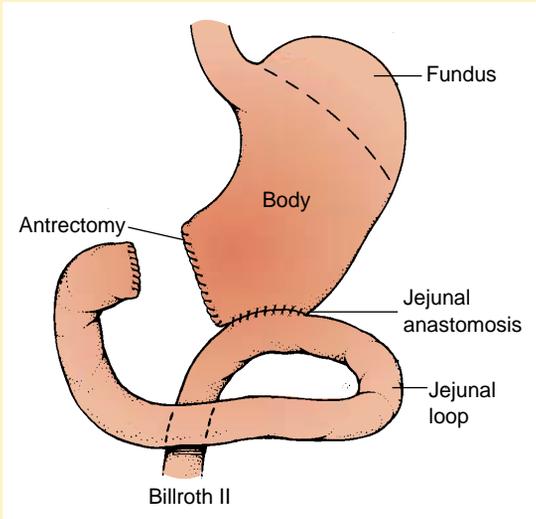

- Acute pain related to the effect of gastric acid secretion on damaged tissue
- Anxiety related to coping with an acute disease
- Imbalanced nutrition related to changes in diet
- Deficient knowledge about prevention of symptoms and management of the condition

Table 37-3 • Surgical Procedures for Peptic Ulcer Disease

OPERATION	DESCRIPTION	COMMENTS	
<b>Vagotomy</b> 	Severing of the vagus nerve. Decreases gastric acid by diminishing cholinergic stimulation to the parietal cells, making them less responsive to gastrin. May be done via open surgical approach, laparoscopy, or thoracoscopy.	May be performed to reduce gastric acid secretion. A drainage type of procedure (see pyloroplasty) is usually performed to assist with gastric emptying (because there is total denervation of the stomach). Some patients experience problems with feeling of fullness, dumping syndrome, diarrhea, and gastritis.	
<b>Truncal vagotomy</b>	Severs the right and left vagus nerves as they enter the stomach at the distal part of the esophagus.	This type of vagotomy is most commonly used to decrease acid secretions and reduce gastric and intestinal motility. Recurrence rate of ulcer is 10%–15%.	
<b>Selective vagotomy</b>	Severs vagal innervation to the stomach but maintains innervation to the rest of the abdominal organs.	No dumping syndrome. No need for drainage procedure. Recurrence rate of ulcer is 10%–15%.	
<b>Proximal (parietal cell) gastric vagotomy</b> without drainage	Denervates acid-secreting parietal cells but preserves vagal innervation to the gastric antrum and pylorus.	Usually accompanies truncal and selective vagotomies, which produce delayed gastric emptying due to decreased innervation.	
<b>Pyloroplasty</b> 	A surgical procedure in which a longitudinal incision is made into the pylorus and transversely sutured closed to enlarge the outlet and relax the muscle.	No dumping syndrome. No need for drainage procedure. Recurrence rate of ulcer is 10%–15%.	
<b>Antrectomy</b> <b>Billroth I (Gastroduodenostomy)</b>		Removal of the lower portion of the antrum of the stomach (which contains the cells that secrete gastrin) as well as a small portion of the duodenum and pylorus. The remaining segment is anastomosed to the duodenum (Billroth I) or to the jejunum (Billroth II).	May be performed in conjunction with a truncal vagotomy. The patient may have problems with feeling of fullness, dumping syndrome, and diarrhea. Recurrence rate of ulcer is < 1%.

(continued)

Table 37-3 • Surgical Procedures for Peptic Ulcer Disease (Continued)

OPERATION	DESCRIPTION	COMMENTS
<p>Billroth II (Gastrojejunostomy)</p>  <p><b>Subtotal gastrectomy with Billroth I or II anastomosis</b></p>	<p>Removal of distal third of stomach; anastomosis with duodenum or jejunum. Removes gastrin-producing cells in the antrum and part of the parietal cells.</p>	<p>Dumping syndrome, anemia, malabsorption, weight loss. Recurrence rate of ulcer is 10%–15%.</p>

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Potential complications may include the following:

- Hemorrhage
- Perforation
- Penetration
- Pyloric obstruction (gastric outlet obstruction)

### Planning and Goals

The goals for the patient may include relief of pain, reduced anxiety, maintenance of nutritional requirements, knowledge about the management and prevention of ulcer recurrence, and absence of complications.

### Nursing Interventions

#### RELIEVING PAIN

Pain relief can be achieved with prescribed medications. The patient should avoid aspirin, foods and beverages that contain caffeine, and decaffeinated coffee, and meals should be eaten at regularly paced intervals in a relaxed setting. Some patients benefit from learning relaxation techniques to help manage stress and pain and to enhance smoking cessation efforts.

#### REDUCING ANXIETY

The nurse assesses the patient's level of anxiety. Patients with peptic ulcers are usually anxious, but their anxiety is not always obvious. Appropriate information is provided at the patient's level of understanding, all questions are answered, and the patient is encouraged to express fears openly. Explaining diagnostic tests and administering medications on schedule also help to reduce anxiety. The nurse interacts with the patient in a relaxed manner, helps identify stressors, and explains various coping techniques

and relaxation methods, such as biofeedback, hypnosis, or behavior modification. The patient's family is also encouraged to participate in care and to provide emotional support.

#### MAINTAINING OPTIMAL NUTRITIONAL STATUS

The nurse assesses the patient for malnutrition and weight loss. After recovery from an acute phase of peptic ulcer disease, the patient is advised about the importance of complying with the medication regimen and dietary restrictions.

#### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

##### Hemorrhage

Gastritis and hemorrhage from peptic ulcer are the two most common causes of upper GI tract bleeding (which may also occur with esophageal varices, as discussed in Chapter 39). Hemorrhage, the most common complication, occurs in about 15% of patients with peptic ulcers (Yamada, 1999). The site of bleeding is usually the distal portion of the duodenum. Bleeding may be manifested by hematemesis or **melena** (tarry stools). The vomited blood can be bright red, or it can have a "coffee grounds" appearance (which is dark) from the oxidation of hemoglobin to methemoglobin. When the hemorrhage is large (2000 to 3000 mL), most of the blood is vomited. Because large quantities of blood may be lost quickly, immediate correction of blood loss may be required to prevent hemorrhagic shock. When the hemorrhage is small, much or all of the blood is passed in the stools, which will appear tarry black because of the digested hemoglobin. Management depends on the amount of blood lost and the rate of bleeding.

The nurse assesses the patient for faintness or dizziness and nausea, which may precede or accompany bleeding. It is important to monitor vital signs frequently and to evaluate the patient for tachycardia, hypotension, and tachypnea. Other nursing interventions include monitoring the hemoglobin and hematocrit,

testing the stool for gross or occult blood, and recording hourly urinary output to detect anuria or oliguria (absence or decreased urine production).

Many times the bleeding from a peptic ulcer stops spontaneously; however, the incidence of recurrent bleeding is high. Because bleeding can be fatal, the cause and severity of the hemorrhage must be identified quickly and the blood loss treated to prevent hemorrhagic shock. Management of upper GI tract bleeding consists of quickly determining the amount of blood lost and the rate of bleeding, rapidly replacing the blood that has been lost, stopping the bleeding, stabilizing the patient, and diagnosing and treating the cause. Related nursing and collaborative interventions include the following:

- Inserting a peripheral IV line for the infusion of saline or lactated Ringer's solution and blood products. The nurse may need to assist with the placement of a pulmonary artery catheter for hemodynamic monitoring. Blood component therapy is initiated if there are signs of shock (eg, tachycardia, sweating, coldness of the extremities).
- Monitoring the hemoglobin and hematocrit to assist in evaluating blood loss
- Inserting an NG tube to distinguish fresh blood from "coffee grounds" material, to aid in the removal of clots and acid, to prevent nausea and vomiting, and to provide a means of monitoring further bleeding
- Administering a room-temperature lavage of saline solution or water. This is controversial; some authorities recommend using ice lavage (Yamada, 1999).
- Inserting an indwelling urinary catheter and monitoring urinary output
- Monitoring vital signs and oxygen saturation and administering oxygen therapy
- Placing the patient in the recumbent position with the legs elevated to prevent hypotension; or, to prevent aspiration from vomiting, placing the patient on the left side
- Treating hemorrhagic shock (described in Chapter 15)

If bleeding cannot be managed by the measures described, other treatment modalities may be used. Transendoscopic coagulation by laser, heat probe, medication, a sclerosing agent, or a combination of these therapies can halt bleeding and make surgical intervention unnecessary. There is much debate regarding how soon endoscopy should be performed. Some believe that endoscopy should be performed in the first 24 hours after hemorrhage has been stabilized. Others believe that endoscopy may be performed during acute bleeding, as long as the esophageal or gastric area can be visualized (blood may decrease visibility) (Yamada, 1999).

For those who are unable to undergo surgery, selective embolization may be used. This procedure involves forcing emboli of autologous blood clots with or without Gelfoam (absorbable gelatin sponge) through a catheter in the artery to a point above the bleeding lesion. A radiologist performs this procedure.

Rebleeding may occur and often warrants surgical intervention. The nurse monitors the patient carefully so that bleeding can be detected quickly. Signs of bleeding include tachycardia, tachypnea, hypotension, mental confusion, thirst, and oliguria. If bleeding recurs within 48 hours after medical therapy has begun, or if more than 6 to 10 units of blood are required within 24 hours to maintain blood volume, the patient is likely to require surgery. Some physicians recommend surgical intervention if a patient hemorrhages three times. Other criteria for surgery are the patient's age (massive hemorrhaging is three times more likely to be fatal in those older than 60 years of age); a history of chronic duodenal ulcer; and

a coincidental gastric ulcer (Yamada, 1999). The area of the ulcer is removed or the bleeding vessels are ligated. Many patients also undergo procedures (eg, vagotomy and pyloroplasty, gastrectomy) aimed at controlling the underlying cause of the ulcers (see Table 37-3).

### Perforation and Penetration

Perforation is the erosion of the ulcer through the gastric serosa into the peritoneal cavity without warning. It is an abdominal catastrophe and requires immediate surgery. Penetration is erosion of the ulcer through the gastric serosa into adjacent structures such as the pancreas, biliary tract, or gastrohepatic omentum. Symptoms of penetration include back and epigastric pain not relieved by medications that were effective in the past. Like perforation, penetration usually requires surgical intervention.

Signs and symptoms of perforation include the following:

- Sudden, severe upper abdominal pain (persisting and increasing in intensity); pain may be referred to the shoulders, especially the right shoulder, because of irritation of the phrenic nerve in the diaphragm.
- Vomiting and collapse (fainting)
- Extremely tender and rigid (boardlike) abdomen
- Hypotension and tachycardia, indicating shock

Because chemical peritonitis develops within a few hours after perforation and is followed by bacterial peritonitis, the perforation must be closed as quickly as possible. In a few patients, it may be deemed safe and advisable to perform surgery for the ulcer disease in addition to suturing the perforation.

Postoperatively, the stomach contents are drained by means of an NG tube. The nurse monitors fluid and electrolyte balance and assesses the patient for peritonitis or localized infection (increased temperature, abdominal pain, paralytic ileus, increased or absent bowel sounds, abdominal distention). Antibiotic therapy is administered parenterally as prescribed.

### Pyloric Obstruction

Pyloric obstruction, also called gastric outlet obstruction (GOO), occurs when the area distal to the pyloric sphincter becomes scarred and stenosed from spasm or edema or from scar tissue that forms when an ulcer alternately heals and breaks down. The patient has nausea and vomiting, constipation, epigastric fullness, anorexia, and, later, weight loss.

In treating the patient with pyloric obstruction, the first consideration is to insert an NG tube to decompress the stomach. Confirmation that obstruction is the cause of the discomfort is accomplished by assessing the amount of fluid aspirated from the NG tube. A residual of more than 400 mL strongly suggests obstruction. Usually an upper GI study or endoscopy is performed to confirm gastric outlet obstruction. Decompression of the stomach and management of extracellular fluid volume and electrolyte balances may improve the patient's condition and avert the need for surgical intervention. A balloon dilatation of the pylorus via endoscopy may be beneficial. If the obstruction is unrelieved by medical management, surgery (in the form of a vagotomy and **antrectomy** or gastrojejunostomy and vagotomy) may be required.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

To manage ulcer disease successfully, the patient is instructed about the factors that will help or aggravate the condition (Chart 37-2). The nurse reviews information about medications to be taken at

Chart 37-2

## Home Care Checklist • The Patient With Peptic Ulcer Disease

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• State the medication regimen and importance of complying with medication schedule.	✓	✓
• State dietary restrictions and foods that may exacerbate condition (caffeine products, milk).	✓	✓
• Identify smoking cessation groups.	✓	
• Identify methods to reduce stress.	✓	✓
• State signs and symptoms of complications:	✓	✓
Hemorrhage—cool skin, confusion, increased heart rate, labored breathing, blood in stool		
Penetration and perforation—severe abdominal pain, rigid and tender abdomen, vomiting, elevated temperature, increased heart rate		
Pyloric obstruction—nausea and vomiting, distended abdomen, abdominal pain		
• State need for follow-up medical care.	✓	✓

home, including name, dosage, frequency, and possible side effects, stressing the importance of continuing to take medications even after signs and symptoms have decreased or subsided. Then the patient is instructed to avoid certain medications and foods that exacerbate symptoms as well as substances that have acid-producing potential (eg, alcohol; caffeinated beverages such as coffee, tea, and colas). It is important to counsel the patient to eat meals at regular times and in a relaxed setting, and to avoid overeating. If relevant, the nurse also informs the patient about the irritant effects of smoking on the ulcer and provides information about smoking cessation programs.

**NURSING ALERT** The nurse reviews with the patient and family the signs and symptoms of complications to be reported. They include hemorrhage (cool skin, confusion, increased heart rate, labored breathing, and blood in the stool); penetration and perforation (severe abdominal pain, rigid and tender abdomen, vomiting, elevated temperature, and increased heart rate); and pyloric obstruction (nausea, vomiting, distended abdomen, and abdominal pain).

The nurse reinforces the importance of follow-up care for approximately 1 year, the need to report recurrence of symptoms, and the need for treating possible problems that occur after surgery, such as intolerance to dairy products and sweet foods.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Reports freedom from pain between meals
2. Feels less anxiety by avoiding stress
3. Complies with therapeutic regimen
  - a. Avoids irritating foods and beverages
  - b. Eats regularly scheduled meals
  - c. Takes prescribed medications as scheduled
  - d. Uses coping mechanisms to deal with stress
4. Maintains weight
5. Is free of complications

## Morbid Obesity

One in three Americans is 20% or more over his or her ideal body weight (U.S. Department of Health and Human Services, 2001). **Morbid obesity** is the term applied to people who are more than

two times their ideal body weight or whose body mass index (BMI) exceeds 30 kg/m<sup>2</sup>. (See Chapter 5.)

Another definition of morbid obesity is body weight that is more than 100 pounds greater than the ideal body weight (Monteforte & Turkelson, 2000). Patients with morbid obesity are at higher risk for health complications, such as cardiovascular disease, arthritis, asthma, bronchitis, and diabetes. They frequently suffer from low self-esteem, impaired body image, and depression.

## Medical Management

Conservative management consists of placing the person on a weight loss diet in conjunction with behavioral modification and exercise; however, diet therapy is usually unsuccessful. There is a belief that depression may be a contributing factor to weight gain, and treatment of the depression with bupropion hydrochloride (Wellbutrin) may be helpful (Wangness, 2000). Some physicians recommend acupuncture and hypnosis before recommending surgery.

### PHARMACOLOGIC MANAGEMENT

Several medications have recently been approved for obesity. They include sibutramine HCl (Meridia) and orlistat (Xenical). By inhibiting the reuptake of serotonin and norepinephrine, sibutramine decreases appetite. Orlistat reduces caloric intake by binding to gastric and pancreatic lipase to prevent digestion of fats. Both medications require a physician's prescription. Sibutramine may increase blood pressure and should not be taken by people with a history of coronary artery disease, angina pectoris, dysrhythmias, or kidney disease; by those taking antidepressants or monoamine oxidase inhibitors; or by pregnant or nursing women. Side effects may include dry mouth, insomnia, headache, increased sweating, and increased heart rate. Side effects of orlistat may include increased bowel movements, gas with oily discharge, decreased food absorption, decreased bile flow, and decreased absorption of some vitamins. A multivitamin is usually recommended for patients taking orlistat. Women who are pregnant or nursing should not take orlistat (Hussar, 2000).

### SURGICAL MANAGEMENT

Bariatric surgery, or surgery for morbid obesity, is performed only after other nonsurgical attempts at weight control have failed. The first surgical procedure to treat morbid obesity was the jejunioileal bypass. This procedure, which resulted in significant

complications, has been largely replaced by gastric restriction procedures. Gastric bypass and vertical banded gastroplasty are the current operations of choice. These procedures may be performed laparoscopically or by an open surgical technique.

In gastric bypass surgery, the proximal segment of the stomach is transected to form a small pouch with a small gastroenterostomy stoma. The Roux-en-Y gastric bypass is the recommended procedure for long-term weight loss. In this procedure, a horizontal row of staples creates a stomach pouch with a 1-cm stoma that is anastomosed with a portion of distal jejunum, creating a gastroenterostomy. The transected proximal portion of the jejunum is anastomosed to the distal jejunum (Fig. 37-3A).

In vertical banded gastroplasty, a double row of staples is applied vertically along the lesser curvature of the stomach, beginning at the angle of His. A small stoma is created at the end of the staples by adding a circle of staples or a band of polypropylene mesh or silicone tubing (see Fig. 37-3B).

After weight loss, the patient may need surgical intervention for body contouring. This may include lipoplasty to remove fat deposits or a panniculectomy to remove excess abdominal skinfolds.

## Nursing Management

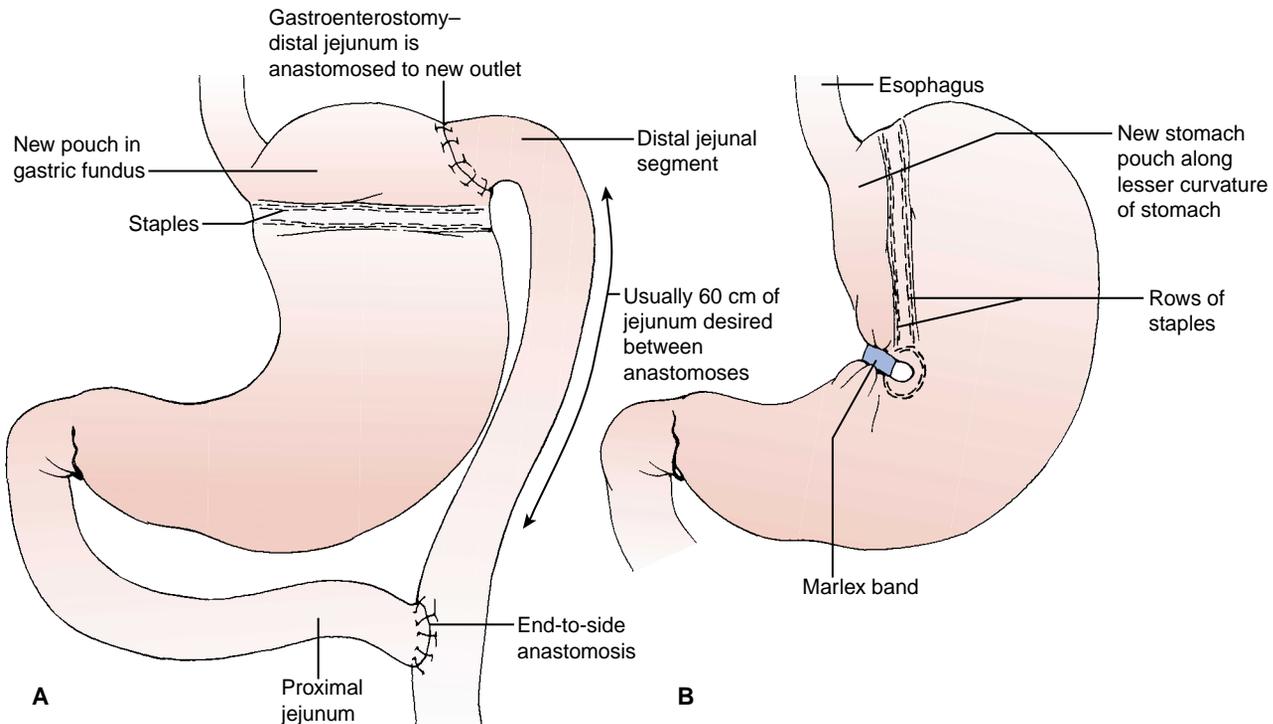

Nursing management focuses on care of the patient after surgery. General postoperative nursing care is similar to that for a patient recovering from a gastric resection, but with attention given to the risks of complications associated with morbid obesity. Complications that may occur in the immediate postoperative period include peritonitis, stomal obstruction, stomal ulcers, atelectasis and pneumonia, thromboembolism, and metabolic imbalances resulting from prolonged vomiting and diarrhea. After bowel sounds have returned and oral intake is resumed, the nurse provides six

small feedings consisting of a total of 600 to 800 calories per day and encourages fluid intake to prevent dehydration.

Patients are usually discharged in 4 to 5 days with detailed dietary instructions. The nurse instructs patients to report excessive thirst or concentrated urine, both of which are indications of dehydration. Psychosocial interventions are also essential for these patients. Efforts are directed toward helping them modify their eating behaviors and cope with changes in body image. The nurse explains that noncompliance by eating too much or too fast or eating high-calorie liquid and soft foods results in vomiting and painful esophageal distention. The nurse discusses dietary instructions before discharge and schedules monthly outpatient visits. Long-term side effects may include increased risk of gallstones, nutritional deficiencies, and potential to regain weight.

## Gastric Cancer

The incidence of cancer of the stomach continues to decrease in the United States; however, it still accounts for 12,400 deaths annually (American Cancer Society, 2002). Most of these deaths occur in people older than 40 years of age, but they occasionally occur in younger people. Men have a higher incidence of gastric cancers than women do. The incidence of gastric cancer is much greater in Japan, which has instituted mass screening programs for earlier diagnosis. Diet appears to be a significant factor. A diet high in smoked foods and low in fruits and vegetables may increase the risk of gastric cancer. Other factors related to the incidence of gastric cancer include chronic inflammation of the stomach, pernicious anemia, achlorhydria, gastric ulcers, *H. pylori* infection, and genetics. The prognosis is poor, because most patients have metastases at the time of diagnosis (Greenlee, 2001).

**FIGURE 37-3** Surgical procedures for morbid obesity. (A) Gastric bypass with roux-en-Y. A horizontal row of staples creates a pouch with a capacity of 50 mL or less. The proximal jejunum is transected and the distal end anastomosed to the new pouch. The proximal segment is anastomosed to the jejunum. (B) Vertical banded gastroplasty. A vertical row of staples along the lesser curvature of the stomach creates a new, smaller stomach pouch of 10 to 15 mL.

## Pathophysiology

Most gastric cancers are adenocarcinomas and can occur in any portion of the stomach. The tumor infiltrates the surrounding mucosa, penetrating the wall of the stomach and adjacent organs and structures. The liver, pancreas, esophagus, and duodenum are often affected at the time of diagnosis. Metastasis through lymph to the peritoneal cavity occurs later in the disease.

## Clinical Manifestations

In the early stages of gastric cancer, symptoms may be absent. Early symptoms are seldom definitive because most gastric tumors begin on the lesser curvature, where they cause little disturbance of gastric functions. Some studies show that early symptoms, such as pain relieved with antacids, resemble those of benign ulcers. Symptoms of progressive disease may include anorexia, dyspepsia (indigestion), weight loss, abdominal pain, constipation, anemia, and nausea and vomiting.

## Assessment and Diagnostic Findings

Usually the physical examination is not helpful in detecting cancer because most gastric tumors are not palpable. Ascites may be apparent if the cancer cells have metastasized to the liver. Endoscopy for biopsy and cytologic washings is the usual diagnostic study, and a barium x-ray examination of the upper GI tract may also be performed. Because metastasis often occurs before warning signs develop, a computed tomography (CT) scan, bone scan, and liver scan are valuable in determining the extent of metastasis. A complete x-ray examination of the GI tract should be performed when any person older than 40 years of age has had indigestion (dyspepsia) of more than 4 weeks' duration.

## Medical Management

There is no successful treatment for gastric carcinoma except removal of the tumor. If the tumor can be removed while it is still localized to the stomach, the patient can be cured. If the tumor has spread beyond the area that can be excised, cure is impossible. Palliative rather than radical surgery is performed if there is metastasis to other vital organs, such as the liver. In many of these patients, effective palliation to prevent discomfort caused by obstruction or dysphagia may be obtained by resection of the tumor (see Gastric Surgery).

If a radical subtotal gastrectomy is performed, the stump of the stomach is anastomosed to the jejunum, as in the gastrectomy for ulcer. When a total gastrectomy is performed, GI continuity is restored by means of an anastomosis between the ends of the esophagus and the jejunum.

If surgical treatment does not offer cure, treatment with chemotherapy may offer further control of the disease or palliation. Commonly used chemotherapeutic medications include cisplatin, irinotecan, or a combination of 5-fluorouracil, doxorubicin (Adriamycin), and mitomycin-C. Some studies are being conducted on the use of chemotherapy before surgery. Radiation therapy also may be used for palliation. Assessment of tumor markers (blood analysis for antigens indicative of colon cancer) such as carcinoembryonic antigen, CA 19-9, and CA 50 may help determine the effectiveness of treatment. If these values were elevated before treatment, they should decrease if the tumor is responding to the treatment (Bobbio-Pallavicini et al., 2001; Kerby & Heslin, 1999).

## NURSING PROCESS: THE PATIENT WITH GASTRIC CANCER

### Assessment

The nurse elicits a dietary history from the patient, focusing on recent nutritional intake and status. Has the patient lost weight? If so, how much and over what period of time? Can the patient tolerate a full diet? If not, what foods can he or she eat? What other changes in eating habits have occurred? Does the patient have an appetite? Is the patient in pain? Do foods, antacids, or medications relieve the pain, make no difference, or worsen the pain? Is there a history of infection with *H. pylori* bacteria? Other health information to obtain includes the patient's smoking and alcohol history and the family history (any first- or second-degree relatives with gastric or other cancer). A psychosocial assessment, including questions about social support, individual and family coping skills, and financial resources, will help the nurse plan for care in acute and community settings.

After the interview, the nurse performs a complete physical examination, carefully assesses the patient's abdomen for tenderness or masses, and also palpates and percusses to detect ascites.

### Nursing Diagnosis

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Anxiety related to the disease and anticipated treatment
- Imbalanced nutrition, less than body requirements, related to anorexia
- Pain related to tumor mass
- Anticipatory grieving related to the diagnosis of cancer
- Deficient knowledge regarding self-care activities

### Planning and Goals

The major goals for the patient may include reduced anxiety, optimal nutrition, relief of pain, and adjustment to the diagnosis and anticipated lifestyle changes.

### Nursing Interventions

#### REDUCING ANXIETY

A relaxed, nonthreatening atmosphere is provided so that patient can express fears, concerns, and possibly anger about the diagnosis and prognosis. The nurse encourages the family in their efforts to support the patient, offering reassurance and supporting positive coping measures. The nurse advises the patient about any procedures and treatments so that the patient knows what to expect. The nurse also may suggest talking with a support person (eg, spiritual advisor), if the patient desires.

#### PROMOTING OPTIMAL NUTRITION

The nurse encourages the patient to eat small, frequent portions of nonirritating foods to decrease gastric irritation. Food supplements should be high in calories, as well as vitamins A and C and iron, to enhance tissue repair. If the patient is unable to eat adequately to meet nutritional requirements, parenteral nutrition may be necessary. Because the patient may develop dumping syndrome when enteral feeding resumes after gastric resection, the nurse explains ways to prevent and manage it (six small feedings daily that are low in carbohydrates and sugar; fluids between meals rather than with meals) and informs the patient that symptoms often resolve after

several months. If a total gastrectomy is performed, parenteral vitamin B<sub>12</sub> will be required indefinitely, because dietary vitamin B<sub>12</sub> is absorbed in the stomach. The nurse monitors the IV therapy and nutritional status and records intake, output, and daily weights to ensure that the patient is maintaining or gaining weight. The nurse assesses for signs of dehydration (thirst, dry mucous membranes, poor skin turgor, tachycardia, decreased urine output) and reviews the results of daily laboratory studies to note any metabolic abnormalities (sodium, potassium, glucose, blood urea nitrogen). Antiemetics are administered as prescribed.

### RELIEVING PAIN

The nurse administers analgesics as prescribed. A continuous infusion of an opioid may be necessary for severe pain. The nurse assesses the frequency, intensity, and duration of the pain to determine the effectiveness of the analgesic being administered. The nurse works with the patient to manage pain by suggesting non-pharmacologic methods for pain relief, such as position changes, imagery, distraction, relaxation exercises (using relaxation audiotapes), backrubs, massage, and periods of rest and relaxation.

### PROVIDING PSYCHOSOCIAL SUPPORT

The nurse helps the patient express fears, concerns, and grief about the diagnosis. It is important to answer the patient's questions honestly and to encourage the patient to participate in treatment decisions. Some patients mourn the loss of a body part and perceive their surgery as a type of mutilation. Some express disbelief and need time and support to accept the diagnosis.

The nurse offers emotional support and involves family members and significant others whenever possible. This includes recognizing mood swings and defense mechanisms (eg, denial, rationalization, displacement, regression) and reassuring the patient and family members that emotional responses are normal and expected. The services of clergy, psychiatric clinical nurse specialists, psychologists, social workers, and psychiatrists are made available, if needed. The nurse projects an empathetic attitude and spends time with the patient. Most patients will begin to participate in self-care activities after they have acknowledged their loss.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

Self-care activities will depend on the mode of treatment used—surgery, chemotherapy, radiation, or palliative care. Patient and family teaching will include information about diet and nutrition, treatment regimens, activity and lifestyle changes, pain management, and possible complications (Chart 37-3). Consul-

tation with a dietitian is essential to determine how the patient's nutritional needs can best be met at home. The nurse teaches the patient or care provider about administration of enteral or parenteral nutrition. If chemotherapy or radiation is prescribed, the nurse provides explanations to the patient and family about what to expect, including the length of treatments, the expected side effects (eg, nausea, vomiting, anorexia, fatigue, neutropenia), and the need for transportation to appointments for treatment. Psychological counseling may also be helpful.

### Continuing Care

The need for ongoing care in the home will depend on the patient's condition and treatment. The home care nurse reinforces nutritional counseling and supervises the administration of any enteral or parenteral feedings; the patient or family member must become skillful in administering the feedings and in detecting and preventing untoward effects or complications related to the feedings (see Chapter 36 to review management of enteral and parenteral feedings). The nurse teaches the patient or a family member to record the patient's daily intake, output, and weight and explains strategies to manage pain, nausea, vomiting, or other symptoms. The nurse also teaches the patient or caregiver to recognize and report signs and symptoms of complications that require medical attention, such as bleeding, obstruction, perforation, or any symptoms that become progressively worse. It is important to explain the chemotherapy or radiation therapy regimen. The patient and family need to know about the care that will be needed during and after treatments (see Chapter 16). Because the prognosis for gastric cancer is so poor, the nurse may need to assist the patient and family with decisions regarding end-of-life care. Referral to hospice may be warranted.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Reports less anxiety
  - a. Expresses fears and concerns about surgery
  - b. Seeks emotional support
2. Attains optimal nutrition
  - a. Eats small, frequent meals high in calories, iron, and vitamins A and C
  - b. Complies with enteral or parenteral nutrition as needed
3. Has less pain
4. Performs self-care activities and adjusts to lifestyle changes
  - a. Resumes normal activities within 3 months
  - b. Alternates periods of rest and activity
  - c. Manages tube feedings

Chart 37-3

#### Home Care Checklist • The Patient With Gastric Cancer

At the completion of the home care instruction, the patient or caregiver will be able to:

- Demonstrate safe management of enteral or parenteral feedings, if applicable.
- Describes dietary restrictions.
- Identifies potential side effects of chemotherapy or radiation therapy, if applicable
- Identifies signs and symptoms of wound infection.
- State signs and symptoms of obstruction or perforation.
- Describes follow-up needs.

	Patient	Caregiver
• Demonstrate safe management of enteral or parenteral feedings, if applicable.	✓	✓
• Describes dietary restrictions.	✓	✓
• Identifies potential side effects of chemotherapy or radiation therapy, if applicable	✓	✓
• Identifies signs and symptoms of wound infection.	✓	✓
• State signs and symptoms of obstruction or perforation.	✓	✓
• Describes follow-up needs.	✓	✓

## Gastric Surgery

Gastric surgery may be performed on patients with peptic ulcers who have life-threatening hemorrhage, obstruction, perforation, or penetration or whose condition does not respond to medication. It also may be indicated for patients with gastric cancer or trauma. Surgical procedures include a vagotomy and **pyloroplasty** (disconnecting nerves that stimulate acid secretion and opening the pylorus), a partial gastrectomy, and a total gastrectomy (removal of the stomach) with either an end-to-end or an end-to-side esophagojejunal anastomosis (see Table 37-3).

### NURSING PROCESS: THE PATIENT UNDERGOING GASTRIC SURGERY

#### Assessment

Before surgery, the nurse assesses the patient's and family's knowledge of preoperative and postoperative surgical routines and the rationale for surgery. The nurse also assesses the patient's nutritional status: Has the patient lost weight? How much? Over how much time? Does the patient have nausea and vomiting? Has the patient had hematemesis? The nurse assesses for the presence of bowel sounds and palpates the abdomen to detect masses or tenderness.

After surgery, the nurse assesses the patient for complications secondary to the surgical intervention, such as hemorrhage, infection, abdominal distention, or decreased nutritional status. (See Chapters 20 and 25.)

#### Diagnosis

##### NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Anxiety related to surgical intervention
- Acute pain related to surgical incision
- Deficient knowledge about surgical procedures and postoperative course
- Imbalanced nutrition, less than body requirements, related to poor nutrition before surgery and altered GI system after surgery

##### COLLABORATIVE PROBLEMS/POTENTIAL COMPLICATIONS

In addition to the complications to which all postoperative patients are subject, the patient undergoing gastric surgery is at increased risk for:

- Hemorrhage
- Dietary deficiencies
- Bile reflux
- Dumping syndrome

#### Planning and Goals

The major goals for the patient undergoing gastric surgery may include reduced anxiety, increased knowledge and understanding about the surgical procedure and postoperative course, optimal nutrition and management of the complications that can interfere with nutrition, relief of pain, avoidance of hemorrhage and steatorrhea, and enhanced self-care skills at home. General postoperative care for the patient who has received general anesthesia, as discussed in Chapter 20, should be followed.

## Nursing Interventions

### REDUCING ANXIETY

An important part of the preoperative nursing care involves allaying the patient's fears and anxieties about the impending surgery and its implications. The nurse encourages the patient to express feelings and answers the patient's and family's questions. If the patient has an acute obstruction, a perforated bowel, or an active GI hemorrhage, adequate psychological preparation may not be possible. In this event, the nurse caring for the patient after surgery should anticipate the concerns, fears, and questions that are likely to surface and should be available for support and further explanations.

### RELIEVING PAIN

After surgery, analgesics may be administered as prescribed to relieve pain and discomfort. It is important to avoid sedating the patient so as not to impair his or her ability to perform pulmonary care activities (deep breathing and coughing) and to ambulate. The nurse assesses the effectiveness of analgesic intervention. Positioning the patient in a Fowler's position promotes comfort and allows emptying of the stomach after a partial gastrectomy.

The nurse maintains functioning of the NG tube to prevent distention and resultant pain and damage to the suture line. Normally, the amount of NG drainage after a total gastrectomy is small.

### INCREASING KNOWLEDGE

The nurse explains routine preoperative and postoperative activities to the patient, which include preoperative medications, NG intubation, IV fluids, abdominal dressings, and pulmonary care. These explanations need to be reinforced after surgery, especially if the patient had emergency surgery.

### RESUMING ENTERAL INTAKE

The patient's nutritional status is evaluated before surgery, because many patients with gastric cancer are malnourished and may require preoperative enteral or, more often, parenteral nutrition (see Chapter 36). After surgery, parenteral nutrition may be continued to meet caloric needs, to replace fluids lost through drainage and vomitus, and to support the patient metabolically until oral intake is adequate.

After the return of bowel sounds and removal of the NG tube, the nurse may give fluids, followed by food in small portions. The nurse adds foods gradually until the patient is able to eat six small meals a day and drink 120 mL of fluid between meals. The key to increasing the dietary content is to offer food and fluids gradually as tolerated and to recognize that each patient's tolerance is different.

### RECOGNIZING OBSTACLES TO ADEQUATE NUTRITION

#### Dysphagia and Gastric Retention

Dysphagia may occur in patients who have had truncal vagotomy, a surgical procedure that can result in trauma to the lower esophagus. Gastric retention may be evidenced by abdominal distention, nausea, and vomiting. Regurgitation may also occur if the patient has eaten too much or too quickly. It also may indicate that edema along the suture line is preventing fluids and food from moving into the intestinal tract. If gastric retention occurs, it may be necessary to reinstate NG suction; pressure must be low to avoid disrupting the suture line.

#### Bile Reflux

Bile reflux gastritis and esophagitis may occur with the removal of the pylorus, which acts as a barrier to the reflux of duodenal contents. Burning epigastric pain and vomiting of bilious material manifest this condition. Eating or vomiting does not relieve the

situation. Agents that bind with bile acid, such as cholestyramine (Questran), may be helpful. Aluminum hydroxide gel (an antacid) and metoclopramide hydrochloride (Reglan) have been used with some success.

### Dumping Syndrome

The term **dumping syndrome** refers to an unpleasant set of vasomotor and GI symptoms that sometimes occur in patients who have had gastric surgery or a form of vagotomy. It may be the mechanical result of surgery in which a small gastric remnant is connected to the jejunum through a large opening. Foods high in carbohydrates and electrolytes must be diluted in the jejunum before absorption can take place, but the passage of food from the stomach remnant into the jejunum is too rapid to allow this to happen. The symptoms that occur are probably a result of rapid distention of the jejunal loop anastomosed to the stomach. The hypertonic intestinal contents draw extracellular fluid from the circulating blood volume into the jejunum to dilute the high concentration of electrolytes and sugars. The ingestion of fluid at mealtime is another factor that causes the stomach contents to empty rapidly into the jejunum.

Early symptoms include a sensation of fullness, weakness, faintness, dizziness, palpitations, diaphoresis, cramping pains, and diarrhea. Later, there is a rapid elevation of blood glucose, followed by increased insulin secretion. This results in a reactive hypoglycemia, which also is unpleasant for the patient. Vasomotor symptoms that occur 10 to 90 minutes after eating are pallor, perspiration, palpitations, headache, and feelings of warmth, dizziness, and even drowsiness. Anorexia may also be a result of the dumping syndrome.

Steatorrhea also may occur in the patient with gastric surgery. It is partially the result of rapid gastric emptying, which prevents adequate mixing with pancreatic and biliary secretions. In mild cases, reducing the intake of fat and administering an antimotility medication can control steatorrhea.

### Vitamin and Mineral Deficiencies

Other dietary deficiencies the nurse should be aware of include malabsorption of organic iron, which may require supplementation with oral or parenteral iron, and a low serum level of vitamin B<sub>12</sub>, which may require supplementation by the intramuscular route. Total gastrectomy results in lack of intrinsic factor, a gastric secretion required for the absorption of vitamin B<sub>12</sub> from the GI tract. Unless this vitamin is supplied by parenteral injection after gastrectomy, the patient inevitably will suffer vitamin B<sub>12</sub> deficiency, which eventually leads to a condition identical to pernicious anemia. All manifestations of pernicious anemia, including macrocytic anemia and combined system disease, may be expected to develop within a period of 5 years or less; they progress in severity thereafter and, in the absence of therapy, are fatal. This complication is avoided by the regular monthly intramuscular injection of 100 to 1000 µg (usual dose is 300 µg) of vitamin B<sub>12</sub>.

This regimen should be started without delay after gastrectomy. Weight loss is a common long-term problem because the patient experiences early fullness, which suppresses the appetite.

### TEACHING DIETARY SELF-MANAGEMENT

Because the patient may experience any of the described conditions affecting nutrition, nursing intervention includes proper dietary instruction. The following teaching points are emphasized:

- To delay stomach emptying, the patient should assume a low Fowler's position during mealtime, and after the meal the patient should lie down for 20 to 30 minutes.
- Antispasmodics, as prescribed, also may aid in delaying the emptying of the stomach.
- Fluid intake with meals is discouraged; instead, fluids may be consumed up to 1 hour before or 1 hour after mealtime.
- Meals should contain more dry items than liquid items.
- The patient can eat fat as tolerated but should keep carbohydrate intake low and avoid concentrated sources of carbohydrates.
- The patient should eat smaller but more frequent meals.
- Dietary supplements of vitamins and medium-chain triglycerides and injections of vitamin B<sub>12</sub> and iron may be prescribed.

The nurse also gives instructions regarding enteral or parenteral supplementation if it is needed.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Occasionally hemorrhage complicates gastric surgery. The patient has the usual signs of rapid blood loss and shock (see Chapter 15) and may vomit considerable amounts of bright red blood. The nurse assesses NG drainage for type and amount; some bloody drainage for the first 12 hours is expected, but excessive bleeding should be reported. The nurse also assesses the abdominal dressing for bleeding. Because this situation is upsetting to the patient and family, the nurse should remain calm. The nurse performs emergency measures, such as NG lavage and administration of blood and blood products.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

Nurse-patient teaching stems from the assessment of the patient's physical and psychological readiness to participate in self-care. The nurse provides information about nutrition, enteral or parenteral nutrition if required, nutritional supplements, pain management, and the symptoms of dumping syndrome and measures to use to prevent or minimize these symptoms (Chart 37-4). It is important to emphasize the continued need for vitamin B<sub>12</sub> injections.

Chart 37-4

#### Home Care Checklist • The Patient With Gastric Resection

At the completion of the home care instruction, the patient or caregiver will be able to:

- Demonstrate enteral or parenteral feedings as applicable.
- State necessary dietary changes.
- Identify available support groups.
- Explain medication regimen.
- Identify signs and symptoms of complications

	Patient	Caregiver
• Demonstrate enteral or parenteral feedings as applicable.	✓	✓
• State necessary dietary changes.	✓	✓
• Identify available support groups.	✓	✓
• Explain medication regimen.	✓	✓
• Identify signs and symptoms of complications	✓	✓

### Continuing Care

Both the patient and the family can benefit from a team approach to discharge planning. The team members include the home care nurse, physician, dietitian, social worker, patient and family; written instructions about meals, activities, medications, and follow-up care are helpful. The home care nurse supervises the administration of any enteral or parenteral feedings, emphasizing information about detection and prevention of untoward effects or complications related to the feedings. Information about community support groups is provided to the patient and family.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Reports decreased anxiety; expresses fears and concerns about surgery
2. Demonstrates knowledge regarding postoperative course by discussing the surgical procedure and postoperative course
3. Attains optimal nutrition
  - a. Maintains a reasonable weight
  - b. Does not have excessive diarrhea
  - c. Tolerates 6 small meals a day
  - d. Does not experience dysphagia, gastric retention, bile reflux, dumping syndrome, or vitamin and mineral deficiencies
4. Attains optimal level of comfort
5. Has no evidence of hemorrhage

### Critical Thinking Exercises

1. You are working in the office of a gastroenterologist. You have a patient coming in today with symptoms of a peptic ulcer. What questions will you ask the patient, and what types of teaching regimen do you anticipate you will need to review with this patient?
2. You are caring for a patient who is to have a gastrectomy to treat gastric cancer. What nutritional needs do you anticipate for this patient preoperatively, immediately postoperatively, and after discharge from the hospital?
3. Your 45-year-old patient who weighs 375 pounds has had gastric bypass to treat morbid obesity. Describe the preoperative interventions for this patient. How would you modify your interventions if the patient had diabetes? If he had angina?

# ● Management of Patients With Intestinal and Rectal Disorders

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Identify the health care teaching needs of patients with constipation or diarrhea.
2. Compare the conditions of malabsorption with regard to their pathophysiology, clinical manifestations, and management.
3. Use the nursing process as a framework for care of patients with diverticulitis.
4. Compare regional enteritis and ulcerative colitis with regard to their pathophysiology, clinical manifestations, diagnostic evaluation, and medical, surgical, and nursing management.
5. Use the nursing process as a framework for care of the patient with an inflammatory bowel disease.
6. Describe the responsibilities of the nurse in meeting the needs of the patient with an ileostomy.
7. Describe the various types of intestinal obstructions and their management.
8. Use the nursing process as a framework for care of the patient with cancer of the colon or rectum.
9. Use the nursing process as a framework for care of the patient with an anorectal condition.

**D**iseases of the gastrointestinal (GI) tract account for about 10% of the total burden of illness in the United States. They account for more than 50 million office visits annually and nearly 10 million hospital admissions. GI diseases probably cost the American public up to \$100 billion yearly and account for 10% of all deaths each year (Goldman & Bennett, 2000). The types of diseases and disorders that affect the lower GI tract are many and varied.

In all age groups, a fast-paced lifestyle, high levels of stress, irregular eating habits, insufficient intake of fiber and water, and lack of daily exercise contribute to GI problems. Nurses can have an impact on these chronic problems by identifying behavior patterns that put patients at risk, by educating the public about prevention and management, and by helping those affected to improve their condition and prevent complications.

## Abnormalities of Fecal Elimination

Changes in patterns of fecal elimination are symptoms of functional disorders or disease of the GI tract. The most common changes seen are constipation, diarrhea, and fecal incontinence. The nurse should be aware of the possible causes and therapeutic management of these problems and of nursing management techniques. Education is important for patients with these abnormalities.

### CONSTIPATION

*Constipation* is a term used to describe an abnormal infrequency or irregularity of defecation, abnormal hardening of stools that makes their passage difficult and sometimes painful, a decrease in stool volume, or retention of stool in the rectum for a prolonged period. Any variation from normal habits may be considered a problem.

Constipation can be caused by certain medications (ie, tranquilizers, anticholinergics, antidepressants, antihypertensives, opioids, antacids with aluminum, and iron); rectal or anal disorders (eg, hemorrhoids, fissures); obstruction (eg, cancer of the bowel); metabolic, neurologic, and neuromuscular conditions (eg, diabetes mellitus, Hirschsprung's disease, Parkinson's disease, multiple sclerosis); endocrine disorders (eg, hypothyroidism, pheochromocytoma); lead poisoning; and connective tissue disorders (eg, scleroderma, lupus erythematosus). Constipation is a major problem for patients taking opioids for chronic pain. Diseases of the colon commonly associated with constipa-

tion are irritable bowel syndrome (IBS) and diverticular disease. Constipation can also occur with an acute disease process in the abdomen (eg, appendicitis).

Other causes include weakness, immobility, debility, fatigue, and an inability to increase intra-abdominal pressure to facilitate the passage of stools, as occurs with emphysema. Many people develop constipation because they do not take the time to defecate or they ignore the urge to defecate. In the United States, constipation is also a result of dietary habits (ie, low consumption of fiber and inadequate fluid intake), lack of regular exercise, and a stress-filled life.

Perceived constipation can also be a problem. This subjective problem occurs when an individual's bowel elimination pattern is not consistent with what he or she perceives as normal. Chronic laxative use is attributed to this problem and is a major health concern in the United States, especially among the elderly population.

### Pathophysiology

The pathophysiology of constipation is poorly understood, but it is thought to include interference with one of three major functions of the colon: mucosal transport (ie, mucosal secretions facilitate the movement of colon contents), myoelectric activity (ie, mixing of the rectal mass and propulsive actions), or the processes of defecation. Any of the causative factors previously identified can interfere with any of these three processes.

The urge to defecate is stimulated normally by rectal distention, which initiates a series of four actions: stimulation of the inhibitory rectoanal reflex, relaxation of the internal sphincter muscle, relaxation of the external sphincter muscle and muscles in the pelvic region, and increased intra-abdominal pressure. Interference with any of these processes can lead to constipation.

If all organic causes are eliminated, idiopathic constipation is diagnosed. If the urge to defecate is ignored, the rectal mucous membrane and musculature become insensitive to the presence of fecal masses, and consequently, a stronger stimulus is required to produce the necessary peristaltic rush for defecation. The initial effect of fecal retention is to produce irritability of the colon, which at this stage frequently goes into spasm, especially after meals, giving rise to colicky midabdominal or low abdominal pains. After several years of this process, the colon loses muscular tone and becomes essentially unresponsive to normal stimuli. Atony or decreased muscle tone occurs with aging. This also leads to constipation because the stool is retained for longer periods.

## Glossary

**appendicitis:** infectious and inflammatory process of the appendix creating acute abdominal pain and nausea

**azotorrhea:** excess of nitrogenous matter in the feces or urine

**colostomy:** surgical opening into the colon by means of a stoma to allow drainage of bowel contents; one type of fecal diversion

**diverticulitis:** inflammation of a diverticulum from obstruction (by fecal matter), resulting in abscess formation

**diverticulosis:** presence of a number of diverticula in the intestine; common in middle age

**diverticulum:** saclike outpouching of the lining of the bowel protruding through the muscle of the intestinal wall, usually caused by high intraluminal pressure

**hemorrhoids:** dilated portions of the anal veins; can occur internal or external to the anal sphincter

**ileostomy:** surgical opening into the ileum by means of a stoma to allow drainage of bowel contents; one type of fecal diversion

**inflammatory bowel disease:** group of chronic disorders (most common are ulcerative colitis and regional enteritis [Crohn's disease]) that result in inflamma-

tion or ulceration (or both) of the bowel lining, associated with abdominal pain, diarrhea, fever, and weight loss

**irritable bowel syndrome:** functional disorder that affects frequency of defecation and consistency of stool; associated with crampy abdominal pain and bloating

**malabsorption:** impaired transport across the mucosa

**peritonitis:** inflammation of the lining of the abdominal cavity, usually as a result of a bacterial infection of an area in the GI tract with leakage of contents into the abdominal cavity

## Clinical Manifestations

Clinical manifestations include abdominal distention, borborygmus (ie, gurgling or rumbling sound caused by passage of gas through the intestine), pain and pressure, decreased appetite, headache, fatigue, indigestion, a sensation of incomplete emptying, straining at stool, and the elimination of small-volume, hard, dry stools.

## Assessment and Diagnostic Findings

Chronic constipation is usually considered idiopathic, but secondary causes should be excluded. In patients with severe, intractable constipation, further diagnostic testing is needed (Wong, 1999). The diagnosis of constipation is based on results of the patient's history, physical examination, possibly a barium enema or sigmoidoscopy, and stool testing for occult blood. These tests are completed to determine whether this symptom results from spasm or narrowing of the bowel. Anorectal manometry (ie, pressure studies) may be performed to determine malfunction of the muscle and sphincter. Defecography and bowel transit studies can also assist in the diagnosis (see Chap. 34).

## Complications

Complications of constipation include hypertension, fecal impaction, hemorrhoids and fissures, and megacolon. Increased arterial pressure can occur with defecation. Straining at stool, which results in the Valsalva maneuver (ie, forcibly exhaling with the glottis closed), has a striking effect on arterial blood pressure. During active straining, the flow of venous blood in the chest is temporarily impeded because of increased intrathoracic pressure. This pressure tends to collapse the large veins in the chest. The atria and the ventricles receive less blood, and consequently less is delivered by the systolic contractions of the left ventricle. The cardiac output is decreased, and there is a transient drop in arterial pressure. Almost immediately after this period of hypotension, a rise in arterial pressure occurs; the pressure is elevated momentarily to a point far exceeding the original level (ie, rebound phenomenon). In patients with hypertension, this compensatory reaction may be exaggerated greatly, and the peaks of pressure attained may be dangerously high—sufficient to rupture a major artery in the brain or elsewhere.

Fecal impaction occurs when an accumulated mass of dry feces cannot be expelled. The mass may be palpable on digital examination, may produce pressure on the colonic mucosa that results in ulcer formation, and frequently may cause seepage of liquid stools.

Hemorrhoids and anal fissures can develop as a result of constipation. **Hemorrhoids** develop as a result of perianal vascular congestion caused by straining. Anal fissures may result from the passage of the hard stool through the anus, tearing the lining of the anal canal.

Megacolon is a dilated and atonic colon caused by a fecal mass that obstructs the passage of colon contents. Symptoms include constipation, liquid fecal incontinence, and abdominal distention. Megacolon can lead to perforation of the bowel.

## Gerontologic Considerations

Physician visits for constipation are more frequent by individuals 65 years of age or older (Yamada et al., 1999). Elderly people report problems with constipation five times more frequently than younger people. A number of factors contribute to this increased frequency. People who have loose-fitting dentures or have lost their teeth have difficulty chewing and frequently choose soft, processed foods that are low in fiber. Convenience foods, also low

in fiber, are widely used by those who have lost interest in eating. Some older people reduce their fluid intake if they are not eating regular meals. Lack of exercise and prolonged bed rest also contribute to constipation by decreasing abdominal muscle tone and intestinal motility as well as anal sphincter tone. Nerve impulses are dulled, and there is decreased sensation to defecate. Many older people who overuse laxatives in an attempt to have a daily bowel movement become dependent on them.

## Medical Management

Treatment is aimed at the underlying cause of constipation and includes education, bowel habit training, increased fiber and fluid intake, and judicious use of laxatives. Management may also include discontinuing laxative abuse. Routine exercise to strengthen abdominal muscles is encouraged. Biofeedback is a technique that can be used to help patients learn to relax the sphincter mechanism to expel stool. Daily addition to the diet of 6 to 12 teaspoonfuls of unprocessed bran is recommended, especially for the treatment of constipation in the elderly. If laxative use is necessary, one of the following may be prescribed: bulk-forming agents, saline and osmotic agents, lubricants, stimulants, or fecal softeners. The physiologic action and patient education information related to these laxatives are identified in Table 38-1. Enemas and rectal suppositories are generally not recommended for constipation and should be reserved for the treatment of impaction or for preparing the bowel for surgery or diagnostic procedures. If long-term laxative use is necessary, a bulk-forming agent may be prescribed in combination with an osmotic laxative.

Doctors prescribe the use of specific medications to enhance colonic transit by increasing propulsive motor activity. Further studies are being carried out on cholinergic agents (eg, bethanechol), cholinesterase inhibitors (eg, neostigmine), and prokinetic agents (eg, metoclopramide) to determine the role these agents can play in treating constipation (Yamada et al., 1999).

## Nursing Management

The nurse elicits information about the onset and duration of constipation, current and past elimination patterns, the patient's expectation of normal bowel elimination, and lifestyle information (eg, exercise and activity level, occupation, food and fluid intake, and stress level) during the health history interview. Past medical and surgical history, current medications, and laxative and enema use are important, as is information about the sensation of rectal pressure or fullness, abdominal pain, excessive straining at defecation, and flatulence.

Patient education and health promotion are important functions of the nurse (Chart 38-1). After the health history is obtained, the nurse sets specific goals for teaching. Goals for the patient include restoring or maintaining a regular pattern of elimination, ensuring adequate intake of fluids and high-fiber foods, learning about methods to avoid constipation, relieving anxiety about bowel elimination patterns, and avoiding complications.

## DIARRHEA

Diarrhea is increased frequency of bowel movements (more than three per day), increased amount of stool (more than 200 g per day), and altered consistency (ie, looseness) of stool. It is usually associated with urgency, perianal discomfort, incontinence, or a combination of these factors. Any condition that causes increased intestinal secretions, decreased mucosal absorption, or altered

**Table 38-1 • Laxatives: Classification, Agent, Action, and Patient Education**

CLASSIFICATION	SAMPLE AGENT	ACTION	PATIENT EDUCATION
Bulk forming	Psyllium hydrophilic mucilloid (Metamucil)	Polysaccharides and cellulose derivatives mix with intestinal fluids, swell, and stimulate peristalsis.	Take with 8 oz water and follow with 8 oz water; do not take dry. Report abdominal distention or unusual amount of flatulence.
Saline agent	Magnesium hydroxide (Milk of Magnesia)	Nonabsorbable magnesium ions alter stool consistency by drawing water into the intestines by osmosis; peristalsis is stimulated. Action occurs within 2 h.	The liquid preparation is more effective than the tablet form. Only short-term use is recommended because of toxicity (CNS or neuromuscular depression, electrolyte imbalance). Magnesium laxatives should not be taken by patients with renal insufficiency.
Lubricant	Mineral oil	Nonabsorbable hydrocarbons soften fecal matter by lubricating the intestinal mucosa; the passage of stool is facilitated. Action occurs within 6–8 h.	Do not take with meals, because mineral oils can impair the absorption of fat-soluble vitamins and delay gastric emptying. Swallow carefully, because drops of oil that gain access to the pharynx can produce a lipid pneumonia.
Stimulant	Bisacodyl (Dulcolax)	Irritates the colon epithelium by stimulating sensory nerve endings and increasing mucosal secretions. Action occurs within 6–8 h.	Catharsis may cause fluid and electrolyte imbalance, especially in the elderly. Tablets should be swallowed, not crushed or chewed. Avoid milk or antacids within 1 hour of taking the medication, because the enteric coating may dissolve prematurely.
Fecal softener	Diocetyl sodium sulfosuccinate (Colace)	Hydrates the stool by its surfactant action on the colonic epithelium (increases the wetting efficiency of intestinal water); aqueous and fatty substances are mixed. Does not exert a laxative action.	Can be used safely by patients who should avoid straining (cardiac patients, patients with anorectal disorders).
Osmotic agent	Polyethylene glycol and electrolytes (Colyte)	Cleanses colon rapidly and induces diarrhea.	This is a large-volume product. It takes time to consume it safely. It can cause considerable nausea and bloating.

motility can produce diarrhea. Irritable bowel syndrome (IBS), inflammatory bowel disease (IBD), and lactose intolerance are frequently the underlying disease processes that cause diarrhea (Stone et al., 1999).

Diarrhea can be acute or chronic. Acute diarrhea is most often associated with infection and is usually self-limiting; chronic diar-

rhea persists for a longer period and may return sporadically. Diarrhea can be caused by certain medications (eg, thyroid hormone replacement, stool softeners and laxatives, antibiotics, chemotherapy, antacids), certain tube feeding formulas, metabolic and endocrine disorders (eg, diabetes, Addison's disease, thyrotoxicosis), and viral or bacterial infectious processes (eg, dysentery, shigellosis, food poisoning). Other disease processes associated with diarrhea are nutritional and malabsorptive disorders (eg, celiac disease), anal sphincter defect, Zollinger-Ellison syndrome, paralytic ileus, intestinal obstruction, and acquired immunodeficiency syndrome (AIDS).

### Chart 38-1

#### Health Promotion: Preventing Constipation

- Describe the physiology of defecation.
- Emphasize the importance of heeding the urge to defecate.
- Discuss normal variations in patterns of defecation.
- Teach how to establish a bowel routine, and explain that having a regular time for defecation (eg, best time is after breakfast) may aid in initiating the reflex.
- Provide dietary information; suggest eating high-residue, high-fiber foods, adding bran daily (must be introduced gradually), and increasing fluid intake (unless contraindicated).
- Explain how an exercise regimen, increased ambulation, and abdominal muscle toning will increase muscle strength and help propel colon contents.
- Describe abdominal toning exercises (contracting abdominal muscles 4 times daily and leg-to-chest lifts 10 to 20 times each day).
- Explain that the normal position (semisquatting) maximizes use of abdominal muscles and force of gravity.

### Pathophysiology

Types of diarrhea include secretory, osmotic, and mixed diarrhea. Secretory diarrhea is usually high-volume diarrhea and is caused by increased production and secretion of water and electrolytes by the intestinal mucosa into the intestinal lumen. Osmotic diarrhea occurs when water is pulled into the intestines by the osmotic pressure of unabsorbed particles, slowing the reabsorption of water. Mixed diarrhea is caused by increased peristalsis (usually from IBD) and a combination of increased secretion and decreased absorption in the bowel. The physiology of diarrhea related to infection is discussed in Chapter 70.

### Clinical Manifestations

In addition to the increased frequency and fluid content of stools, the patient usually has abdominal cramps, distention, intestinal rumbling (ie, borborygmus), anorexia, and thirst. Painful spasmodic

contractions of the anus and ineffectual straining (ie, tenesmus) may occur with defecation. Other symptoms depend on the cause and severity of the diarrhea but are related to dehydration and to fluid and electrolyte imbalances.

Watery stools are characteristic of small bowel disease, whereas loose, semisolid stools are associated more often with disorders of the colon. Voluminous, greasy stools suggest intestinal malabsorption, and the presence of mucus and pus in the stools suggests inflammatory enteritis or colitis. Oil droplets on the toilet water are almost always diagnostic of pancreatic insufficiency. Nocturnal diarrhea may be a manifestation of diabetic neuropathy.

## Assessment and Diagnostic Findings

When the cause of the diarrhea is not obvious, the following diagnostic tests may be performed: complete blood cell count, chemical profile, urinalysis, routine stool examination, and stool examinations for infectious or parasitic organisms, bacterial toxins, blood, fat, and electrolytes. Endoscopy or barium enema may assist in identifying the cause.

## Complications

Complications of diarrhea include the potential for cardiac dysrhythmias because of significant fluid and electrolyte loss (especially loss of potassium). Urinary output of less than 30 mL per hour for 2 to 3 consecutive hours, muscle weakness, paresthesia, hypotension, anorexia, and drowsiness with a potassium level of less than 3.0 mEq/L (3 mmol/L) must be reported. Decreased potassium levels cause cardiac dysrhythmias (ie, atrial and ventricular tachycardia, ventricular fibrillation, and premature ventricular contractions) that can lead to death.

## Medical Management

Primary management is directed at controlling symptoms, preventing complications, and eliminating or treating the underlying disease. Certain medications (eg, antibiotics, anti-inflammatory agents) may reduce the severity of the diarrhea and treat the underlying disease.

## Nursing Management

The nurse's role includes assessing and monitoring the characteristics and pattern of diarrhea. A health history addresses the patient's medication therapy, medical and surgical history, and dietary patterns and intake. Reports of recent exposure to an acute illness or recent travel to another geographic area are important. Assessment includes abdominal auscultation and palpation for abdominal tenderness. Inspection of the abdomen and mucous membranes and skin is important to determine hydration status. Stool samples are obtained for testing.

During an episode of acute diarrhea, the nurse encourages bed rest and intake of liquids and foods low in bulk until the acute attack subsides. When food intake is tolerated, the nurse recommends a bland diet of semisolid and solid foods. The patient should avoid caffeine, carbonated beverages, and very hot and very cold foods, because they stimulate intestinal motility. It may be necessary to restrict milk products, fat, whole-grain products, fresh fruits, and vegetables for several days. The nurse administers antidiarrheal medications such as diphenoxylate (Lomotil) and loperamide (Imodium) as prescribed. Intravenous fluid therapy may be necessary for rapid rehydration, especially for the el-

derly and those with preexisting GI conditions (eg, IBD). It is important to closely monitor serum electrolyte levels. The nurse immediately reports evidence of dysrhythmias or a change in the level of consciousness.

**NURSING ALERT** Elderly persons can become dehydrated quickly and develop low potassium levels (ie, hypokalemia) as a result of diarrhea. The older person taking digitalis must be aware of how quickly dehydration and hypokalemia can occur with diarrhea. The nurse instructs this person to recognize the signs of hypokalemia, because low levels of potassium intensify the action of digitalis, which can lead to digitalis toxicity.

The perianal area may become excoriated because diarrheal stool contains digestive enzymes that can irritate the skin. The patient should follow a perianal skin care routine to decrease irritation and excoriation. It is important to use skin sealants and moisture barriers as needed. The older person's skin is very sensitive because of decreased turgor and reduced subcutaneous fat layers.

## FECAL INCONTINENCE

The term *fecal incontinence* describes the involuntary passage of stool from the rectum. Several factors influence fecal continence—the ability of the rectum to sense and accommodate stool, the amount and consistency of stool, the integrity of the anal sphincters and musculature, and rectal motility.

## Pathophysiology

Fecal incontinence can result from trauma (eg, after surgical procedures involving the rectum), a neurologic disorder (eg, stroke, multiple sclerosis, diabetic neuropathy, dementia), inflammation, infection, radiation treatment, fecal impaction, pelvic floor relaxation, laxative abuse, medications, or advancing age (ie, weakness or loss of anal or rectal muscle tone). It is an embarrassing and socially incapacitating problem that requires a many-tiered approach to treatment and much adaptation on the patient's part.

## Clinical Manifestations

Patients may have minor soiling, occasional urgency and loss of control, or complete incontinence. Patients may also experience poor control of flatus, diarrhea, or constipation.

## Assessment and Diagnostic Findings

Diagnostic studies are necessary because the treatment of fecal incontinence depends on the cause. A rectal examination and other endoscopic examinations such as a flexible sigmoidoscopy are performed to rule out tumors, inflammation, or fissures. X-ray studies such as barium enema, computed tomography (CT) scans, anorectal manometry, and transit studies may be helpful in identifying alterations in intestinal mucosa and muscle tone or in detecting other structural or functional problems.

## Medical Management

Although there is no known cause or cure for fecal incontinence, specific management techniques can help the patient achieve a better quality of life. If fecal incontinence is related to diarrhea,

the incontinence may disappear when diarrhea is successfully treated. Fecal incontinence is frequently a symptom of a fecal impaction. After the impaction is removed and the rectum is cleansed, normal functioning of the anorectal area can resume. If the fecal incontinence is related to a more permanent condition, other treatments are initiated. Biofeedback therapy can be of assistance if the problem is decreased sensory awareness or sphincter control. Bowel training programs can also be effective. Surgical procedures include surgical reconstruction, sphincter repair, or fecal diversion.

## Nursing Management

The nurse takes a thorough health history, including information about previous surgical procedures, chronic illnesses, bowel habits and problems, and current medication regimen. The nurse also completes an examination of the rectal area.

The nurse initiates a bowel-training program that involves setting a schedule to establish bowel regularity. The goal is to assist the patient to achieve fecal continence. If this is not possible, the goal should be to manage the problem so the person can have predictable, planned elimination (Stone et al., 1999). Sometimes, it is necessary to use suppositories to stimulate the anal reflex. After the patient has achieved a regular schedule, the suppository can be discontinued. Biofeedback can be used in conjunction with these therapies to help the patient improve sphincter contractility and rectal sensitivity.

Fecal incontinence can also cause problems with perineal skin integrity. Maintaining skin integrity is a priority, especially in the debilitated or elderly patient. Incontinence briefs, although helpful in containing the fecal material, allow for increased skin contact with the feces and may cause excoriation of the skin. The nurse encourages and teaches meticulous skin hygiene.

Continence sometimes cannot be achieved, and the nurse assists the patient and family to accept and cope with this chronic situation. The patient can use fecal incontinence devices, which include external collection devices and internal drainage systems. External devices are special pouches that are drainable. They are attached to a synthetic adhesive skin barrier specially designed to conform to the buttocks. Internal drainage systems can be used to eliminate fecal skin contact and are especially useful when there is extensive excoriation or skin breakdown. A large catheter is inserted into the rectum and is connected to a drainage system.

## IRRITABLE BOWEL SYNDROME

IBS is one of the most common GI problems. Approximately one in six otherwise healthy persons report classic symptoms of IBS (Wolfe, 2000). It occurs more commonly in women than in men, and the cause is still unknown. Although no anatomic or biochemical abnormalities have been found that explain the common symptoms, various factors are associated with the syndrome: heredity, psychological stress or conditions such as depression and anxiety, a diet high in fat and stimulating or irritating foods, alcohol consumption, and smoking. The small intestine has become a focus of investigation as an additional site of dysmotility in IBS, and cluster contractions in the jejunum and ileum are being studied (Wolfe, 2000). The diagnosis is made only after tests have been completed that prove the absence of structural or other disorders.

## Pathophysiology

IBS results from a functional disorder of intestinal motility. The change in motility may be related to the neurologic regulatory system, infection or irritation, or a vascular or metabolic disturbance. The peristaltic waves are affected at specific segments of the intestine and in the intensity with which they propel the fecal matter forward. There is no evidence of inflammation or tissue changes in the intestinal mucosa.

## Clinical Manifestations

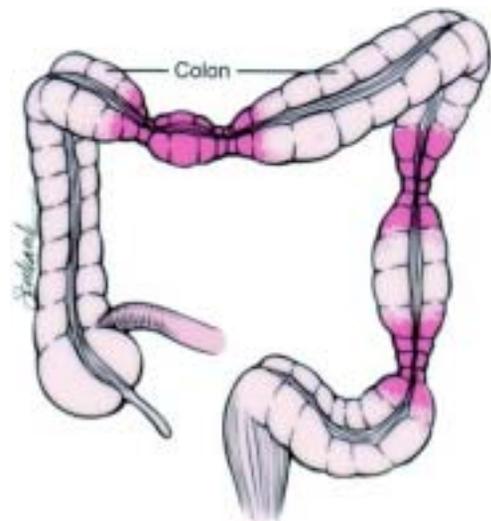

There is a wide variability in symptom presentation. Symptoms range in intensity and duration from mild and infrequent to severe and continuous. The primary symptom is an alteration in bowel patterns—constipation, diarrhea, or a combination of both. Pain, bloating, and abdominal distention often accompany this change in bowel pattern. The abdominal pain is sometimes precipitated by eating and is frequently relieved by defecation.

## Assessment and Diagnostic Findings

A definite diagnosis of IBS requires tests that prove the absence of structural or other disorders. Stool studies, contrast x-ray studies, and proctoscopy may be performed to rule out other colon diseases. Barium enema and colonoscopy may reveal spasm, distention, or mucus accumulation in the intestine (Fig. 38-1). Manometry and electromyography are used to study intraluminal pressure changes generated by spasticity.

## Medical Management

The goals of treatment are aimed at relieving abdominal pain, controlling the diarrhea or constipation, and reducing stress. Restriction and then gradual reintroduction of foods that are possibly irritating may help determine what types of food are acting as irritants (eg, beans, caffeinated products, fried foods, alcohol, spicy foods). A healthy, high-fiber diet is prescribed to help control the diarrhea and constipation. Exercise can assist in reducing anxiety and increasing intestinal motility. Patients often find it helpful to participate in a stress reduction or behavior-modification program.

**FIGURE 38-1** In IBS, the spastic contractions of the bowel can be seen in x-ray contrast studies.

Hydrophilic colloids (ie, bulk) and antidiarrheal agents (eg, loperamide) may be given to control the diarrhea and fecal urgency. Antidepressants can assist in treating underlying anxiety and depression. Anticholinergics and calcium channel blockers decrease smooth muscle spasm, decreasing cramping and constipation.

## Nursing Management

The nurse's role is to provide patient and family education. The nurse emphasizes teaching and reinforces good dietary habits. The patient is encouraged to eat at regular times and to chew food slowly and thoroughly. The patient should understand that, although adequate fluid intake is necessary, fluid should not be taken with meals because this results in abdominal distention. Alcohol use and cigarette smoking are discouraged.

## CONDITIONS OF MALABSORPTION

**Malabsorption** is the inability of the digestive system to absorb one or more of the major vitamins (especially vitamin B<sub>12</sub>), minerals (ie, iron and calcium), and nutrients (ie, carbohydrates, fats, and proteins). Interruptions in the complex digestive process may occur anywhere in the digestive system and cause decreased absorption. Diseases of the small intestine are the most common cause of malabsorption.

## Pathophysiology

The conditions that cause malabsorption can be grouped into the following categories:

- Mucosal (transport) disorders causing generalized malabsorption (eg, celiac sprue, regional enteritis, radiation enteritis)
- Infectious diseases causing generalized malabsorption (eg, small bowel bacterial overgrowth, tropical sprue, Whipple's disease)
- Luminal problems causing malabsorption (eg, bile acid deficiency, Zollinger-Ellison syndrome, pancreatic insufficiency)
- Postoperative malabsorption (eg, after gastric or intestinal resection)
- Disorders that cause malabsorption of specific nutrients (eg, disaccharidase deficiency leading to lactose intolerance)

Table 38-2 lists the clinical and pathologic aspects of malabsorptive diseases.

## Clinical Manifestations

The hallmarks of malabsorption syndrome from any cause are diarrhea or frequent, loose, bulky, foul-smelling stools that have increased fat content and are often grayish. Patients often have associated abdominal distention, pain, increased flatus, weakness, weight loss, and a decreased sense of well-being. The chief result of malabsorption is malnutrition, manifested by weight loss and other signs of vitamin and mineral deficiency (eg, easy bruising, osteoporosis, anemia). Patients with a malabsorption syndrome, if untreated, become weak and emaciated because of starvation and dehydration. Failure to absorb the fat-soluble vitamins A, D, and K causes a corresponding avitaminosis.

## Assessment and Diagnostic Findings

Several diagnostic tests may be prescribed, including stool studies for quantitative and qualitative fat analysis, lactose tolerance tests, D-xylose absorption tests, and Schilling tests. The hydrogen breath

test that is used to evaluate carbohydrate absorption (see Chap. 34) is performed if carbohydrate malabsorption is suspected. Endoscopy with biopsy of the mucosa is the best diagnostic tool. Biopsy of the small intestine is performed to assay enzyme activity or to identify infection or destruction of mucosa. Ultrasound studies, CT scans, and x-ray findings can reveal pancreatic or intestinal tumors that may be the cause. A complete blood cell count is used to detect anemia. Pancreatic function tests can assist in the diagnosis of specific disorders.

## Medical Management

Intervention is aimed at avoiding dietary substances that aggravate malabsorption and at supplementing nutrients that have been lost. Common supplements are water-soluble vitamins (eg, B<sub>12</sub>, folic acid), fat-soluble vitamins (ie, A, D, and K), and minerals (eg, calcium, iron). Primary disease states may be managed surgically or nonsurgically. Dietary therapy is aimed at reducing gluten intake in patients with celiac sprue. Folic acid supplements are prescribed for patients with tropical sprue. Antibiotics (eg, tetracycline, ampicillin) are sometimes needed in the treatment of tropical sprue and bacterial overgrowth syndromes. Antidiarrheal agents may be used to decrease intestinal spasms. Parenteral fluids may be necessary to treat dehydration.

## Nursing Management

The nurse provides patient and family education regarding diet and the use of nutritional supplements (Chart 38-2). It is important to monitor patients with diarrhea for fluid and electrolyte imbalances. The nurse conducts ongoing assessments to determine if the clinical manifestations related to the nutritional deficits have abated. Patient education includes information about the risk of osteoporosis related to malabsorption of calcium.

## Acute Inflammatory Intestinal Disorders

Any part of the lower GI tract is susceptible to acute inflammation caused by bacterial, viral, or fungal infection. Two such situations are appendicitis and diverticulitis. These two conditions can lead to **peritonitis**, an inflammatory process within the abdomen.

## APPENDICITIS

The appendix is a small, finger-like appendage about 10 cm (4 in) long that is attached to the cecum just below the ileocecal valve. The appendix fills with food and empties regularly into the cecum. Because it empties inefficiently and its lumen is small, the appendix is prone to obstruction and is particularly vulnerable to infection (ie, appendicitis).

**Appendicitis**, the most common cause of acute abdomen in the United States, is the most common reason for emergency abdominal surgery. About 7% of the population will have appendicitis at some time in their lives; males are affected more than females, and teenagers more than adults. Although it can occur at any age, it occurs most frequently between the ages of 10 and 30 years (Yamada et al., 1999).

## Pathophysiology

The appendix becomes inflamed and edematous as a result of either becoming kinked or occluded by a fecalith (ie, hardened mass of stool), tumor, or foreign body. The inflammatory process

Table 38-2 • Characteristics of Diseases of Malabsorption

DISEASES/DISORDERS	PHYSIOLOGIC PATHOLOGY	CLINICAL FEATURES
Gastric resection with gastrojejunostomy	Decreased pancreatic stimulation because of duodenal bypass; poor mixing of food, bile, pancreatic enzymes; decreased intrinsic factor	Weight loss, moderate steatorrhea, anemia (combination of iron deficiency, vitamin B <sub>12</sub> malabsorption, folate deficiency)
Pancreatic insufficiency (chronic pancreatitis, pancreatic carcinoma, pancreatic resection, cystic fibrosis)	Reduced intraluminal pancreatic enzyme activity, with maldigestion of lipids and proteins	History of abdominal pain followed by weight loss; marked steatorrhea, <b>azotorrhea</b> (excess of nitrogenous matter in the feces or urine); also frequent glucose intolerance (70% in pancreatic insufficiency)
Ileal dysfunction (resection or disease)	Loss of ileal absorbing surface leads to reduced bile-salt pool size and reduced vitamin B <sub>12</sub> absorption; bile in colon inhibits fluid absorption	Diarrhea, weight loss with steatorrhea, especially when greater than 100 cm resection, decreased vitamin B <sub>12</sub> absorption
Stasis syndromes (surgical strictures, blind loops, enteric fistulas, multiple jejunal diverticula, scleroderma)	Overgrowth of intraluminal intestinal bacteria, especially anaerobic organisms, to greater than 10 <sup>6</sup> /mL results in deconjugation of bile salts, leading to decreased effective bile-salt pool size, also bacterial utilization of vitamin B <sub>12</sub>	Weight loss, steatorrhea; low vitamin B <sub>12</sub> absorption; may have low D-xylose absorption
Zollinger-Ellison syndrome	Hyperacidity in duodenum inactivates pancreatic enzymes	Ulcer diathesis, steatorrhea
Lactose intolerance	Deficiency of intestinal lactase results in high concentration of intraluminal lactose with osmotic diarrhea	Varied degrees of diarrhea and cramps after ingestion of lactose-containing foods; positive lactose intolerance test, decreased intestinal lactase
Celiac disease (gluten enteropathy)	Toxic response to a gluten fraction by surface epithelium results in destruction of absorbing surface	Weight loss, diarrhea, bloating, anemia (low iron, folate), osteomalacia, steatorrhea, azotorrhea, low D-xylose absorption; folate and iron malabsorption
Tropical sprue	Unknown toxic factor results in mucosal inflammation, partial villous atrophy	Weight loss, diarrhea, anemia (low folate, vitamin B <sub>12</sub> ); steatorrhea; low D-xylose absorption, low vitamin B <sub>12</sub> absorption
Whipple's disease	Bacterial invasion of intestinal mucosa	Arthritis, hyperpigmentation, lymphadenopathy, serous effusions, fever, weight loss; steatorrhea, azotorrhea
Certain parasitic diseases (giardiasis, strongyloidiasis, coccidiosis, capillariasis)	Damage to or invasion of surface mucosa	Diarrhea, weight loss; steatorrhea; organism may be seen on jejunal biopsy or recovered in stool
Immunoglobulinopathy	Decreased local intestinal defenses, lymphoid hyperplasia, lymphopenia	Frequent association with <i>Giardia</i> : hypogammaglobulinemia or isolated IgA deficiency

increases intraluminal pressure, initiating a progressively severe, generalized or upper abdominal pain that becomes localized in the right lower quadrant of the abdomen within a few hours. Eventually, the inflamed appendix fills with pus.

### Clinical Manifestations

Vague epigastric or periumbilical pain progresses to right lower quadrant pain and is usually accompanied by a low-grade fever and nausea and sometimes by vomiting. Loss of appetite is common. Local tenderness is elicited at McBurney's point when pressure is applied (Fig. 38-2). Rebound tenderness (ie, production or intensification of pain when pressure is released) may be present. The extent of tenderness and muscle spasm and the existence of constipation or diarrhea depend not so much on the severity of the appendiceal infection as on the location of the appendix. If the appendix curls around behind the cecum, pain and tenderness may be felt in the lumbar region. If its tip is in the pelvis, these signs may be elicited only on rectal examination. Pain on

defecation suggests that the tip of the appendix is resting against the rectum; pain on urination suggests that the tip is near the bladder or impinges on the ureter. Some rigidity of the lower portion of the right rectus muscle may occur. Rovsing's sign may be elicited by palpating the left lower quadrant; this paradoxically causes pain to be felt in the right lower quadrant (see Fig. 38-2). If the appendix has ruptured, the pain becomes more diffuse; abdominal distention develops as a result of paralytic ileus, and the patient's condition worsens.

Constipation can also occur with an acute process such as appendicitis. Laxatives administered in this instance may produce perforation of the inflamed appendix. In general, a laxative or cathartic should never be given while the person has fever, nausea, or pain.

### Assessment and Diagnostic Findings

Diagnosis is based on results of a complete physical examination and on laboratory and x-ray findings. The complete blood cell count demonstrates an elevated white blood cell count. The leukocyte

### Chart 38-2 • PATIENT EDUCATION Managing Lactose Intolerance

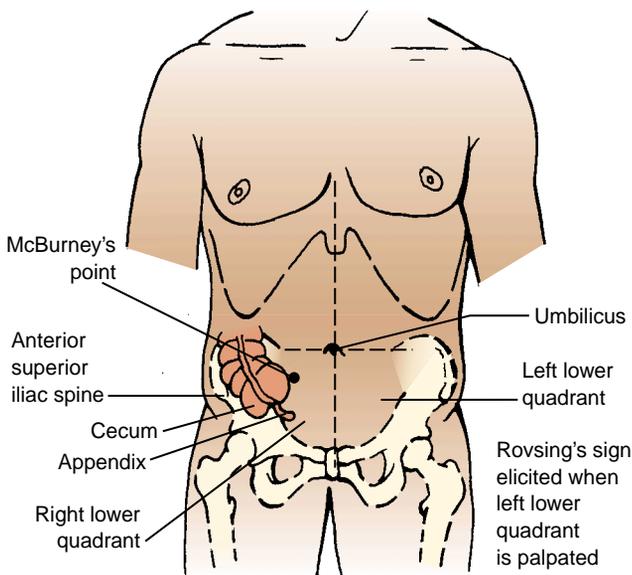

The following information may be helpful for patients who cannot tolerate lactose:

- Deficiency of lactase, a digestive enzyme essential for the absorption of lactose from the intestines, results in an intolerance to milk.
- Elimination of milk and milk substances can abolish symptoms.
- Many processed foods have fillers, such as dried milk, added to them.
- Pretreatment of foods with lactase preparations (eg, LactAid drops) before ingestion can reduce symptoms.
- Most people can tolerate 1 to 2 cups of milk or milk products daily without major problems; they are best tolerated if ingested in small amounts during the day.
- Lactase activity of yogurt with “active cultures” helps the digestion of lactose within the intestine better than lactase preparations do.
- Milk and milk products are rich sources of calcium and vitamin D; elimination of milk from the diet may result in calcium and vitamin D deficiencies; decreased intake without supplements can lead to osteoporosis.

count may exceed 10,000 cells/mm<sup>3</sup>, and the neutrophil count may exceed 75%. Abdominal x-ray films, ultrasound studies, and CT scans may reveal a right lower quadrant density or localized distention of the bowel.

## Complications

The major complication of appendicitis is perforation of the appendix, which can lead to peritonitis or an abscess. The incidence of perforation is 10% to 32%. The incidence is higher in young

**FIGURE 38-2** When the appendix is inflamed, tenderness can be noted in the right lower quadrant at McBurney's point, which is between the umbilicus and the anterior superior iliac spine. Rovsing's sign is pain felt in the right lower quadrant after the left lower quadrant has been palpated.

children and the elderly. Perforation generally occurs 24 hours after the onset of pain. Symptoms include a fever of 37.7°C (100°F) or higher, a toxic appearance, and continued abdominal pain or tenderness.

## Gerontologic Considerations

Acute appendicitis does not occur frequently in the elderly population. Classic signs and symptoms are altered and may vary greatly. Pain may be absent or minimal. Symptoms may be vague, suggesting bowel obstruction or another process. Fever and leukocytosis may not be present. As a result, diagnosis and prompt treatment may be delayed, causing potential complications and mortality. The patient may have no symptoms until the appendix ruptures. The incidence of perforated appendix is higher in the elderly population because many of these patients do not seek health care as quickly as younger patients.

## Medical Management

Surgery is indicated if appendicitis is diagnosed. To correct or prevent fluid and electrolyte imbalance and dehydration, antibiotics and intravenous fluids are administered until surgery is performed. Analgesics can be administered after the diagnosis is made. Appendectomy (ie, surgical removal of the appendix) is performed as soon as possible to decrease the risk of perforation. It may be performed under a general or spinal anesthetic with a low abdominal incision or by laparoscopy.

## Nursing Management

Goals include relieving pain, preventing fluid volume deficit, reducing anxiety, eliminating infection from the potential or actual disruption of the GI tract, maintaining skin integrity, and attaining optimal nutrition.

The nurse prepares the patient for surgery, which includes an intravenous infusion to replace fluid loss and promote adequate renal function and antibiotic therapy to prevent infection. If there is evidence or likelihood of paralytic ileus, a nasogastric tube is inserted. An enema is not administered because it can lead to perforation.

After surgery, the nurse places the patient in a semi-Fowler position. This position reduces the tension on the incision and abdominal organs, helping to reduce pain. An opioid, usually morphine sulfate, is prescribed to relieve pain. When tolerated, oral fluids are administered. Any patient who was dehydrated before surgery receives intravenous fluids. Food is provided as desired and tolerated on the day of surgery.

The patient may be discharged on the day of surgery if the temperature is within normal limits, there is no undue discomfort in the operative area, and the appendectomy was uncomplicated. Discharge teaching for the patient and family is imperative. The nurse instructs the patient to make an appointment to have the surgeon remove the sutures between the fifth and seventh days after surgery. Incision care and activity guidelines are discussed; normal activity can usually be resumed within 2 to 4 weeks.

If there is a possibility of peritonitis, a drain is left in place at the area of the incision. Patients at risk for this complication may be kept in the hospital for several days and are monitored carefully for signs of intestinal obstruction or secondary hemorrhage. Secondary abscesses may form in the pelvis, under the diaphragm, or

in the liver, elevating the temperature and pulse rate and increasing the leukocyte count.

When the patient is ready for discharge, the nurse teaches the patient and family to care for the incision and perform dressing changes and irrigations as prescribed. A home care nurse may be needed to assist with this care and to monitor the patient for complications and wound healing. Other potential complications of appendectomy are listed in Table 38-3.

## DIVERTICULAR DISEASE

A **diverticulum** is a saclike outpouching of the lining of the bowel that extends through a defect in the muscle layer. Diverticula may occur anywhere along the GI tract. **Diverticulosis** exists when multiple diverticula are present without inflammation or symptoms. Diverticular disease of the colon is very common in developed countries, and its prevalence increases with age. More than 35% of Americans older than 60 years of age have diverticulosis. The incidence increases to 50% among those in the ninth decade of life (Keighley, 1999). **Diverticulitis** results when food and bacteria retained in a diverticulum produce infection and inflammation that can impede drainage and lead to perforation or abscess formation. Diverticulitis is most common (95%) in the sigmoid colon. Approximately 20% of patients with diverticulosis have diverticulitis at some point. A congenital predisposition is suspected when the disorder occurs in those younger than 40 years of age. A low intake of dietary fiber is considered a predisposing factor, but the exact cause is unknown. Diverticulitis may occur in acute attacks or may persist as a continuing, smoldering infection. Most patients remain entirely asymptomatic. The symptoms manifested generally result from its potential complications—abscesses, fistulas, obstruction, and hemorrhage.

### Pathophysiology

A diverticulum forms when the mucosa and submucosal layers of the colon herniate through the muscular wall because of high intraluminal pressure, low volume in the colon (ie, fiber-deficient contents), and decreased muscle strength in the colon wall (ie, muscular hypertrophy from hardened fecal masses). Bowel con-

tents can accumulate in the diverticulum and decompose, causing inflammation and infection. A diverticulum can become obstructed and then inflamed if the obstruction continues. The inflammation tends to spread to the surrounding bowel wall, giving rise to irritability and spasticity of the colon (ie, diverticulitis). Abscesses develop and may eventually perforate, leading to peritonitis and erosion of the blood vessels (arterial) with bleeding.

### Clinical Manifestations

Chronic constipation often precedes the development of diverticulosis by many years. Frequently, no problematic symptoms occur with diverticulosis. Signs of acute diverticulosis are bowel irregularity and intervals of diarrhea, abrupt onset of crampy pain in the left lower quadrant of the abdomen, and a low-grade fever. The patient may have nausea and anorexia, and some bloating or abdominal distention may occur. With repeated local inflammation of the diverticula, the large bowel may narrow with fibrotic strictures, leading to cramps, narrow stools, and increased constipation. Weakness, fatigue, and anorexia are common symptoms. With acute diverticulosis, the patient reports mild to severe pain in the lower left quadrant. The condition, if untreated, can lead to septicemia.

### Assessment and Diagnostic Findings

A CT scan is the procedure of choice and can reveal abscesses. Abdominal x-ray findings may demonstrate free air under the diaphragm if a perforation has occurred from the diverticulitis. Diverticulosis may be diagnosed using barium enema, which shows narrowing of the colon and thickened muscle layers. If there are symptoms of peritoneal irritation and when the diagnosis is diverticulitis, barium enema is contraindicated because of the potential for perforation.

A colonoscopy may be performed if there is no acute diverticulitis or after resolution of an acute episode to visualize the colon, determine the extent of the disease, and rule out other conditions. Laboratory tests that assist in diagnosis include a complete blood cell count, revealing an elevated leukocyte count, and elevated sedimentation rate.

**Table 38-3 • Potential Complications and Nursing Interventions After Appendectomy**

COMPLICATION	NURSING INTERVENTIONS
Peritonitis	Observe for abdominal tenderness, fever, vomiting, abdominal rigidity, and tachycardia. Employ constant nasogastric suction. Correct dehydration as prescribed. Administer antibiotic agents as prescribed.
Pelvic abscess	Evaluate for anorexia, chills, fever, and diaphoresis. Observe for diarrhea, which may indicate pelvic abscess. Prepare patient for rectal examination. Prepare patient for surgical drainage procedure.
Subphrenic abscess (abscess under the diaphragm)	Assess patient for chills, fever, and diaphoresis. Prepare for x-ray examination. Prepare for surgical drainage of abscess.
Ileus (paralytic and mechanical)	Assess for bowel sounds. Employ nasogastric intubation and suction. Replace fluids and electrolytes by intravenous route as prescribed. Prepare for surgery, if diagnosis of mechanical ileus is established.

## Complications

Complications of diverticulitis include peritonitis, abscess formation, and bleeding. If an abscess develops, the associated findings are tenderness, a palpable mass, fever, and leukocytosis. An inflamed diverticulum that perforates results in abdominal pain localized over the involved segment, usually the sigmoid; local abscess or peritonitis follows. Abdominal pain, a rigid boardlike abdomen, loss of bowel sounds, and signs and symptoms of shock occur with peritonitis. Noninflamed or slightly inflamed diverticula may erode areas adjacent to arterial branches, causing massive rectal bleeding.

### Gerontologic Considerations

The incidence of diverticular disease increases with age because of degeneration and structural changes in the circular muscle layers of the colon and because of cellular hypertrophy. The symptoms are less pronounced in the elderly than in other adults. The elderly may not have abdominal pain until infection occurs. They may delay reporting symptoms because they fear surgery or are afraid that they may have cancer. Blood in the stool is overlooked frequently, especially in the elderly, because of a failure to examine the stool or the inability to see changes because of diminished vision.

## Medical Management

### DIETARY AND MEDICATION MANAGEMENT

Diverticulitis can usually be treated on an outpatient basis with diet and medicine therapy. When symptoms occur, rest, analgesics, and antispasmodics are recommended. Initially, the diet is clear liquid until the inflammation subsides; then, a high-fiber, low-fat diet is recommended. This type of diet helps to increase stool volume, decrease colonic transit time, and reduce intraluminal pressure. Antibiotics are prescribed for 7 to 10 days. A bulk-forming laxative also is prescribed.

In acute cases of diverticulitis with significant symptoms, hospitalization is required. Hospitalization is often indicated for those who are elderly, immunocompromised, or taking corticosteroids. Withholding oral intake, administering intravenous fluids, and instituting nasogastric suctioning if vomiting or distention occurs rests the bowel. Broad-spectrum antibiotics are prescribed for 7 to 10 days. An opioid is prescribed for pain relief; morphine is not used because it increases segmentation and intraluminal pressures. Oral intake is increased as symptoms subside. A low-fiber diet may be necessary until signs of infection decrease.

Antispasmodics such as propantheline bromide (Pro-Banthine) and oxyphenyclimine (Daricon) may be prescribed. Normal stools can be achieved by using bulk preparations (Metamucil) or stool softeners (Colace), by instilling warm oil into the rectum, or by inserting an evacuant suppository (Dulcolax). Such a prophylactic plan can reduce the bacterial flora of the bowel, diminish the bulk of the stool, and soften the fecal mass so that it moves more easily through the area of inflammatory obstruction.

### SURGICAL MANAGEMENT

Although acute diverticulitis usually subsides with medical management, immediate surgical intervention is necessary if complications (eg, perforation, peritonitis, abscess formation, hemorrhage, obstruction) occur. Alternatively, when the acute episode of diverticulitis resolves, surgery may be recommended to prevent repeated episodes. Two types of surgery are considered:

- One-stage resection in which the inflamed area is removed and a primary end-to-end anastomosis is completed

- Multiple-staged procedures for complications such as obstruction or perforation (Fig. 38-3)

The type of surgery performed depends on the extent of complications found during surgery. When possible, the area of diverticulitis is resected and the remaining bowel is joined end to end (ie, primary resection and end-to-end anastomosis). This is performed through traditional surgical or laparoscopically assisted colectomy. A two-stage resection may be performed in which the diseased colon is resected (as in a one-stage procedure) but no anastomosis is performed; both ends of the bowel are brought out onto the abdomen as stomas. This “double-barrel” colostomy is then reanastomosed in a later procedure. Fecal diversion procedures are discussed later in this chapter.

## NURSING PROCESS: THE PATIENT WITH DIVERTICULITIS

### Assessment

During the health history, the nurse asks the patient about the onset and duration of pain and about past and present elimination patterns. The nurse reviews dietary habits to determine fiber intake and asks the patient about straining at stool, history of constipation with periods of diarrhea, tenesmus (ie, spasms of the anal sphincter with pain and persistent urge to defecate), abdominal bloating, and distention.

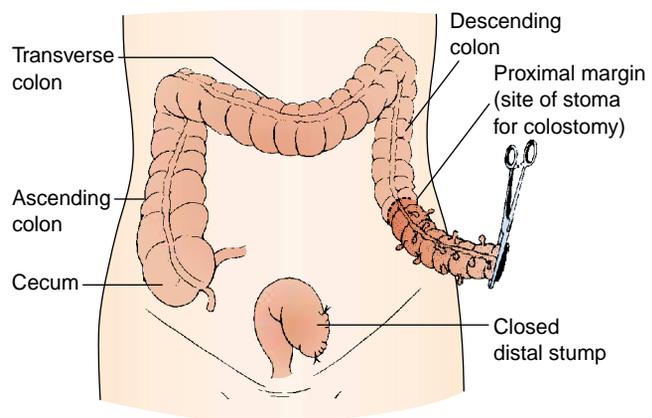

Assessment includes auscultation for the presence and character of bowel sounds and palpation for lower left quadrant pain, tenderness, or firm mass. The stool is inspected for pus, mucus, or blood. It is important to monitor temperature, pulse, and blood pressure for abnormal variations.

### Diagnosis

#### NURSING DIAGNOSES

Based on the assessment data, the nursing diagnoses may include the following:

- Constipation related to narrowing of the colon from thickened muscular segments and strictures
- Acute pain related to inflammation and infection

**FIGURE 38-3** The Hartmann procedure for diverticulitis: primary resection for diverticulitis of the colon. The affected segment (*clamp attached*) has been divided at its distal end. In a primary anastomosis, the proximal margin (*dotted line*) is transected and the bowel attached end-to-end. In a two-stage procedure, a colostomy is constructed at the proximal margin with the distal stump oversewn (Hartmann procedure, as shown) or brought to the outer surface as a mucous fistula. The second stage consists of colostomy takedown and anastomosis.

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Potential complications that may develop include the following:

- Peritonitis
- Abscess formation
- Bleeding

### Planning and Goals

The major goals for the patient may include attainment and maintenance of normal elimination patterns, pain relief, and absence of complications.

### Nursing Interventions

#### MAINTAINING NORMAL ELIMINATION PATTERNS

The nurse recommends a fluid intake of 2 L per day (within limits of the patient's cardiac and renal reserve) and suggests foods that are soft but have increased fiber to increase the bulk of the stool and facilitate peristalsis, thereby promoting defecation. An individualized exercise program is encouraged to improve abdominal muscle tone. It is important to review the patient's daily routine to establish a schedule for meals and a set time for defecation and to assist in identifying habits that may have suppressed the urge to defecate. The nurse encourages daily intake of bulk laxatives such as Metamucil, which helps to propel feces through the colon. Stool softeners are administered as prescribed to decrease straining at stool, which decreases intestinal pressure. Oil retention enemas may be prescribed to soften the stool, making it easier to pass.

#### RELIEVING PAIN

Analgesics (eg, meperidine) to relieve the pain of diverticulitis and antispasmodic agents to decrease intestinal spasm are administered as prescribed. The nurse records the intensity, duration, and location of pain to determine if the inflammatory process worsens or subsides.

#### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

The major nursing focus is to prevent complications by identifying patients at risk and managing their symptoms as needed. The nurse assesses for the following signs of perforation:

- Increased abdominal pain and tenderness accompanied by abdominal rigidity
- Elevated white blood cell count
- Elevated sedimentation rate
- Increased temperature
- Tachycardia
- Hypotension

Perforation is a surgical emergency. The clinical manifestations of perforation and peritonitis and the care of the patient with peritonitis are presented in the next section. The nurse monitors vital signs and urine output and administers intravenous fluids to replace volume loss as needed.

#### HOME AND COMMUNITY-BASED CARE

Because patients and their family members and health care providers tend to focus on the most obvious needs and issues, the nurse reminds the patient and family about the importance of continuing health promotion and screening practices. The nurse educates patients who have not been involved in these practices in the past about their importance and refers the patients to appropriate health care providers.

### Evaluation

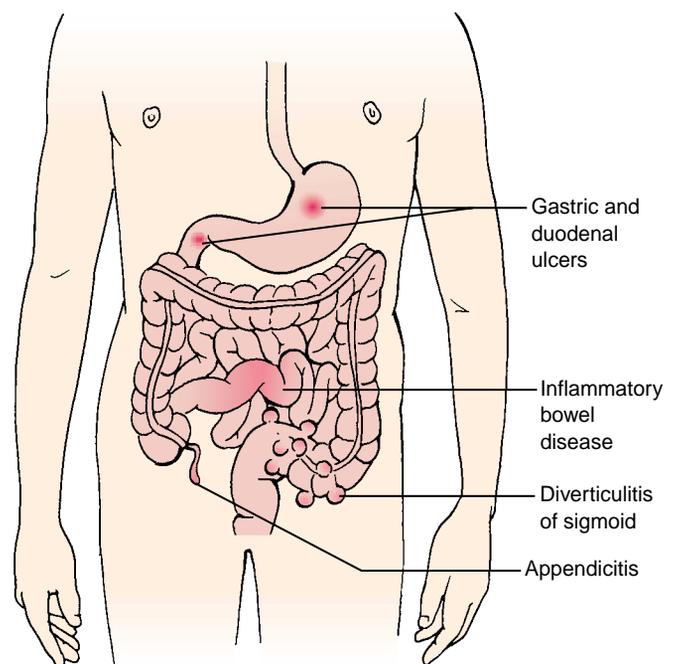

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Attains a normal pattern of elimination
  - a. Reports less abdominal cramping and pain
  - b. Reports the passage of soft, formed stool without pain
  - c. Adds unprocessed bran to foods
  - d. Drinks at least 10 glasses of fluid each day (if fluid intake is tolerated)
  - e. Exercises daily
2. Reports decreased pain
  - a. Requests analgesics as needed
  - b. Adheres to a low-fiber diet during acute episodes
3. Recovers without complications
  - a. Is afebrile
  - b. Has normal blood pressure
  - c. Has a soft, nontender abdomen with normal bowel sounds
  - d. Maintains adequate urine output
  - e. Has no blood in the stool

### PERITONITIS

Peritonitis is inflammation of the peritoneum, the serous membrane lining the abdominal cavity and covering the viscera. Usually, it is a result of bacterial infection; the organisms come from diseases of the GI tract or, in women, from the internal reproductive organs. Peritonitis can also result from external sources such as injury or trauma (eg, gunshot wound, stab wound) or an inflammation that extends from an organ outside the peritoneal area, such as the kidney. The most common bacteria implicated are *Escherichia coli*, *Klebsiella*, *Proteus*, and *Pseudomonas*. Inflammation and paralytic ileus are the direct effects of the infection. Other common causes of peritonitis are appendicitis, perforated ulcer, diverticulitis, and bowel perforation (Fig. 38-4). Peritonitis may also be associated with abdominal surgical procedures and peritoneal dialysis.

**FIGURE 38-4** Common gastrointestinal causes of peritonitis.

## Pathophysiology

Peritonitis is caused by leakage of contents from abdominal organs into the abdominal cavity, usually as a result of inflammation, infection, ischemia, trauma, or tumor perforation. Bacterial proliferation occurs. Edema of the tissues results, and exudation of fluid develops in a short time. Fluid in the peritoneal cavity becomes turbid with increasing amounts of protein, white blood cells, cellular debris, and blood. The immediate response of the intestinal tract is hypermotility, soon followed by paralytic ileus with an accumulation of air and fluid in the bowel.

## Clinical Manifestations

Symptoms depend on the location and extent of the inflammation. The early clinical manifestations of peritonitis frequently are the symptoms of the disorder causing the condition. At first, a diffuse type of pain is felt. The pain tends to become constant, localized, and more intense near the site of the inflammation. Movement usually aggravates it. The affected area of the abdomen becomes extremely tender and distended, and the muscles become rigid. Rebound tenderness and paralytic ileus may be present. Usually, nausea and vomiting occur and peristalsis is diminished. The temperature and pulse rate increase, and there is almost always an elevation of the leukocyte count.

## Assessment and Diagnostic Findings

The leukocyte count is elevated. The hemoglobin and hematocrit levels may be low if blood loss has occurred. Serum electrolyte studies may reveal altered levels of potassium, sodium, and chloride.

An abdominal x-ray is obtained, and findings may show air and fluid levels as well as distended bowel loops. A CT scan of the abdomen may show abscess formation. Peritoneal aspiration and culture and sensitivity studies of the aspirated fluid may reveal infection and identify the causative organisms.

## Complications

Frequently, the inflammation is not localized and the whole abdominal cavity becomes involved in a generalized sepsis. Sepsis is the major cause of death from peritonitis. Shock may result from septicemia or hypovolemia. The inflammatory process may cause intestinal obstruction, primarily from the development of bowel adhesions.

The two most common postoperative complications are wound evisceration and abscess formation. Any suggestion from the patient that an area of the abdomen is tender or painful or “feels as if something just gave way” must be reported. The sudden occurrence of serosanguineous wound drainage strongly suggests wound dehiscence (see Chap. 20).

## Medical Management

Fluid, colloid, and electrolyte replacement is the major focus of medical management. The administration of several liters of an isotonic solution is prescribed. Hypovolemia occurs because massive amounts of fluid and electrolytes move from the intestinal lumen into the peritoneal cavity and deplete the fluid in the vascular space.

Analgesics are prescribed for pain. Antiemetics are administered as prescribed for nausea and vomiting. Intestinal intubation and suction assist in relieving abdominal distention and in promoting intestinal function. Fluid in the abdominal cavity can

cause pressure that restricts expansion of the lungs and causes respiratory distress. Oxygen therapy by nasal cannula or mask can promote adequate oxygenation, but airway intubation and ventilatory assistance occasionally are required.

Massive antibiotic therapy is usually initiated early in the treatment of peritonitis. Large doses of a broad-spectrum antibiotic are administered intravenously until the specific organism causing the infection is identified and the appropriate antibiotic therapy can be initiated.

Surgical objectives include removing the infected material and correcting the cause. Surgical treatment is directed toward excision (ie, appendix), resection with or without anastomosis (ie, intestine), repair (ie, perforation), and drainage (ie, abscess). With extensive sepsis, a fecal diversion may need to be created.

## Nursing Management

Ongoing assessment of pain, vital signs, GI function, and fluid and electrolyte balance is important. The nurse reports the nature of the pain, its location in the abdomen, and any shifts in location. Administering analgesic medication and positioning the patient for comfort are helpful in decreasing pain. The patient is placed on the side with knees flexed; this position decreases tension on the abdominal organs. Accurate recording of all intake and output and central venous pressure assists in calculating fluid replacement. The nurse administers and monitors closely intravenous fluids.

Signs that indicate that peritonitis is subsiding include a decrease in temperature and pulse rate, softening of the abdomen, return of peristaltic sounds, passing of flatus, and bowel movements. The nurse increases fluid and food intake gradually and reduces parenteral fluids as prescribed. A worsening clinical condition may indicate a complication, and the nurse must prepare the patient for emergency surgery.

Drains are frequently inserted during the surgical procedure, and the nurse must observe and record the character of the drainage postoperatively. Care must be taken when moving and turning the patient to prevent the drains from being dislodged. It is also important for the nurse to prepare the patient and family for discharge by teaching the patient to care for the incision and drains if the patient will be sent home with the drains still in place.

## Inflammatory Bowel Disease

The term **inflammatory bowel disease** refers to two chronic inflammatory GI disorders: regional enteritis (ie, Crohn's disease or granulomatous colitis) and ulcerative colitis. Both disorders have striking similarities but also several differences. Table 38-4 compares regional enteritis and ulcerative colitis.

The incidence of IBD in the United States has increased in the past century; 10,000 to 15,000 new cases occur annually (Yamada et al., 1999). In the past, a higher rate was observed among Caucasians in general and the Jewish population in particular. Data now indicate a higher risk for African Americans and a lower risk for Jewish people, and women appear to be at higher risk than before. People between the ages of 10 and 30 are at greatest risk.

Despite vast amounts of research, the cause of IBD is still unknown. Researchers think it is triggered by environmental agents such as pesticides, food additives, tobacco, and radiation (Kirsner & Shorter, 2000). Nonsteroidal anti-inflammatory drugs have been found to exacerbate IBD. Allergies and immune disorders have also been suggested as causes. Abnormal response to dietary

**Table 38-4 • Comparison of Regional Enteritis and Ulcerative Colitis**

FACTOR	REGIONAL ENTERITIS	ULCERATIVE COLITIS
<b>Course</b>	Prolonged, variable	Exacerbations, remissions
<b>Pathology</b>		
Early	Transmural thickening	Mucosal ulceration
Late	Deep, penetrating granulomas	Mucosal minute ulceration
<b>Clinical Manifestations</b>		
Location	Ileum, right colon (usually)	Rectum, left colon
Bleeding	Usually not, but may occur	Common—severe
Perianal involvement	Common	Rare—mild
Fistulas	Common	Rare
Rectal involvement	About 20%	Almost 100%
Diarrhea	Less severe	Severe
<b>Diagnostic Study Findings</b>		
Radiography	Regional, discontinuous lesions Narrowing of colon Thickening of bowel wall Mucosal edema Stenosis, fistulas	Diffuse involvement No narrowing of colon No mucosal edema Stenosis rare Shortening of colon Abnormal inflamed mucosa
Sigmoidoscopy	May be unremarkable unless accompanied by perianal fistulas	
Colonoscopy	Distinct ulcerations separated by relatively normal mucosa in right colon	Friable mucosa with pseudo-polyps or ulcers in left colon
<b>Therapeutic Management</b>	Corticosteroids, sulfonamides (sulfasalazine [Azulfidine]) Antibiotics Parenteral nutrition Partial or complete colectomy, with ileostomy or anastomosis Rectum can be preserved in some patients Recurrence common	Corticosteroids, sulfonamides; sulfasalazine useful in preventing recurrence Bulk hydrophilic agents Antibiotics Proctocolectomy, with ileostomy Rectum can be preserved in only a few patients “cured” by colectomy
<b>Systemic Complications</b>	Small bowel obstruction Right-sided hydronephrosis Nephrolithiasis Cholelithiasis Arthritis Retinitis, iritis Erythema nodosum	Toxic megacolon Perforation Hemorrhage Malignant neoplasms Pyelonephritis Nephrolithiasis Cholangiocarcinoma Arthritis Retinitis, iritis Erythema nodosum

or bacterial antigens has been studied extensively, and genetic factors also are being studied. There is a high prevalence of coexistent IBS, which complicates the overall symptom presentation.

## REGIONAL ENTERITIS (CROHN'S DISEASE)

Regional enteritis commonly occurs in adolescents or young adults but can appear at any time of life. It is more common in women, and it occurs frequently in the older population (between the ages of 50 and 80). It can occur anywhere along the GI tract, but the most common areas are the distal ileum and colon. The incidence of Crohn's disease has risen over the past 30 years. Crohn's disease is seen two times more often in patients who smoke than in nonsmokers (Rose, 1998).

## Pathophysiology

Regional enteritis is a subacute and chronic inflammation that extends through all layers (ie, transmural lesion) of the bowel wall from the intestinal mucosa. It is characterized by periods of remissions and exacerbations. The disease process begins with edema and thickening of the mucosa. Ulcers begin to appear on the inflamed mucosa. These lesions are not in continuous contact with one another and are separated by normal tissue. Fistulas, fissures, and abscesses form as the inflammation extends into the peritoneum. Granulomas occur in one half of patients. In advanced cases, the intestinal mucosa has a cobblestone appearance. As the disease advances, the bowel wall thickens and becomes fibrotic, and the intestinal lumen narrows. Diseased bowel loops sometimes adhere to other loops surrounding them.

## Clinical Manifestations

In regional enteritis, the onset of symptoms is usually insidious, with prominent lower right quadrant abdominal pain and diarrhea unrelieved by defecation. Scar tissue and the formation of granulomas interfere with the ability of the intestine to transport products of the upper intestinal digestion through the constricted lumen, resulting in crampy abdominal pains. There is abdominal tenderness and spasm. Because eating stimulates intestinal peristalsis, the crampy pains occur after meals. To avoid these bouts of crampy pain, the patient tends to limit food intake, reducing the amounts and types of food to such a degree that normal nutritional requirements are not met. The result is weight loss, malnutrition, and secondary anemia. Ulcers in the membranous lining of the intestine and other inflammatory changes result in a weeping, swollen intestine that continually empties an irritating discharge into the colon. Disrupted absorption causes chronic diarrhea and nutritional deficits. The result is a person who is thin and emaciated from inadequate food intake and constant fluid loss. In some patients, the inflamed intestine may perforate, leading to intra-abdominal and anal abscesses. Fever and leukocytosis occur. Chronic symptoms include diarrhea, abdominal pain, steatorrhea, anorexia, weight loss, and nutritional deficiencies.

Abscesses, fistulas, and fissures are common. Symptoms extend beyond the GI tract and commonly include joint involvement (eg, arthritis), skin lesions (eg, erythema nodosum), ocular disorders (eg, conjunctivitis), and oral ulcers. The clinical course and symptoms can vary; in some patients, periods of remission and exacerbation occur, but in others, the disease follows a fulminating course.

## Assessment and Diagnostic Findings

A proctosigmoidoscopic examination is usually performed initially to determine whether the rectosigmoid area is inflamed. A stool examination is also performed; the result may be positive for occult blood and steatorrhea (ie, excessive fat in the feces). The most conclusive diagnostic aid for regional enteritis is a barium study of the upper GI tract that shows the classic “string sign” on an x-ray film of the terminal ileum, indicating the constriction of a segment of intestine. Endoscopy and intestinal biopsy may be used for confirmation of the diagnosis. A barium enema may show ulcerations (the cobblestone appearance described earlier), fissures, and fistulas. A CT scan may show bowel wall thickening and fistula tracts.

A complete blood cell count is performed to assess hematocrit and hemoglobin levels (usually decreased) and the white blood cell count (may be elevated). The sedimentation rate is usually elevated. Albumin and protein levels may be decreased, indicating malnutrition.

## Complications

Complications of regional enteritis include intestinal obstruction or stricture formation, perianal disease, fluid and electrolyte imbalances, malnutrition from malabsorption, and fistula and abscess formation. A fistula is an abnormal communication between two body structures, either internal (ie, between two structures) or external (ie, between an internal structure and the outside surface of the body). The most common type of small bowel fistula that results from regional enteritis is the enterocutaneous fistula (ie, between the small bowel and the skin). Abscesses can be the result of an internal fistula tract into an area that results in fluid accumulation and infection. Patients with regional enteritis are also at increased risk for colon cancer.

## ULCERATIVE COLITIS

Ulcerative colitis is a recurrent ulcerative and inflammatory disease of the mucosal and submucosal layers of the colon and rectum. The incidence of ulcerative colitis is highest in Caucasians and people of Jewish heritage (Yamada et al., 1999). The peak incidence is between 30 and 50 years of age. It is a serious disease, accompanied by systemic complications and a high mortality rate. Eventually, 10% to 15% of the patients develop carcinoma of the colon.

## Pathophysiology

Ulcerative colitis affects the superficial mucosa of the colon and is characterized by multiple ulcerations, diffuse inflammations, and desquamation or shedding of the colonic epithelium. Bleeding occurs as a result of the ulcerations. The mucosa becomes edematous and inflamed. The lesions are contiguous, occurring one after the other. Abscesses form, and infiltrate is seen in the mucosa and submucosa with clumps of neutrophils in the crypt lumens (ie, crypt abscesses). The disease process usually begins in the rectum and spreads proximally to involve the entire colon. Eventually, the bowel narrows, shortens, and thickens because of muscular hypertrophy and fat deposits.

## Clinical Manifestations

The clinical course is usually one of exacerbations and remissions. The predominant symptoms of ulcerative colitis are diarrhea, lower left quadrant abdominal pain, intermittent tenesmus, and rectal bleeding. The bleeding may be mild or severe, and pallor results. The patient may have anorexia, weight loss, fever, vomiting, and dehydration, as well as cramping, the feeling of an urgent need to defecate, and the passage of 10 to 20 liquid stools each day. The disease is classified as mild, severe, or fulminant, depending on the severity of the symptoms. Hypocalcemia and anemia frequently develop. Rebound tenderness may occur in the right lower quadrant. Extraintestinal symptoms include skin lesions (eg, erythema nodosum), eye lesions (eg, uveitis), joint abnormalities (eg, arthritis), and liver disease.

## Assessment and Diagnostic Findings

The patient should be assessed for tachycardia, hypotension, tachypnea, fever, and pallor. Other assessments include the level of hydration and nutritional status. The abdomen should be examined for characteristics of bowel sounds, distention, and tenderness. These findings assist in determining the severity of the disease.

The stool is positive for blood, and laboratory test results reveal a low hematocrit and hemoglobin concentration in addition to an elevated white blood cell count, low albumin levels, and an electrolyte imbalance. Abdominal x-ray studies are useful for determining the cause of symptoms. Free air in the peritoneum and bowel dilation or obstruction should be excluded as a source of the presenting symptoms. Sigmoidoscopy or colonoscopy and barium enema are valuable in distinguishing this condition from other diseases of the colon with similar symptoms. A barium enema may show mucosal irregularities, focal strictures or fistulas, shortening of the colon, and dilation of bowel loops. Endoscopy may reveal friable, inflamed mucosa with exudate and ulcerations. This procedure assists in defining the extent and severity of the disease. CT scanning, magnetic resonance imaging, and ultrasound can identify abscesses and perirectal in-

involvement. Leukocyte scanning (see Chap. 34) is useful when severe colitis prohibits the use of endoscopy to determine the extent of inflammation.

**NURSING ALERT** In acute ulcerative colitis, cathartics are contraindicated when the patient is being prepared for barium enema or endoscopy because they may exacerbate the condition, which can lead to megacolon (ie, excessive dilation of the colon), perforation, and death. If the patient needs to have these diagnostic tests, a liquid diet for a few days before radiography and a gentle tap-water enema on the day of the examination may be prescribed. Colonoscopy is contraindicated in severe disease because of the risk of perforation.

Careful stool examination for parasites and other microbes is performed to rule out dysentery caused by common intestinal organisms, especially *Entamoeba histolytica* and *Clostridium difficile*.

## Complications

Complications of ulcerative colitis include toxic megacolon, perforation, and bleeding as a result of ulceration, vascular engorgement, and highly vascular granulation tissue. In toxic megacolon, the inflammatory process extends into the muscularis, inhibiting its ability to contract and resulting in colonic distention. Symptoms include fever, abdominal pain and distention, vomiting, and fatigue. Colonic perforation from toxic megacolon is associated with a high mortality rate (15% to 50%) (Grendell et al., 1998). If the patient with toxic megacolon does not respond within 24 to 48 hours to medical management with nasogastric suction, intravenous fluids with electrolytes, corticosteroids, and antibiotics, surgery is required. Total colectomy is indicated. For many patients, surgery becomes necessary to relieve the effects of the disease and to treat these serious complications; an ileostomy usually is performed. The surgical procedures involved and the care of patients with this type of fecal diversion are discussed later in this chapter.

Patients with IBD also have a significantly increased risk of osteoporotic fractures due to decreased bone mineral density. Corticosteroid therapy may also contribute to the diminished bone mass.

## Medical Management of Chronic Inflammatory Bowel Disease

Medical treatment for regional enteritis and ulcerative colitis is aimed at reducing inflammation, suppressing inappropriate immune responses, providing rest for a diseased bowel so that healing may take place, improving quality of life, and preventing or minimizing complications.

Most patients maintain long-term well-being interspersed with short intervals of illness (Hanauer, 2001). Management depends on the disease location, severity, and complications.

### NUTRITIONAL THERAPY

Oral fluids and a low-residue, high-protein, high-calorie diet with supplemental vitamin therapy and iron replacement are prescribed to meet nutritional needs, reduce inflammation, and control pain and diarrhea. Fluid and electrolyte imbalances from dehydration caused by diarrhea are corrected by intravenous therapy as necessary if the patient is hospitalized or by oral supplementation if the patient can be managed at home. Any foods that exacerbate diarrhea are avoided. Milk may contribute to diarrhea in those with lactose intolerance. Cold foods and smoking are avoided because

both increase intestinal motility. Parenteral nutrition may be indicated.

### PHARMACOLOGIC THERAPY

Sedatives and antidiarrheal and antiperistaltic medications are used to minimize peristalsis to rest the inflamed bowel. They are continued until the patient's stools approach normal frequency and consistency.

Aminosalicylate formulations such as sulfasalazine (Azulfidine) are often effective for mild or moderate inflammation and are used to prevent or reduce recurrences in long-term maintenance regimens. Newer sulfa-free aminosalicylates (eg, mesalamine [Asacol, Pentasa]) have been developed and shown effective in preventing and treating recurrence of inflammation (Wolfe, 2000). Antibiotics are used for secondary infections, particularly for purulent complications such as abscesses, perforation, and peritonitis.

Corticosteroids are used to treat severe and fulminant disease. These corticosteroids (eg, prednisone) can be administered orally in outpatient treatment or parenterally in hospitalized patients. Topical (ie, rectal administration) corticosteroids are also widely used in the treatment of distal colon disease. When the dosage of corticosteroids is reduced or stopped, the symptoms of disease may return. If corticosteroids are continued, adverse sequelae such as hypertension, fluid retention, cataracts, hirsutism (ie, abnormal hair growth), adrenal suppression, and loss of bone density may develop.

Immunomodulators (eg, azathioprene [Imuran], 6-mercaptopurine, methotrexate, cyclosporin) have been used to alter the immune response (Wolfe, 2000). The exact mechanism of action of these medications in treating IBD is unknown. They are used for patients with severe disease who have failed other therapies. These medications are useful in maintenance regimens to prevent relapses. Newer biologic therapies are being studied, and it is hoped that they will lead to improvement in the treatment of patients with chronically active disease (Yamada et al., 1999).

### SURGICAL MANAGEMENT

When nonsurgical measures fail to relieve the severe symptoms of IBD, surgery may be recommended. The most common indications for surgery are medically intractable disease, poor quality of life, or complications from the disease or medical therapy (Wolfe, 2000).

More than one half of all patients with regional enteritis require surgery at some point. Recurrence of inflammation and disease after surgery in regional enteritis is inevitable. The rate of recurrence after surgery is 20% to 40% in the first 5 years. Patients younger than 25 years of age have the highest recurrence rate. Surgery for regional enteritis is indicated for refractory disease or complications (Wolfe, 2000). The procedure of choice is a total colectomy and ileostomy.

A newer surgical procedure developed for patients with severe regional enteritis is intestinal transplant. This technique is now available to children and to young and middle-age adults who have lost intestinal function from disease. Although not a cure, this procedure may eventually provide improvement in quality of life for some who are terminally ill. The technical and immunologic problems with this procedure remain formidable, and the costs and mortality rates remain high (Wolfe, 2000).

Approximately 15% to 20% of patients with ulcerative colitis require surgical intervention (Tierney et al., 2000). Indications for surgery include lack of improvement and continued deterioration, profuse bleeding, perforation, stricture formation, and cancer. Surgical excision usually improves quality of life.

Proctocolectomy with ileostomy (ie, complete excision of colon, rectum, and anus) is recommended when the rectum is severely involved.

One type of surgical technique that can be helpful is strictureplasty, in which the blocked or narrowed section of the bowel is widened, leaving the bowel intact. If a lesion can be delineated in regional enteritis or if a complication has occurred, the lesion is resected, and the remaining portions of the bowel are anastomosed. Surgical removal of up to 50% of the small bowel usually can be tolerated. Other types of surgical procedures, known as fecal diversions, are discussed later in this chapter.

**Total Colectomy With Ileostomy.** An **ileostomy**, the surgical creation of an opening into the ileum or small intestine (usually by means of an ileal stoma on the abdominal wall), is commonly performed after a total colectomy (ie, excision of the entire colon). It allows for drainage of fecal matter (ie, effluent) from the ileum to the outside of the body. The drainage is very mushy and occurs at frequent intervals. Nursing management of the patient with an ileostomy is discussed in a later section of this chapter.

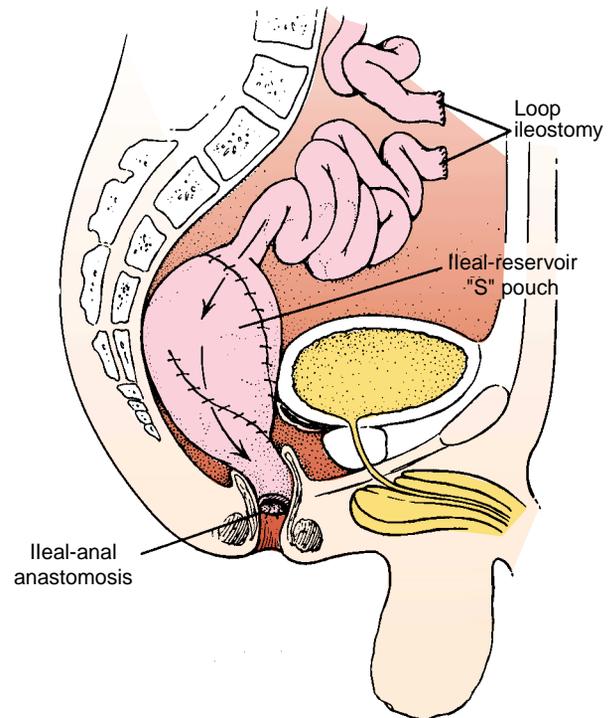

**Total Colectomy With Continent Ileostomy.** Another procedure involves the removal of the entire colon and creation of the continent ileal reservoir (ie, Kock pouch). This procedure eliminates the need for an external fecal collection bag. Approximately 30 cm of the distal ileum is reconstructed to form a reservoir with a nipple valve that is created by pulling a portion of the terminal ileal loop back into the ileum. GI effluent can accumulate in the pouch for several hours and then be removed by means of a catheter inserted through the nipple valve. The major problem with the Kock pouch is malfunction of the nipple valve, which occurs in about 20% of the patients (Yamada et al., 1999).

**Total Colectomy With Ileoanal Anastomosis.** A total colectomy with ileoanal anastomosis is another surgical procedure that eliminates the need for a permanent ileostomy. It establishes an ileal reservoir, and anal sphincter control of elimination is retained. The procedure involves connecting a portion of the ileum to the anus (ie, ileoanal anastomosis) in conjunction with removal of the colon and the rectal mucosa (ie, total abdominal colectomy and mucosal proctectomy) (Fig. 38-5). A temporary diverting loop ileostomy is constructed at the time of surgery and closed about 3 months later.

With ileoanal anastomosis, the diseased colon and rectum are removed, voluntary defecation is maintained, and anal continence is preserved. The ileal reservoir decreases the number of bowel movements by 50%, from approximately 14 to 20 per day to 7 to 10 per day. Nighttime elimination is gradually reduced to one bowel movement. Complications of ileoanal anastomosis include irritation of the perianal skin from leakage of fecal contents, stricture formation at the anastomosis site, and small bowel obstruction.

## Nursing Management

Nursing management of patients with IBD may be medical, surgical, or both. Patients in the community setting or those recently diagnosed may primarily require education about diet and medications and referral to support groups. Hospitalized patients with long-standing or severe disease also require careful monitoring, parenteral nutrition, fluid replacement, and possibly emergent surgery. The surgical procedures may involve a fecal diversion,

**FIGURE 38-5** A mucosal proctectomy precedes anastomosis of the ileal reservoir. A temporary loop ileostomy diverts effluent for several months.

with attendant needs for physical care, emotional support, and extensive teaching about management of the ostomy.

## NURSING PROCESS: MANAGEMENT OF THE PATIENT WITH INFLAMMATORY BOWEL DISEASE

### Assessment

The nurse takes a health history to identify the onset, duration, and characteristics of abdominal pain; the presence of diarrhea or fecal urgency, straining at stool (tenesmus), nausea, anorexia, or weight loss; and family history of IBD. It is important to discuss dietary patterns, including the amounts of alcohol, caffeine, and nicotine containing products used daily and weekly. The nurse asks about patterns of bowel elimination, including character, frequency, and presence of blood, pus, fat, or mucus. It is important to note allergies and food intolerance, especially milk (lactose) intolerance. The patient may identify sleep disturbances if diarrhea or pain occurs at night.

Assessment includes auscultating the abdomen for bowel sounds and their characteristics; palpating the abdomen for distention, tenderness, or pain; and inspecting the skin for evidence of fistula tracts or symptoms of dehydration. The stool is inspected for blood and mucus.

With regional enteritis, pain is usually localized in the right lower quadrant, where hyperactive bowel sounds can be heard because of borborygmus and increased peristalsis. Abdominal tenderness is noticed on palpation. The most prominent symptom is intermittent pain that occurs with diarrhea but does not decrease after defecation. Pain in the periumbilical region usually indicates involvement of the terminal ileum. With ulcerative col-

itis, the abdomen may be distended, and rebound tenderness may be present. Rectal bleeding is a significant sign.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the nursing diagnoses may include the following:

- Diarrhea related to the inflammatory process
- Acute pain related to increased peristalsis and GI inflammation
- Deficient fluid volume deficit related to anorexia, nausea, and diarrhea
- Imbalanced nutrition, less than body requirements, related to dietary restrictions, nausea, and malabsorption
- Activity intolerance related to fatigue
- Anxiety related to impending surgery
- Ineffective coping related to repeated episodes of diarrhea
- Risk for impaired skin integrity related to malnutrition and diarrhea
- Risk for ineffective therapeutic regimen management related to insufficient knowledge concerning the process and management of the disease

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Potential complications that may develop include the following:

- Electrolyte imbalance
- Cardiac dysrhythmia related to electrolyte depletion
- GI bleeding with fluid volume loss
- Perforation of the bowel

## Planning and Goals

The major goals for the patient include attainment of normal bowel elimination patterns, relief of abdominal pain and cramping, prevention of fluid volume deficit, maintenance of optimal nutrition and weight, avoidance of fatigue, reducing anxiety, promoting effective coping, absence of skin breakdown, learning about the disease process and therapeutic regimen, and avoidance of complications.

## Nursing Interventions

### MAINTAINING NORMAL ELIMINATION PATTERNS

The nurse determines if there is a relationship between diarrhea and certain foods, activity, or emotional stress. Identifying precipitating factors, the frequency of bowel movements, and the character, consistency, and amount of stool passed is important. The nurse provides ready access to a bathroom, commode, or bedpan and keeps the environment clean and odor free. It is important to administer antidiarrheal medications as prescribed, to record the frequency and consistency of stools after therapy is initiated, and to encourage bed rest to decrease peristalsis.

### RELIEVING PAIN

The character of the pain is described as dull, burning, or crampy. Asking about its onset is relevant. Does it occur before or after meals, during the night, or before elimination? Is the pattern constant or intermittent? Is it relieved with medications? The nurse

administers anticholinergic medications as prescribed 30 minutes before a meal to decrease intestinal motility and administers analgesics as prescribed for pain. Position changes, local application of heat (as prescribed), diversional activities, and the prevention of fatigue also are helpful for reducing pain.

### MAINTAINING FLUID INTAKE

To detect fluid volume deficit, the nurse keeps an accurate record of oral and intravenous fluids and maintains a record of output (ie, urine, liquid stool, vomitus, and wound or fistula drainage). The nurse monitors daily weights for fluid gains or losses and assesses the patient for signs of fluid volume deficit (ie, dry skin and mucous membranes, decreased skin turgor, oliguria, exhaustion, decreased temperature, increased hematocrit, elevated urine specific gravity, and hypotension). It is important to encourage oral intake of fluids and to monitor the intravenous flow rate. The nurse initiates measures to decrease diarrhea (eg, dietary restrictions, stress reduction, antidiarrheal agents).

### MAINTAINING OPTIMAL NUTRITION

Parenteral nutrition (PN) is used when the symptoms of IBD are severe. With PN, the nurse maintains an accurate record of fluid intake and output as well as the patient's daily weight. The patient should gain 0.5 kg daily during PN therapy. Because PN is very high in glucose and can cause hyperglycemia, blood glucose levels are monitored every 6 hours. Elemental feedings high in protein and low in fat and residue are instituted after PN therapy because they are digested primarily in the jejunum, do not stimulate intestinal secretions, and allow the bowel to rest. The nurse notes intolerance if the patient exhibits nausea, vomiting, diarrhea, or abdominal distention.

If oral foods are tolerated, small, frequent, low-residue feedings are given to avoid overdistending the stomach and stimulating peristalsis. It is important for the patient to restrict activity to conserve energy, reduce peristalsis, and reduce calorie requirements.

### PROMOTING REST

The nurse recommends intermittent rest periods during the day and schedules or restricts activities to conserve energy and reduce the metabolic rate. It is important to encourage activity within the limits of the patient's capacity. The nurse suggests bed rest for a patient who is febrile, has frequent diarrheal stools, or is bleeding. The patient on bed rest should perform active exercises to maintain muscle tone and prevent thromboembolic complications. If the patient is unable to perform these active exercises, the nurse performs passive exercises and joint range of motion. Activity restrictions are modified as needed on a day-to-day basis.

### REDUCING ANXIETY

Rapport can be established by being attentive and displaying a calm, confident manner. The nurse allows time for the patient to ask questions and express feelings. Careful listening and sensitivity to nonverbal indicators of anxiety (eg, restlessness, tense facial expressions) are helpful. The patient may be emotionally labile because of the consequences of the disease; the nurse tailors information about possible impending surgery to the patient's level of understanding and desire for detail. If surgery is planned, pictures and illustrations help to explain the surgical procedure and help the patient to visualize what a stoma looks like.

### ENHANCING COPING MEASURES

Because the patient may feel isolated, helpless, and out of control, understanding and emotional support are essential. The patient may respond to stress in a variety of ways that may alienate others, including anger, denial, and social self-isolation.

The nurse needs to recognize that the patient's behavior may be affected by a number of factors unrelated to inherent emotional characteristics. Any patient suffering the discomforts of frequent bowel movements and rectal soreness is anxious, discouraged, and depressed. It is important to develop a relationship with the patient that supports all attempts to cope with these stresses. It is also important to communicate that the patient's feelings are understood by encouraging the patient to talk and express his or her feelings and to discuss any concerns. Stress reduction measures that may be used include relaxation techniques, visualization, breathing exercises, and biofeedback. Professional counseling may be needed to help the patient and family manage issues associated with chronic illness.

### PREVENTING SKIN BREAKDOWN

The nurse examines the patient's skin frequently, especially the perianal skin. Perianal care, including the use of a skin barrier, is important after each bowel movement. The nurse gives immediate attention to reddened or irritated areas over a bony prominence and uses pressure-relieving devices to prevent skin breakdown. Consultation with a wound care specialist or enterostomal therapist is often helpful.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Serum electrolyte levels are monitored daily, and electrolyte replacements are administered as prescribed. It is important to report evidence of dysrhythmias or change in level of consciousness immediately.

The nurse closely monitors rectal bleeding and administers blood component therapy and volume expanders as prescribed to prevent hypovolemia. It is important to monitor the blood pressure for hypotension and to obtain coagulation and hematocrit and hemoglobin profiles frequently. Vitamin K may be prescribed to increase clotting factors.

The nurse closely monitors the patient for indications of perforation (ie, acute increase in abdominal pain, rigid abdomen, vomiting, or hypotension) and obstruction and toxic megacolon (ie, abdominal distention, decreased or absent bowel sounds, change in mental status, fever, tachycardia, hypotension, dehydration, and electrolyte imbalances).

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

The nurse assesses the patient's understanding of the disease process and his or her need for additional information about medical management (eg, medications, diet) and surgical interventions. The nurse provides information about nutritional management; a bland, low-residue, high-protein, high-calorie, and high-vitamin diet relieves symptoms and decreases diarrhea. It is important to provide the rationale for the use of corticosteroids and anti-inflammatory, antibacterial, antidiarrheal, and antispasmodic medications. The nurse emphasizes the importance of taking medications as prescribed and not abruptly discontinuing them (especially corticosteroids) to avoid development of serious medical problems (Chart 38-3). The nurse reviews ileostomy care as necessary (see Nursing Management of the Patient with an Ileostomy). Patient education information can be obtained from the National Foundation for Ileitis and Colitis.

#### Continuing Care

Patients with chronic inflammatory disease are managed at home with follow-up care by their physician or through an outpatient clinic. Those whose nutritional status is compromised and who are receiving PN need home care nursing to ensure that their nutritional requirements are being met and that they or their caregivers can follow through with the instructions for PN. Patients who are medically managed need to understand that their disease can be controlled and that they can lead a healthy life between exacerbations. Control implies management based on an understanding of the disease and its treatment. Patients in the home setting need information about their medications (ie, name, dose, side effects, and frequency of administration) and need to take medications on schedule. Medication reminders such as containers that separate pills according to day and time or daily checklists are helpful.

During a flare-up, the nurse encourages patients to rest as needed and to modify activities according to their energy levels. Patients should limit tasks that impose strain on the lower abdominal muscles. They should sleep in a room close to the bathroom because of the frequent diarrhea (10 to 20 times per day); quick access to a toilet helps alleviate the worry of embarrassment if an accident occurs. Room deodorizers help control odors.

Dietary modifications can control but not cure the disease; the nurse recommends a low-residue, high-protein, high-calorie diet, especially during an acute phase. It is important to encourage patients to keep a record of the foods that irritate the bowel and to eliminate them from the diet and to remind patients to drink at least eight glasses of water each day.

Chart 38-3

#### Home Care Checklist • Managing Inflammatory Bowel Disease

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Verbalize an understanding of the disease process.	✓	✓
• Discuss nutritional management: bland, low-residue, high-protein, high-vitamin diet; identify foods to include and foods to be avoided.	✓	✓
• Describe medication regimen; identify medications by name, use, route, and frequency.	✓	✓
• Identify measures to be used to treat exacerbation of symptoms, to include rest, dietary modifications, medications.	✓	✓
• Identify measures to be used to promote fluid and electrolyte balance during acute exacerbations	✓	✓
• Demonstrate management of PN therapy, if applicable; identifies possible complications and interventions	✓	✓
• Incorporate stress reduction measures into life-style	✓	

The prolonged nature of the disease has an impact on the patient and often strains his or her family life and financial resources as well. Family support is vital; however, some family members may be resentful, guilty, and tired and feel unable to continue coping with the emotional demands of the illness and the physical demands of caring for another. Some patients with IBD do not socialize for fear of being embarrassed. Many prefer to eat alone. Because they have lost control over elimination, they may fear losing control over other aspects of their lives. They need time to express their fears and frustrations. Individual and family counseling may be helpful.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Reports a decrease in the frequency of diarrhea stools
  - a. Complies with dietary restrictions; maintains bed rest
  - b. Takes medications as prescribed
2. Has reduced pain
3. Maintains fluid volume balance
  - a. Drinks 1 to 2 L of oral fluids daily
  - b. Has a normal body temperature
  - c. Displays adequate skin turgor and moist mucous membranes
4. Attains optimal nutrition; tolerates small, frequent feedings without diarrhea
5. Avoids fatigue
  - a. Rests periodically during the day
  - b. Adheres to activity restrictions
6. Is less anxious
7. Copes successfully with diagnosis
  - a. Expresses feelings freely
  - b. Uses appropriate stress reduction behaviors
8. Maintains skin integrity
  - a. Cleans perianal skin after defecation
  - b. Uses lotion or ointment as skin barrier
9. Acquires an understanding of the disease process
  - a. Modifies diet appropriately to decrease diarrhea
  - b. Adheres to medication regimen
10. Recovers without complications
  - a. Maintains electrolytes within normal ranges
  - b. Maintains normal sinus or baseline cardiac rhythm
  - c. Maintains fluid balance
  - d. Experiences no perforation or rectal bleeding

## NURSING MANAGEMENT OF THE PATIENT REQUIRING AN ILEOSTOMY

Some patients with IBD eventually require permanent fecal diversion with creation of an ileostomy to manage symptoms and to treat or prevent complications. The Plan of Nursing Care 38-1 summarizes care for the patient requiring an ostomy.

### Providing Preoperative Care

A period of preparation with intensive replacement of fluid, blood, and protein is necessary before surgery is performed. Antibiotics may be prescribed. If the patient has been taking corticosteroids, they will be continued during the surgical phase to prevent steroid-induced adrenal insufficiency. Usually, the patient is given a low-residue diet, provided in frequent, small feedings. All other preoperative measures are similar to those for general

abdominal surgery. The abdomen is marked for the proper placement of the stoma by the surgeon or the enterostomal therapist. Care is taken to ensure that the ostomy stoma is conveniently placed—usually in the right lower quadrant about 2 inches below the waist, in an area away from previous scars, bony prominence, skin folds, or fistulas.

The patient must have a thorough understanding of the surgery to be performed and what to expect after surgery. Information about an ileostomy is presented to the patient by means of written materials, models, and discussion. Preoperative teaching includes management of drainage from the stoma, the nature of drainage, and the need for nasogastric intubation, parenteral fluids, and possibly perineal packing.

### Providing Postoperative Care

General abdominal surgery wound care is required. The nurse observes the stoma for color and size. It should be pink to bright red and shiny. For the traditional ileostomy, a temporary plastic bag with adhesive facing is placed over the ileostomy and firmly pressed onto surrounding skin. The nurse monitors the ileostomy for fecal drainage, which should begin about 72 hours after surgery. The drainage is a continuous liquid from the small intestine because the stoma does not have a controlling sphincter. The contents drain into the plastic bag and are thus kept from coming into contact with the skin. They are collected and measured when the bag becomes full. If a continent ileal reservoir was created, as described for the Kock pouch, continuous drainage is provided by an indwelling reservoir catheter for 2 to 3 weeks after surgery. This allows the suture lines to heal.

As with other patients undergoing abdominal surgery, the nurse encourages those with an ileostomy to engage in early ambulation. It is important to administer prescribed pain medications as required.

Because these patients lose much fluid in the early postoperative period, an accurate record of fluid intake, urinary output, and fecal discharge is necessary to help gauge the fluid needs of the patient. There may be 1000 to 2000 mL of fluid lost each day in addition to expected fluid loss through urine, perspiration, respiration, and other sources. With this loss, sodium and potassium are depleted. The nurse monitors laboratory values and administers electrolyte replacements as prescribed. Intravenous fluids are administered to replace fluid losses for 4 to 5 days.

Nasogastric suction is also a part of immediate postoperative care, with the tube requiring frequent irrigation, as prescribed. The purpose of nasogastric suction is to prevent a buildup of gastric contents. After the tube is removed, the nurse offers sips of clear liquids and gradually progresses the diet. It is important to immediately report nausea and abdominal distention, which may indicate obstruction.

By the end of the first week, rectal packing is removed. Because this procedure may be uncomfortable, the nurse may administer an analgesic an hour before it is performed. After the packing is removed, the perineum is irrigated two or three times daily until full healing takes place.

### PROVIDING EMOTIONAL SUPPORT

The patient understandably may think that everyone is aware of the ileostomy and may view the stoma as a mutilation compared with other abdominal incisions that heal and are hidden. Because

*(text continues on page 1050)*

## Plan of Nursing Care

### The Patient Undergoing Ostomy Surgery

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Deficient knowledge about the surgical procedure and preoperative preparation

**Goal:** Understands the surgical process and the necessary preoperative preparations

##### Preoperative Care

(continued)

## Plan of Nursing Care

### The Patient Undergoing Ostomy Surgery (Continued)

#### Nursing Interventions

- a. Choose the drainage appliance that will provide a secure fit around the stoma. Measure the stoma size with a measuring guide provided by the ostomy manufacturer and compare with the opening on the pouch. About 3-mm ( $\frac{1}{8}$ -in) clearance should be provided around the stoma.
- b. Remove any plastic covering that protects the appliance adhesive. *Note:* The pouch is applied by pressing the adhesive for 30 s to the skin or skin barrier.
3. Demonstrate how to change the appliance before leakage occurs. Be aware that the elderly person may have diminished vision and difficulty handling equipment.
4. When appropriate, demonstrate how to irrigate the colostomy (usually on the 4th–5th day). Recommend that irrigation be performed at a consistent time, depending on the type of colostomy.

#### Rationale

- a. The appliance opening should be larger than the stoma for an adequate fit. Available brands come in different sizes to fit the stoma. Adjustments are made as necessary.
- b. The appliance is ready to apply directly to the skin or skin protector.
3. Manipulation of the appliance is a learned motor skill that requires practice and positive reinforcement.
4. Colostomy irrigation is used to regulate the passage of fecal material; alternatively the bowel can be allowed to evacuate naturally.

#### Expected Outcomes

**Nursing Diagnosis:** Risk for impaired skin integrity related to irritation of the peristomal skin by the effluent

**Goal:** Maintenance of skin integrity

1. Provide information about signs and symptoms of irritated or inflamed skin. Use pictures if possible.
2. Teach patient how to cleanse the peristomal skin gently.
3. Demonstrate how to apply a skin barrier (powder, gel, paste, wafer).
4. Demonstrate how to remove the pouch.

1. Peristomal skin should be slightly pink without abrasions and similar to that of the entire abdomen.
2. Mild friction with warm water and a gentle soap cleanses the skin and minimizes irritation and possible abrasions. Patting the skin dry prevents tissue trauma.
3. Skin barriers protect the peristomal skin from enzymes and bacteria.
4. Gently separate adhesive from the skin to avoid irritation. Never pull!

- Describes appearance of healthy skin
- Correctly cleanses the skin
- Successfully applies a skin barrier
- Gently removes the drainage appliance without skin damage
- Demonstrates intact skin around the colostomy stoma

**Nursing Diagnosis:** Potential imbalanced nutrition, less than body requirements, related to avoidance of foods that may cause GI discomfort

**Goal:** Achievement of an optimal nutritional intake

1. Conduct a complete nutritional assessment to identify any foods that may increase peristalsis by irritating the bowel.
2. Advise the patient to avoid food products with a cellulose or hemicellulose base (nuts, seeds).
3. Recommend moderation in intake of certain irritating fruits such as prunes, grapes, and bananas.

1. Patients react differently to certain foods because of individual sensitivity.
2. Cellulose food products are the non-digestible residue of plant foods. They hold water, provide bulk, and stimulate elimination.
3. These fruits tend to increase the quantity of effluent.

- Modifies diet to avoid offensive foods yet maintains adequate nutritional intake
- Avoids foods such as peanuts
- Modifies intake of certain fruits

(continued)

## Plan of Nursing Care

### The Patient Undergoing Ostomy Surgery (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Sexual dysfunction related to altered body image

**Goal:** Attainment of satisfactory sexual performance

1. Encourage the patient to verbalize concerns and fears. The sexual partner is welcomed to participate in the discussion.	1. Expressed needs help the therapist develop a plan of care.	• Expresses fears and concerns
2. Recommend alternative sexual positions.	2. Avoid patient embarrassment with the visual appearance of the stoma. Avoid peristomal skin irritation secondary to friction.	• Discusses alternative sexual positions
3. Seek assistance from a sexual therapist, enterostomal therapist, or advanced practice nurse.	3. Some patients need professional sexual counseling.	• Accepts services of a professional counselor

**Nursing Diagnosis:** Risk for deficient fluid volume related to anorexia and vomiting and increased loss of fluids and electrolytes from GI tract

**Goal:** Attainment of fluid balance

1. Estimate fluid intake and output: a. Strict intake and output  b. Daily weights	1. Provides indication of fluid balance. a. An early indicator of fluid imbalance is a daily, significant difference between intake and output. The average person ingests (food, fluids) and loses (urine, feces, lungs) about 2 L of fluid every 24 h. b. A gain/loss of 1 L of fluid is reflected in a body weight change of 2.2 lb.	• Maintains fluid balance
2. Assess serum and urinary values of sodium and potassium.	2. Sodium is the major electrolyte regulating water balance. Vomiting results in decreased urinary and serum sodium levels. Urinary sodium values, in contrast to serum values, reflect early, sensitive changes in sodium balance. Sodium works in conjunction with potassium, which is also decreased with vomiting. A significant deficiency in potassium is associated with a decrease in intracellular potassium bicarbonate, which leads to acidosis and compensatory hyperventilation.	• Maintains normal serum and urinary values for sodium and potassium
3. Observe and record skin turgor and the appearance of the tongue.	3. Adequate hydration is reflected by the skin's ability to return to its normal shape after being grasped between the fingers. <i>Note:</i> In the older person, it is normal for the return to be delayed. Changes in the mucous membrane covering the tongue are accurate and early indicators of hydration status.	• Normal skin turgor • Surface of tongue is pink, with a moist mucous membrane

there is loss of a body part and a major change in anatomy, the patient often goes through the various phases of grieving—shock, disbelief, denial, rejection, anger, and restitution. Nursing support through these phases is important, and understanding of the patient's emotional outlook in each instance should determine the approach taken. For example, teaching may be ineffective until the patient is ready to learn. Concern about body image may

lead to questions related to family relationships, sexual function, and for women, the ability to become pregnant and to deliver a baby normally. Patients need to know that someone understands and cares about them. A calm, nonjudgmental attitude exhibited by the nurse aids in gaining the patient's confidence. It is important to recognize the dependency needs of these patients. Their prolonged illness can make them irritable, anxious, and de-

pressed. The nurse can coordinate patient care through meetings attended by consultants such as the physician, psychologist, psychiatrist, social worker, enterostomal therapist, and dietitian. The team approach is important in facilitating the often complex care of this patient.

Conversely, a surgical procedure to create an ileostomy can produce dramatic positive changes in patients who have suffered from IBD for several years. After the continuous discomfort of the disease has decreased and patients learn how to take care of the ileostomy, they often develop a more positive outlook. Until they progress to this phase, an empathetic and tolerant approach by the nurse plays an important part in recovery. The sooner the patient masters the physical care of the ileostomy, the sooner he or she will psychologically accept it.

The support of other ostomates is also helpful. The United Ostomy Association is dedicated to the rehabilitation of ostomates. This organization gives patients useful information about living with an ostomy through an educational program of literature, lectures, and exhibits. Local associations offer visiting services by qualified members who provide hope and rehabilitation services to new ostomy patients. Hospitals and other health care agencies may have an enterostomal therapy nurse on staff who can serve as a valuable resource person for the ileostomy patient.

### MANAGING SKIN AND STOMA CARE

The patient with a traditional ileostomy cannot establish regular bowel habits because the contents of the ileum are fluid and are discharged continuously. The patient must wear a pouch at all times. Stomal size and pouch size vary initially; the stoma should be rechecked 3 weeks after surgery, when the edema has subsided. The final size and type of appliance is selected in 3 months, after the patient's weight has stabilized, and the stoma shrinks to a stable shape.

The location and length of the stoma are significant in the management of the ileostomy by the patient. The surgeon positions the stoma as close to the midline as possible and at a location where even an obese patient with a protruding abdomen can care for it easily. Usually, the ileostomy stoma is about 2.5 cm (1 in) long, which makes it convenient for the attachment of an appliance.

Skin excoriation around the stoma can be a persistent problem. Peristomal skin integrity may be compromised by several factors, such as an allergic reaction to the ostomy appliance, skin barrier, or paste; chemical irritation from the effluent; mechanical injury from the removal of the appliance; and possible infection. If irritation and yeast growth occur, nystatin powder (Mycostatin) is dusted lightly on the peristomal skin.

### CHANGING AN APPLIANCE

A regular schedule for changing the pouch before leakage occurs must be established for those with a traditional ileostomy. The patient can be taught to change the pouch in a manner similar to that described in Chart 38-4.

The amount of time a person can keep the appliance sealed to the body surface depends on the location of the stoma and on body structure. The usual wearing time is 5 to 7 days. The appliance is emptied every 4 to 6 hours or at the same time the patient empties the bladder. An emptying spout at the bottom of the appliance is closed with a special clip made for this purpose.

Most pouches are disposable and odor-proof. Foods such as spinach and parsley act as deodorizers in the intestinal tract; foods that cause odors include cabbage, onions, and fish. Bismuth subcarbonate tablets, which may be prescribed and taken by mouth three or four times each day, are effective in reducing odor. A stool

thickener, such as diphenoxylate (Lomotil), can also be prescribed and taken orally to assist in odor control.

### IRRIGATING A CONTINENT ILEOSTOMY

For a continent ileostomy (ie, Kock pouch), the nurse teaches the patient to drain the pouch, as described in Chart 38-5. A catheter is inserted into the reservoir to drain the fluid. The length of time between drainage periods is gradually increased until the reservoir needs to be drained only every 4 to 6 hours and irrigated once each day. A pouch is not necessary; instead, most patients wear a small dressing over the opening.

When the fecal discharge is thick, water can be injected through the catheter to loosen and soften it. The consistency of the effluent is affected by food intake. At first, drainage is only 60 to 80 mL, but as time goes on, the amount increases significantly. The internal Kock pouch stretches, eventually accommodating 500 to 1000 mL. The patient learns to use the sensation of pressure in the pouch as a gauge to determine how often the pouch should be drained.

### MANAGING DIETARY AND FLUID NEEDS

A low-residue diet is followed for the first 6 to 8 weeks. Strained fruits and vegetables are given. These foods are important sources of vitamins A and C. Later, there are few dietary restrictions, except for avoiding foods that are high in fiber or hard-to-digest kernels, such as celery, popcorn, corn, poppy seeds, caraway seeds, and coconut. Foods are reintroduced one at a time. The nurse assesses the patient's tolerance for these foods and reminds him or her to chew food thoroughly.

Fluids may be a problem during the summer, when fluid lost through perspiration adds to the fluid loss through the ileostomy. Fluids such as Gatorade are helpful in maintaining the electrolyte balance. If the fecal discharge is too watery, fibrous foods (eg, whole-grain cereals, fresh fruit skins, beans, corn, nuts) are restricted. If the effluent is excessively dry, salt intake is increased. Increased intake of water or fluid does not increase the effluent, because excess water is excreted in the urine.

### PREVENTING COMPLICATIONS

Monitoring for complications is an ongoing activity for the patient with an ileostomy. Minor complications occur in about 40% of patients who have an ileostomy; less than 20% of the complications require surgical intervention (Kirsner & Shorter, 2000).

Common complications include skin irritation, diarrhea, stomal stenosis, urinary calculi, and cholelithiasis. Peristomal skin irritation, the most common complication of an ileostomy, results from leakage of effluent. A pouch that does not fit well is often the cause. The nurse or an enterostomal therapist adjusts the pouch and skin barriers are applied. Diarrhea, manifested by very irritating effluent that rapidly fills the pouch (every hour or sooner), can quickly lead to dehydration and electrolyte losses. Supplemental water, sodium, and potassium are administered to prevent hypovolemia and hypokalemia. Antidiarrheal agents are administered. Stenosis is caused by circular scar tissue that forms at the stoma site. The scar tissue must be surgically released. Urinary calculi occur in about 10% of ileostomy patients because of dehydration from decreased fluid intake. Intense lower abdominal pain that radiates to the legs, hematuria, and signs of dehydration indicate that the urine should be strained. Fluid intake is encouraged. Sometimes, small stones are passed during urination; otherwise, treatment is necessary to crush or remove the calculi (see Chap. 45).

Cholelithiasis (ie, gallstones) occurs three times more commonly in patients with an ileostomy than in the general population

Chart 38-4

### GUIDELINES FOR Changing an Ostomy Appliance

Changing an ileostomy appliance is necessary to prevent leakage (the bag is usually changed every 5 to 7 days), to allow for examination of the skin around the stoma, and to assist in controlling odor if this becomes a problem. The appliance should be changed at any time that the patient complains of burning or itching under the disk or pain in the area of the stoma; routine changes should be performed early in the morning before breakfast or 2 to 4 hours after a meal, when the bowel is least active.

#### NURSING ACTION

1. Promote patient comfort and involvement in the procedure.
  - a. Have the patient assume a relaxed position.
  - b. Provide privacy.
  - c. Explain details of the procedure.
  - d. Expose the ileostomy area; remove the ileostomy belt (if worn).
2. Remove the appliance.
  - a. Have the patient sit on the toilet or on a chair facing the toilet. A patient who prefers to stand should face the toilet.
  - b. The appliance (pouch) can be removed by gently pushing the skin away from the adhesive.

#### RATIONALE

1. Providing a relaxed atmosphere and adequate explanations help the patient to become an active participant in the procedure.
2. These positions facilitate disposal or drainage.

#### Selected Ostomy Pouches and Accessories

(continued)

Chart 38-4

### GUIDELINES FOR Changing an Ostomy Appliance (Continued)

#### NURSING ACTION

3. Cleanse the skin:
  - a. Wash the skin gently with a soft cloth moistened with tepid water and mild soap; the patient may prefer to bathe before putting on a clean appliance.
  - b. Rinse and dry the skin thoroughly after cleansing.
4. Apply appliance (when there is *no* skin irritation):
  - a. An appropriate skin barrier is applied to the peristomal skin before the appliance is applied.
  - b. Remove cover from adherent surface of disk of disposable plastic appliance and apply directly to the skin.
  - c. Press firmly in place for 30 s to ensure adherence.

5. Apply appliance (when there is skin irritation):
  - a. Cleanse the skin thoroughly but gently; pat dry.
  - b. Apply Kenalog spray; blot excess moisture with a cotton pledget and dust lightly with nystatin (Mycostatin) powder.

OR

Apply as an alternative a wafer of Stomahesive (Squibb), which is commercially available. The stomal opening should be cut the same size as the stoma; use a cutting guide (supplied with Stomahesive). The wafer is applied directly to the skin.

- c. Another alternative is to moisten a karaya gum washer and apply when it is tacky. If the skin is moist, karaya powder may be applied first and any excess dusted off gently.
- d. The pouch is then applied to the treated skin.
6. Check the pouch bottom for closure; use the rubber band or clip provided.

#### RATIONALE

3. The patient may shower with or without the pouch.
  - a. Micropore or waterproof tape applied to the sides of the face-plate will keep it secure during bathing.
  - b. Moisture or soap residue will interfere with appliance adhesion.
4. Many appliances have a built-in skin barrier. The skin should be thoroughly dried before applying the appliance.

Pressing the appliance into place. Courtesy of Convatec, a Squibb Company.

5.
  - a. To remove debris.
  - b. The corticosteroid preparation (Kenalog) helps to decrease inflammation. The antifungal agent (nystatin) treats those types of infections that are common around stomas. A prescription is required for either medication.

Stomahesive is a substance that facilitates healing of excoriated skin. It adheres well even to moist, irritated skin.

- c. Karaya also facilitates skin healing. Tackiness promotes adherence.
- d. This will allow skin to heal while the appliance is in place.
6. Proper closure controls leakage.

because of changes in the absorption of bile acids that occur postoperatively. Spasm of the gallbladder causes severe upper right abdominal pain that can radiate to the back and right shoulder (see Chap. 40).

#### PROMOTING HOME AND COMMUNITY-BASED CARE

##### Teaching Patients Self-Care

The spouse and family should be familiar with the adjustment that will be necessary when the patient returns home. They need to know why it is necessary for the patient to occupy the bathroom for 10 minutes or more at certain times of the day and why certain equipment is needed. Their understanding is necessary to re-

duce tension; a relaxed patient tends to have fewer problems. Visits from an enterostomal therapy nurse may be arranged to ensure that the patient is progressing as expected and to provide additional guidance and teaching as needed.

The patient needs to know the commercial name of the pouch to be used so that he or she can obtain a ready supply and should have information about obtaining other supplies. The names and contact information of the local enterostomal therapy nurse and local self-help groups are often helpful. Any special restrictions on driving or working also need to be reviewed. The nurse teaches the patient about common postoperative complications and how to recognize and report them (Chart 38-6).

Chart 38-5

### GUIDELINES FOR Draining a Continent Ileostomy (Kock Pouch)

A continent ileostomy is the surgical creation of a pouch of small intestine that can serve as an internal receptacle for fecal discharge; a nipple valve is constructed at the outlet. Postoperatively, a catheter extends from the stoma and is attached to a closed drainage suction system. To ensure patency of the catheter, usually every 3 hours 10 to 20 mL of normal saline is instilled gently into the pouch; return flow is not aspirated but is allowed to drain by gravity.

After approximately 2 weeks, when the healing process has progressed to the point at which the catheter is removed from the stoma, the patient is taught to drain the pouch. The equipment required includes a catheter, tissues, water-soluble lubricant, gauze squares, a syringe, irrigating solution in a bowl, and an emesis or receiving basin.

The following procedure is used to drain the pouch; the patient is helped to participate in this procedure to learn to perform it unassisted.

#### NURSING ACTION

1. Lubricate the catheter and gently insert it about 5 cm (2 in), at which point some resistance may be felt at the valve or nipple.
2. If there is much resistance, fill a syringe with 20 mL of air or water and inject it through the catheter, while still exerting some pressure on the catheter.
3. Place the other end of the catheter in a drainage basin held below the level of the stoma. Later this process can be carried out at the toilet with drainage delivered into the toilet bowl.
4. After drainage, the catheter is removed and the area around the stoma is gently washed with warm water. Pat dry and apply an absorbent pad over the stoma. Fasten the pad with hypoallergenic tape.

#### RATIONALE

1. When gentle pressure is used, the catheter usually will enter the pouch.
2. This will permit the catheter to enter the pouch.
3. Gravity facilitates drainage. Drainage may include flatus as well as effluent.
4. The entire procedure requires about 5 to 10 min; at first it is performed every 3 h. The time between procedures is gradually lengthened to three times daily.

## Intestinal Obstruction

Intestinal obstruction exists when blockage prevents the normal flow of intestinal contents through the intestinal tract. Two types of processes can impede this flow.

- **Mechanical obstruction:** An intraluminal obstruction or a mural obstruction from pressure on the intestinal walls occurs. Examples are intussusception, polypoid tumors and neoplasms, stenosis, strictures, adhesions, hernias, and abscesses.
- **Functional obstruction:** The intestinal musculature cannot propel the contents along the bowel. Examples are amyloidosis, muscular dystrophy, endocrine disorders such as diabetes mellitus, or neurologic disorders such as Parkinson's

disease. The blockage also can be temporary and the result of the manipulation of the bowel during surgery.

The obstruction can be partial or complete. Its severity depends on the region of bowel affected, the degree to which the lumen is occluded, and especially the degree to which the vascular supply to the bowel wall is disturbed.

Most bowel obstructions occur in the small intestine. Adhesions are the most common cause of small bowel obstruction, followed by hernias and neoplasms. Other causes include intussusception, volvulus (ie, twisting of the bowel), and paralytic ileus. About 15% of intestinal obstructions occur in the large bowel; most of these are found in the sigmoid colon (Wolfe, 2000). The most common causes are carcinoma, diverticulitis, inflammatory bowel disorders, and benign tumors. Table 38-5 and Figure 38-6 list mechanical causes of obstruction and describe how they occur.

Chart 38-6

### Home Care Checklist • Managing Ostomy Care

At the completion of the home care instruction, the patient or caregiver will be able to:

- Demonstrate ostomy care, including wound cleansing, irrigation, and appliance changing.
- Describe the importance of maintaining peristomal skin integrity.
- Identify sources for obtaining additional dressing and appliance supplies.
- Identify dietary restrictions (foods that can cause diarrhea and constipation).
- Identify measures to be used to promote fluid and electrolyte balance.
- Describe medication regimen: identify medications by name, use, route, and frequency.
- Describe potential complications and necessary actions to be taken if complications occur.
- Identify how to contact enterostomal therapist or home health nurse.

	Patient	Caregiver
• Demonstrate ostomy care, including wound cleansing, irrigation, and appliance changing.	✓	✓
• Describe the importance of maintaining peristomal skin integrity.	✓	✓
• Identify sources for obtaining additional dressing and appliance supplies.	✓	✓
• Identify dietary restrictions (foods that can cause diarrhea and constipation).	✓	✓
• Identify measures to be used to promote fluid and electrolyte balance.	✓	✓
• Describe medication regimen: identify medications by name, use, route, and frequency.	✓	✓
• Describe potential complications and necessary actions to be taken if complications occur.	✓	✓
• Identify how to contact enterostomal therapist or home health nurse.	✓	✓

**Table 38-5 • Mechanical Causes of Intestinal Obstruction**

CAUSE	COURSE OF EVENTS	RESULT
Adhesions	Loops of intestine become adherent to areas that heal slowly or scar after abdominal surgery.	After surgery, adhesions produce a kinking of an intestinal loop.
Intussusception	One part of the intestine slips into another part located below it (like a telescope shortening).	The intestinal lumen becomes narrowed.
Volvulus	Bowel twists and turns on itself.	Intestinal lumen becomes obstructed. Gas and fluid accumulate in the trapped bowel.
Hernia	Protrusion of intestine through a weakened area in the abdominal muscle or wall.	Intestinal flow may be completely obstructed. Blood flow to the area may be obstructed as well.
Tumor	A tumor that exists within the wall of the intestine extends into the intestinal lumen, or a tumor outside the intestine causes pressure on the wall of the intestine.	Intestinal lumen becomes partially obstructed; if the tumor is not removed, complete obstruction results.

## SMALL BOWEL OBSTRUCTION

### Pathophysiology

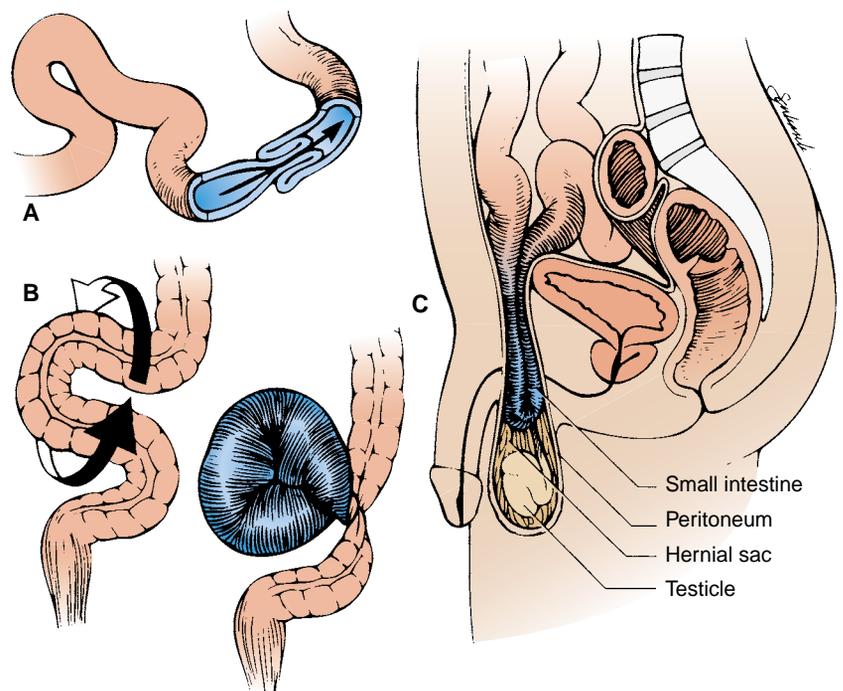

Intestinal contents, fluid, and gas accumulate above the intestinal obstruction. The abdominal distention and retention of fluid reduce the absorption of fluids and stimulate more gastric secretion. With increasing distention, pressure within the intestinal lumen increases, causing a decrease in venous and arteriolar capillary pressure. This causes edema, congestion, necrosis, and eventual rupture or perforation of the intestinal wall, with resultant peritonitis.

Reflux vomiting may be caused by abdominal distention. Vomiting results in a loss of hydrogen ions and potassium from

the stomach, leading to a reduction of chlorides and potassium in the blood and to metabolic alkalosis. Dehydration and acidosis develop from loss of water and sodium. With acute fluid losses, hypovolemic shock may occur.

### Clinical Manifestations

The initial symptom is usually crampy pain that is wavelike and colicky. The patient may pass blood and mucus, but no fecal matter and no flatus. Vomiting occurs. If the obstruction is complete, the peristaltic waves initially become extremely vigorous and eventually assume a reverse direction, with the intestinal contents propelled toward the mouth instead of toward the rectum. If the

**FIGURE 38-6** Three causes of intestinal obstruction. (A) Intussusception invagination or shortening of the colon caused by the movement of one segment of bowel into another. (B) Volvulus of the sigmoid colon; the twist is counterclockwise in most cases. Note the edematous bowel. (C) Hernia (inguinal). The sac of the hernia is a continuation of the peritoneum of the abdomen. The hernial contents are intestine, omentum, or other abdominal contents that pass through the hernial opening into the hernial sac.

obstruction is in the ileum, fecal vomiting takes place. First, the patient vomits the stomach contents, then the bile-stained contents of the duodenum and the jejunum, and finally, with each paroxysm of pain, the darker, fecal-like contents of the ileum. The unmistakable signs of dehydration become evident: intense thirst, drowsiness, generalized malaise, aching, and a parched tongue and mucous membranes. The abdomen becomes distended. The lower the obstruction is in the GI tract, the more marked the abdominal distention. If the obstruction continues uncorrected, hypovolemic shock occurs from dehydration and loss of plasma volume.

### Assessment and Diagnostic Findings

Diagnosis is based on the symptoms described previously and on x-ray findings. Abdominal x-ray studies show abnormal quantities of gas, fluid, or both in the bowel. Laboratory studies (ie, electrolyte studies and a complete blood cell count) reveal a picture of dehydration, loss of plasma volume, and possible infection.

### Medical Management

Decompression of the bowel through a nasogastric or small bowel tube (see Chap. 36) is successful in most cases. When the bowel is completely obstructed, the possibility of strangulation warrants surgical intervention. Before surgery, intravenous therapy is necessary to replace the depleted water, sodium, chloride, and potassium.

The surgical treatment of intestinal obstruction depends largely on the cause of the obstruction. In the most common causes of obstruction, such as hernia and adhesions, the surgical procedure involves repairing the hernia or dividing the adhesion to which the intestine is attached. In some instances, the portion of affected bowel may be removed and an anastomosis performed. The complexity of the surgical procedure for intestinal obstruction depends on the duration of the obstruction and the condition of the intestine.

### Nursing Management

Nursing management of the nonsurgical patient with a small bowel obstruction includes maintaining the function of the nasogastric tube, assessing and measuring the nasogastric output, assessing for fluid and electrolyte imbalance, monitoring nutritional status, and assessing improvement (eg, return of normal bowel sounds, decreased abdominal distention, subjective improvement in abdominal pain and tenderness, passage of flatus or stool). The nurse reports discrepancies in intake and output, worsening of pain or abdominal distention, and increased nasogastric output. If the patient's condition does not improve, the nurse prepares him or her for surgery. The exact nature of the surgery depends on the cause of the obstruction. Nursing care of the patient after surgical repair of a small bowel obstruction is similar to that for other abdominal surgeries (see Chap. 20).

## LARGE BOWEL OBSTRUCTION

### Pathophysiology

As in small bowel obstruction, large bowel obstruction results in an accumulation of intestinal contents, fluid, and gas proximal to the obstruction. Obstruction in the large bowel can lead to severe distention and perforation unless some gas and fluid can flow back through the ileal valve. Large bowel obstruction, even if complete, may be undramatic if the blood supply to the colon is not disturbed.

If the blood supply is cut off, however, intestinal strangulation and necrosis (ie, tissue death) occur; this condition is life threatening. In the large intestine, dehydration occurs more slowly than in the small intestine because the colon can absorb its fluid contents and can distend to a size considerably beyond its normal full capacity.

### Clinical Manifestations

Large bowel obstruction differs clinically from small bowel obstruction in that the symptoms develop and progress relatively slowly. In patients with obstruction in the sigmoid colon or the rectum, constipation may be the only symptom for days. Eventually, the abdomen becomes markedly distended, loops of large bowel become visibly outlined through the abdominal wall, and the patient has crampy lower abdominal pain. Finally, fecal vomiting develops. Symptoms of shock may occur.

### Assessment and Diagnostic Findings

Diagnosis is based on symptoms and on x-ray studies. Abdominal x-ray studies (flat and upright) show a distended colon. Barium studies are contraindicated.

### Medical Management

A colonoscopy may be performed to untwist and decompress the bowel. A cecostomy, in which a surgical opening is made into the cecum, may be performed for patients who are poor surgical risks and urgently need relief from the obstruction. The procedure provides an outlet for releasing gas and a small amount of drainage. A rectal tube may be used to decompress an area that is lower in the bowel. The usual treatment, however, is surgical resection to remove the obstructing lesion. A temporary or permanent colostomy may be necessary. An ileoanal anastomosis may be performed if it is necessary to remove the entire large colon.

### Nursing Management

The nurse's role is to monitor the patient for symptoms that indicate that the intestinal obstruction is worsening and to provide emotional support and comfort. The nurse administers intravenous fluids and electrolytes as prescribed. If the patient's condition does not respond to nonsurgical treatment, the nurse prepares the patient for surgery. This preparation includes preoperative teaching as the patient's condition indicates. After surgery, general abdominal wound care and routine postoperative nursing care are provided.

## COLORECTAL CANCER

Tumors of the colon and rectum are relatively common; the colorectal area (the colon and rectum combined) is now the third most common site of new cancer cases and deaths in the United States. Colorectal cancer is a disease of Western cultures; there were an estimated 148,300 new cases and 56,000 deaths from the disease in 2002 (American Cancer Society, 2002).

The incidence increases with age (the incidence is highest for people older than 85 years of age) and is higher for people with a family history of colon cancer and those with IBD or polyps. The exact cause of colon and rectal cancer is still unknown, but risk factors have been identified (Chart 38-7).

### Chart 38-7 Risk Factors for Colorectal Cancer

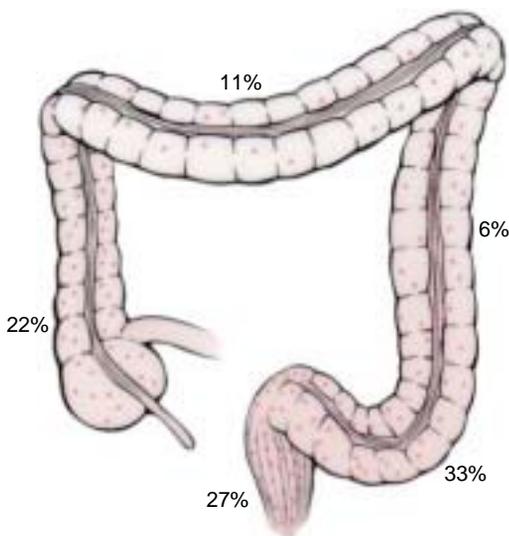

Increasing age  
 Family history of colon cancer or polyps  
 Previous colon cancer or adenomatous polyps  
 History of inflammatory bowel disease  
 High-fat, high-protein (with high intake of beef), low-fiber diet  
 Genital cancer or breast cancer (in women)

The distribution of cancer sites throughout the colon is shown in Figure 38-7 (Goldman, & Bennett, 2000). Changes in this distribution have occurred in recent years. The incidence of cancer in the sigmoid and rectal areas has decreased, whereas the incidence of cancer in the cecum, ascending, and descending colon has increased.

Improved screening strategies have helped to reduce the number of deaths in recent years. Of the more than 148,000 people diagnosed each year, fewer than half that number die annually (Beyers et al., 2001). Early diagnosis and prompt treatment could save almost three of every four people with colorectal cancer. If the disease is detected and treated at an early stage, the 5-year survival rate is 90%, but only 34% of colorectal cancers are found at an early stage. Survival rates after late diagnosis are very low. Most people are asymptomatic for long periods and seek health care only when they notice a change in bowel habits or rectal bleeding. Prevention and early screening are key to detection and reduction of mortality rates.

## Pathophysiology

Cancer of the colon and rectum is predominantly (95%) adenocarcinoma (ie, arising from the epithelial lining of the intestine). It may start as a benign polyp but may become malignant, invade and destroy normal tissues, and extend into surrounding structures. Cancer cells may break away from the primary

**FIGURE 38-7** Percentage distribution of cancer sites in the colon and rectum.

tumor and spread to other parts of the body (most often to the liver).

## Clinical Manifestations

The symptoms are greatly determined by the location of the cancer, the stage of the disease, and the function of the intestinal segment in which it is located. The most common presenting symptom is a change in bowel habits. The passage of blood in the stools is the second most common symptom. Symptoms may also include unexplained anemia, anorexia, weight loss, and fatigue.

The symptoms most commonly associated with right-sided lesions are dull abdominal pain and melena (ie, black, tarry stools). The symptoms most commonly associated with left-sided lesions are those associated with obstruction (ie, abdominal pain and cramping, narrowing stools, constipation, and distention), as well as bright red blood in the stool. Symptoms associated with rectal lesions are tenesmus (ie, ineffective, painful straining at stool), rectal pain, the feeling of incomplete evacuation after a bowel movement, alternating constipation and diarrhea, and bloody stool.

## Assessment and Diagnostic Findings

Along with an abdominal and rectal examination, the most important diagnostic procedures for cancer of the colon are fecal occult blood testing, barium enema, proctosigmoidoscopy, and colonoscopy (see Chap. 34). As many as 60% of colorectal cancer cases can be identified by sigmoidoscopy with biopsy or cytology smears (Yamada et al., 1999).

Carcinoembryonic antigen (CEA) studies may also be performed. Although CEA may not be a highly reliable indicator in diagnosing colon cancer because not all lesions secrete CEA, studies show that CEA levels are reliable in predicting prognosis. With complete excision of the tumor, the elevated levels of CEA should return to normal within 48 hours. Elevations of CEA at a later date suggest recurrence (Yamada et al., 1999).

## Complications

Tumor growth may cause partial or complete bowel obstruction. Extension of the tumor and ulceration into the surrounding blood vessels results in hemorrhage. Perforation, abscess formation, peritonitis, sepsis, and shock may occur.

## Gerontologic Considerations

The incidence of carcinoma of the colon and rectum increases with age. These cancers are considered common malignancies in advanced age. Only prostate cancer and lung cancer in men exceed colorectal cancer. Among women, only breast cancer exceeds the incidence of colorectal cancer (Lueckenotte, 2000). Symptoms are often insidious. Cancer patients usually report fatigue, which is caused primarily by iron-deficiency anemia. In early stages, minor changes in bowel patterns and occasional bleeding may occur. The later symptoms most commonly reported by the elderly are abdominal pain, obstruction, tenesmus, and rectal bleeding.

Colon cancer in the elderly has been closely associated with dietary carcinogens. Lack of fiber is a major causative factor because the passage of feces through the intestinal tract is prolonged, which extends exposure to possible carcinogens. Excess fat is believed to alter bacterial flora and convert steroids into compounds that have carcinogenic properties.

## Medical Management

The patient with symptoms of intestinal obstruction is treated with intravenous fluids and nasogastric suction. If there has been significant bleeding, blood component therapy may be required.

Treatment for colorectal cancer depends on the stage of the disease (Chart 38-8) and consists of surgery to remove the tumor, supportive therapy, and adjuvant therapy. Data demonstrate delays in tumor recurrence and increases in survival time for patients who receive some form of adjuvant therapy—chemotherapy, radiation therapy, immunotherapy, or multimodality therapy.

### ADJUVANT THERAPY

The standard adjuvant therapy administered to patients with Dukes' class C colon cancer is the 5-fluorouracil plus levamisole regimen (Wolfe, 2000). Patients with Dukes' class B or C rectal cancer are given 5-fluorouracil and high doses of pelvic irradiation. Mitomycin is also used. Radiation therapy is used before, during, and after surgery to shrink the tumor, to achieve better results from surgery, and to reduce the risk of recurrence. For inoperative or unresectable tumors, irradiation is used to provide significant relief from symptoms. Intracavity and implantable devices are used to deliver radiation to the site. The response to adjuvant therapy varies.

### SURGICAL MANAGEMENT

Surgery is the primary treatment for most colon and rectal cancers. It may be curative or palliative. Advances in surgical techniques can enable the patient with cancer to have sphincter-saving devices that restore continuity of the GI tract (Tierney et al., 2000). The type of surgery recommended depends on the location and size of the tumor. Cancers limited to one site can be removed through the colonoscope. Laparoscopic colotomy with polypectomy minimizes the extent of surgery needed in some cases. A laparoscope is used as a guide in making an incision into the colon; the tumor mass is then excised. Use of the neodymium/yttrium-aluminum-garnet (Nd:YAG) laser has proved effective with some lesions as well. Bowel resection is indicated for most class A lesions and all class B and C lesions. Surgery is sometimes recommended for class D colon cancer, but the goal of surgery in this instance is

palliative; if the tumor has spread and involves surrounding vital structures, it is considered nonresectable.

Surgical procedures include the following:

- Segmental resection with anastomosis (ie, removal of the tumor and portions of the bowel on either side of the growth, as well as the blood vessels and lymphatic nodes) (Fig. 38-8).
- Abdominoperineal resection with permanent sigmoid colectomy (ie, removal of the tumor and a portion of the sigmoid and all of the rectum and anal sphincter) (Fig. 38-9).
- Temporary colostomy followed by segmental resection and anastomosis and subsequent reanastomosis of the colostomy, allowing initial bowel decompression and bowel preparation before resection
- Permanent colostomy or ileostomy for palliation of unresectable obstructing lesions
- Construction of a coloanal reservoir called a colonic J pouch is performed in two steps. A temporary loop ileostomy is constructed to divert intestinal flow, and the newly constructed J pouch (made from 6 to 10 cm of colon) is reattached to the anal stump. About 3 months after the initial stage, the ileostomy is reversed, and intestinal continuity is restored. The anal sphincter and therefore continence are preserved.

A **colostomy** is the surgical creation of an opening (ie, stoma) into the colon. It can be created as a temporary or permanent fecal diversion. It allows the drainage or evacuation of colon contents to the outside of the body. The consistency of the drainage is related to the placement of the colostomy, which is dictated by the location of the tumor and the extent of invasion into surrounding tissues (Fig. 38-10). With improved surgical techniques, colostomies are performed on fewer than one third of patients with colorectal cancer.

### Gerontologic Considerations

The elderly are at increased risk for complications after surgery and may have difficulty managing colostomy care. They may have decreased vision, impaired hearing, and difficulty with fine motor coordination. It may be helpful for the patient to handle ostomy equipment and simulate cleaning the peristomal skin and irrigating the stoma before surgery. Skin care is a major concern in the elderly ostomate because of the skin changes that occur with aging—the epithelial and subcutaneous fatty layers become thin, and the skin is irritated easily. To prevent skin breakdown, special attention is paid to skin cleansing and the proper fit of an appliance. Arteriosclerosis causes decreased blood flow to the wound and stoma site. As a result, transport of nutrients is delayed, and healing time may be prolonged. Some patients have delayed elimination after irrigation because of decreased peristalsis and mucus production. Most patients require 6 months before they feel comfortable with their ostomy care.

Chart  
38-8

### Staging of Colorectal Cancer: Dukes' Classification—Modified Staging System

**Class A:** Tumor limited to muscular mucosa and submucosa

**Class B<sub>1</sub>:** Tumor extends into mucosa

**Class B<sub>2</sub>:** Tumor extends through entire bowel wall into serosa or pericolic fat, no nodal involvement

**Class C<sub>1</sub>:** Positive nodes, tumor is limited to bowel wall

**Class C<sub>2</sub>:** Positive nodes, tumor extends through entire bowel wall

**Class D:** Advanced and metastasis to liver, lung, or bone

Another staging system, the TNM (tumor, nodal involvement, metastasis) classification, may be used to describe the anatomic extent of the primary tumor, depending on

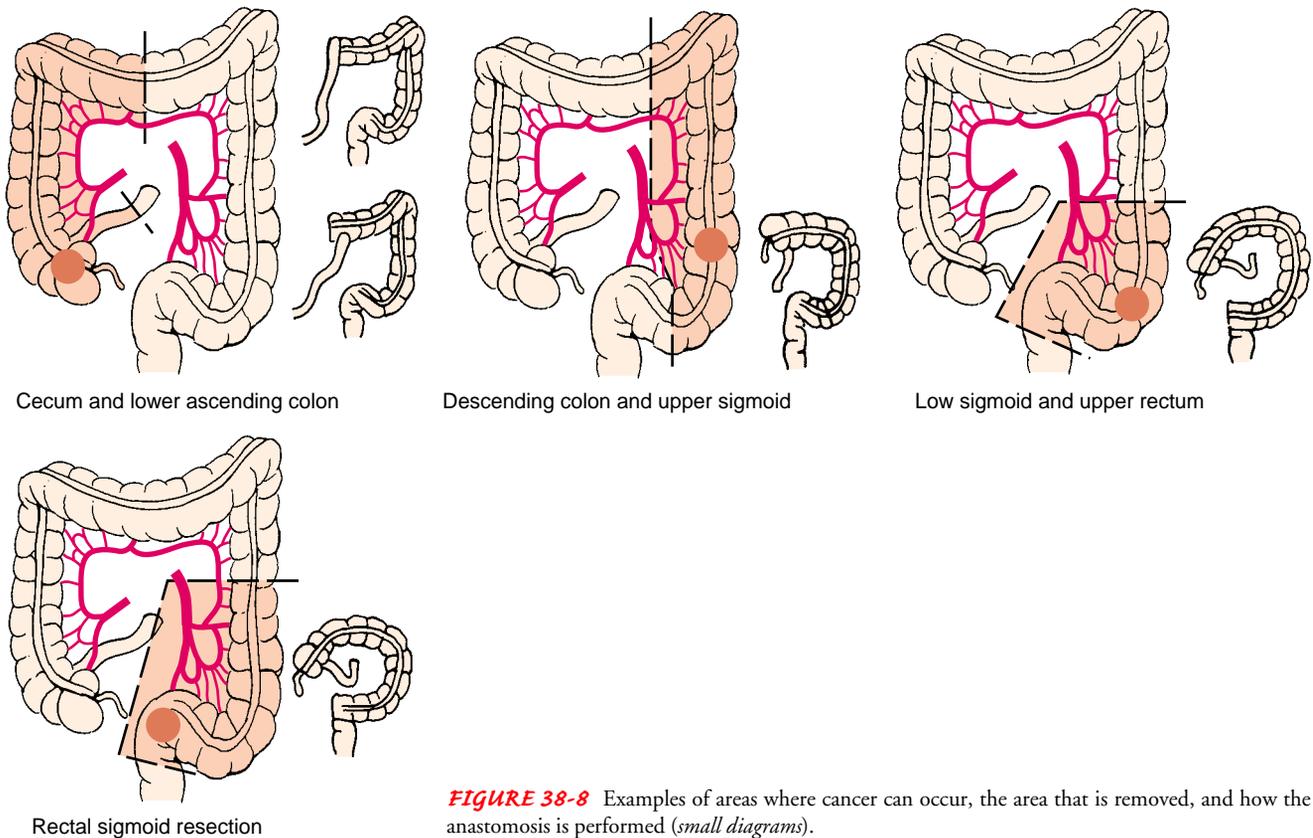

- Size, invasion depth and surface spread
- Extent of nodal involvement
- Presence or absence of metastasis

Rudy, D. R., & Zdon, M. J. (2000). Update on colorectal cancer. *American Family Physician*, 61 (6), 1759–1770, 1773–1774.

## NURSING PROCESS: THE PATIENT WITH COLORECTAL CANCER

### Assessment

The nurse completes a health history to obtain information about fatigue, abdominal or rectal pain (eg, location, frequency, duration, association with eating or defecation), past and present elimination patterns, and characteristics of stool (eg, color, odor,

**FIGURE 38-8** Examples of areas where cancer can occur, the area that is removed, and how the anastomosis is performed (*small diagrams*).

consistency, presence of blood or mucus). Additional information includes a history of IBD or colorectal polyps, a family history of colorectal disease, and current medication therapy. The nurse identifies dietary habits, including fat and fiber intake, as well as amounts of alcohol consumed. The nurse describes and documents a history of weight loss.

Assessment includes auscultating the abdomen for bowel sounds and palpating the abdomen for areas of tenderness, distention, and solid masses. Stool specimens are inspected for character and presence of blood.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the major nursing diagnoses may include the following:

- Imbalanced nutrition, less than body requirements, related to nausea and anorexia
- Risk for deficient fluid volume related to vomiting and dehydration
- Anxiety related to impending surgery and the diagnosis of cancer
- Risk for ineffective therapeutic regimen management related to knowledge deficit concerning the diagnosis, the surgical procedure, and self-care after discharge
- Impaired skin integrity related to the surgical incisions (abdominal and perianal), the formation of a stoma, and frequent fecal contamination of peristomal skin
- Disturbed body image related to colostomy

- Ineffective sexuality patterns related to presence of ostomy and changes in body image and self-concept

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Potential complications that may develop include the following:

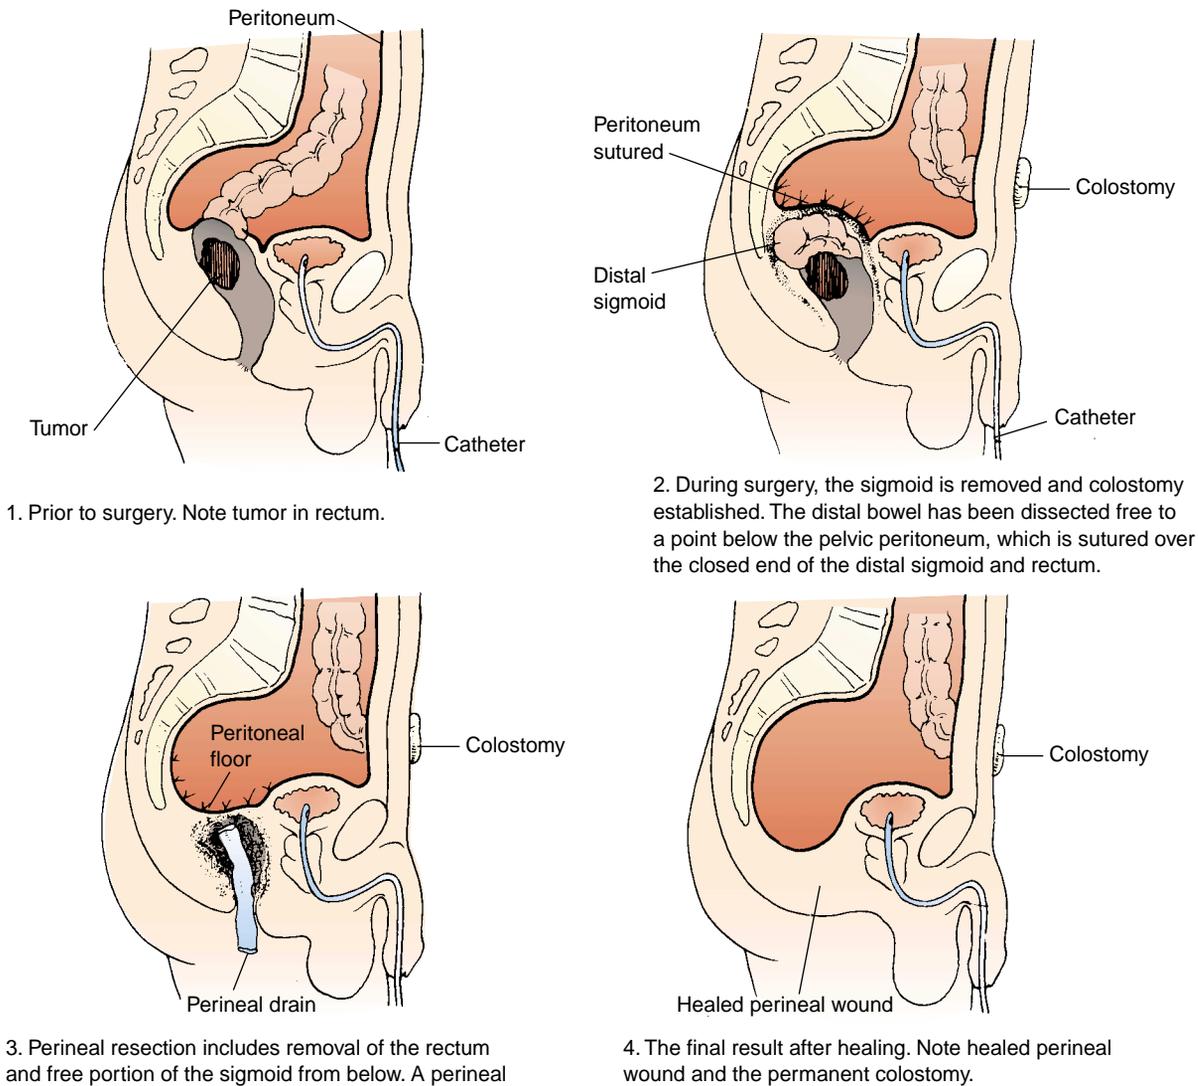

- Intraoperative infection
- Complete large bowel obstruction
- GI bleeding
- Bowel perforation
- Peritonitis, abscess, and sepsis

### Planning and Goals

The major goals for the patient may include attainment of optimal level of nutrition; maintenance of fluid and electrolyte balance; reduction of anxiety; learning about the diagnosis, surgical procedure, and self-care after discharge; maintenance of optimal tissue healing; protection of peristomal skin; learning how to irrigate the colostomy and change the appliance; expressing feelings and concerns about the colostomy and the impact on himself or herself; and avoidance of complications.

### PREPARING THE PATIENT FOR SURGERY

The patient anticipating surgery for colorectal cancer has many concerns, needs, and fears. He or she may be physically debilitated and emotionally distraught with concern about lifestyle changes after surgery, prognosis, ability to perform in established roles, and finances. Priorities for nursing care include preparing

**FIGURE 38-9** Abdominoperineal resection for carcinoma of the rectum.

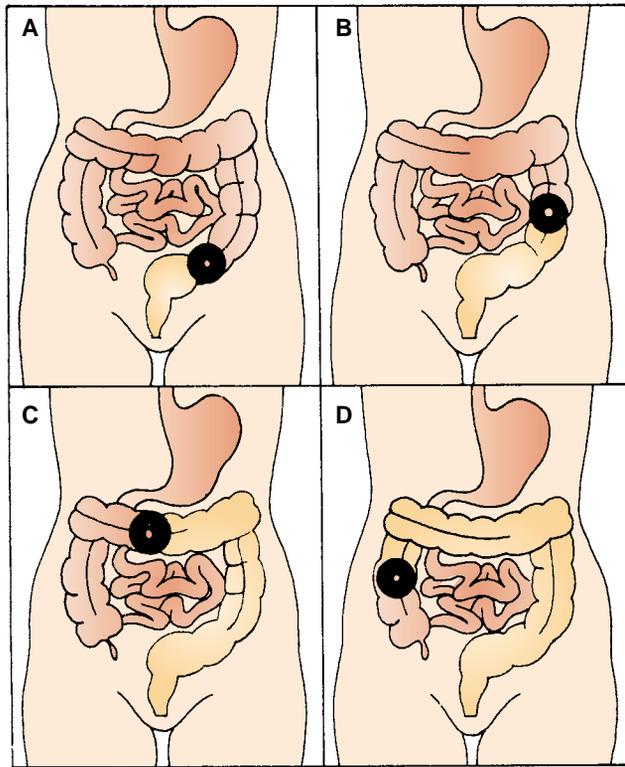

the patient physically for surgery, providing information about postoperative care, including stoma care if a colostomy is to be created, and supporting the patient and family emotionally.

Physical preparation for surgery involves building the patient's stamina in the days preceding surgery and cleansing and sterilizing the bowel the day before surgery. If the patient's condition permits, the nurse recommends a diet high in calories, protein, and carbohydrates and low in residue for several days before surgery to provide adequate nutrition and minimize cramping by decreasing excessive peristalsis. A full-liquid diet may be prescribed 24 to 48 hours before surgery to decrease bulk. If the patient is hospitalized in the days preceding surgery, PN may be required to replace depleted nutrients, vitamins, and minerals. In some instances, PN may be given at home before surgery. Antibiotics such as sulfonamides, neomycin, and cephalexin are administered the day before surgery to reduce intestinal bacteria. The bowel is cleansed with laxatives, enemas, or colonic irrigations the evening before and the morning of surgery.

For the patient who is very ill and hospitalized, the nurse measures and records intake and output, including vomitus, to provide an accurate record of fluid balance. The patient's intake of oral food and fluids may be restricted to prevent vomiting. The

nurse administers antiemetics as prescribed. Full or clear liquids may be tolerated, or the patient may be allowed nothing by mouth. A nasogastric tube may be inserted to drain accumulated fluids and prevent abdominal distention. The nurse monitors the abdomen for increasing distention, loss of bowel sounds, and pain or rigidity, which may indicate obstruction or perforation. It also is important to monitor intravenous fluids and electrolytes. Monitoring serum electrolyte levels can detect the hypokalemia and hyponatremia that occur with GI fluid loss. The nurse observes for signs of hypovolemia (eg, tachycardia, hypotension, decreased pulse volume), assesses hydration status, and reports decreased skin turgor, dry mucous membranes, and concentrated urine.

The nurse assesses the patient's knowledge about the diagnosis, prognosis, surgical procedure, and expected level of functioning after surgery. It is important to include information about the physical preparation for surgery, the expected appearance and care of the wound, the technique of ostomy care (if applicable), dietary restrictions, pain control, and medication management in the teaching plan (see Plan of Nursing Care 38-1). If the patient will be admitted the day of surgery, the physician's office may arrange for the patient to be seen by an enterostomal therapist in the days preceding surgery. The ther-

**FIGURE 38-10** A diagrammatic representation of the placement of permanent colostomies. The nature of the discharge varies with the site. Shaded areas show sections of bowel removed. With a sigmoid colostomy (A) the feces are solid. With a descending colostomy (B) the feces are semimushy. With a transverse colostomy (C) the feces are mushy. With an ascending colostomy (D) the feces are fluid.

apist helps determine the optimal site for the stoma and provides teaching about care. If the patient is hospitalized before the day of surgery, the staff enterostomal therapist is involved in the preoperative teaching. All procedures are explained in language the patient understands.

### PROVIDING EMOTIONAL SUPPORT

Patients anticipating bowel surgery for colorectal cancer may be very anxious. They may grieve about the diagnosis, the impending surgery, and possible permanent colostomy. Patients undergoing surgery for a temporary colostomy may express fears and concerns similar to those of a person with a permanent stoma. All members of the health care team, including the enterostomal therapy nurse, should be available for assistance and support. The nurse's role is to assess the patient's anxiety level and coping mechanisms and suggest methods for reducing anxiety such as deep-breathing exercises and visualizing a successful recovery from surgery and cancer. Other supportive measures include providing privacy and teaching relaxation techniques to the patient. Time is set aside to listen to the patient who wishes to talk, cry, or ask questions. The nurse can arrange a meeting with a spiritual advisor if the patient desires or with the physicians if the patient wishes to discuss the treatment or prognosis. To promote patient comfort, the nurse projects a relaxed, professional, and empathetic attitude. See Nursing Research Profile 38-1 about the importance of spiritual well-being for patients with colorectal cancer.

The patient undergoing a colostomy may find the anticipated changes in body image and lifestyle profoundly disturbing. Because the stoma is located on the abdomen, the patient may think that everyone will be aware of the ostomy. The nurse helps reduce this fear by presenting facts about the surgical procedure and the creation and management of the ostomy. If the patient is receptive, the nurse can use diagrams, photographs, and appliances to explain and clarify. Because the patient is experiencing emotional stress, the nurse may need to repeat some of the information. The nurse provides time for the patient and family to ask questions; the nurse's acceptance and understanding of the patient's concerns and feelings convey a caring, competent attitude that promotes confidence and cooperation. Consultation with an enterostomal therapist during the preoperative period can be extremely helpful, as can speaking with a person who is successfully managing a colostomy. The United Ostomy Association provides useful information about living with an ostomy through literature, lectures, and exhibits. Visiting services by qualified members and rehabilitation services for new ostomy patients are provided.

### NURSING RESEARCH PROFILE 38-1

#### *Spiritual Needs of Patients with Colorectal Cancer*

Fernsler, J., Klemm, P., & Miller, M. (1999). Spiritual well-being and demands of illness in people with colorectal cancer. *Cancer Nursing*, 22(2), 134–140.

#### Purpose

Patients with colorectal cancer must be assisted in coping with the demands of the illness and its treatment. Using the Demands of Illness Inventory (DOI) and the Spiritual Well-Being Scale (SWBS), the authors of this descriptive study looked closely at the events that individuals experience in response to a cancer diagnosis and attempted to determine whether those events relate to spiritual well-being. The purpose of the study was to identify the demands of the illness and determine their relationship to spiritual well-being.

#### Study Sample and Findings

The sample for this study consisted of 121 respondents to questionnaires who were at least 21 years old and had been treated for colon, rectal, or anal cancer. Two thirds of the respondents reported a Christian affiliation. Results showed that the illness exerted the greatest demands (highest DOI scores) on those in the youngest age group

(21–45 years) and on those with terminal illness. These respondents also reported lower levels of spiritual well-being.

Subjects who reported significantly lower ( $p < .05$ ) DOI levels related to their physical symptoms, monitoring symptoms, and treatment issues also reported higher levels of spiritual well-being.

#### Nursing Implications

Nurses who care for cancer patients must be aware of the intense illness-related demands placed on their patients, especially on those in the younger age range and those with a terminal diagnosis. Nurses should explore interventions to assist patients in coping with these demands, especially interventions to enhance the patients' spiritual resources.

This study had several limitations. All responses were self-reported, and measures were taken at only one point in time. Other studies need to be conducted to determine whether the findings can be generalized.

### PROVIDING POSTOPERATIVE CARE

Postoperative nursing care for patients undergoing colon resection or colostomy is similar to nursing care for any abdominal surgery patient (see Chap. 20), including pain management during the immediate postoperative period. The nurse also monitors the patient for complications such as leakage from the site of the anastomosis, prolapse of the stoma, perforation, stoma retraction, fecal impaction, skin irritation, and pulmonary complications associated with abdominal surgery. The nurse assesses the abdomen for returning peristalsis and assesses the initial stool characteristics. It is important to help patients with a colostomy out of bed on the first postoperative day and encourage them to begin participating in managing the colostomy.

### MAINTAINING OPTIMAL NUTRITION

The nurse teaches all patients undergoing surgery for colorectal cancer about the health benefits to be derived from consuming a healthy diet. The diet is individualized as long as it is well balanced and does not cause diarrhea or constipation. The return to normal diet is rapid.

A complete nutritional assessment is important for patients with a colostomy. The patient avoids foods that cause excessive odor and gas, including foods in the cabbage family, eggs, fish, beans, and high-cellulose products such as peanuts. It is important to determine whether the elimination of specific foods is causing any nutritional deficiency. Nonirritating foods are substituted for those that are restricted so that deficiencies are corrected. The nurse advises the patient to experiment with an irritating food several times before restricting it, because an initial sensitivity may decrease with time. The nurse can help the patient identify any foods or fluids that may be causing diarrhea, such as fruits, high-fiber foods, soda, coffee, tea, or carbonated beverages. Purgative, bismuth subgallate, bismuth subcarbonate, or diphenoxylate with atropine (Lomotil) help control the diarrhea. For constipation, prune or apple juice or a mild laxative is effective. The nurse suggests fluid intake of at least 2 L of fluid per day.

### PROVIDING WOUND CARE

The nurse frequently examines the abdominal dressing during the first 24 hours after surgery to detect signs of hemorrhage. It is important to help the patient splint the abdominal incision during coughing and deep breathing to lessen tension on the edges of the incision. The nurse monitors temperature, pulse, and respiratory rate for elevations, which may indicate an infectious process. If the patient has a colostomy, the stoma is examined for swelling (slight edema from surgical manipulation is normal), color (a healthy stoma is pink or red), discharge (a small amount of oozing is normal), and bleeding (an abnormal sign).

If the malignancy has been removed using the perineal route, the perineal wound is observed for signs of hemorrhage. This wound may contain a drain or packing, which is removed gradually. Bits of tissue may slough off for a week. This process is hastened by mechanical irrigation of the wound or with sitz baths performed two or three times each day initially. The condition of the perineal wound and any bleeding, infection, or necrosis are documented.

### MONITORING AND MANAGING COMPLICATIONS

The patient is observed for signs and symptoms of complications. It is important to frequently assess the abdomen, including decreasing or changing bowel sounds and increasing abdominal girth, to detect bowel obstruction. The nurse monitors vital signs for increased temperature, pulse, and respirations and for de-

creased blood pressure, which may indicate an intra-abdominal infectious process. It is important to report rectal bleeding immediately because it indicates hemorrhage. The nurse monitors hematocrit and hemoglobin levels and administers blood component therapy as prescribed. Any abrupt change in abdominal pain is reported promptly. Elevated white blood cell counts and temperature or symptoms of shock are reported because they may indicate sepsis. The nurse administers antibiotics as prescribed.

Pulmonary complications are always a concern with abdominal surgery; patients older than 50 years of age are at risk, especially if they are or have been receiving sedatives or are being maintained on bed rest for a prolonged period. Two primary pulmonary complications are pneumonia and atelectasis. Frequent activity (eg, turning the patient from side to side every 2 hours), deep breathing, coughing, and early ambulation can reduce the risks for these complications. Table 38-6 lists possible postoperative complications.

The incidence of complications related to the colostomy is about one half that seen with an ileostomy. Some common complications are prolapse of the stoma (usually from obesity), perforation (from improper stoma irrigation), stoma retraction, fecal impaction, and skin irritation. Leakage from an anastomotic site can occur if the remaining bowel segments are diseased or weakened. Leakage from an intestinal anastomosis causes abdominal distention and rigidity, temperature elevation, and signs of shock. Surgical repair is necessary.

### REMOVING AND APPLYING THE COLOSTOMY APPLIANCE

The colostomy begins to function 3 to 6 days after surgery. The nurse manages the colostomy and teaches the patient about its care until the patient can take over. The nurse teaches skin care and how to apply and remove the drainage pouch. Care of the peristomal skin is an ongoing concern because excoriation or ulceration can develop quickly. The presence of such irritation makes adhering the ostomy appliance difficult, and adhering the ostomy appliance to irritated skin can worsen the skin condition. The effluent discharge and the degree to which it is irritating vary with the type of ostomy. With a transverse colostomy, the stool is soft and mushy and irritating to the skin. With a descending or sigmoid colostomy, the stool is fairly solid and less irritating to the skin. Other skin problems include yeast infections and allergic dermatitis.

If the patient wants to bathe or shower before putting on the clean appliance, micropore tape applied to the sides of the pouch will keep it secure during bathing. To remove the appliance, the patient assumes a comfortable sitting or standing position and gently pushes the skin down from the faceplate while pulling the pouch up and away from the stoma. Gentle pressure prevents the skin from being traumatized and any liquid fecal contents from spilling out. The nurse advises the patient to protect the peristomal skin by then washing the area gently with a moist, soft cloth and a mild soap. Soap acts as a mild abrasive agent to remove enzyme residue from fecal spillage. The patient should remove any excess skin barrier. While the skin is being cleansed, a gauze dressing can cover the stoma, or a vaginal tampon can be inserted gently to absorb excess drainage. After cleansing, the patient pats the skin completely dry with a gauze pad, taking care not to rub the area. The patient can lightly dust nystatin (Mycostatin) powder on the peristomal skin if irritation or yeast growth is present.

Smoothly applying the drainage appliance for a secure fit requires practice and a well-fitting appliance. Patients can choose from a wide variety of appliances, depending on their individual

**Table 38-6 • Potential Complications and Nursing Interventions After Intestinal Surgery**

COMPLICATION	NURSING INTERVENTIONS
Paralytic ileus	Initiate or continue nasogastric intubation as prescribed. Prepare patient for x-ray study. Ensure adequate fluid and electrolyte replacement. Administer prescribed antibiotics if patient has symptoms of peritonitis.
Mechanical obstruction	Assess patient for intermittent colicky pain, nausea, and vomiting.
<b><i>Intra-abdominal Septic Conditions</i></b>	
Peritonitis	Evaluate patient for nausea, hiccups, chills, spiking fever, tachycardia. Administer antibiotics as prescribed. Prepare patient for drainage procedure. Administer parenteral fluid and electrolyte therapy as prescribed. Prepare patient for surgery if condition deteriorates.
Abscess formation	Administer antibiotics as prescribed. Apply warm compresses as prescribed. Prepare for surgical drainage.
<b><i>Surgical Wound Complications</i></b>	
Infection	Monitor temperature; report temperature elevation. Observe for redness, tenderness, and pain around wound. Assist in establishing local drainage. Obtain specimen of drainage material for culture and sensitivity studies.
Wound disruption	Observe for sudden appearance of profuse serous drainage from wound. Cover wound area with sterile towels held in place with binder. Prepare patient immediately for surgery.
Intraperitoneal infection and abdominal wound infection	Monitor for evidence of constant or generalized abdominal pain, rapid pulse, and elevation of temperature. Prepare for tube decompression of bowel. Administer fluids and electrolytes by IV route as prescribed. Administer antibiotics as prescribed.
<b><i>Anastomotic Complications</i></b>	
Dehiscence of anastomosis	Prepare patient for surgery.
Fistulas	Assist in bowel decompression. Administer parenteral fluids as prescribed to correct fluid and electrolyte deficits.

needs. The stoma is measured to determine the correct size for the pouch; the pouch opening should be about 0.3 cm ( $\frac{1}{8}$  in) larger than the stoma. After the skin is cleansed according to the previously described procedure, the patient applies the peristomal skin barrier (ie, wafer, paste, or powder). Mild skin irritation may require dusting the skin with karaya or Stomahesive powder before attaching the pouch. The patient removes the backing from the adherent surface of the appliance, and places the bag down over the stoma for 30 seconds. The patient empties or changes the drainage appliance when it is one-third to one-fourth full so that the weight of its contents does not cause the appliance to separate from the adhesive disk and spill the contents. Most appliances are disposable and odor resistant; commercially prepared deodorizers are available.

For some patients, colostomy appliances are not always necessary. As soon as the patient has learned a routine for evacuation, bags may be dispensed with, and a closed ostomy appliance or a simple dressing of disposable tissue (often covered with plastic wrap) is used, held in place by an elastic belt. Except for gas and a slight amount of mucus, nothing escapes from the colostomy opening between irrigations. Colostomy plugs that expand on insertion to prevent passage of flatus and feces are available.

### IRRIGATING THE COLOSTOMY

The purpose of irrigating a colostomy is to empty the colon of gas, mucus, and feces so that the patient can go about social and business activities without fear of fecal drainage. A stoma does not have voluntary muscular control and may empty at irregular intervals. Regulating the passage of fecal material is achieved by irrigating the colostomy or allowing the bowel to evacuate naturally without irrigations. The choice often depends on the individual and the type of the colostomy. By irrigating the stoma at a regular time, there is less gas and retention of the irrigant. The time for irrigating the colostomy should be consistent with the schedule the person will follow after leaving the hospital. Chart 38-9 delineates the irrigating procedure.

### SUPPORTING A POSITIVE BODY IMAGE

The patient is encouraged to verbalize feelings and concerns about altered body image and to discuss the surgery and the stoma (if one was created). A supportive environment and a supportive attitude on the nurse's part are crucial in promoting the patient's adaptation to the changes brought about by the surgery. If applicable, the patient must learn colostomy care and begin to plan for incorporating stoma care into daily life. The nurse helps the patient overcome aversion to the stoma or fear

Chart 38-9

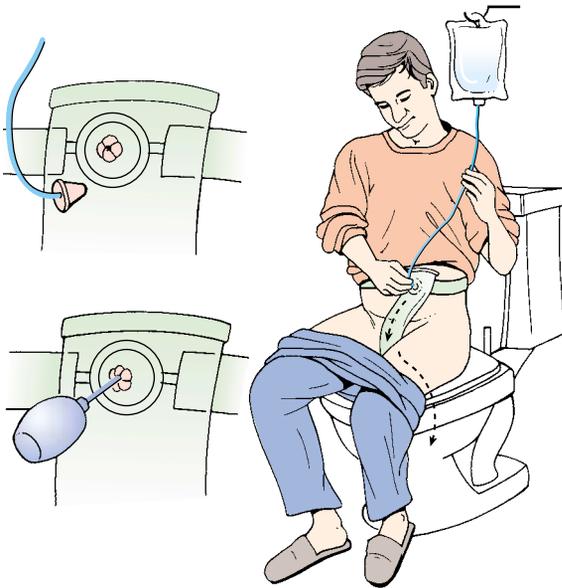

## GUIDELINES FOR Irrigating a Colostomy

A colostomy is irrigated to empty the colon of feces, gas, or mucus, cleanse the lower intestinal tract, and establish a regular pattern of evacuation so that normal life activities may be pursued. A suitable time for the irrigation is selected that is compatible with the patient's posthospital pattern of activity (preferably after a meal). Irrigation should be performed at the same time each day.

Before the procedure, the patient sits on a chair in front of the toilet or on the toilet itself. An irrigating reservoir containing 500 to 1500 mL of lukewarm tapwater is hung 45 to 50 cm (18 to 20 in) above the stoma (shoulder height when the patient is seated). The dressing or pouch is removed. The following procedure is used; the patient is helped to participate in the procedure to learn to perform it unassisted.

### NURSING ACTION

1. Apply an irrigating sleeve or sheath to the stoma. Place the end in the commode.

2. Allow some of the solution to flow through the tubing and catheter/cone.
3. Lubricate the catheter/cone and gently insert it into the stoma. Insert the catheter no more than 8 cm (3 in). Hold the shield/cone gently, but firmly, against the stoma to prevent backflow of water.
4. If the catheter does not advance easily, allow water to flow slowly while advancing catheter. *Never force the catheter!*
5. Allow tepid fluid to enter the colon slowly. If cramping occurs, clamp off the tubing and allow the patient to rest before progressing. Water should flow in over a 5- to 10-minute period.
6. Hold the shield/cone in place 10 seconds after the water has been instilled; then gently remove it.
7. Allow 10 to 15 minutes for most of the return; then dry the bottom of the sleeve/sheath and attach it to the top, or apply the appropriate clamp to the bottom of the sleeve.
8. Leave the sleeve/sheath in place for 30 to 45 minutes while the patient gets up and moves around.
9. Cleanse the area with a mild soap and water; pat the area dry.
10. Replace the colostomy dressing or appliance.

### RATIONALE

1. This helps to control odor and splashing and allows feces and water to flow directly into the commode.

Colostomy irrigation. (A) Irrigating catheter has a cone attachment to prevent injury to stomal tissue. (B) Irrigating fluid is instilled with sleeve in place. Drainage contents empty into toilet. (C) The bulb syringe method can be used to stimulate fecal drainage. Note that a portion of the hard nozzle is removed and a catheter attached to minimize stomal irritation.

2. Air bubbles in the setup are released so that air is not introduced into the colon, which would cause crampy pain.
3. Lubrication permits ease of insertion of the catheter/cone.
4. A slow rate of flow helps to relax the bowel and facilitates passage of the catheter.
5. Painful cramps usually are caused by too rapid a flow or by too much solution; 300 mL of fluid may be all that is needed to stimulate evacuation. Volume may be increased with subsequent irrigations to 500, 1000, or 1500 mL as needed by the patient for effective results.
7. Most of the water, feces, and flatus will be expelled in 10 to 15 minutes.
8. Ambulation stimulates peristalsis and completion of the irrigation return.
9. Cleanliness and dryness will provide the patient with hours of comfort.
10. The patient should use an appliance until the colostomy is sufficiently controlled. A dressing may be all that is needed.

of self-injury by providing care and teaching in an open, accepting manner and by encouraging the patient to talk about his or her feelings about the stoma.

### DISCUSSING SEXUALITY ISSUES

The nurse encourages the patient to discuss feelings about sexuality and sexual function. Some patients may initiate questions about sexual activity directly or give indirect clues about their fears. Some may view the surgery as mutilating and a threat to their sexuality; some fear impotence. Others may express worry about odor or leakage from the pouch during sexual activity. Although the appliance presents no deterrent to sexual activity, some patients wear silk or cotton covers and smaller pouches during sex. Alternative sexual positions are recommended, as well as alternative methods of stimulation to satisfy sexual drives. The nurse assesses the patient's needs and attempts to identify specific concerns. If the nurse is uncomfortable with this or if the patient's concerns seem complex, it is appropriate for the nurse to seek assistance from an enterostomal therapy nurse, sex counselor or therapist, or advanced practice nurse.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

Patient education and discharge planning require the combined efforts of the physician, nurse, enterostomal therapist, social worker, and dietitian. Patients are given specific information, individualized to their needs, about ostomy care and signs and symptoms of potential complications. Dietary instructions are essential to help patients identify and eliminate irritating foods that can cause diarrhea or constipation. It is important to teach patients about their prescribed medications (ie, action, purpose, and possible side effects).

The nurse reviews treatments (eg, irrigations, wound cleansing) and dressing changes and encourages the family to participate. Because the hospital stay is short, the patient may not be able to become proficient in stoma care techniques before discharge. Many patients need referral to a home care agency and the telephone number of the local chapter of the American Cancer Society. The home care nurse goes to the home to provide further care and teaching and to assess how well the patient and family are adjusting to the colostomy. The home environment is assessed for adequacy of resources that allow the patient to accomplish self-care. A family member may assume responsibility for purchasing the equipment and supplies needed at home.

Patients need very specific directions about when to call the physician. They need to know which complications require prompt attention (ie, bleeding, abdominal distention and rigidity, diarrhea, fever, wound drainage, and disruption of suture line). If radiation therapy is planned, the possible side effects (ie, anorexia, vomiting, diarrhea, and exhaustion) are reviewed.

#### Continuing Care

Ongoing care of the patient with cancer and a colostomy often extends well beyond the initial hospital stay. Home care nurses manage ostomy follow-up care, manage the assessment and care of the debilitated patient, and coordinate adjuvant therapy. The home care visits also provide the nurse with opportunities to assess the patient's physical and emotional status and the patient's and family's ability to carry out recommended management strategies. Visits from an enterostomal therapy nurse are available to the patient and family as they learn to care for the ostomy and work through their feelings about it, the diagnosis of cancer, and the

future. Some patients are interested in and can benefit from involvement in an ostomy support group.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Consumes a healthy diet
  - a. Avoids foods and fluids that cause diarrhea
  - b. Substitutes nonirritating foods and fluids for those that are restricted
2. Maintains fluid balance
  - a. Experiences no vomiting or diarrhea
  - b. Experiences no signs or symptoms of dehydration
3. Feels less anxious
  - a. Expresses concerns and fears freely
  - b. Uses coping measures to manage stress
4. Acquires information about diagnosis, surgical procedure, preoperative preparation, and self-care after discharge
  - a. Discusses the diagnosis, surgical procedure, and postoperative self-care
  - b. Demonstrates techniques of ostomy care
5. Maintains clean incision, stoma, and perineal wound
6. Expresses feelings and concerns about self
  - a. Gradually increases participation in stoma and peristomal skin care
  - b. Discusses feelings related to changed appearance
7. Discusses sexuality in relation to ostomy and to changes in body image
8. Recovers without complications
  - a. Is afebrile
  - b. Regains normal bowel activity
  - c. Exhibits no signs and symptoms of perforation or bleeding

### POLYPS OF THE COLON AND RECTUM

A polyp is a mass of tissue that protrudes into the lumen of the bowel. Polyps can occur anywhere in the intestinal tract and rectum. They can be classified as neoplastic (ie, adenomas and carcinomas) or non-neoplastic (ie, mucosal and hyperplastic). Non-neoplastic polyps, which are benign epithelial growths, are common in the Western world. They occur more commonly in the large intestine than in the small intestine. Although most polyps do not develop into invasive neoplasms, they must be identified and followed closely. Adenomatous polyps are more common in men. The proportion of these polyps arising in the proximal part of the colon increases with age (after 40 years of age). Prevalence rates vary from 25% to 60%, depending on age. Non-neoplastic polyps occur in 80% of the population, and their frequency increases with age (Wolfe, 2000).

Clinical manifestations depend on the size of the polyp and the amount of pressure it exerts on intestinal tissue. The most common symptom is rectal bleeding. Lower abdominal pain may also occur. If the polyp is large enough, symptoms of obstruction occur. The diagnosis is based on history and digital rectal examination, barium enema studies, sigmoidoscopy, or colonoscopy.

After a polyp is identified, it should be removed. There are several methods: colonoscopy with the use of special equipment (ie, biopsy forceps and snares), laparoscopy, or colonoscopic excision with laparoscopic visualization. The latter technique enables immediate detection of potential problems and allows laparoscopic

resection and repair of the major complications of perforation and bleeding that may occur with polypectomy. Microscopic examination of the polyp then identifies the type of polyp and indicates what further surgery is required.

## Diseases of the Anorectum

Anorectal disorders are common, and more than one half of the population will experience one at some time during their lives (Yamada et al., 1999). Patients with anorectal disorders seek medical care primarily because of pain, rectal bleeding, or change in bowel habits. Other common complaints are protrusion of hemorrhoids, anal discharge, perianal itching, swelling, anal tenderness, stenosis, and ulceration. Constipation results from delaying defecation because of anorectal pain.

There has been a steady increase in the frequency of sexually transmitted diseases in recent decades, leading to the identification of new anorectal syndromes. The prevalence of these conditions is increasing. These syndromes include venereal infections such as syphilis, gonorrhea, herpes, chlamydia, and candidiasis, and they are most commonly seen in male homosexuals who practice anorectal intercourse (Wolfe, 2000).

### ANORECTAL ABSCESS

An anorectal abscess is caused by obstruction of an anal gland, resulting in retrograde infection. People with regional enteritis or immunosuppressive conditions such as AIDS are particularly susceptible to these infections. Many of these abscesses result in fistulas.

An abscess may occur in a variety of spaces in and around the rectum. It often contains a quantity of foul-smelling pus and is painful. If the abscess is superficial, swelling, redness, and tenderness are observed. A deeper abscess may result in toxic symptoms, lower abdominal pain, and fever.

Palliative therapy consists of sitz baths and analgesics. However, prompt surgical treatment to incise and drain the abscess is the treatment of choice. When a deeper infection exists with the possibility of a fistula, the fistulous tract must be excised. If possible, the fistula is excised when the abscess is incised and drained, or a second procedure to do so may be necessary. The wound may be packed with gauze and allowed to heal by granulation.

### ANAL FISTULA

An anal fistula is a tiny, tubular, fibrous tract that extends into the anal canal from an opening located beside the anus (Fig. 38-11A). Fistulas usually result from an infection. They may also develop from trauma, fissures, or regional enteritis. Pus or stool may leak constantly from the cutaneous opening. Other symptoms may be the passage of flatus or feces from the vagina or bladder, depending on the fistula tract. Untreated fistulas may cause systemic infection with related symptoms.

Surgery is always recommended, because few fistulas heal spontaneously. A fistulectomy (ie, excision of the fistulous tract) is the recommended surgical procedure. The lower bowel is evacuated thoroughly with several prescribed enemas. During surgery, the sinus tract is identified by inserting a probe into it or by injecting the tract with methylene blue solution. The fistula is dissected out or laid open by an incision from its rectal opening to its outlet. The wound is packed with gauze.

### ANAL FISSURE

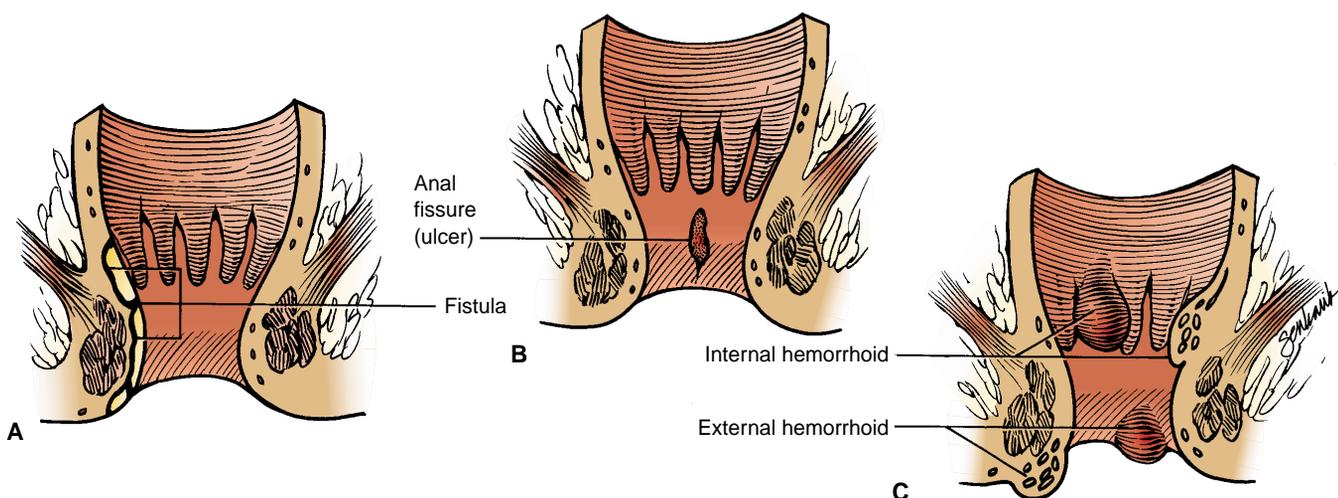

An anal fissure is a longitudinal tear or ulceration in the lining of the anal canal (see Fig. 38-11B). Fissures are usually caused by the trauma of passing a large, firm stool or from persistent tightening of the anal canal because of stress and anxiety (leading to constipation). Other causes include childbirth, trauma, and overuse of laxatives.

Extremely painful defecation, burning, and bleeding characterize fissures. Most of these fissures heal if treated by conservative measures, which include stool softeners and bulk agents, an increase in water intake, sitz baths, and emollient suppositories. A suppository combining an anesthetic with a corticosteroid helps relieve the discomfort. Anal dilation under anesthesia may be required.

If fissures do not respond to conservative treatment, surgery is indicated. The procedure considered by most surgeons to be the procedure of choice is the lateral internal sphincterotomy with excision of the fissure; the success rate is 90% to 95% (Rieghley, 1999).

### HEMORRHOIDS

Hemorrhoids are dilated portions of veins in the anal canal. They are very common. By the age of 50, about 50% of people have hemorrhoids to some extent (Corman, 1998). Shearing of the

**FIGURE 38-11** Various types of anal lesions. (A) Fistula. (B) Fissure. (C) External and internal hemorrhoids.

mucosa during defecation results in the sliding of the structures in the wall of the anal canal, including the hemorrhoidal and vascular tissues. Increased pressure in the hemorrhoidal tissue due to pregnancy may initiate hemorrhoids or aggravate existing ones. Hemorrhoids are classified as one of two types. Those above the internal sphincter are called internal hemorrhoids, and those appearing outside the external sphincter are called external hemorrhoids (see Fig. 38-11C).

Hemorrhoids cause itching and pain and are the most common cause of bright red bleeding with defecation. External hemorrhoids are associated with severe pain from the inflammation and edema caused by thrombosis (ie, clotting of blood within the hemorrhoid). This may lead to ischemia of the area and eventual necrosis. Internal hemorrhoids are not usually painful until they bleed or prolapse when they become enlarged.

Hemorrhoid symptoms and discomfort can be relieved by good personal hygiene and by avoiding excessive straining during defecation. A high-residue diet that contains fruit and bran along with an increased fluid intake may be all the treatment that is necessary to promote the passage of soft, bulky stools to prevent straining. If this treatment is not successful, the addition of hydrophilic bulk-forming agents such as psyllium and mucilloid may help. Warm compresses, sitz baths, analgesic ointments and suppositories, astringents (eg, witch hazel), and bed rest allow the engorgement to subside.

There are several types of nonsurgical treatments for hemorrhoids. Infrared photocoagulation, bipolar diathermy, and laser therapy are newer techniques that are used to affix the mucosa to the underlying muscle. Injecting sclerosing solutions is also effective for small, bleeding hemorrhoids. These procedures help prevent prolapse.

A conservative surgical treatment of internal hemorrhoids is the rubber-band ligation procedure. The hemorrhoid is visualized through the anoscope, and its proximal portion above the mucocutaneous lines is grasped with an instrument. A small rubber band is then slipped over the hemorrhoid. Tissue distal to the rubber band becomes necrotic after several days and sloughs off. Fibrosis occurs; the result is that the lower anal mucosa is drawn up and adheres to the underlying muscle. Although this treatment has been satisfactory for some patients, it has proven painful for others and may cause secondary hemorrhage. It has been known to cause perianal infection.

Cryosurgical hemorrhoidectomy, another method for removing hemorrhoids, involves freezing the hemorrhoid for a sufficient time to cause necrosis. Although it is relatively painless, this procedure is not widely used because the discharge is very foul smelling and wound healing is prolonged. The Nd:YAG laser is useful in excising hemorrhoids, particularly external hemorrhoidal tags. The treatment is quick and relatively painless. Hemorrhage and abscess are rare postoperative complications.

The previously described methods of treating hemorrhoids are not effective for advanced thrombosed veins, which must be treated by more extensive surgery. Hemorrhoidectomy, or surgical excision, can be performed to remove all the redundant tissue involved in the process. During surgery, the rectal sphincter is usually dilated digitally and the hemorrhoids are removed with a clamp and cautery or are ligated and then excised. After the operative procedures are completed, a small tube may be inserted through the sphincter to permit the escape of flatus and blood; pieces of Gelfoam or Oxycel gauze may be placed over the anal wounds.

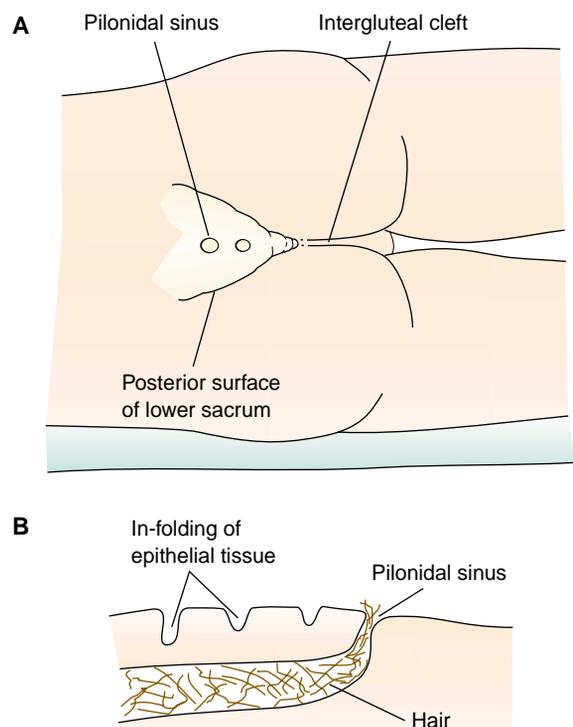

## SEXUALLY TRANSMITTED ANORECTAL DISEASES

Three infectious syndromes that are related to sexually transmitted diseases have been identified. Proctitis involves the rectum. It is commonly associated with recent anal-receptive intercourse with an infected partner. Symptoms include a mucopurulent discharge or bleeding, pain in the area, and diarrhea. The pathogens most frequently involved are *Neisseria gonorrhoeae* (53%), *Chlamydia* (20%), herpes simplex virus (18%), and *Treponema pallidum* (9%) (Yamada et al., 1999). Proctocolitis involves the rectum and lowest portion of the descending colon. Symptoms are similar to proctitis but may also include watery or bloody diarrhea, cramps, pain, and bloating. Enteritis involves more of the descending colon, and symptoms include watery, bloody diarrhea; abdominal pain; and weight loss. The most common pathogens causing enteritis are *E. histolytica*, *Giardia lamblia*, *Shigella*, and *Campylobacter* (Wolfe, 2000).

Sigmoidoscopy is performed to identify portions of the anorectum involved. Samples are taken with rectal swabs, and cultures are obtained to identify the pathogens involved. The treatment of choice for bacterial infections is antibiotics (ie, cefixime, doxycycline, and penicillin). Acyclovir is given to those with viral infections. Infections from *E. histolytica* and *G. lamblia* are treated with antiamebic therapy (ie, metronidazole). Ciprofloxacin is an effective treatment for *Shigella*. Antibiotics of choice for *Campylobacter* infection are erythromycin and ciprofloxacin.

## PILONIDAL SINUS OR CYST

A pilonidal sinus or cyst is found in the intergluteal cleft on the posterior surface of the lower sacrum (Fig. 38-12). Current theories suggest that it results from local trauma that causes the pen-

**FIGURE 38-12** (A) Pilonidal sinus on lower sacrum about 5 cm (2 in) above the anus in the intergluteal cleft. (B) Note: Hair particles emerge from the sinus tract and localized indentations (pits) can appear on the skin near the sinus openings.

etration of hairs into the epithelium and subcutaneous tissue (Yamada et al., 1999). It may also be formed congenitally by an infolding of epithelial tissue beneath the skin, which may communicate with the skin surface through one or several small sinus openings. Hair frequently is seen protruding from these openings, and this gives the cyst its name, *pilonidal* (ie, a nest of hair). The cysts rarely cause symptoms until adolescence or early adult life, when infection produces an irritating drainage or an abscess. Perspiration and friction easily irritate this area.

In the early stages of the inflammation, the infection may be controlled by antibiotic therapy, but after an abscess has formed, surgery is indicated. The abscess is incised and drained under local anesthesia. After the acute process resolves, further surgery is performed to excise the cyst and the secondary sinus tracts. The wound is allowed to heal by granulation. Gauze dressings are placed in the wound to keep its edges separated while healing occurs.

## NURSING PROCESS: THE PATIENT WITH AN ANORECTAL CONDITION

### Assessment

The nurse takes a health history to determine the presence and characteristics of itching, burning, or pain. Does it occur during bowel movements? How long does it last? Is any abdominal pain associated with it? Does any bleeding occur from the rectum? How much? How frequently? Is it bright red? Is there any other discharge, such as mucus or pus? Other questions relate to elimination patterns and laxative use, diet history (including fiber intake), the amount of exercise, activity levels, and occupation (especially one that involves prolonged sitting or standing). Assessment also includes inspection of the stool for blood or mucus and the perianal area for hemorrhoids, fissures, irritation, or pus.

### Diagnosis

#### NURSING DIAGNOSES

Based on the assessment data, the major nursing diagnoses may include the following:

- Constipation related to ignoring the urge to defecate because of pain during elimination
- Anxiety related to impending surgery and embarrassment
- Acute pain related to irritation, pressure, and sensitivity in the anorectal area from anorectal disease and sphincter spasms after surgery
- Urinary retention related to postoperative reflex spasm and fear of pain
- Risk for ineffective therapeutic regimen management

#### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

- Hemorrhage

### Planning and Goals

The major goals for the patient may include adequate elimination patterns, reduction of anxiety, pain relief, promotion of urinary elimination, managing the therapeutic regimen, and absence of complications.

## Nursing Interventions

### RELIEVING CONSTIPATION

The nurse encourages intake of at least 2 L of water daily to provide adequate hydration and recommends high-fiber foods to promote bulk in the stool and to make it easier to pass fecal matter through the rectum. Bulk laxatives such as Metamucil and stool softeners are administered as prescribed. The patient is advised to set aside a time for moving the bowels and to heed the urge to defecate as promptly as possible. It may be helpful to have the patient perform relaxation exercises before defecating to relax the abdominal and perineal muscles, which may be constricted or in spasm. Administering an analgesic before a bowel movement is beneficial.

### REDUCING ANXIETY

Patients facing rectal surgery may be upset and irritable because of discomfort, pain, and embarrassment. The nurse identifies specific psychosocial needs and individualizes the plan of care. The nurse maintains the patient's privacy while providing care and by limiting visitors, if the patient desires. Soiled dressings are removed from the room promptly to prevent unpleasant odors; room deodorizers may be needed if dressings are foul smelling.

### RELIEVING PAIN

During the first 24 hours after rectal surgery, painful spasms of the sphincter and perineal muscles may occur. Control of pain is a prime consideration. The patient is encouraged to assume a comfortable position. Flotation pads under the buttocks when sitting help to decrease the pain, as may ice and analgesic ointments. Warm compresses may promote circulation and soothe irritated tissues. Sitz baths taken three or four times each day can relieve soreness and pain by relaxing sphincter spasm. Twenty-four hours after surgery, topical anesthetic agents may be beneficial in relieving local irritation and soreness. Medications may include topical anesthetics (ie, suppositories), astringents, antiseptics, tranquilizers, and antiemetics. Patients are more compliant and less apprehensive if they are free of pain.

Wet dressings saturated with equal parts of cold water and witch hazel help relieve edema. When wet compresses are being used continuously, the petrolatum is applied around the anal area to prevent skin maceration. The patient is instructed to assume a prone position at intervals because this position promotes dependent drainage of edematous fluid.

### PROMOTING URINARY ELIMINATION

Voiding may be a problem after surgery because of a reflex spasm of the sphincter at the outlet of the bladder and a certain amount of muscle guarding from apprehension and pain. The nurse tries all methods to encourage voluntary voiding (ie, increasing fluid intake, listening to running water, and dripping water over the urinary meatus) before resorting to catheterization. After rectal surgery, urinary output is closely monitored.

### MONITORING AND MANAGING COMPLICATIONS

The operative site is examined frequently for rectal bleeding. The nurse assesses the patient for systemic indicators of excessive bleeding (ie, tachycardia, hypotension, restlessness, and thirst). After hemorrhoidectomy, hemorrhage may occur from the veins that were cut. If a tube has been inserted through the sphincter after surgery, evidence of bleeding may be visible on the dressings. If bleeding is obvious, direct pressure is applied to the area, and the physician is notified. It is important to avoid using moist heat because it encourages vessel dilation and bleeding.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

Most patients with anorectal conditions are not hospitalized. Those who have surgical procedures to correct the condition often are discharged directly from the outpatient surgical center. If they are hospitalized, it is for a short time, usually only 24 hours. Patient teaching is essential to facilitate recovery at home.

The nurse instructs the patient to keep the perianal area as clean as possible by gently cleansing with warm water and then drying with absorbent cotton wipes. The patient avoids rubbing the area with toilet tissue. Instructions are provided about how to take a sitz bath and how to test the temperature of the water. Sitz baths may be given in the bathtub or plastic sitz bath unit three or four times each day. Sitz baths should follow each bowel movement for 1 to 2 weeks after surgery. The nurse encourages the patient to respond quickly to the urge to defecate to prevent constipation. The diet is modified to increase fluids and fiber. Moderate exercise is encouraged, and the patient is taught about the prescribed diet, the significance of proper eating habits and exercise, and the laxatives that can be taken safely.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Attains a normal pattern of elimination
  - a. Sets aside a time for defecation, usually after a meal or at bedtime
  - b. Responds to the urge to defecate and takes the time to sit on the toilet and try to defecate
  - c. Uses relaxation exercises as needed
  - d. Increases fluid intake to 2 L per day
  - e. Adds high-fiber foods to diet
  - f. Reports passage of soft, formed stools
  - g. Reports decreased abdominal discomfort
2. Is less anxious
3. Has less pain
  - a. Modifies body position and activities to minimize pain and discomfort
  - b. Applies warmth or cold to anorectal area
  - c. Takes sitz baths four times each day
4. Voids without difficulty
5. Adheres to the therapeutic regimen
  - a. Keeps perianal area dry
  - b. Eats bulk-forming foods
  - c. Has a soft, formed stool on a regular basis
6. Exhibits no evidence of complications
  - a. Has a clean incision
  - b. Has normal vital signs
  - c. Shows no signs of hemorrhage

because he has type 2 diabetes mellitus. When you complete your initial nursing assessment, you notice that his abdomen is distended and rigid and that bowel sounds are absent throughout all fields. Analyze these findings, indicate what you think the possible causes may be, and explain the actions you would take and why. Explain how this man's diagnosis of diabetes mellitus affects his plan of nursing care and his medical management.

2. During a conversation with a neighbor, you learn that she has recently seen her doctor and that she has been diagnosed with IBS. She asks you to help her understand this process and to explain the reason for the dietary restrictions her doctor has given her. Her doctor also prescribed a laxative and an antidepressant. She explains the amount of stress she has been under at work. Identify the facts that you know about this process and how the actions of the doctor would help in this situation. What will you tell your neighbor?

3. You are caring for a patient who has been diagnosed with colon cancer. He recently underwent a colonoscopy where the growth was detected in the lower portion of the descending colon. The patient is scheduled for a colon resection. You know that he will return from surgery with a sigmoid colostomy. What will you need to do during the preoperative period to prepare your patient for this surgery? What will be the nursing diagnoses and related interventions that are a priority during the immediate postoperative period? Explain how you would meet the postoperative emotional and health education needs of the patient with a colostomy.

4. You are assigned to a general medical clinic. Two patients with inflammatory bowel disease arrive for their appointments. One of the patients, a 52-year-old woman, has recently been diagnosed with Crohn's disease. The other patient, a 21-year-old woman, was diagnosed with ulcerative colitis at 15 years of age and has had an ileostomy since the age of 19 years. Compare the two disease processes in terms of their pathophysiology, clinical manifestations, course of the illness, and therapeutic management. What similarities and differences would you expect to find in the nutritional and pharmacologic therapies for these two patients? What assessment parameters would you use to identify the psychosocial needs of each of these patients.

# ● Assessment and Management of Patients With Hepatic Disorders

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Identify the metabolic functions of the liver and the alterations in these functions that occur with liver disease.
2. Explain liver function tests and the clinical manifestations of liver dysfunction in relation to pathophysiologic alterations of the liver.
3. Relate jaundice, portal hypertension, ascites, varices, nutritional deficiencies, and hepatic coma to pathophysiologic alterations of the liver.
4. Describe the medical, surgical, and nursing management of patients with esophageal varices.
5. Compare the various types of hepatitis and their causes, prevention, clinical manifestations, management, prognosis, and home health care needs.
6. Use the nursing process as a framework for care of the patient with cirrhosis of the liver.
7. Compare the nonsurgical and surgical management of patients with cancer of the liver.
8. Describe the postoperative nursing care of the patient undergoing liver transplantation.

**L**iver disorders are common and may result from a virus or exposure to toxic substances such as alcohol. Another liver disorder is cancer: hepatocellular carcinoma is a highly malignant tumor that is difficult to treat and often fatal. In the United States, hepatocellular cancer accounts for less than 1% of all cancers, but in other parts of the world, it accounts for up to 50% of cancer cases. The difference is thought to be due to the percentage of the population who are carriers of the hepatitis B virus, which predisposes individuals to hepatocellular cancer. Liver cancer can originate in the liver or can metastasize to the liver from other sites.

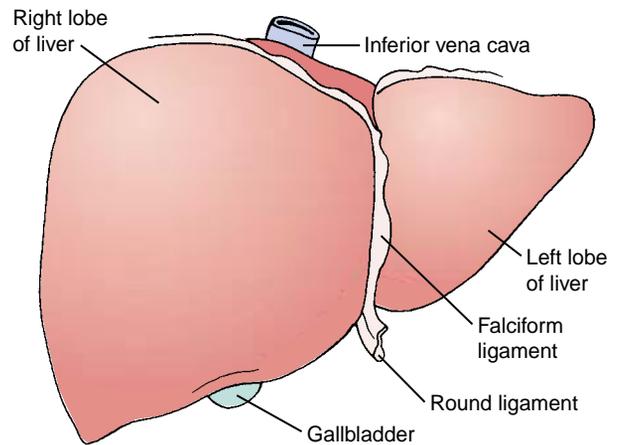

Liver function is complex, and liver dysfunction affects all body systems. For this reason, the nurse must understand how the liver functions and must have expert assessment and clinical management skills to care for patients undergoing complex diagnostic and treatment procedures. The nurse also must understand technological advances in the management of liver disorders.

## Anatomic and Physiologic Overview

The liver, the largest gland of the body, can be considered a chemical factory that manufactures, stores, alters, and excretes a large number of substances involved in metabolism. The location of the liver is essential in this function, because it receives nutrient-rich blood directly from the gastrointestinal (GI) tract and then either stores or transforms these nutrients into chemicals that are used elsewhere in the body for metabolic needs. The liver is especially important in the regulation of glucose and protein metabolism. The liver manufactures and secretes bile, which has a major role in the digestion and absorption of fats in the GI tract. It removes waste products from the bloodstream and secretes them into the bile. The bile produced by the liver is stored temporarily in the gallbladder until it is needed for digestion, at which time the gallbladder empties and bile enters the intestine (Fig. 39-1).

### ANATOMY OF THE LIVER

The liver is located behind the ribs in the upper right portion of the abdominal cavity. It weighs about 1,500 g and is divided into four lobes. A thin layer of connective tissue surrounds each lobe,

**FIGURE 39-1** The liver and biliary system.

extending into the lobe itself and dividing the liver mass into small units called lobules (O'Grady, Lake & Howdle, 2000).

The circulation of the blood into and out of the liver is of major importance in its function. The blood that perfuses the liver comes from two sources. Approximately 75% of the blood supply comes from the portal vein, which drains the GI tract and is rich in nutrients. The remainder of the blood supply enters by way of the hepatic artery and is rich in oxygen. Terminal branches of these two blood supplies join to form common capillary beds, which constitute the sinusoids of the liver (Fig. 39-2). Thus, a mixture of venous and arterial blood bathes the liver cells (hepatocytes). The sinusoids empty into a venule that occupies the center of each liver lobule and is called the central vein. The central veins join to form the hepatic vein, which constitutes the venous drainage from the liver and empties into the inferior vena cava, close to the diaphragm. Thus, there are two sources of blood flowing into the liver and only one exit pathway (O'Grady et al., 2000).

In addition to hepatocytes, phagocytic cells belonging to the reticuloendothelial system are present in the liver. Other organs that contain reticuloendothelial cells are the spleen, bone marrow,

## Glossary

**asterixis:** involuntary flapping movements of the hands associated with metabolic liver dysfunction

**balloon tamponade:** use of balloons placed within the esophagus and proximal portion of the stomach and inflated to compress bleeding vessels (esophageal and gastric varices)

**Budd-Chiari syndrome:** hepatic vein thrombosis resulting in noncirrhotic portal hypertension

**cirrhosis:** a chronic liver disease characterized by fibrotic changes and the formation of dense connective tissue within the liver, subsequent degenerative changes, and loss of functioning cells

**constructional apraxia:** inability to draw figures in two or three dimensions

**cryoablation:** method of treating malignant hepatic lesions that involves exposing the

tumor to temperatures below  $-20^{\circ}\text{C}$  and subsequent thawing. This surgical intervention is performed via a probe through which liquid nitrogen flows.

**hepatic encephalopathy:** central nervous system dysfunction resulting from liver disease; frequently associated with elevated ammonia levels that produce changes in mental status, altered level of consciousness, and coma

**fetor hepaticus:** sweet, slightly fecal odor to the breath, presumed to be of intestinal origin; prevalent with the extensive collateral portal circulation in chronic liver disease

**fulminant hepatic failure:** sudden, severe onset of acute liver failure that occurs within 8 weeks of the first symptoms of jaundice

**orthotopic liver transplantation (OLT):** grafting of a donor liver into the normal

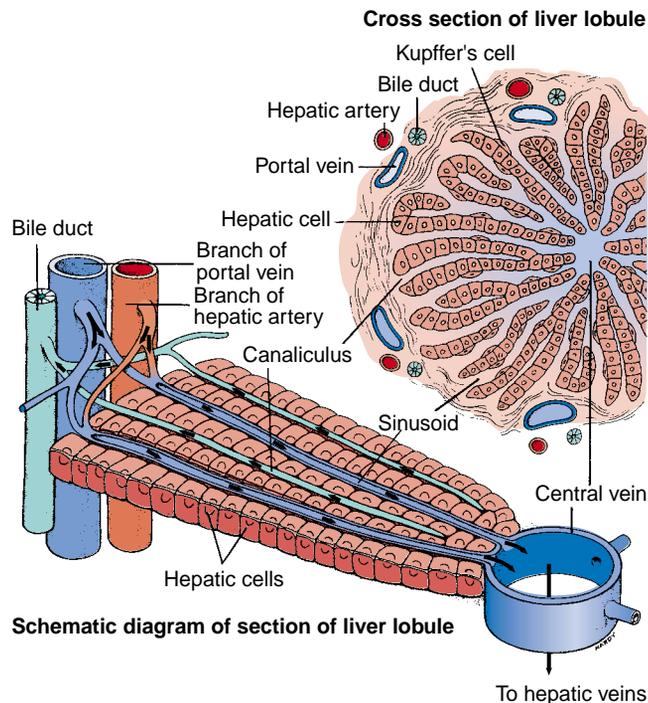

anatomic location, with removal of the diseased native liver

**portal hypertension:** elevated pressure in the portal circulation resulting from obstruction of venous flow into and through the liver

**sclerotherapy:** the injection of substances into or around esophagogastric varices to cause constriction, thickening, and hardening of the vessel and thus to stop bleeding

**variceal banding:** procedure that involves the endoscopic placement of a rubber band-like device over esophageal varices to ligate the area and stop bleeding

**xenograft:** transplantation of organs from one species to another

**FIGURE 39-2** A section of liver lobule showing the location of hepatic veins, hepatic cells, liver sinusoids, and branches of the portal vein and hepatic artery.

lymph nodes, and lungs. In the liver, these cells are called Kupffer cells. Their main function is to engulf particulate matter (such as bacteria) that enters the liver through the portal blood.

The smallest bile ducts, called canaliculi, are located between the lobules of the liver. The canaliculi receive secretions from the hepatocytes and carry them to larger bile ducts, which eventually form the hepatic duct. The hepatic duct from the liver and the cystic duct from the gallbladder join to form the common bile duct, which empties into the small intestine. The sphincter of Oddi, located at the junction where the common bile duct enters the duodenum, controls the flow of bile into the intestine. Disorders of the gallbladder are described in Chapter 40.

## FUNCTIONS OF THE LIVER

### Glucose Metabolism

The liver plays a major role in the metabolism of glucose and the regulation of blood glucose concentration. After a meal, glucose is taken up from the portal venous blood by the liver and converted into glycogen, which is stored in the hepatocytes. Subsequently, the glycogen is converted back to glucose and released as needed into the bloodstream to maintain normal levels of blood glucose. Additional glucose can be synthesized by the liver through a process called gluconeogenesis. For this process, the liver uses amino acids from protein breakdown or lactate produced by exercising muscles (Bacon & Di Bisceglie, 2000).

### Ammonia Conversion

Use of amino acids from protein for gluconeogenesis results in the formation of ammonia as a byproduct. The liver converts this metabolically generated ammonia into urea. Ammonia produced by bacteria in the intestines is also removed from portal blood for

urea synthesis. In this way, the liver converts ammonia, a potential toxin, into urea, a compound that can be excreted in the urine.

### Protein Metabolism

The liver also plays an important role in protein metabolism. It synthesizes almost all of the plasma proteins (except gamma globulin), including albumin, alpha and beta globulins, blood clotting factors, specific transport proteins, and most of the plasma lipoproteins. Vitamin K is required by the liver for synthesis of prothrombin and some of the other clotting factors. Amino acids serve as the building blocks for protein synthesis.

### Fat Metabolism

The liver is also active in fat metabolism. Fatty acids can be broken down for the production of energy and the production of ketone bodies (acetoacetic acid, beta-hydroxybutyric acid, and acetone). Ketone bodies are small compounds that can enter the bloodstream and provide a source of energy for muscles and other tissues. Breakdown of fatty acids into ketone bodies occurs primarily when the availability of glucose for metabolism is limited, as during starvation or in uncontrolled diabetes. Fatty acids and their metabolic products are also used for the synthesis of cholesterol, lecithin, lipoproteins, and other complex lipids. Under some conditions, lipids may accumulate in the hepatocytes, resulting in the abnormal condition called fatty liver.

### Vitamin and Iron Storage

Vitamins A, B, and D and several of the B-complex vitamins are stored in large amounts in the liver. Certain substances, such as iron and copper, are also stored in the liver. Because the liver is rich in these substances, liver extracts have been used for therapy for a wide range of nutritional disorders.

### Drug Metabolism

The liver metabolizes many medications, such as barbiturates, opioids, sedative agents, anesthetics, and amphetamines. Metabolism generally results in loss of activity of the medication, although in some cases activation of the medication may occur. One of the important pathways for medication metabolism involves conjugation (binding) of the medication with a variety of compounds, such as glucuronic or acetic acid, to form more soluble substances. The conjugated products may be excreted in the feces or urine, similar to bilirubin excretion. If an oral medication (absorbed from the GI tract) is metabolized by the liver to a great extent before it reaches the systemic circulation (first-pass effect), the amount of medication actually reaching the systemic circulation (oral bioavailability) will be decreased. Bioavailability is the fraction of the administered drug that reaches the systemic circulation. Some medications have such a large first-pass effect that their use is essentially limited to the parenteral route, or oral doses must be substantially larger than parenteral doses to achieve the same effect.

### Bile Formation

Bile is continuously formed by the hepatocytes and collected in the canaliculi and bile ducts. It is composed mainly of water and electrolytes such as sodium, potassium, calcium, chloride, and bicarbonate, and it also contains significant amounts of lecithin, fatty acids, cholesterol, bilirubin, and bile salts. Bile is collected

and stored in the gallbladder and is emptied into the intestine when needed for digestion. The functions of bile are excretory, as in the excretion of bilirubin; bile also serves as an aid to digestion through the emulsification of fats by bile salts.

Bile salts are synthesized by the hepatocytes from cholesterol. After conjugation or binding with amino acids (taurine and glycine), they are excreted into the bile. The bile salts, together with cholesterol and lecithin, are required for emulsification of fats in the intestine, which is necessary for efficient digestion and absorption. Bile salts are then reabsorbed, primarily in the distal ileum, into portal blood for return to the liver and are again excreted into the bile. This pathway from hepatocytes to bile to intestine and back to the hepatocytes is called the enterohepatic circulation. Because of the enterohepatic circulation, only a small fraction of the bile salts that enter the intestine are excreted in the feces. This decreases the need for active synthesis of bile salts by the liver cells.

## Bilirubin Excretion

Bilirubin is a pigment derived from the breakdown of hemoglobin by cells of the reticuloendothelial system, including the Kupffer cells of the liver. Hepatocytes remove bilirubin from the blood and chemically modify it through conjugation to glucuronic acid, which makes the bilirubin more soluble in aqueous solutions. The conjugated bilirubin is secreted by the hepatocytes into the adjacent bile canaliculi and is eventually carried in the bile into the duodenum.

In the small intestine, bilirubin is converted into urobilinogen, which is in part excreted in the feces and in part absorbed through the intestinal mucosa into the portal blood. Much of this reabsorbed urobilinogen is removed by the hepatocytes and is secreted into the bile once again (enterohepatic circulation). Some of the urobilinogen enters the systemic circulation and is excreted by the kidneys in the urine. Elimination of bilirubin in the bile represents the major route of excretion for this compound.

The bilirubin concentration in the blood may be increased in the presence of liver disease, when the flow of bile is impeded (ie, with gallstones in the bile ducts), or with excessive destruction of red blood cells. With bile duct obstruction, bilirubin does not enter the intestine; as a consequence, urobilinogen is absent from the urine and decreased in the stool. Biliary tract disorders are discussed in Chapter 40.

### Gerontologic Considerations

The Gerontologic Considerations Box outlines age-related changes in the liver. The most common change in the liver in the elderly is a decrease in its size and weight, accompanied by a decrease in total hepatic blood flow. In general, however, these decreases are proportional to the decreases in body size and weight seen in normal aging. Results of liver function tests do not normally change in the elderly; abnormal results in an elderly patient indicate abnormal liver function and are not the result of the aging process itself.

The immune system is altered in the aged, and a less responsive immune system may be responsible for the increased incidence and severity of hepatitis B in the elderly and the increased incidence of liver abscesses secondary to decreased phagocytosis by the Kupffer cells. With the advent of hepatitis B vaccine as the standard for prevention, the incidence of hepatic diseases may decrease in the future.

Metabolism of medications by the liver appears to decrease in the elderly, but such changes are usually accompanied by changes

## Gerontologic Considerations

### Age-Related Changes of the Hepatobiliary System

- Steady decrease in size and weight of the liver, particularly in women
- Decrease in blood flow
- Decrease in replacement/repair of liver cells after injury
- Reduced drug metabolism
- Slow clearance of hepatitis B surface antigen
- Decline in drug clearance capability
- Increased prevalence of gallstones due to the increase in cholesterol secretion in bile
- Decreased gallbladder contraction after a meal
- Atypical clinical presentation of biliary disease
- More severe complications of biliary tract disease

in intestinal absorption, renal excretion, and altered body distribution of some medications secondary to changes in fat deposition. These alterations necessitate careful medication administration and monitoring; if appropriate, reduced dosages may be needed to prevent medication toxicity.

## Assessment

### HEALTH HISTORY

If liver function test results are abnormal, the patient may need to be evaluated for liver disease. In such cases, the health history will focus on exposure of the patient to hepatotoxic substances or infectious agents. The patient's occupational, recreational, and travel history may assist in identifying exposure to hepatotoxins (eg, industrial chemicals, other toxins) responsible for illness. The patient's history of alcohol and drug use, including but not limited to the use of injectable drugs, provides additional information about exposure to toxins and infectious agents. Many medications (including acetaminophen, ketoconazole, and valproic acid) are responsible for hepatic dysfunction and disease. A careful medication history to assess hepatic dysfunction should address all prescribed and over-the-counter medications, herbal remedies, and dietary supplements used by the patient currently and in the past.

Lifestyle behaviors that increase the risk for exposure to infectious agents are identified. Injectable drug use, sexual practices, and a history of foreign travel are all potential risk factors for liver disease. The amount and type of alcohol consumption are identified using screening tools (questionnaires) that have been developed for this purpose (see Chap. 5).

The history also includes an evaluation of the patient's past medical history to identify risk factors for the development of liver disease. Current and past medical conditions, including those of a psychological or psychiatric nature, are identified. The family history includes questions about familial liver disorders that may have their etiology in alcohol abuse or gallstone disease, as well as other familial or genetic diseases, such as hemochromatosis, Wilson's disease, or alpha-1 antitrypsin disease (see "Genetics in Nursing Practice" in Chap. 42).

The history also includes reviewing symptoms that suggest liver disease. Symptoms that may have their etiology in liver disease but are not specific to hepatic dysfunction include jaundice, malaise, weakness, fatigue, pruritus, abdominal pain, fever, anorexia,

weight gain, edema, increasing abdominal girth, hematemesis, melena, hematochezia (passage of bloody stools), easy bruising, decreased libido in men and secondary amenorrhea in women, changes in mental acuity, personality changes, and sleep disturbances.

## PHYSICAL EXAMINATION

The nurse assesses the patient for physical signs that may occur with liver dysfunction, including pallor of chronic illness and jaundice. The skin, mucosa, and sclerae are inspected for jaundice, and the extremities are assessed for muscle atrophy, edema, and skin excoriation secondary to scratching. The nurse observes the skin for petechiae or ecchymotic areas (bruises), spider angiomas, and palmar erythema. The male patient is assessed for unilateral or bilateral gynecomastia and testicular atrophy due to endocrine changes. The patient's cognitive status (recall, memory, abstract thinking) and neurologic status are assessed. The nurse observes for general tremor, asterixis, weakness, and slurred speech. These symptoms are discussed later.

The nurse assesses the abdomen for dilated abdominal wall veins, ascites, and a fluid wave (discussed later). The abdomen is palpated to assess liver size and to detect any tenderness over the liver. The liver may be palpable in the right upper quadrant. A palpable liver presents as a firm, sharp ridge with a smooth surface (Fig. 39-3). The nurse estimates liver size by percussing its upper and lower borders. When the liver is not palpable but tenderness is suspected, tapping the lower right thorax briskly may elicit tenderness. For comparison, the nurse then performs a similar maneuver on the left lower thorax.

If the liver is palpable, the examiner notes and records its size and consistency, whether it is tender, and whether its outline is regular or irregular. If the liver is enlarged, the degree to which it descends below the right costal margin is recorded to provide some indication of its size. The examiner determines whether the liver's edge is sharp and smooth or blunt, and whether the enlarged liver is nodular or smooth. The liver of a patient with cir-

**FIGURE 39-3** Technique for palpating the liver. The examiner places one hand under the right lower rib cage and presses downward with light pressure with the other hand.

rhosis is small and hard, whereas the liver of a patient with acute hepatitis is soft, and the hand easily moves the edge.

Tenderness of the liver implies recent acute enlargement with consequent stretching of the liver capsule. The absence of tenderness may imply that the enlargement is of long-standing duration. The liver of a patient with viral hepatitis is tender, whereas that of a patient with alcoholic hepatitis is not. Enlargement of the liver is an abnormal finding requiring evaluation.

## Diagnostic Evaluation

### LIVER FUNCTION TESTS

More than 70% of the parenchyma of the liver may be damaged before liver function test results become abnormal. Function is generally measured in terms of serum enzyme activity (ie, alkaline phosphatase, lactic dehydrogenase, serum aminotransferases) and serum concentrations of proteins (albumin and globulins), bilirubin, ammonia, clotting factors, and lipids. Several of these tests may be helpful for assessing patients with liver disease. However, the nature and extent of hepatic dysfunction cannot be determined by these tests alone, as many other disorders can affect their results.

Serum aminotransferases (also called transaminases) are sensitive indicators of injury to the liver cells and are useful in detecting acute liver disease such as hepatitis. Alanine aminotransferase (ALT) (formerly called serum glutamic-pyruvic transaminase [SGPT]), aspartate aminotransferase (AST) (formerly called serum glutamic-oxaloacetic transaminase [SGOT]), and gamma glutamyl transferase (GGT) (also called G-glutamyl transpeptidase) are the most frequently used tests of liver damage. ALT levels increase primarily in liver disorders and may be used to monitor the course of hepatitis or cirrhosis or the effects of treatments that may be toxic to the liver. AST is present in tissues that have high metabolic activity; thus, the level may be increased if there is damage to or death of tissues of organs such as the heart, liver, skeletal muscle, and kidney. Although not specific to liver disease, levels of AST may be increased in cirrhosis, hepatitis, and liver cancer. Increased GGT levels are associated with cholestasis but can also be due to alcoholic liver disease. Although the kidney has the highest level of the enzyme, the liver is considered the source of normal serum activity. The test determines liver cell dysfunction and is a sensitive indicator of cholestasis. Its main value in liver disease is confirming the hepatic origin of an elevated alkaline phosphatase level. Common liver function tests are listed in Table 39-1.

### LIVER BIOPSY

Liver biopsy is the removal of a small amount of liver tissue, usually through needle aspiration. It permits examination of liver cells. The most common indication is to evaluate diffuse disorders of the parenchyma and to diagnose space-occupying lesions. Liver biopsy is especially useful when clinical findings and laboratory tests are not diagnostic. Bleeding and bile peritonitis after liver biopsy are the major complications; therefore, coagulation studies are obtained, their values are noted, and abnormal results are treated before liver biopsy is performed. Other techniques for liver biopsy are preferred if ascites or coagulation abnormalities exist. A liver biopsy can be performed percutaneously under ultrasound guidance or transvenously through the right internal jugular vein to right hepatic vein under fluoroscopic control. Liver biopsy can also be performed laparoscopically. Nursing responsibilities related to percutaneous liver biopsy are summarized in Chart 39-1.

Table 39-1 • Liver Function Studies

TEST	NORMAL	CLINICAL FUNCTIONS
<b>Pigment Studies</b>		
Serum bilirubin, direct	0–0.3 mg/dL (0–5.1 μmol/L)	These studies measure the ability of the liver to conjugate and excrete bilirubin. Results are abnormal in liver and biliary tract disease and are associated with jaundice clinically.
Serum bilirubin, total	0–0.9 mg/dL (1.7–20.5 μmol/L)	
Urine bilirubin	0(0)	
Urine urobilinogen	0.05–2.5 mg/24 h (0.09–4.23 μmol/24 h)	
Fecal urobilinogen (infrequently used)	40–200 mg/24 h (0.068–0.34 mmol/24 h)	
<b>Protein Studies</b>		
Total serum protein	7.0–7.5 g/dL (70–75 g/L)	Proteins are manufactured by the liver. Their levels may be affected in a variety of liver impairments. Albumin: Cirrhosis Chronic hepatitis Edema, ascites Globulin: Cirrhosis Liver disease Chronic obstructive jaundice Viral hepatitis A/G ratio is reversed in chronic liver disease (decreased albumin and increased globulin). Prothrombin time may be prolonged in liver disease. It will not return to normal with vitamin K in severe liver cell damage. Serum alkaline phosphatase is manufactured in bones, liver, kidneys, and intestine and excreted through biliary tract. In absence of bone disease, it is a sensitive measure of biliary tract obstruction. The studies are based on release of enzymes from damaged liver cells. These enzymes are elevated in liver cell damage. Elevated in alcohol abuse. Marker for biliary cholestasis. Liver converts ammonia to urea. Ammonia level rises in liver failure. Cholesterol levels are elevated in biliary obstruction and decreased in parenchymal liver disease.
Serum albumin	4.0–5.5 g/dL (40–55 g/L)	
Serum globulin	1.7–3.3 g/dL (17–33 g/L)	
Serum protein electrophoresis		
Albumin	4.0–5.5 g/dL (40–55 g/L)	
α <sub>1</sub> -Globulin	0.15–0.25 g/dL (1.5–2.5 g/L)	
α <sub>2</sub> -Globulin	0.43–.75 g/dL (4.3–7.5 g/L)	
β-Globulin	0.5–1.0 g/dL (5–10 g/L)	
γ-Globulin	0.6–1.3 g/dL (6–13 g/L)	
Albumin/globulin (A/G) ratio	A > G or 1.5:1–2.5:1	
<b>Prothrombin Time</b>	100% or 12–16 seconds	
<b>Serum Alkaline Phosphatase</b>	Varies with method: 2–5 Bodansky units 30–50 IU/L at 34°C (17–142 U/L at 30°C) (20–90 U/L at 30°C)	
<b>Serum Aminotransferase or Transaminase Studies</b>		
AST (SGOT)	10–40 units (4.8–19 U/L)	
ALT (SGPT)	5–35 units (2.4–17 U/L)	
<b>GGT, GGTP</b>	10–48 IU/L	
<b>LDH</b>	100–200 units (100–225 U/L)	
<b>Serum Ammonia</b>	20–120 μg/dL (11.1–67.0 μmol/L) 150–250 mg/dL (3.90–6.50 mmol/L)	
<b>Cholesterol</b>		
Ester	60% of total (fraction of total cholesterol: 0.60)	
HDL (high-density lipoprotein)	HDL Male: 35–70 mg/dL, Female: 35–85 mg/dL	
LDL (low-density lipoprotein)	LDL < 130 μg/dL	
<b>ADDITIONAL STUDIES</b>		<b>CLINICAL FUNCTIONS</b>
Barium study of esophagus		For varices, which indicate increased portal blood pressure
Abdominal x-ray		To determine gross liver size
Liver scan with radiotagged iodinated rose bengal, gold, technetium, or gallium		To show size and shape of liver; to show replacement of liver tissue with scars, cysts, or tumor
Cholecystogram and cholangiogram		For gallbladder and bile duct visualization
Celiac axis arteriography		For liver and pancreas visualization
Splenoportogram (splenic portal venography)		To determine adequacy of portal blood flow
Laparoscopy		Direct visualization of anterior surface of liver, gallbladder, and mesentery through a trocar
Liver biopsy (percutaneous or transjugular)		To determine anatomic changes in liver tissue
Measurement of portal pressure		Elevated in cirrhosis of the liver
Esophagoscopy/endoscopy		To search for esophageal varices and other abnormalities
Electroencephalogram		Abnormal in hepatic coma and impending hepatic coma
Ultrasonography		To show size of abdominal organs and presence of masses
Computed tomography (CT scan)		To detect hepatic neoplasms; diagnose cysts, abscesses, and hematomas; and distinguish between obstructive and nonobstructive jaundice. Detects cerebral atrophy in hepatic encephalopathy.
Angiography		Visualizes hepatic circulation and detects presence and nature of hepatic masses
Magnetic resonance imaging (MRI)		To detect hepatic neoplasms; diagnose cysts, abscesses, and hematomas. Detects cerebral atrophy in encephalopathy.
Endoscopic retrograde cholangiopancreatography (ERCP)		Visualizes biliary structures via endoscopy

Chart 39-1

## GUIDELINES FOR Assisting With Percutaneous Liver Biopsy

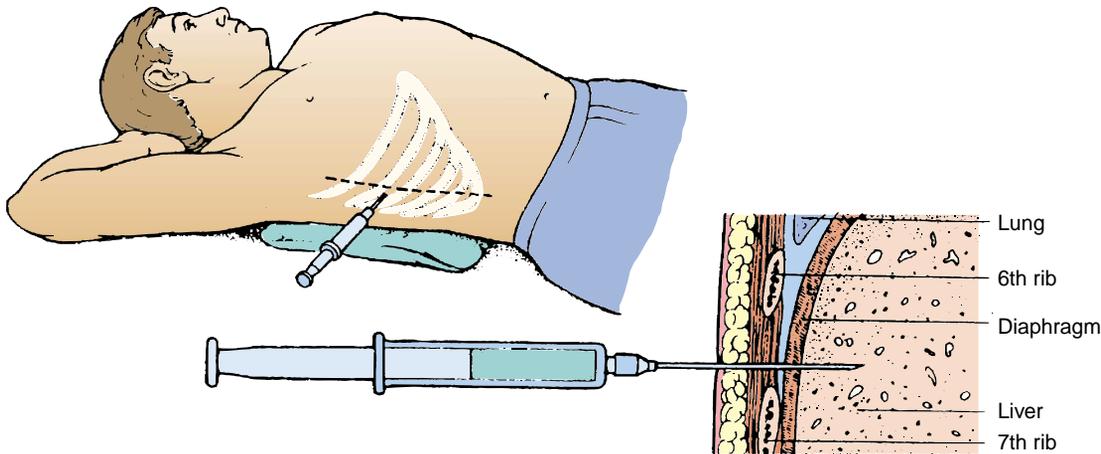

### NURSING ACTIVITIES

#### PREPROCEDURE

1. Ascertain that results of coagulation tests (prothrombin time, partial thromboplastin time, and platelet count) are available and that compatible donor blood is available.
2. Check for signed consent; confirm that informed consent has been provided.
3. Measure and record the patient's pulse, respirations, and blood pressure immediately before biopsy.
4. Describe to the patient in advance: steps of the procedure; sensations expected; after-effects anticipated; restrictions of activity and monitoring procedures to follow.

#### DURING PROCEDURE

5. Support the patient during the procedure.
6. Expose the right side of the patient's upper abdomen (right hypochondriac).
7. Instruct the patient to inhale and exhale deeply several times, finally to exhale, and to hold breath at the end of expiration. The physician promptly introduces the biopsy needle by way of the transthoracic (intercostal) or transabdominal (subcostal) route, penetrates the liver, aspirates, and withdraws.
8. Instruct the patient to resume breathing.

#### POSTPROCEDURE

9. Immediately after the biopsy, assist the patient to turn onto the right side; place a pillow under the costal margin, and caution the patient to remain in this position, recumbent and immobile, for several hours. Instruct the patient to avoid coughing or straining.
10. Measure and record the patient's pulse, respiratory rate, and blood pressure at 10- to 15-minute intervals for the first hour, then every 30 minutes for the next 1 to 2 hours or until the patient's condition stabilizes.
11. If the patient is discharged after the procedure, instruct the patient to avoid heavy lifting and strenuous activity for 1 week.

### RATIONALE

Many patients with liver disease have clotting defects and are at risk for bleeding.

Prebiopsy values provide a basis on which to compare the patient's vital signs and evaluate status after the procedure. Explanations allay fears and ensure cooperation.

Encouragement and support of the nurse enhance comfort and promote a sense of security.

The skin at the site of penetration will be cleansed and a local anesthetic will be infiltrated.

Holding the breath immobilizes the chest wall and the diaphragm; penetration of the diaphragm thereby is avoided, and the risk of lacerating the liver is minimized.

In this position, the liver capsule at the site of penetration is compressed against the chest wall, and the escape of blood or bile through the perforation is prevented.

Changes in vital signs may indicate bleeding, severe hemorrhage, or bile peritonitis, the most frequent complications of liver biopsy.

Activity restriction reduces the risk of bleeding at the biopsy puncture site.

## OTHER DIAGNOSTIC TESTS

Ultrasonography, computed tomography (CT), and magnetic resonance imaging (MRI) are used to identify normal structures and abnormalities of the liver and biliary tree. A radioisotope liver scan may be performed to assess liver size and hepatic blood flow and obstruction.

Laparoscopy (insertion of a fiber-optic endoscope through a small abdominal incision) is used to examine the liver and other pelvic structures. It is also used to perform guided liver biopsy, to determine the etiology of ascites, and to diagnose and stage tumors of the liver and other abdominal organs.

## Hepatic Dysfunction

Hepatic dysfunction results from damage to the liver's parenchymal cells, either directly from primary liver diseases or indirectly from obstruction of bile flow or derangements of hepatic circulation. Liver dysfunction may be acute or chronic; chronic dysfunction is far more common than acute.

Chronic liver disease, including **cirrhosis**, is the seventh most common cause of death in the United States among young and middle-aged adults. More than 40% of those deaths are associated with alcohol. The rate of chronic liver disease for men is twice that for women, and chronic liver disease is more common among African Americans than Caucasians.

Disease processes that lead to hepatocellular dysfunction may be caused by infectious agents such as bacteria and viruses and by anoxia, metabolic disorders, toxins and medications, nutritional deficiencies, and hypersensitivity states. The most common cause of parenchymal damage is malnutrition, especially that related to alcoholism.

The parenchymal cells respond to most noxious agents by replacing glycogen with lipids, producing fatty infiltration with or without cell death or necrosis. This is commonly associated with inflammatory cell infiltration and growth of fibrous tissue. Cell regeneration can occur if the disease process is not too toxic to the cells. The result of chronic parenchymal disease is the shrunken, fibrotic liver seen in cirrhosis.

The consequences of liver disease are numerous and varied. Their ultimate effects are often incapacitating or life-threatening, and their presence is ominous. Treatment often is difficult. Among the most common and significant symptoms of liver disease are the following:

- Jaundice, resulting from increased bilirubin concentration in the blood
- Portal hypertension, ascites, and varices, resulting from circulatory changes within the diseased liver and producing severe GI hemorrhages and marked sodium and fluid retention
- Nutritional deficiencies, which result from the inability of the damaged liver cells to metabolize certain vitamins; responsible for impaired functioning of the central and peripheral nervous systems and for abnormal bleeding tendencies
- Hepatic encephalopathy or coma, reflecting accumulation of ammonia in the serum due to impaired protein metabolism by the diseased liver

## JAUNDICE

When the bilirubin concentration in the blood is abnormally elevated, all the body tissues, including the sclerae and the skin, become yellow-tinged or greenish-yellow, a condition called jaun-

dice. Jaundice becomes clinically evident when the serum bilirubin level exceeds 2.5 mg/dL (43 fmol/L). Increased serum bilirubin levels and jaundice may result from impairment of hepatic uptake, conjugation of bilirubin, or excretion of bilirubin into the biliary system. There are several types of jaundice: hemolytic, hepatocellular, obstructive, or jaundice due to hereditary hyperbilirubinemia. Hepatocellular and obstructive jaundice are the two types commonly associated with liver disease.

### Hemolytic Jaundice

Hemolytic jaundice is the result of an increased destruction of the red blood cells, the effect of which is to flood the plasma with bilirubin so rapidly that the liver, although functioning normally, cannot excrete the bilirubin as quickly as it is formed. This type of jaundice is encountered in patients with hemolytic transfusion reactions and other hemolytic disorders. The bilirubin in the blood of these patients is predominantly of the unconjugated, or free, type. Fecal and urine urobilinogen levels are increased, but the urine is free of bilirubin. Patients with this type of jaundice, unless their hyperbilirubinemia is extreme, do not experience symptoms or complications as a result of the jaundice per se. Prolonged jaundice, however, even if mild, predisposes to the formation of pigment stones in the gallbladder, and extremely severe jaundice (levels of free bilirubin exceeding 20 to 25 mg/dL) poses a risk for brain stem damage.

### Hepatocellular Jaundice

Hepatocellular jaundice is caused by the inability of damaged liver cells to clear normal amounts of bilirubin from the blood. The cellular damage may be from infection, such as in viral hepatitis (eg, hepatitis A, B, C, D, or E) or other viruses that affect the liver (eg, yellow fever virus, Epstein-Barr virus), from medication or chemical toxicity (eg, carbon tetrachloride, chloroform, phosphorus, arsenicals, certain medications), or from alcohol. Cirrhosis of the liver is a form of hepatocellular disease that may produce jaundice. It is usually associated with excessive alcohol intake, but it may also be a late result of liver cell necrosis caused by viral infection. In prolonged obstructive jaundice, cell damage eventually develops, so that both types appear together.

Patients with hepatocellular jaundice may be mildly or severely ill, with lack of appetite, nausea, malaise, fatigue, weakness, and possible weight loss. In some cases of hepatocellular disease, jaundice may not be obvious. The serum bilirubin concentration and urine urobilinogen level may be elevated. In addition, AST and ALT levels may be increased, indicating cellular necrosis. The patient may report headache, chills, and fever if the cause is infectious. Depending on the cause and extent of the liver cell damage, hepatocellular jaundice may or may not be completely reversible.

### Obstructive Jaundice

Obstructive jaundice of the extrahepatic type may be caused by occlusion of the bile duct by a gallstone, an inflammatory process, a tumor, or pressure from an enlarged organ. The obstruction may also involve the small bile ducts within the liver (ie, intrahepatic obstruction), caused, for example, by pressure on these channels from inflammatory swelling of the liver or by an inflammatory exudate within the ducts themselves. Intrahepatic obstruction resulting from stasis and inspissation (thickening) of bile within the canaliculi may occur after the ingestion of certain medications,

which are referred to as cholestatic agents. These include phenothiazines, antithyroid medications, sulfonyleureas, tricyclic antidepressants, nitrofurantoin, androgens, and estrogens.

Whether the obstruction is intrahepatic or extrahepatic, and whatever its cause may be, bile cannot flow normally into the intestine but is backed up into the liver substance. It is then reabsorbed into the blood and carried throughout the entire body, staining the skin, mucous membranes, and sclerae. It is excreted in the urine, which becomes deep orange and foamy. Because of the decreased amount of bile in the intestinal tract, the stools become light or clay-colored. The skin may itch intensely, requiring repeated soothing baths. Dyspepsia and intolerance to fatty foods may develop because of impaired fat digestion in the absence of intestinal bile. AST, ALT, and GGT levels generally rise only moderately, but bilirubin and alkaline phosphatase levels are elevated.

### Hereditary Hyperbilirubinemia

Increased serum bilirubin levels (hyperbilirubinemia) resulting from several inherited disorders can also produce jaundice. Gilbert's syndrome is a familial disorder characterized by an increased level of unconjugated bilirubin that causes jaundice. Although serum bilirubin levels are increased, liver histology and liver function test results are normal, and there is no hemolysis. This syndrome affects 2% to 5% of the population.

Other conditions that are probably caused by inborn errors of biliary metabolism include Dubin–Johnson syndrome (chronic idiopathic jaundice, with pigment in the liver) and Rotor's syndrome (chronic familial conjugated hyperbilirubinemia without pigment in the liver); “benign” cholestatic jaundice of pregnancy, with retention of conjugated bilirubin, probably secondary to unusual sensitivity to the hormones of pregnancy; and probably also benign recurrent intrahepatic cholestasis.

### PORTAL HYPERTENSION

Obstructed blood flow through the damaged liver results in increased blood pressure (**portal hypertension**) throughout the portal venous system. Although portal hypertension is commonly associated with hepatic cirrhosis, it can also occur with noncirrhotic liver disease. While splenomegaly (enlarged spleen) with possible hypersplenism is a common manifestation of portal hypertension, two major consequences of portal hypertension are ascites and varices.

In ascites, fluid accumulates in the abdominal cavity. Although ascites is often a result of liver damage, it may also occur with disorders such as cancer, kidney disease, and heart failure. Varices are varicosities that develop from elevated pressures transmitted to all of the veins that drain into the portal system. They are prone to rupture and often are the source of massive hemorrhages from the upper GI tract and the rectum. In addition, blood clotting abnormalities, often seen in patients with severe liver disease, increase the likelihood of bleeding.

### ASCITES

#### Pathophysiology

The mechanisms responsible for the development of ascites are not completely understood. Portal hypertension and the resulting increase in capillary pressure and obstruction of venous blood flow through the damaged liver are contributing factors. The failure of the liver to metabolize aldosterone increases sodium and water retention by the kidney. Sodium and water retention, in-

creased intravascular fluid volume, and decreased synthesis of albumin by the damaged liver all contribute to fluid moving from the vascular system into the peritoneal space. Loss of fluid into the peritoneal space causes further sodium and water retention by the kidney in an effort to maintain the vascular fluid volume, and the process becomes self-perpetuating.

As a result of liver damage, large amounts of albumin-rich fluid, 15 L or more, may accumulate in the peritoneal cavity as ascites. With the movement of albumin from the serum to the peritoneal cavity, the osmotic pressure of the serum decreases. This, combined with increased portal pressure, results in movement of fluid into the peritoneal cavity (Fig. 39-4).

### Clinical Manifestations

Increased abdominal girth and rapid weight gain are common presenting symptoms of ascites. The patient may be short of breath and uncomfortable from the enlarged abdomen, and striae and distended veins may be visible over the abdominal wall. Fluid and electrolyte imbalances are common.

### Assessment and Diagnostic Evaluation

The presence and extent of ascites are assessed by percussion of the abdomen. When fluid has accumulated in the peritoneal cavity, the flanks bulge when the patient assumes a supine position. The presence of fluid can be confirmed either by percussing for shifting dullness or by detecting a fluid wave (Fig. 39-5). A fluid wave is likely to be found only when a large amount of fluid is present.

### Physiology/Pathophysiology

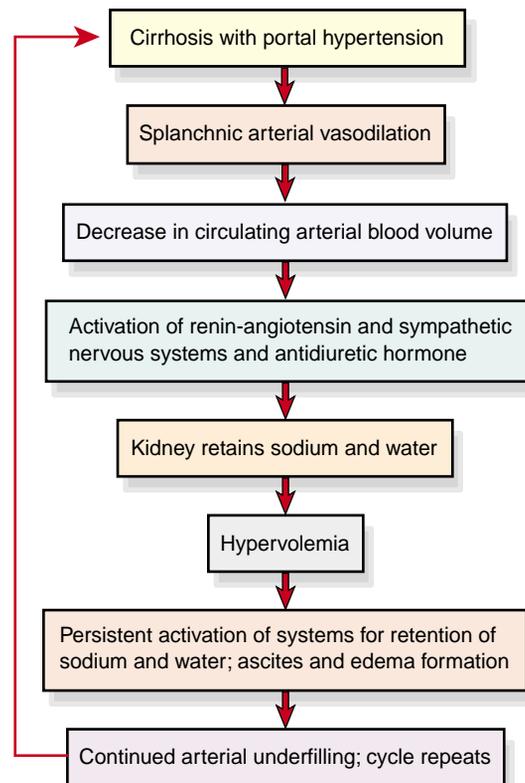

FIGURE 39-4 Pathogenesis of ascites (arterial vasodilation theory).

**FIGURE 39-5** Assessing for abdominal fluid wave. The examiner places the hands along the side of the patient's flank, then strikes one flank sharply, detecting any fluid wave with the other hand. An assistant's hand is placed (ulnar side down) along the patient's midline to prevent the fluid wave from being transmitted through the tissues of the abdominal wall.

Daily measurement and recording of abdominal girth and body weight are essential to assess the progression of ascites and its response to treatment.

## Medical Management

### DIETARY MODIFICATION

The goal of treatment for the patient with ascites is a negative sodium balance to reduce fluid retention. Table salt, salty foods, salted butter and margarine, and all ordinary canned and frozen foods (foods that are not specifically prepared for low-sodium diets) should be avoided. It may take 2 to 3 months for the patient's taste buds to adjust to unsalted foods. In the meantime, the taste of unsalted foods can be improved by using salt substitutes such as lemon juice, oregano, and thyme. Commercial salt substitutes need to be approved by the physician because those containing ammonia could precipitate hepatic coma. Most salt substitutes contain potassium and should be avoided if the patient has impaired renal function. The patient should make liberal use of powdered, low-sodium milk and milk products. If fluid accumulation is not controlled with this regimen, the daily sodium allowance may be reduced further to 500 mg, and diuretics may be administered.

Dietary control of ascites via strict sodium restriction is difficult to achieve at home. The likelihood that the patient will follow even a 2-g sodium diet increases if the patient and the person preparing meals understand the rationale for the diet and receive periodic guidance about selecting and preparing appropriate foods. Approximately 10% of patients with ascites respond to these measures alone. Nonresponders and those who find sodium restriction difficult require diuretic therapy.

### DIURETICS

Use of diuretics along with sodium restriction is successful in 90% of patients with ascites. Spironolactone (Aldactone), an aldosterone-

blocking agent, is most often the first-line therapy in patients with ascites from cirrhosis. When used with other diuretics, spironolactone helps prevent potassium loss. Oral diuretics such as furosemide (Lasix) may be added but should be used cautiously because with long-term use they may also induce severe sodium depletion (hyponatremia).

Ammonium chloride and acetazolamide (Diamox) are contraindicated because of the possibility of precipitating hepatic coma. Daily weight loss should not exceed 1 to 2 kg (2.2 to 4.4 lb) in patients with ascites and peripheral edema or 0.5 to 0.75 kg (1.1 to 1.65 lb) in patients without edema. Fluid restriction is not attempted unless the serum sodium concentration is very low.

Possible complications of diuretic therapy include fluid and electrolyte disturbances (including hypovolemia, hypokalemia, hyponatremia, and hypochloremic alkalosis) and encephalopathy. Encephalopathy may be precipitated by dehydration and hypovolemia. Also, when potassium stores are depleted, the amount of ammonia in the systemic circulation increases, which may cause impaired cerebral functioning and encephalopathy.

### BED REST

In patients with ascites, an upright posture is associated with activation of the renin-angiotensin-aldosterone system and sympathetic nervous system (Porth, 2002). This results in reduced renal glomerular filtration and sodium excretion and a decreased response to loop diuretics. Bed rest may be a useful therapy, especially for patients whose condition is refractory to diuretics.

### PARACENTESIS

Paracentesis is the removal of fluid (ascites) from the peritoneal cavity through a small surgical incision or puncture made through the abdominal wall under sterile conditions. Ultrasound guidance may be indicated in some patients at high risk for bleeding because of an abnormal coagulation profile or in those who have had previous abdominal surgery and who may have adhesions. Paracentesis was once considered a routine form of treatment for ascites but is now performed primarily for diagnostic examination of ascitic fluid, for treatment of massive ascites that is resistant to nutritional and diuretic therapy and that is causing severe problems to the patient, and as a prelude to diagnostic imaging studies, peritoneal dialysis, or surgery. A sample of the ascitic fluid may be sent to the laboratory for analysis. Cell count, albumin and total protein levels, culture, and occasionally other tests are performed.

Use of large-volume (5 to 6 liters) paracentesis has been shown to be a safe method for treating patients with severe ascites. This technique, in combination with the intravenous infusion of salt-poor albumin or other colloid, has become the standard treatment for refractory, massive ascites (Krige & Beckingham, 2001; Menon & Kamath, 2000). The salt-poor albumin helps reduce edema by causing the ascitic fluid to be drawn back into the bloodstream and ultimately eliminated by the kidneys. The procedure provides only temporary removal of fluid; it rapidly recurs, necessitating repeated removal. Nursing care of the patient undergoing paracentesis is presented in Chart 39-2.

### OTHER METHODS OF TREATMENT

Insertion of a peritoneovenous shunt to redirect ascitic fluid from the peritoneal cavity into the systemic circulation is a treatment modality for ascites, but this procedure is seldom used because of the high complication rate and high incidence of shunt failure. The shunt is reserved for those who are resistant to diuretic therapy, are not candidates for liver transplantation, have abdominal adhesions, or are ineligible for other procedures because of severe medical conditions, such as cardiac disease.

Chart  
39-2

## Assisting With a Paracentesis

**Preprocedure**

1. Prepare the patient by providing the necessary information and instructions about the procedure and by offering reassurance.
2. Instruct the patient to void.
3. Gather appropriate sterile equipment and collection receptacles.
4. Place patient in upright position on edge of bed with feet supported on stool, or place in chair. Fowler's position should be used for the patient confined to bed.
5. Place sphygmomanometer cuff around patient's arm to allow monitoring of blood pressure during the procedure.

**Procedure**

1. The physician, using aseptic technique, inserts the trocar through a puncture wound below the umbilicus. The fluid drains from the abdomen through a drainage tube into a container.
2. Help the patient maintain position throughout procedure.
3. Measure and record blood pressure at frequent intervals from the beginning of the procedure.
4. Monitor the patient closely for signs of vascular collapse: pallor, increased pulse rate, or decreased blood pressure.

**Postprocedure**

1. Return patient to bed or to a comfortable sitting position.
2. Measure, describe, and record the fluid collected.
3. Label samples of fluid and send to laboratory.
4. Continue to monitor vital signs every 15 minutes for 1 hour, every 30 minutes over 2 hours, then every hour over 2 hours and then every 4 hours. Monitor temperature after procedure and every 4 hours.
5. Assess for hypovolemia, electrolyte loss, changes in mental status, and encephalopathy.
6. Check puncture site when taking vital signs for bleeding and leakage.
7. Provide patient education (especially if patient is discharged after procedure) regarding monitoring for bleeding or excess drainage from puncture site, avoiding heavy lifting or straining, changing position slowly, and monitoring for fever.

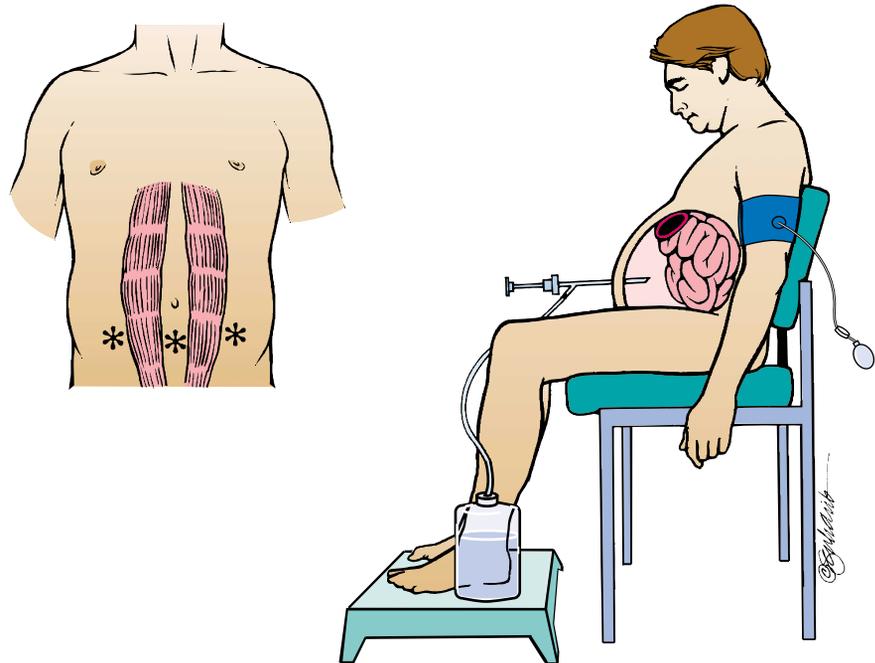

Figure on *left* shows possible sites for insertion of trocar.

**Nursing Management**

If a patient with ascites from liver dysfunction is hospitalized, nursing measures include assessment and documentation of intake and output, abdominal girth, and daily weight to assess fluid status. The nurse monitors serum ammonia and electrolyte levels to assess electrolyte balance, response to therapy, and indicators of encephalopathy.

**PROMOTING HOME AND COMMUNITY-BASED CARE**

**Teaching Patients Self-Care.** The patient treated for ascites is likely to be discharged with some ascites still present. Before hospital discharge, the nurse teaches the patient and family about the treatment plan, including the need to avoid all alcohol intake, adhere to a low-sodium diet, take medications as prescribed, and

check with the physician before taking any new medications (Chart 39-3). Additional patient and family teaching addresses skin care and the need to weigh the patient daily and to watch for and report signs and symptoms of complications.

**Continuing Care.** A referral for home care may be warranted, especially if the patient lives alone or cannot provide self-care. The home visit enables the nurse to assess changes in the patient's condition and weight, abdominal girth, skin, and cognitive and emotional status. The home care nurse assesses the home environment and the availability of resources needed to adhere to the treatment plan (eg, a scale to obtain daily weights, facilities to prepare and store appropriate foods, resources to purchase needed medications). It is important to assess the patient's adherence to the treatment plan and the ability to buy, prepare, and eat

## Chart 39-3

## Home Care Checklist • Management of Ascites

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Make appropriate dietary choices consistent with dietary prescription and recommendations.	✓	✓
• State the importance of weighing self daily and keeping a daily record of weight.	✓	✓
• Maintain record of weight daily and identify daily weight-loss goals.	✓	✓
• List weight changes (loss or gain) that should be reported to the primary health care provider.	✓	✓
• Explain the rationale for monitoring and recording daily intake and output.	✓	✓
• Identify changes in output that should be reported to primary health care provider (decreasing urine output).	✓	✓
• Identify rationale for fluid restrictions (if needed), and comply with fluid restriction.	✓	✓
• Discuss importance of avoiding nonsteroidal anti-inflammatory agents, medications (eg, cough mixtures) containing alcohol, antibiotics or antacids containing salt.	✓	✓
• Describe effects, side effects, and monitoring parameters for diuretic therapy.	✓	✓
• Identify need to stop all alcohol intake as critical to well-being.	✓	✓
• Explain how to contact Alcoholics Anonymous or alcohol counselors in related organizations.	✓	✓
• Demonstrate how to care for skin, alleviate pressure over bony prominences by turning when in bed or chair, and decrease edema by position changes.	✓	✓
• Identify early signs and symptoms of complications (encephalopathy, spontaneous bacterial peritonitis, dehydration, electrolyte abnormalities, azotemia).	✓	✓

appropriate foods. The nurse reinforces previous teaching and emphasizes the need for regular follow-up and the importance of keeping scheduled health care appointments.

## ESOPHAGEAL VARICES

Bleeding or hemorrhage from esophageal varices occurs in approximately one third of patients with cirrhosis and varices. The mortality rate resulting from the first bleeding episode is 45% to 50%; it is one of the major causes of death in patients with cirrhosis (Pomier-Layrargues, Villeneuve, Deschenes et al., 2001). The mortality rate increases with each subsequent bleeding episode.

### Pathophysiology

Esophageal varices are dilated, tortuous veins usually found in the submucosa of the lower esophagus, but they may develop higher in the esophagus or extend into the stomach. This condition nearly always is caused by portal hypertension, which in turn is due to obstruction of the portal venous circulation within the damaged liver.

Because of increased obstruction of the portal vein, venous blood from the intestinal tract and spleen seeks an outlet through collateral circulation (new pathways of return to the right atrium). The effect is increased pressure, particularly in the vessels in the submucosal layer of the lower esophagus and upper part of the stomach. These collateral vessels are not very elastic but rather are tortuous and fragile and bleed easily (Fig. 39-6). Less common causes of varices are abnormalities of the circulation in the splenic vein or superior vena cava and hepatic venothrombosis.

Bleeding esophageal varices are life-threatening and can result in hemorrhagic shock, producing decreased cerebral, hepatic, and renal perfusion. In turn, there is an increased nitrogen load from bleeding into the GI tract and an increased serum ammonia level, increasing the risk for encephalopathy. Usually the dilated veins cause no symptoms unless the portal pressure increases sharply and the mucosa or supporting structures become thin. Then massive hemorrhage takes place.

Factors that contribute to hemorrhage are muscular exertion from lifting heavy objects; straining at stool; sneezing, coughing, or

vomiting; esophagitis; irritation of vessels by poorly chewed foods or irritating fluids; or reflux of stomach contents (especially alcohol). Salicylates and any medication that erodes the esophageal mucosa or interferes with cell replication also may contribute to bleeding.

### Clinical Manifestations

The patient with bleeding esophageal varices may present with hematemesis, melena, or general deterioration in mental or physical status and often has a history of alcohol abuse. Signs and

### Physiology/Pathophysiology

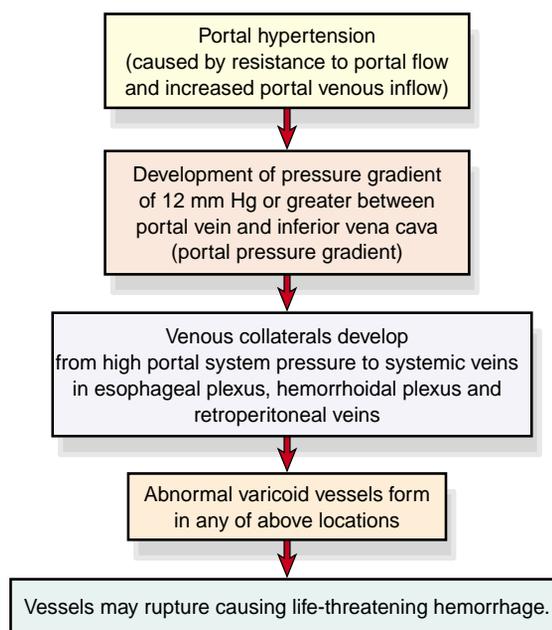

FIGURE 39-4 Pathogenesis of bleeding esophageal varices.

symptoms of shock (cool clammy skin, hypotension, tachycardia) may be present.

## Assessment and Diagnostic Findings

Endoscopy is used to identify the bleeding site, along with barium swallow, ultrasonography, CT, and angiography.

### ENDOSCOPY

Immediate endoscopy (see Chap. 34) is indicated to identify the cause and the site of bleeding; at least 30% of patients suspected of bleeding from esophageal varices bleed from other sources (gastritis, ulcers). Nursing support can be effective in relieving anxiety during this often-stressful experience. Careful monitoring can detect early signs of cardiac dysrhythmias, perforation, and hemorrhage.

After the examination, fluids are not given until the gag reflex returns. Lozenges and gargles may be used to relieve throat discomfort if the patient's physical condition and mental status permit. If the patient is actively bleeding, oral intake will not be permitted and the patient will be prepared for further diagnostic and therapeutic procedures.

### PORTAL HYPERTENSION MEASUREMENTS

Portal hypertension may be suspected if dilated abdominal veins and hemorrhoids are detected. A palpable enlarged spleen (splenomegaly) and ascites may also be present. Portal venous pressure can be measured directly or indirectly. Indirect measurement of the hepatic vein pressure gradient is the most common procedure; it requires insertion of a fluid-filled balloon catheter into the antecubital or femoral vein. The catheter is advanced under fluoroscopy to a hepatic vein. A "wedged" pressure (similar to pulmonary artery wedge pressure) is obtained by occluding the blood flow in the blood vessel; pressure in the unoccluded vessel is also measured. Although the values obtained may underestimate portal pressure, this measurement may be obtained several times to evaluate the results of therapy.

Direct measurement of portal vein pressure can be obtained by several methods. During laparotomy, a needle may be introduced into the spleen; a manometer reading of more than 20 mL saline is abnormal. Another direct measurement requires insertion of a catheter into the portal vein or one of its branches. Endoscopic measurement of pressure within varices is used only in conjunction with endoscopic sclerotherapy.

### LABORATORY TESTS

Laboratory tests may include various liver function tests, such as serum aminotransferase, bilirubin, alkaline phosphatase, and serum proteins. Splenoportography, which involves serial or segmental x-rays, is used to detect extensive collateral circulation in esophageal vessels, which would indicate varices. Other tests are hepatoportography and celiac angiography. These are usually performed in the operating room or radiology department.

## Medical Management

Bleeding from esophageal varices can quickly lead to hemorrhagic shock and is an emergency. This patient is critically ill, requiring aggressive medical care and expert nursing care, and is usually transferred to the intensive care unit for close monitoring and management. See Chapter 15 for a discussion of care of the patient in shock.

The extent of bleeding is evaluated and vital signs are monitored continuously when hematemesis and melena are present. Signs of

potential hypovolemia are noted, such as cold clammy skin, tachycardia, a drop in blood pressure, decreased urine output, restlessness, and weak peripheral pulses. Blood volume is monitored by a central venous pressure or arterial catheter. Oxygen is administered to prevent hypoxia and to maintain adequate blood oxygenation.

Because patients with bleeding esophageal varices have intravascular volume depletion and are subject to electrolyte imbalance, intravenous fluids with electrolytes and volume expanders are provided to restore fluid volume and replace electrolytes. Transfusion of blood components also may be required. An indwelling urinary catheter is usually inserted to permit frequent monitoring of urine output.

A variety of pharmacologic, endoscopic, and surgical approaches are used to treat bleeding esophageal varices, but none is ideal and most are associated with considerable risk to the patient. Non-surgical treatment of bleeding esophageal varices is preferable because of the high mortality rate of emergency surgery for control of bleeding esophageal varices and because of the poor physical condition of the patient with severe liver dysfunction.

### PHARMACOLOGIC THERAPY

In an actively bleeding patient, medications are administered initially because they can be obtained and administered quickly; other therapies take longer to initiate. Vasopressin (Pitressin) may be the initial mode of therapy because it produces constriction of the splanchnic arterial bed and a resulting decrease in portal pressure. It may be administered intravenously or by intra-arterial infusion (Menon & Kamath, 2000). Either method requires close monitoring by the nurse. Vital signs and the presence or absence of blood in the gastric aspirate indicate the effectiveness of vasopressin. Monitoring of fluid intake and output and electrolyte levels is necessary because hyponatremia may occur and vasopressin may have an antidiuretic effect. Coronary artery disease is a contraindication to the use of vasopressin, because coronary vasoconstriction is a side effect that may precipitate myocardial infarction.

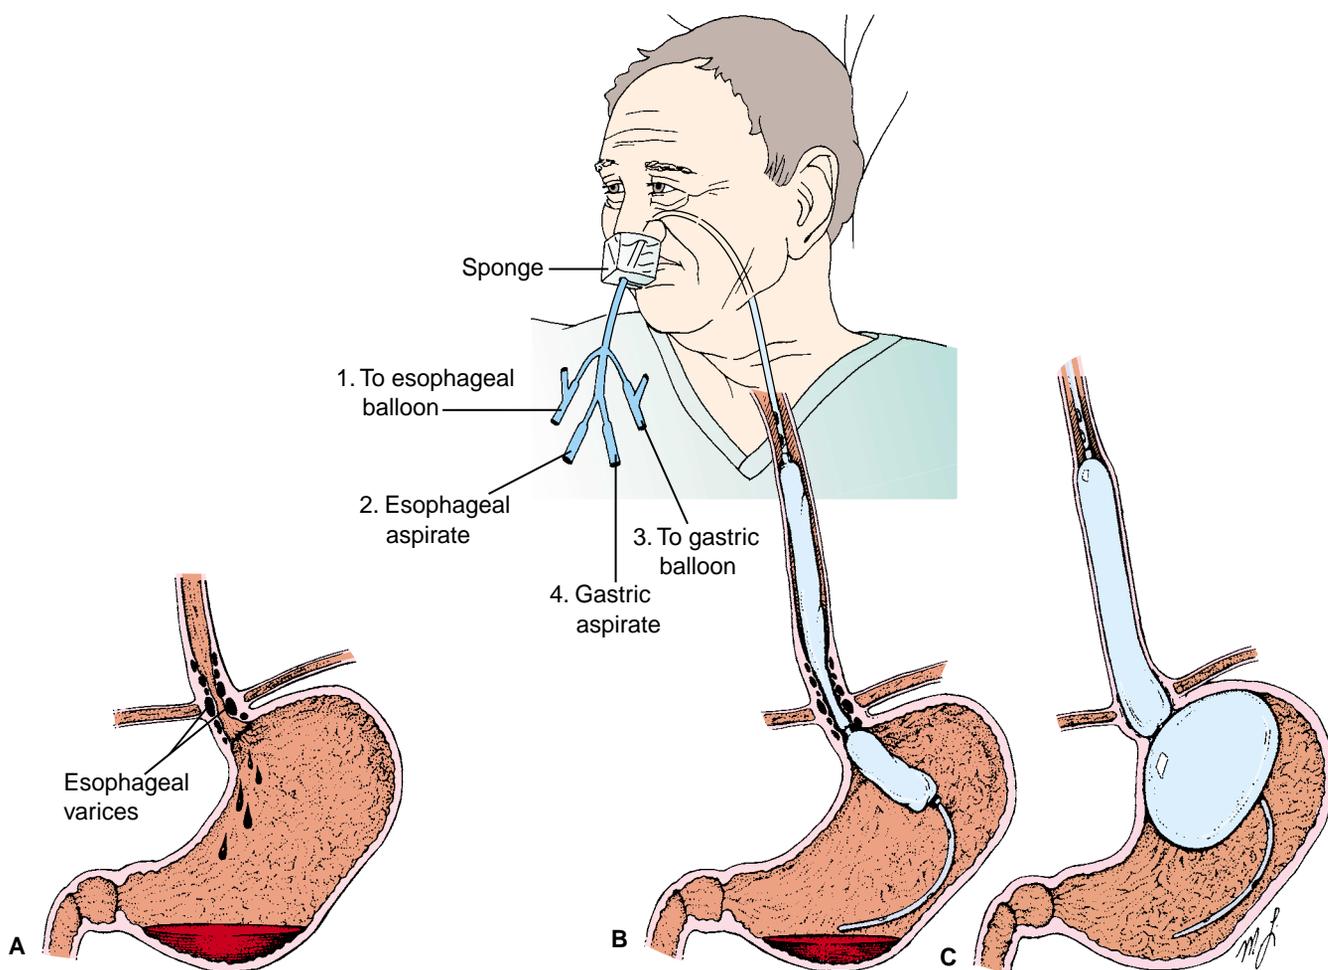

The combination of vasopressin and nitroglycerin (administered by the intravenous, sublingual, or transdermal route) has been effective in reducing or preventing the side effects (constriction of coronary vessels and angina) caused by vasopressin alone.

Somatostatin and octreotide (Sandostatin) have been reported to be more effective than vasopressin in decreasing bleeding from esophageal varices without the vasoconstrictive effects of vasopressin. These medications cause selective splanchnic vasoconstriction. Propranolol (Inderal) and nadolol (Corgard), beta-blocking agents that decrease portal pressure, have been shown to prevent bleeding from esophageal varices in some patients; however, it is recommended that they be used only in combination with other treatment modalities such as sclerotherapy, variceal banding, or balloon tamponade. Nitrates such as isosorbide (Isordil) lower portal pressure by venodilation and decreased cardiac output. Further studies of these and other medications are necessary to evaluate their use in the treatment and prevention of bleeding episodes.

### BALLOON TAMPONADE

To control hemorrhage in certain patients, **balloon tamponade** may be used. In this procedure, pressure is exerted on the cardia (upper orifice of the stomach) and against the bleeding varices by a double-balloon tamponade (Sengstaken-Blakemore tube) (Fig. 39-7). The tube has four openings, each with a specific purpose: gastric aspiration, esophageal aspiration, inflation of the gastric balloon, and inflation of the esophageal balloon.

The balloon in the stomach is inflated with 100 to 200 mL of air. An x-ray confirms proper positioning of the gastric balloon. Then the tube is pulled gently to exert a force against the gastric

**FIGURE 39-7** Esophageal balloon tamponade to treat esophageal varices. (A) Dilated, bleeding esophageal veins (varices) of the lower esophagus. (B) A four-lumen esophageal tamponade tube with balloons (uninflated) in place. (C) Compression of bleeding esophageal varices by inflated esophageal and gastric balloons. The gastric and esophageal outlets permit the nurse to aspirate secretions.

cardia. Traction may be applied with weights or by attachment to a football helmet. Irrigation of the tubing is performed to detect bleeding; if returns are clear, the esophageal balloon is not inflated. If bleeding continues, the esophageal balloon is inflated. The desired pressure in the esophageal and gastric balloons is 25 to 40 mm Hg, as measured by the manometer. There is a possibility of injury or rupture of the esophagus with inflation of the esophageal balloon, so constant nursing surveillance is necessary.

Gastric suction is provided by connecting the gastric catheter outlet to suction. The tubing is irrigated hourly, and drainage will indicate whether bleeding has been controlled. Room-temperature lavage or irrigation may be used in the gastric balloon. The pressure within the esophageal balloon is measured and recorded every 2 to 4 hours via the manometer to detect underinflation or overinflation with potential for esophageal injury. When it appears that bleeding has stopped, the balloons are carefully and sequentially deflated. The esophageal balloon is deflated first and the patient is monitored for recurrent bleeding. After several hours without bleeding, the gastric balloon may be deflated safely. If there is still no bleeding, the tamponade tube is removed. The therapy is used for as short a time as possible to control bleeding while emergency treatment is completed and definitive therapies are instituted (no longer than 24 hours).

Although balloon tamponade has been fairly successful, there are some inherent dangers. Displacement of the tube and the inflated balloon into the oropharynx can cause life-threatening obstruction of the airway and asphyxiation. This may occur if a patient pulls on the tube because of confusion or discomfort. It may also result from rupture of the gastric balloon, allowing the esophageal balloon to move into the oropharynx. Sudden rupture of the balloon causes airway obstruction and aspiration of gastric contents into the lungs. The tube is tested before insertion to minimize this risk. Aspiration of blood and secretions into the lungs is frequently associated with balloon tamponade, especially in the stuporous or comatose patient. Endotracheal intubation before insertion of the tube protects the airway and minimizes the risk of aspiration. Ulceration and necrosis of the nose, the mucosa of the stomach, or the esophagus may occur if the tube is left in place or inflated too long or at too high a pressure.

**NURSING ALERT** The patient being treated with balloon tamponade must never be left alone because of the risk for serious complications. The patient must be monitored closely and continuously. Precautions must be taken to ensure that the patient does not pull on or inadvertently displace the tube.

These potential complications necessitate intensive and expert care. A confused or restless patient with this tube in place and balloons inflated requires close monitoring to prevent its displacement. Nursing measures include frequent mouth and nasal care. For secretions that accumulate in the mouth, tissues should be within easy reach of the patient. Oral suction may be necessary to remove oral secretions. Because of the many potential complications, balloon tamponade tubes are used only as a temporary measure.

The patient with esophageal hemorrhage is usually extremely anxious and frightened. Knowing that the nurse is nearby and will respond immediately can help alleviate some of this anxiety. Tube insertion is uncomfortable and never pleasant. Explanations during the procedure and while the tube is in place may be reassuring to the patient.

Although the use of balloon tamponade stops the bleeding in 90% of patients, bleeding recurs in 60% to 70%, necessitating other treatment modalities (eg, sclerotherapy or banding) (Menon & Kamath, 2000). Once the balloons are deflated or the tube is removed, the patient must be assessed frequently because of the high risk for recurrent bleeding.

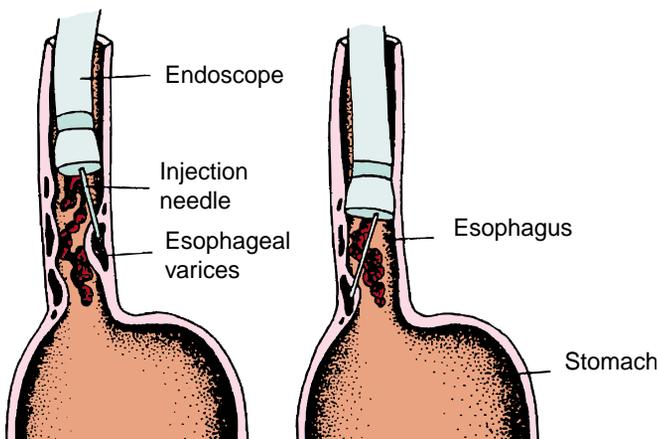

### ENDOSCOPIC SCLEROTHERAPY

In endoscopic **sclerotherapy** (Fig. 39-8) (also referred to as injection sclerotherapy), a sclerosing agent is injected through a fiberoptic endoscope into the bleeding esophageal varices to promote thrombosis and eventual sclerosis. The procedure has been used successfully to treat acute GI hemorrhage (Menon & Kamath, 2000; O'Grady et al., 2000). Endoscopic variceal sclerotherapy has been used in the primary prophylaxis of variceal bleeding, but the results are poorer than those of pharmacotherapy (Sarin, Lamba, Kumar et al., 1999).

After treatment, the patient must be observed for bleeding, perforation of the esophagus, aspiration pneumonia, and esophageal stricture. Antacids may be administered after the procedure to counteract the effects of peptic reflux.

### ESOPHAGEAL BANDING THERAPY (VARICEAL BAND LIGATION)

In **variceal banding** (Fig. 39-9), a modified endoscope loaded with an elastic rubber band is passed through an overtube directly onto the varix (or varices) to be banded. After suctioning the bleeding varix into the tip of the endoscope, the rubber band is slipped over the tissue, causing necrosis, ulceration, and eventual sloughing of the varix.

**FIGURE 39-8** Endoscopic or injection sclerotherapy. Injection of sclerosing agent into esophageal varices through an endoscope promotes thrombosis and eventual sclerosis, thereby obliterating the varices.

Variceal banding is comparable to endoscopic sclerotherapy in the effective control of bleeding. Compared with sclerotherapy, variceal banding also significantly reduces rebleeding rates, mortality, procedure-related complications, and the number of sessions needed to eradicate varices. Complications include superficial ulceration and dysphagia, transient chest discomfort, and rarely esophageal strictures (Menon & Kamath, 2000). Recently, endoscopic variceal band ligation has been shown to be safe and more effective than propranolol for preventing a first bleeding episode (Sarin et al., 1999).

### TRANSJUGULAR INTRAHEPATIC PORTOSYSTEMIC SHUNTING

Transjugular intrahepatic portosystemic shunting (TIPS) is a method of treating esophageal varices in which a cannula is threaded into the portal vein by the transjugular route. An expandable stent is inserted and serves as an intrahepatic shunt between the portal circulation and the hepatic vein (Fig. 39-10), reducing portal hypertension.

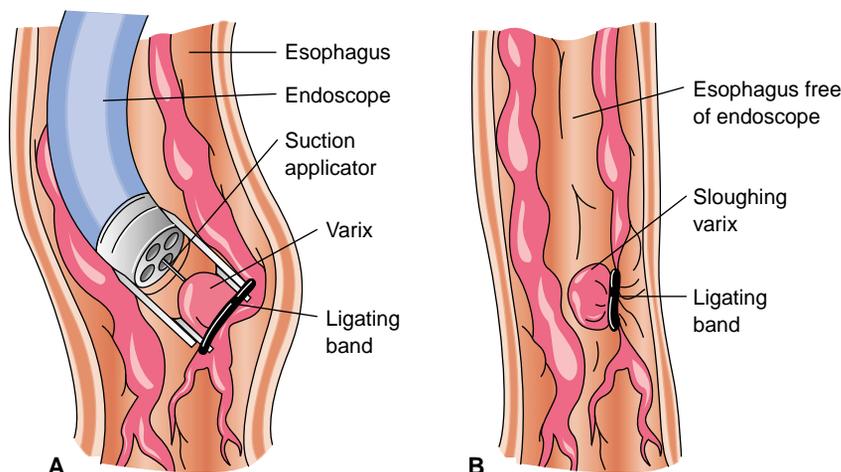

Creation of a TIPS is indicated for the treatment of recurrent variceal bleeding refractory to pharmacologic or endoscopic therapy. It has also been indicated for the control of refractory ascites. This technique is also used as a bridge to liver transplantation. Complications may include bleeding, sepsis, heart failure, organ perforation, shunt thrombosis, and progressive liver failure (Pomier-Layrargues et al., 2001).

### SURGICAL MANAGEMENT

Several surgical procedures have been developed to treat esophageal varices and to minimize rebleeding, but they are often accompanied by significant risk. Procedures that may be used for esophageal varices are direct surgical ligation of varices; splenorenal, mesocaval, and portacaval venous shunts to relieve portal pressure; and esophageal transection with devascularization. Use of these procedures is controversial, and studies regarding their effectiveness and outcomes are ongoing (Bacon & Di Bisceglie, 2000).

**Surgical Bypass Procedures.** Surgical decompression of the portal circulation can prevent variceal bleeding if the shunt remains patent (Bacon & Di Bisceglie, 2000). One of the various surgical shunting procedures (Fig. 39-11) is the distal splenorenal shunt made between the splenic vein and the left renal vein after splenectomy. A mesocaval shunt is created by anastomosing the superior mesenteric vein to the proximal end of the vena cava or to the side of the vena cava using grafting material. The goal of distal splenorenal and mesocaval shunts is to drain only a portion of venous blood from the portal bed to decrease portal pressure; thus, they are considered selective shunts. The liver continues to receive some portal flow, and the incidence of encephalopathy may be reduced. Portacaval shunts divert all portal flow to the vena cava via end-to-side or side-to-side approaches, so they are considered nonselective shunts.

These procedures are extensive and are not always successful because of secondary thrombosis in the veins used for the shunt as well as complications (eg, encephalopathy, accelerated liver failure). The efficacy of these procedures has been studied extensively. The most recent studies have found that all shunts are equally effective in preventing recurrent variceal bleeding but may cause further impairment of liver function and encephalopathy. Partial portacaval shunts with interposition grafts are as effective as other shunts but are associated with a lower rate of encephalopathy (de Franchis, 2000; Krige & Beckingham, 2001; Orozco & Mercado, 2000). The severity of the disease (by Child's classification) and the

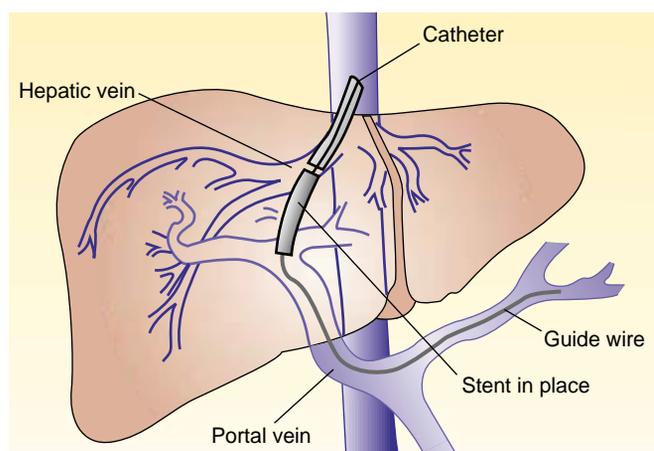

**FIGURE 39-9** Esophageal banding. (A) A rubber band-like ligature is slipped over an esophageal varix via an endoscope. (B) Necrosis results and the varix eventually sloughs off.

potential for future liver transplantation guide the physician's choice of intervention. If the cause of portal hypertension is the rare **Budd-Chiari syndrome** or other venous obstructive disease, a portacaval or a mesoatrial shunt may be performed (see Fig. 39-11). The mesoatrial shunt is required when the infrahepatic vena cava is thrombosed and must be bypassed.

**Devascularization and Transection.** Devascularization and staplegun transection procedures to separate the bleeding site from the high-pressure portal system have been used in the emergency management of variceal bleeding. The lower end of the esophagus is reached through a small gastrostomy incision; a staplegun permits anastomosis of the transected ends of the esophagus. Rebleeding is a risk, and the outcomes of these procedures vary among patient populations.

**NURSING ALERT** Postoperative care is similar to that for any abdominal surgery, but the risk for complications (hypovolemic or hemorrhagic shock, hepatic encephalopathy, electrolyte imbalance, metabolic and respiratory alkalosis, alcohol withdrawal syndrome, and seizures) is high. The surgical procedures do not alter the course of the progressive liver disease, and bleeding may recur as new collateral vessels develop.

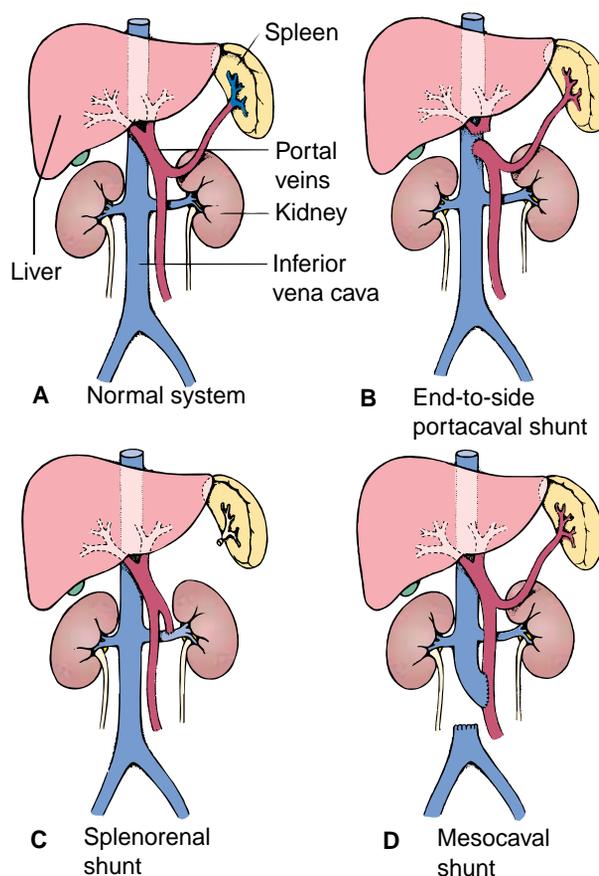

**FIGURE 39-10** Transjugular intrahepatic portosystemic shunt (TIPS). A stent is inserted via catheter to the portal vein to divert blood flow and reduce portal hypertension.

## Nursing Management

Overall nursing assessment includes monitoring the patient's physical condition and evaluating emotional responses and cognitive status. The nurse monitors and records vital signs and assesses the patient's nutritional and neurologic status. This assessment will assist in identifying hepatic encephalopathy resulting from the breakdown of blood in the GI tract and a rising serum ammonia level. Manifestations range from drowsiness to encephalopathy and coma.

Complete rest of the esophagus may be indicated with bleeding, so parenteral nutrition is initiated. Gastric suction usually is

**FIGURE 39-11** Portal systemic shunts. Normal portal system is shown in (A); examples of portal shunts to reduce portal pressure are shown in (B) to (D).

initiated to keep the stomach as empty as possible and to prevent straining and vomiting. The patient often complains of severe thirst, which may be relieved by frequent oral hygiene and moist sponges to the lips. The nurse closely monitors the blood pressure. Vitamin K therapy and multiple blood transfusions often are indicated because of blood loss. A quiet environment and calm reassurance may help to relieve the patient's anxiety and reduce agitation.

Bleeding anywhere in the body is anxiety-provoking, resulting in a crisis for the patient and family. If the patient has been a heavy user of alcohol, delirium secondary to alcohol withdrawal can complicate the situation. The nurse provides support and explanations regarding medical and nursing interventions. Monitoring the patient closely will help in detecting and managing complications.

Management modalities and nursing care of the patient with bleeding esophageal varices are summarized in Table 39-2.

## HEPATIC ENCEPHALOPATHY AND COMA

**Hepatic encephalopathy**, a life-threatening complication of liver disease, occurs with profound liver failure and may result from the accumulation of ammonia and other toxic metabolites in the blood. Hepatic coma represents the most advanced stage of hepatic encephalopathy. Some researchers describe a false or weak neurotransmitter as a cause, but the exact mechanism is not fully understood. These false neurotransmitters may be generated from an intestinal source and result in the precipitation of encephalopathy. Many other theories exist about the causes of encephalopathy, including excess tryptophan and its metabolites,

**Table 39-2 • Management Modalities and Nursing Care for the Patient With Bleeding Esophageal Varices**

TREATMENT MODALITY*	ACTION	NURSING PRIORITIES
<b>Nonsurgical Modalities</b>		
Pharmacologic agents		
Vasopressin (Pitressin)	Reduces portal pressure by constricting splanchnic arteries	Observe response to therapy. Monitor for side effects: <i>vasopressin</i> —angina; nitroglycerin may be prescribed to prevent or treat angina. <i>propranolol and nadolol</i> —decreased pulse pressure, impaired cardiovascular response to hemorrhage.
Propranolol (Inderal)/nadolol (Corgard)	Reduces portal pressure by $\beta$ -adrenergic blocking action	Support patient during treatment. Explain procedure to patient briefly to obtain cooperation with insertion and maintenance of esophageal tamponade tube and reduce patient's fear of the procedure. Monitor closely to prevent inadvertent removal or displacement of tube, subsequent airway obstruction, and aspiration. Provide frequent oral hygiene.
Somatostatin/octreotide (Sandostatin)	Reduces portal pressure by selective vasodilation of portal system	Ensure patency of the nasogastric tube to prevent aspiration. Observe gastric aspirate for blood and cessation of bleeding.
Balloon tamponade	Exerts pressure directly to bleeding sites in esophagus and stomach	Observe for aspiration, perforation of the esophagus, and recurrence of bleeding after treatment.
Room-temperature saline lavage	Clears blood and secretions before endoscopy and other procedures	Observe for recurrence of bleeding, esophageal perforation. Observe for rebleeding and signs of infection.
Injection sclerotherapy	Promotes thrombosis and sclerosing of bleeding sites by injection of sclerosing agent into the esophageal varices	
Variceal banding	Provides thrombosis and mucosal necrosis of bleeding sites by band ligation	
Transjugular intrahepatic portosystemic shunting (TIPS)	Reduces portal pressure by creating a shunt within the liver between the portal and systemic venous system.	
<b>Surgical Modalities</b>		
Portal-systemic shunting	Reduces portal hypertension by diverting blood flow away from obstructed portal system	Observe for development of portal-systemic encephalopathy (altered mental status, neurologic dysfunction), hepatic failure, and rebleeding. Requires intensive, expert nursing care for prolonged period.
Surgical ligation of varices	Ties off blood vessels at the site of bleeding	Observe for rebleeding.
Esophageal transection and devascularization	Separates bleeding site from portal system	Observe for rebleeding. Provide postthoracotomy care.

\*Several modalities may be used concurrently or in sequence.

and endogenous benzodiazepines or opiates. Benzodiazepine-like chemicals (compounds) have been detected in the plasma and cerebrospinal fluid of patients with hepatic encephalopathy due to cirrhosis (Bacon & Di Bisceglie, 2000).

Portal-systemic encephalopathy, the most common type of hepatic encephalopathy, occurs primarily in patients with cirrhosis with portal hypertension and portal-systemic shunting.

## Pathophysiology

Ammonia accumulates because damaged liver cells fail to detoxify and convert to urea the ammonia that is constantly entering the bloodstream. Ammonia enters the bloodstream as a result of its absorption from the GI tract and its liberation from kidney and muscle cells. The increased ammonia concentration in the blood causes brain dysfunction and damage, resulting in hepatic encephalopathy.

Circumstances that increase serum ammonia levels tend to aggravate or precipitate hepatic encephalopathy. The largest source of ammonia is the enzymatic and bacterial digestion of dietary and blood proteins in the GI tract. Ammonia from these sources is increased as a result of GI bleeding (ie, bleeding esophageal varices or chronic GI bleeding), a high-protein diet, bacterial infections, and uremia. The ingestion of ammonium salts also increases the blood ammonia level. In the presence of alkalosis or hypokalemia, increased amounts of ammonia are absorbed from the GI tract and from the renal tubular fluid. Conversely, serum ammonia is decreased by elimination of protein from the diet and by the administration of antibiotic agents, such as neomycin sulfate, that reduce the number of intestinal bacteria capable of converting urea to ammonia (Dudek, 2001).

Other factors unrelated to increased serum ammonia levels that may cause hepatic encephalopathy in susceptible patients include excessive diuresis, dehydration, infections, surgery, fever, and some medications (sedative agents, tranquilizers, analgesic agents, and diuretic medications that cause potassium loss). Table 39-3 presents the stages of hepatic encephalopathy, common signs and symptoms, and potential nursing diagnoses for each stage.

## Clinical Manifestations

The earliest symptoms of hepatic encephalopathy include minor mental changes and motor disturbances. The patient appears slightly confused, has alterations in mood, becomes unkempt, and has altered sleep patterns. The patient tends to sleep during the day and have restlessness and insomnia at night. As hepatic encephalopathy progresses, the patient may be difficult to awaken.

**Asterixis** (flapping tremor of the hands) may occur (Fig. 39-12). Simple tasks, such as handwriting, become difficult. A handwriting or drawing sample (eg, star figure), taken daily, may provide graphic evidence of progression or reversal of hepatic encephalopathy. Inability to reproduce a simple figure (Fig. 39-13) is referred to as **constructional apraxia**. In the early stages of hepatic encephalopathy, the deep tendon reflexes are hyperactive; with worsening of hepatic encephalopathy, these reflexes disappear and the extremities may become flaccid.

## Assessment and Diagnostic Findings

The electroencephalogram (EEG) shows generalized slowing, an increase in the amplitude of brain waves, and characteristic triphasic waves. Occasionally, **fetor hepaticus**, a sweet, slightly fecal odor to the breath presumed to be of intestinal origin may be noticed. The odor has also been described as similar to that of freshly mowed grass, acetone, or old wine. Fetor hepaticus is prevalent with extensive collateral portal circulation in chronic liver disease. In a more advanced stage, there are gross disturbances of consciousness and the patient is completely disoriented with respect to time and place. With further progression of the disorder, the patient lapses into frank coma and may have seizures. Approximately 35% of all patients with cirrhosis of the liver die in hepatic coma.

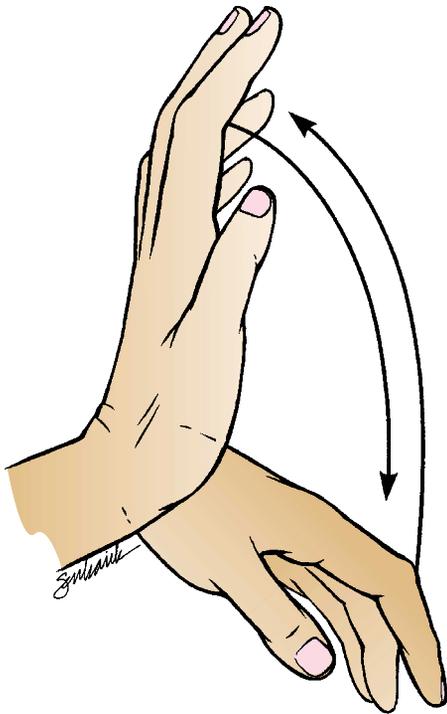

## Medical Management

Lactulose (Cephulac) is administered to reduce serum ammonia levels. It acts by several mechanisms that promote the excretion of ammonia in the stool: (1) ammonia is kept in the ionized state, resulting in a fall in colon pH, reversing the normal passage of ammonia from the colon to the blood; (2) evacuation of the bowel takes place, which decreases the ammonia

**Table 39-3 • Stages of Hepatic Encephalopathy and Possible Nursing Diagnoses\***

STAGE	CLINICAL SYMPTOMS	CLINICAL SIGNS AND EEG CHANGES	SELECTED POTENTIAL NURSING DIAGNOSES
1	Normal level of consciousness with periods of lethargy and euphoria; reversal of day–night sleep patterns	Asterixis; impaired writing and ability to draw line figures. Normal EEG.	Activity intolerance Self-care deficit Disturbed sleep pattern
2	Increased drowsiness; disorientation; inappropriate behavior; mood swings; agitation	Asterixis; fetor hepaticus. Abnormal EEG with generalized slowing.	Impaired social interaction Ineffective role performance Risk for injury
3	Stuporous; difficult to rouse; sleeps most of time; marked confusion; incoherent speech	Asterixis; increased deep tendon reflexes; rigidity of extremities. EEG markedly abnormal.	Imbalanced nutrition Impaired mobility Impaired verbal communication
4	Comatose; may not respond to painful stimuli	Absence of asterixis; absence of deep tendon reflexes; flaccidity of extremities. EEG markedly abnormal.	Risk for aspiration Impaired gas exchange Impaired tissue integrity Disturbed sensory perception

\*Nursing diagnoses are likely to progress, so that most nursing diagnoses present at earlier stages will occur during later stages as well.

**FIGURE 39-12** Asterixis or “liver flap” may occur in hepatic encephalopathy. The patient is asked to hold the arm out with the hand held upward (dorsiflexed). Within a few seconds, the hand falls forward involuntarily and then quickly returns to the dorsiflexed position.

absorbed from the colon; and (3) the fecal flora are changed to organisms that do not produce ammonia from urea. Two or three soft stools per day are desirable; this indicates that lactulose is performing as intended.

**NURSING ALERT** The patient receiving lactulose is monitored closely for the development of watery diarrheal stools, because they indicate a medication overdose.

Possible side effects include intestinal bloating and cramps, which usually disappear within a week. To mask the sweet taste,

**FIGURE 39-13** Effects of constructional apraxia. Deterioration of handwriting and inability to draw a simple star figure occurs with progressive hepatic encephalopathy. With permission from Sherlock S. & Dooley, J. (1997). *Diseases of the liver and biliary system* (10th ed). Olney Mead, Blackwell Scientific Ltd.

to which some patients object, lactulose can be diluted with fruit juice. The patient is closely monitored for hypokalemia and dehydration. Other laxatives are not prescribed during lactulose administration because their effects would disturb dosage regulation. Lactulose can be administered by nasogastric tube or enema for patients who are comatose or in whom oral administration is contraindicated or impossible.

Other aspects of management include intravenous administration of glucose to minimize protein breakdown, administration of vitamins to correct deficiencies, and correction of electrolyte imbalances (especially potassium). Additional principles of management of hepatic encephalopathy include the following:

- Therapy is directed toward treating or removing the cause.
- Neurologic status is assessed frequently. A daily record is kept of handwriting and performance in arithmetic to monitor mental status.
- Fluid intake and output and body weight are recorded each day.
- Vital signs are measured and recorded every 4 hours.
- Potential sites of infection (peritoneum, lungs) are assessed frequently, and abnormal findings are reported promptly.
- Serum ammonia level is monitored daily.
- Protein intake is restricted in patients who are comatose or who have encephalopathy that is refractory to lactulose and antibiotic therapy (Chart 39-4).
- Reduction in the absorption of ammonia from the GI tract is accomplished by the use of gastric suction, enemas, or oral antibiotics.
- Electrolyte status is monitored and corrected if abnormal.
- Sedatives, tranquilizers, and analgesic medications are discontinued.
- Benzodiazepine antagonists (flumazenil [Romazicon]) may be administered to improve encephalopathy whether or not the patient has previously taken benzodiazepines.

## Nursing Management

The nurse is responsible for maintaining a safe environment to prevent injury, bleeding, and infection. The nurse administers the prescribed treatments and monitors the patient for the many potential complications. The nurse also communicates with the pa-

Chart  
39-4

### Nutritional Management of Hepatic Encephalopathy

- Prevent the formation and absorption of toxins, principally ammonia, from the intestine.
- Keep daily protein intake between 1.0 and 1.5 g/kg, depending on the degree of decompensation.
- Avoid protein restriction if possible, even in those with encephalopathy. If necessary, implement temporary restriction of 0.5 g/kg.
- For patients who are truly protein-intolerant, provide additional nitrogen in the form of an amino acid supplement. Use of branched-chain amino acids is still controversial.
- Provide small, frequent meals and an evening snack of complex carbohydrates to avoid protein loading.
- Substitute vegetable protein for animal protein in as high a percentage as possible.

tient's family to keep them informed about the patient's status, and supports them by explaining the procedures and treatments that are part of the patient's care. If the patient recovers from hepatic encephalopathy and coma, rehabilitation is likely to be prolonged. Thus, the patient and family will require assistance to understand the causes of this severe complication and to recognize that it may recur.

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** If the patient has recovered from hepatic encephalopathy and is to be discharged home, the nurse instructs the family to watch for subtle signs of recurrent encephalopathy. In the acute phase of hepatic encephalopathy, dietary protein may be reduced to 0.8 to 1.0 g/kg per day. During recovery, and in the home situation, it is important to instruct the patient in maintenance of a low-protein, high-calorie diet. Protein may then be added in 10-g increments every 3 to 5 days. Any relapse is treated by a return to the previous level. The limits of tolerance are usually 40 to 60 g/day (1.0 to 1.5 g/kg per day). Continued use of lactulose in the home environment is not uncommon, and the patient and family should monitor its efficacy and side effects closely. Use of vegetable rather than animal protein may be indicated in patients whose total daily protein tolerance is less than 1 g/kg. Vegetable protein intake may result in improved nitrogen balance without precipitating or advancing hepatic encephalopathy (Menon & Kamath, 2000; Seymour & Whelan, 1999).

**Continuing Care.** Referral for home care is warranted for the patient who returns home after recovery from hepatic encephalopathy. The home care nurse assesses the patient's physical and mental status and collaborates closely with the physician. The home visit also provides an opportunity for the nurse to assess the home environment and the ability of the patient and family to monitor signs and symptoms and to follow the treatment regimen. Home care visits are particularly important if the patient lives alone, because encephalopathy may affect the patient's ability to remember or follow the treatment regimen. The nurse reinforces previous teaching and reminds the patient and family about the importance of dietary restrictions, close monitoring, and follow-up.

## OTHER MANIFESTATIONS OF LIVER DYSFUNCTION

### Edema and Bleeding

Many patients with liver dysfunction develop generalized edema from hypoalbuminemia that results from decreased hepatic production of albumin. The production of blood clotting factors by the liver is also reduced, leading to an increased incidence of bruising, epistaxis, bleeding from wounds, and, as described above, GI bleeding.

### Vitamin Deficiency

Decreased production of several clotting factors may be due, in part, to deficient absorption of vitamin K from the GI tract. This probably is caused by the inability of liver cells to use vitamin K to make prothrombin. Absorption of the other fat-soluble vitamins (vitamins A, D, and E) as well as dietary fats may also be impaired because of decreased secretion of bile salts into the intestine.

Another group of problems common to patients with severe chronic liver dysfunction results from inadequate intake of sufficient vitamins. Among the specific deficiency states that occur on this basis are:

- Vitamin A deficiency, resulting in night blindness and eye and skin changes
- Thiamine deficiency, leading to beriberi, polyneuritis, and Wernicke-Korsakoff psychosis
- Riboflavin deficiency, resulting in characteristic skin and mucous membrane lesions
- Pyridoxine deficiency, resulting in skin and mucous membrane lesions and neurologic changes
- Vitamin C deficiency, resulting in the hemorrhagic lesions of scurvy
- Vitamin K deficiency, resulting in hypoprothrombinemia, characterized by spontaneous bleeding and ecchymoses
- Folic acid deficiency, resulting in macrocytic anemia

The threat of these avitaminoses provides the rationale for supplementing the diet of every patient with chronic liver disease (especially if alcohol-related) with ample quantities of vitamins A, B complex, C, and K and folic acid.

### Metabolic Abnormalities

Abnormalities of glucose metabolism also occur; the blood glucose level may be abnormally high shortly after a meal (a diabetic-type glucose tolerance test result), but hypoglycemia may occur during fasting because of decreased hepatic glycogen reserves and decreased gluconeogenesis. Because the ability to metabolize medications is decreased, medications must be used cautiously and usual medication dosages must be reduced for the patient with liver failure.

Many endocrine abnormalities also occur with liver dysfunction because the liver cannot metabolize hormones normally, including androgens or sex hormones. Gynecomastia, amenorrhea, testicular atrophy, loss of pubic hair in the male, and menstrual irregularities in the female and other disturbances of sexual function and sex characteristics are thought to result from failure of the damaged liver to inactivate estrogens normally.

### Pruritus and Other Skin Changes

Patients with liver dysfunction resulting from biliary obstruction commonly develop severe itching (pruritus) due to retention of bile salts. Patients may develop vascular (or arterial) spider angiomas (Fig. 39-14) on the skin, generally above the waistline. These are numerous small vessels resembling a spider's legs. These are most frequently associated with cirrhosis, especially in alcoholic liver disease. Patients may also develop reddened palms ("liver palms" or palmar erythema).

## Management of Patients With Viral Hepatic Disorders

### VIRAL HEPATITIS

Viral hepatitis is a systemic, viral infection in which necrosis and inflammation of liver cells produce a characteristic cluster of clinical, biochemical, and cellular changes. To date, five definitive

**FIGURE 39-14** Spider angioma. This vascular (arterial) spider appears on the skin. Beneath the elevated center and radiating branches, the blood vessels are looped and tortuous.

types of viral hepatitis have been identified: hepatitis A, B, C, D, and E. Hepatitis A and E are similar in mode of transmission (fecal–oral route), whereas hepatitis B, C, and D share many characteristics. Terms associated with viral hepatitis are listed in Chart 39-5. The increasing incidence of viral hepatitis is a pub-

lic health concern. The disease is important because it is easy to transmit, has high morbidity, and causes prolonged loss of time from school or employment.

It is estimated that 60% to 90% of cases of viral hepatitis go unreported. The occurrence of subclinical cases, failure to recognize mild cases, and misdiagnosis are thought to contribute to the underreporting. Although approximately 40% of all persons in the United States have antibodies against hepatitis A virus, many cannot recall an earlier episode or the occurrence of the symptoms of hepatitis (O’Grady et al., 2000). Table 39-4 compares the major forms of viral hepatitis.

## HEPATITIS A VIRUS (HAV)

HAV accounts for 20% to 25% of cases of clinical hepatitis in the developed world. Hepatitis A, formerly called infectious hepatitis, is caused by an RNA virus of the Enterovirus family. The mode of transmission of this disease is the fecal–oral route, primarily through the ingestion of food or liquids infected by the virus. The virus has been found in the stool of infected patients before the onset of symptoms and during the first few days of illness. Typically, a child or a young adult acquires the infection at school by poor hygiene, hand-to-mouth contact, or close contact at play. The virus is carried home, where haphazard sanitary habits spread it through the family. It is more prevalent in developing countries or in areas with overcrowding and poor sanitation. An infected food handler can spread the disease, and people can contract it by consuming water or shellfish from sewage-contaminated waters. Outbreaks have occurred in day care centers and institutions for the developmentally delayed because of lapses in hygiene. It is rarely, if ever, transmitted by blood transfusions. Hepatitis A can be transmitted during sexual activity; this is more likely with

### Chart 39-5

## Hepatitis Terms and Abbreviations

### Hepatitis A

HAV	Hepatitis A virus; etiologic agent of hepatitis A (formerly infectious hepatitis)
Anti-HAV	Antibody to hepatitis A virus; appears in serum soon after onset of symptoms; disappears after 3–12 months
IgM anti-HAV	IgM antibody to HAV; indicates recent infection with HAV; positive up to 6 months after infection

### Hepatitis B

HBV	Hepatitis B virus; etiologic agent of hepatitis B (formerly serum hepatitis)
HBsAg	Hepatitis B surface antigen (Australian antigen); indicates acute or chronic hepatitis B or carrier state; indicates infectious state
Anti-HBs	Antibody to hepatitis B surface antigen; indicates prior exposure and immunity to hepatitis; may indicate passive antibody from HBIG or immune response from hepatitis B vaccine
HB <sub>e</sub> Ag	Hepatitis B e-antigen; present in serum early in course; indicates highly infectious stage of hepatitis B; persistence in serum indicates progression to chronic hepatitis
Anti-HB <sub>e</sub>	Antibody to hepatitis B e-antigen; suggests low titer of HBV
HBcAg	Hepatitis B core antigen; found in liver cells; not easily detected in serum
Anti-HBc	Antibody to hepatitis B core antigen; most sensitive indicator of hepatitis B; appears late in the acute phase of the disease; indicates infection of HBV at some time in the past
IgM anti-HBc	IgM antibody to HBcAg; present for up to 6 months after HBV infection

### Hepatitis C

HCV	Hepatitis C virus (formerly non-A, non-B virus); may be more than one virus
-----	---

### Hepatitis D

HDV	Hepatitis D virus (delta agent); etiologic agent to hepatitis D; HBV required for replication
HD <sub>Ag</sub>	Hepatitis delta antigen; detectable in early acute HDV infection
Anti-HDV	Antibody to HDV; indicates past or present infection with HDV

### Hepatitis E

HEV	Hepatitis E virus; etiologic agent of hepatitis E
-----	---

### Hepatitis G

HGV	Hepatitis G virus; also known as GB virus C
-----	---

**Table 39-4 • Comparison of Major Forms of Viral Hepatitis**

	HEPATITIS A	HEPATITIS B	HEPATITIS C	HEPATITIS D	HEPATITIS E
<i>Previous names</i>	Infectious hepatitis	Serum hepatitis	Non-A, non-B hepatitis		
<b>Epidemiology</b>					
<i>Cause</i>	Hepatitis A virus (HAV)	Hepatitis B virus (HBV)	Hepatitis C virus (HCV)	Hepatitis D virus (HDV)	Hepatitis E virus (HEV)
<i>Mode of transmission</i>	Fecal–oral route; poor sanitation. Person-to-person contact. Waterborne; foodborne. Transmission possible with oral–anal contact during sex.	Parenterally; by intimate contact with carriers or those with acute disease; sexual and oral–oral contact. Perinatal transmission from mothers to infants. An important occupational hazard for health care personnel.	Transfusion of blood and blood products; exposure to contaminated blood through equipment or drug paraphernalia. Transmission possible with sex with infected partner; risk increased with STD.	Same as HBV. HBV surface antigen necessary for replication; pattern similar to that of hepatitis B.	Fecal–oral route; person to person contact may be possible, although risk appears low
<i>Incubation (days)</i>	15–50 days	28–160 days	15–160 days	21–140 days	15–65 days
<i>Immunity</i>	Average: 30 days Homologous	Average: 70–80 days Homologous	Average: 50 days Second attack may indicate weak immunity or infection with another agent.	Average: 35 days Homologous	Average: 42 days Unknown
<b>Nature of Illness</b>					
<i>Signs and symptoms</i>	May occur with or without symptoms; flulike illness <i>Preicteric phase:</i> Headache, malaise, fatigue, anorexia, fever <i>Icteric phase:</i> Dark urine, jaundice of sclera and skin, tender liver	May occur without symptoms May develop arthralgias, rash	Similar to HBV; less severe and anicteric	Similar to HBV	Similar to HAV. Very severe in pregnant women.
<i>Outcome</i>	Usually mild with recovery. Fatality rate: <1%. No carrier state or increased risk of chronic hepatitis, cirrhosis, or hepatic cancer.	May be severe. Fatality rate: 1%–10%. Carrier state possible. Increased risk of chronic hepatitis, cirrhosis, and hepatic cancer.	Frequent occurrence of chronic carrier state and chronic liver disease. Increased risk of hepatic cancer.	Similar to HBV but greater likelihood of carrier state, chronic active hepatitis, and cirrhosis	Similar to HAV except very severe in pregnant women

oral–anal contact, anal intercourse, and a greater number of sex partners (CDC, 2002).

The incubation period is estimated to be 15 to 50 days, with an average of 30 days (O’Grady et al., 2000). The illness may be prolonged, lasting 4 to 8 weeks. It generally lasts longer and is more severe in those older than 40 years of age. Recovery is the rule; hepatitis A rarely progresses to acute liver necrosis or fulminant hepatitis, terminating in cirrhosis of the liver or death. Hepatitis A confers immunity against itself, but the person may contract other forms of hepatitis. The mortality rate of hepatitis A is approximately 0.5% for those under 40 years of age and increases to 1% to 2% for those over 40. No carrier state exists, and no chronic hepatitis is associated with hepatitis A. The virus is present only briefly in the serum; by the time jaun-

dice occurs, the patient is likely to be noninfectious (O’Grady et al., 2000).

### Clinical Manifestations

Many patients are anicteric (without jaundice) and symptomless. When symptoms appear, they are of a mild, flu-like upper respiratory tract infection, with low-grade fever. Anorexia, an early symptom, is often severe. It is thought to result from release of a toxin by the damaged liver or by failure of the damaged liver cells to detoxify an abnormal product. Later, jaundice and dark urine may become apparent. Indigestion is present in varying degrees, marked by vague epigastric distress, nausea, heartburn, and flatulence. The patient may also develop a strong aversion to the taste

of cigarettes or the presence of cigarette smoke and other strong odors. These symptoms tend to clear as soon as the jaundice reaches its peak, perhaps 10 days after its initial appearance. Symptoms may be mild in children; in adults, the symptoms may be more severe and the course of the disease prolonged.

### Assessment and Diagnostic Findings

The liver and spleen are often moderately enlarged for a few days after onset; otherwise, apart from jaundice, there are few physical signs. Hepatitis A antigen may be found in the stool a week to 10 days before illness and for 2 to 3 weeks after symptoms appear. HAV antibodies are detectable in the serum, but usually not until symptoms appear. Analysis of subclasses of immunoglobulins can help determine whether the antibody represents acute or past infection.

### Prevention

A number of strategies exist to prevent transmission of HAV. Patients and their families need to be made aware of these and encouraged to consider them if recommended by their primary health care provider.

In February 1995, the Food and Drug Administration approved the first vaccine against hepatitis A for use in the United States. Effective and safe HAV vaccines include Havrix and Vagta (Koff, 2001). It is recommended that the two-dose vaccine be given to adults 18 years of age or older, with the second dose 6 to 12 months after the first. Protection against hepatitis A develops within several weeks after the first dose of the vaccine. Children and adolescents 2 to 18 years of age receive three doses, with the second dose 1 month after the first and the third dose 6 to 12 months later. It is estimated that protection against hepatitis A may last for at least 20 years (CDC, 1999). No country has as yet recommended universal vaccination against hepatitis A. Hepatitis A vaccine is recommended for travelers to locations where sanitation and hygiene are unsatisfactory. Vaccination is also recommended for those from other high-risk groups (homosexual men, injection/intravenous drug users, staff of day care centers, and health care personnel) (CDC, 2002). The vaccine has also been used to interrupt community-wide outbreaks. As with other vaccinations, precautions must be taken to ensure prevention, detection, and treatment of hypersensitivity reactions to the vaccine.

Type A hepatitis can be prevented in those not previously vaccinated by the intramuscular administration of globulin during the incubation period, if given within 2 weeks of exposure. This bolsters the person's antibody production and provides 6 to 8 weeks of passive immunity. Immune globulin may suppress overt symptoms of the disease; the resulting subclinical case of hepatitis A would produce active immunity to subsequent episodes of the virus.

Immune globulin is also recommended for household members and sexual contacts of people with hepatitis A. Susceptible people in the same household as the patient are usually also infected by the time the diagnosis is made and should receive immune globulin. Day care center and restaurant workers with exposure to or infected with hepatitis A should also receive immune globulin to provide passive immunity (CDC, 1999). Although rare, systemic reactions to immune globulin may occur. Caution is required when anyone who has previously had angioedema, hives, or other allergic reactions is treated with any human immune globulin. Epinephrine should be available in case a systemic, anaphylactic reaction occurs.

#### Chart 39-6

### Community Prevention of Hepatitis A

- Proper community and home sanitation
- Conscientious individual hygiene
- Safe practices for preparing and dispensing food
- Effective health supervision of schools, dormitories, extended care facilities, barracks, and camps
- Community health education programs
- Mandatory reporting of viral hepatitis to local health departments
- Vaccination for travelers to developing countries, illegal drug users (injection and noninjection drug users), men who have sex with men, and persons with chronic liver disease
- Vaccination to interrupt community-wide outbreaks

Preexposure prophylaxis is recommended for those traveling to developing countries and settings with poor or uncertain sanitation conditions but who do not have sufficient time to acquire protection by administration of hepatitis A vaccine (CDC, 1999). Community interventions for preventing hepatitis A are outlined in Chart 39-6.

### Medical Management

Bed rest during the acute stage and a diet that is both acceptable to the patient and nutritious are part of the treatment and nursing care. During the period of anorexia, the patient should receive frequent small feedings, supplemented, if necessary, by IV fluids with glucose. Because this patient often has an aversion to food, gentle persistence and creativity may be required to stimulate the appetite. Optimal food and fluid levels are necessary to counteract weight loss and slow recovery. Even before the icteric phase, however, many patients recover their appetites (Chart 39-7).

The patient's sense of well-being as well as laboratory test results are generally appropriate guides to bed rest and restriction of physical activity. Gradual but progressive ambulation seems to hasten recovery, provided the patient rests after activity and does not participate in activities to the point of fatigue.

### Nursing Management

The patient is usually managed at home unless symptoms are severe. Therefore, the nurse assists the patient and family in coping with the temporary disability and fatigue that are common in hepatitis and instructs them to seek additional health care if the

#### Chart 39-7

### Dietary Management of Viral or Drug-Related Hepatitis

- Recommend small, frequent meals.
- Provide intake of 2,000 to 3,000 kcal/day during acute illness.
- Although early studies indicate that a high-protein, high-calorie diet may be beneficial, advise patient not to force food and to restrict fat intake.
- Carefully monitor fluid balance.
- If anorexia and nausea and vomiting persist, enteral feedings may be necessary.
- Instruct patient to abstain from alcohol during acute illness and for 6 months after recovery.
- Advise patient to avoid substances (medication, herbs, illicit drugs, and toxins) that may affect liver function.

symptoms persist or worsen. The patient and family also need specific guidelines about diet, rest, follow-up blood work, and the importance of avoiding alcohol, as well as sanitation and hygiene measures (particularly hand washing) to prevent spread of the disease to other family members.

Specific teaching to patients and families about reducing the risk of contracting hepatitis A includes good personal hygiene, stressing careful hand washing (after bowel movements and before eating), and environmental sanitation (safe food and water supply, as well as effective sewage disposal).

**NURSING ALERT** The Food and Drug Administration (CDC, 2001) has approved a combined hepatitis A and B vaccine (Twinrix) for vaccination of persons 18 years of age and older with indications for both hepatitis A and B vaccination. Vaccination consists of three doses, on the same schedule as that used for single-antigen hepatitis B vaccine.

## HEPATITIS B VIRUS (HBV)

Unlike hepatitis A, which is transmitted primarily by the fecal–oral route, hepatitis B is transmitted primarily through blood (percutaneous and permucosal routes). HBV has been found in blood, saliva, semen, and vaginal secretions and can be transmitted through mucous membranes and breaks in the skin. HBV is also transferred from carrier mothers to their babies, especially in areas with a high incidence (ie, Southeast Asia). The infection is usually not via the umbilical vein, but from the mother at the time of birth and during close contact afterward.

HBV has a long incubation period. It replicates in the liver and remains in the serum for relatively long periods, allowing transmission of the virus. Those at risk for developing hepatitis B include surgeons, clinical laboratory workers, dentists, nurses, and respiratory therapists. Staff and patients in hemodialysis and oncology units and sexually active homosexual and bisexual men and injection drug users are also at increased risk. Screening of blood donors has greatly reduced the occurrence of hepatitis B after blood transfusion.

Most people (>90%) who contract hepatitis B infections will develop antibodies and recover spontaneously in 6 months. The mortality rate from hepatitis B has been reported to be as high as 10%. Another 10% of patients who have hepatitis B progress to a carrier state or develop chronic hepatitis with persistent HBV infection and hepatocellular injury and inflammation. It remains a major cause of cirrhosis and hepatocellular carcinoma worldwide (Chart 39-8).

Chart 39-8

### Risk Factors for Hepatitis B

- Frequent exposure to blood, blood products, or other body fluids
- Health care workers: hemodialysis staff, oncology and chemotherapy nurses, personnel at risk for needlesticks, operating room staff, respiratory therapists, surgeons, dentists
- Hemodialysis
- Male homosexual and bisexual activity
- IV/injection drug use
- Close contact with carrier of HBV
- Travel to or residence in area with uncertain sanitary conditions
- Multiple sexual partners
- Recent history of sexually transmitted disease
- Receipt of blood or blood products (eg, clotting factor concentrate)

## Clinical Manifestations

Clinically, the disease closely resembles hepatitis A, but the incubation period is much longer (1 to 6 months). Signs and symptoms of hepatitis B may be insidious and variable. Fever and respiratory symptoms are rare; some patients have arthralgias and rashes. The patient may have loss of appetite, dyspepsia, abdominal pain, generalized aching, malaise, and weakness. Jaundice may or may not be evident. If jaundice occurs, light-colored stools and dark urine accompany it. The liver may be tender and enlarged to 12 to 14 cm vertically. The spleen is enlarged and palpable in a few patients; the posterior cervical lymph nodes may also be enlarged. Subclinical episodes also occur frequently.

## Assessment and Diagnostic Findings

HBV is a DNA virus composed of the following antigenic particles:

- HBcAg—hepatitis B core antigen (antigenic material in an inner core)
- HBsAg—hepatitis B surface antigen (antigenic material on surface of HBV)
- HBeAg—an independent protein circulating in the blood
- HBxAg—gene product of X gene of HBV/DNA

Each antigen elicits its specific antibody and is a marker for different stages of the disease process:

- anti-HBc—antibody to core antigen or HBV; persists during the acute phase of illness; may indicate continuing HBV in the liver
- anti-HBs—antibody to surface determinants on HBV; detected during late convalescence; usually indicates recovery and development of immunity
- anti-HBe—antibody to hepatitis B e-antigen; usually signifies reduced infectivity
- anti-HBxAg—antibody to the hepatitis B x-antigen; may indicate ongoing replication of HBV

HBsAg appears in the circulation in 80% to 90% of infected patients 1 to 10 weeks after exposure to HBV and 2 to 8 weeks before the onset of symptoms or an increase in transferase (transaminase) levels. Patients with HBsAg that persists for 6 or more months after acute infection are considered HBsAg carriers (Befeler & Di Bisceglie, 2000). HBeAg is the next antigen of HBV to appear in the serum. It usually appears within a week of the appearance of HBsAg and before changes in aminotransferase levels, disappearing from the serum within 2 weeks. HBV DNA, detected by polymerase chain reaction testing, appears in the serum at about the same time as HBeAg. HBcAg is not always detected in the serum in HBV infection.

About 15% of American adults are positive for anti-HBs, which indicates that they have had hepatitis B. Anti-HBs may be positive in as many as two thirds of IV/injection drug users.

## Prevention

The goals of prevention are to interrupt the chain of transmission, to protect people at high risk with active immunization through the use of hepatitis B vaccine, and to use passive immunization for unprotected people exposed to HBV.

### PREVENTING TRANSMISSION

Continued screening of blood donors for the presence of hepatitis B antigens will further decrease the risk of transmission by

blood transfusion. The use of disposable syringes, needles, and lancets and the introduction of needleless IV administration systems reduce the risk of spreading this infection from one patient to another or to health care personnel during the collection of blood samples or the administration of parenteral therapy. Good personal hygiene is fundamental to infection control. In the clinical laboratory, work areas should be disinfected daily. Gloves are worn when handling all blood and body fluids as well as HBsAg-positive specimens, or when there is potential exposure to blood (blood drawing) or to patients' secretions. Eating and smoking are prohibited in the laboratory and in other areas exposed to secretions, blood, or blood products. Patient education regarding the nature of the disease, its infectiousness, and prognosis is a critical factor in preventing transmission and protecting contacts.

### ACTIVE IMMUNIZATION: HEPATITIS B VACCINE

Active immunization is recommended for individuals at high risk for hepatitis B (eg, health care personnel and hemodialysis patients). In addition, individuals with hepatitis C and other chronic liver diseases should receive the vaccine (CDC, 1999). A yeast-recombinant hepatitis B vaccine (Recombivax HB) is used to provide active immunity. Long-term studies of healthy adults and children indicate that immunologic memory remains intact for at least 5 to 10 years, although antibody levels may become low or undetectable. Measurable levels of antibodies may not be essential for protection. In those with normal immune systems, booster doses are not generally required. The CDC (2002) does not recommend booster doses at this time except for hemodialysis patients. The need for booster doses may be revisited if reports of hepatitis B increase or an increased prevalence of the carrier state develops, indicating that protection is declining.

A hepatitis B vaccine prepared from plasma of humans chronically infected with HBV is used only rarely and in patients who are immunodeficient or allergic to recombinant yeast-derived vaccines.

Both forms of the hepatitis B vaccine are administered intramuscularly in three doses, the second and third doses 1 and 6 months after the first dose. The third dose is very important in producing prolonged immunity. Hepatitis B vaccination should be administered to adults in the deltoid muscle. Antibody response may be measured by anti-HBs levels 1 to 3 months after completing the basic course of vaccine, but this testing is not routine and not currently recommended. Individuals who fail to respond may benefit from one to three additional doses (Koff, 2001).

People at high risk, including nurses and other health care personnel exposed to blood or blood products, should receive active immunization. Health care workers who have had frequent contact with blood are screened for anti-HBs to determine whether immunity is already present from previous exposure. The vaccine produces active immunity to HBV in 90% of healthy people (Koff, 2001). It does not provide protection to those already exposed to HBV and provides no protection against other types of viral hepatitis. Side effects of immunization are infrequent; soreness and redness at the injection site are the most common complaints.

Because hepatitis B infection is frequently transmitted sexually, hepatitis B vaccination is recommended for all unvaccinated persons being evaluated for a sexually transmitted disease (STD). It is also recommended for those with a history of an STD, persons with multiple sex partners, those who have sex with injection drug users, and sexually active men who have sex with other men (CDC, 2002).

Universal childhood vaccination for hepatitis B prevention has been instituted in the United States. Vaccination was initially targeted for select high-risk populations, but the U.S. Public

Health Service and the CDC (1999) have endorsed universal vaccination of all infants. Catch-up vaccination is also recommended for all children and adolescents up to the age of 19 who were not previously immunized. Studies (Chang, 2000; Wu et al., 1999) show that universal vaccination of all newborns in endemic areas has dramatically reduced the carrier rate among children and the incidence of childhood hepatocellular carcinoma. In the United States, studies regarding the effectiveness of the vaccine are ongoing, but it is known that clinical infection is rarely observed during long-term follow-up of known responders (ie, health care workers) who seroconverted within 3 months of the third dose of vaccine (Bircher et al., 1999). Development of chronic carrier states has not been reported in adult responders to the vaccine.

### PASSIVE IMMUNITY: HEPATITIS B IMMUNE GLOBULIN

Hepatitis B immune globulin (HBIG) provides passive immunity to hepatitis B and is indicated for people exposed to HBV who have never had hepatitis B and have never received hepatitis B vaccine. Specific indications for postexposure vaccine with HBIG include: (1) inadvertent exposure to HBsAg-positive blood through percutaneous (needlestick) or transmucosal (splashes in contact with mucous membrane) routes, (2) sexual contact with people positive for HBsAg, and (3) perinatal exposure (babies born to HBV-infected mothers should receive HBIG within 12 hours of delivery). HBIG, which provides passive immunity, is prepared from plasma selected for high titers of anti-HBs. Prompt immunization with HBIG (within hours to a few days after exposure to hepatitis B) increases the likelihood of protection. Both active and passive immunization are recommended for people exposed to hepatitis B through sexual contact or through percutaneous or transmucosal routes. If HBIG and hepatitis B vaccine are administered at the same time, separate sites and separate syringes should be used. Prophylaxis with high doses of HBIG started at the time of liver transplantation and continued indefinitely improves survival by thwarting recurrence of hepatitis B (Bacon & Di Bisceglie, 2000). There has been no evidence that HIV infection can be transmitted by HBIG.

### Gerontologic Considerations

The elderly patient who contracts hepatitis B has a serious risk of severe liver cell necrosis or fulminant hepatic failure, particularly if other illnesses are present. The patient is seriously ill and the prognosis is poor, so efforts should be undertaken to eliminate other factors (eg, medications, alcohol) that may affect liver function.

### Medical Management

The goals of treatment are to minimize infectivity, normalize liver inflammation, and decrease symptoms. Of all the agents that have been used to treat chronic type B viral hepatitis, alpha interferon as the single modality of therapy offers the most promise. This regimen of 5 million units daily or 10 million units three times weekly for 4 to 6 months results in remission of disease in approximately one third of patients (Befeler & Di Bisceglie, 2000). The long-term benefits of this treatment are being assessed. Interferon must be administered by injection and has significant side effects, including fever, chills, anorexia, nausea, myalgias, and fatigue. Late side effects are more serious and may necessitate dosage reduction or discontinuation. These include bone marrow suppression, thyroid dysfunction, alopecia, and bacterial infections.

Two antiviral agents (lamivudine [Epvir] and adefovir [Hepsera]) oral nucleoside analogs, have been approved for use in

chronic hepatitis B in the United States. Viral resistance may be an issue with these agents, and studies of their effectiveness alone and in combination with other therapies are ongoing (Befeler & Di Bisceglie, 2000).

Bed rest may be recommended, regardless of other treatment, until the symptoms of hepatitis have subsided. Activities are restricted until the hepatic enlargement and elevated levels of serum bilirubin and liver enzymes have disappeared. Gradually increased activity is then allowed.

Adequate nutrition should be maintained; proteins are restricted when the liver's ability to metabolize protein byproducts is impaired, as demonstrated by symptoms. Measures to control the dyspeptic symptoms and general malaise include the use of antacids and antiemetics, but all medications should be avoided if vomiting occurs. If vomiting persists, the patient may require hospitalization and fluid therapy. Because of the mode of transmission, the patient is evaluated for other bloodborne diseases (eg, HIV infection).

## Nursing Management

Convalescence may be prolonged, with complete symptomatic recovery sometimes requiring 3 to 4 months or longer. During this stage, gradual resumption of physical activity is encouraged after the jaundice has resolved.

The nurse identifies psychosocial issues and concerns, particularly the effects of separation from family and friends if the patient is hospitalized during the acute and infective stages. Even if not hospitalized, the patient will be unable to work and must avoid sexual contact. Planning is required to minimize alterations in sensory perception. Planning that includes the family helps to decrease their fears and anxieties about the spread of the disease.

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** Because of the prolonged period of convalescence, the patient and family must be prepared for home care. Provision for adequate rest and nutrition must be ensured. The nurse informs family members and friends who have had intimate contact with the patient about the risks of contracting hepatitis B and makes arrangements for them to receive hepatitis B vaccine or hepatitis B immune globulin as prescribed. Those at risk must be aware of the early signs of hepatitis B and of ways to reduce risk to themselves by avoiding all modes of transmission. Patients with all forms of hepatitis should avoid drinking alcohol.

**Continuing Care.** Follow-up visits by a home care nurse may be needed to assess the patient's progress and answer family members' questions about disease transmission. A home visit also permits assessment of the patient's physical and psychological status and the patient and family's understanding of the importance of adequate rest and nutrition. The nurse also reinforces previous instructions. Because of the risk of transmission through sexual intercourse, strategies to prevent exchange of body fluids are advised, such as abstinence or the use of condoms. The nurse emphasizes the importance of keeping follow-up appointments and participating in other health promotion activities and recommended health screenings.

## HEPATITIS C VIRUS (HCV)

A significant proportion of cases of viral hepatitis are neither hepatitis A, hepatitis B, nor hepatitis D; as a result, they are classified as hepatitis C (formerly referred to as non-A, non-B hepatitis, or

NANB hepatitis). Whereas blood transfusions and sexual contact once accounted for most cases of hepatitis C in the United States, other parenteral means, such as sharing contaminated needles by IV/injection drug users and unintentional needlesticks and other injuries in health care workers, now account for a significant number of cases. There are approximately 35,000 new cases of hepatitis C in the United States each year. About 4 million persons (1.8% of the U.S. population) have been infected with HCV, making it the most common chronic blood-borne infection nationally. A fourfold increase in the number of adults diagnosed with HCV is projected from 1990 to 2015. The highest prevalence of hepatitis C is in adults 40 to 59 years of age, and in this age group its prevalence is highest in African Americans. There are 10,000 to 12,000 deaths each year in the United States due to hepatitis C; it has been suggested that these are underestimates. HCV is the underlying cause of about one-third of cases of hepatocellular carcinoma, and it is the most common reason for liver transplantation (NIH Consensus Conference, 2002).

Individuals at special risk for hepatitis C include IV/injection drug users, sexually active people with multiple partners, patients receiving frequent transfusions or those who require large volumes of blood, and health care personnel. The incubation period is variable and may range from 15 to 160 days. The clinical course of acute hepatitis C is similar to that of hepatitis B; symptoms are usually mild. A chronic carrier state occurs frequently, however, and there is an increased risk of chronic liver disease, including cirrhosis or liver cancer, after hepatitis C. Small amounts of alcohol taken regularly appear to encourage progression of the disease. Therefore, alcohol and medications that may affect the liver should be avoided (Chart 39-9).

There is no benefit from rest, diet, or vitamin supplements. Recent studies have demonstrated that a combination of interferon (Intron-A) and ribavirin (Rebetol), two antiviral agents, is effective in producing improvement in patients with hepatitis C and in treating relapses. Some patients experience complete remission with combination therapy, which is the treatment of choice according to the FDA (Cheney, Chopra & Graham, 2000). Hemolytic anemia, the most frequent side effect, may be severe enough to require discontinuation of treatment. Ribavirin must be used with caution in women of childbearing age. A molecule (polyethylene glycol moiety [PEG]) added to the interferon keeps it in the body longer without reducing its efficacy and extends the dosing interval to once a week. Pegylated interferon (Pegasys) is now available (Lauer & Walker, 2001; Sheffield et al., 2001).

Screening of blood has reduced the incidence of hepatitis associated with blood transfusions, and public health programs are helping to reduce the number of cases associated with shared needles in illicit drug use.

### Chart 39-9 Risk Factors for Hepatitis C

- Recipient of blood products or organ transplant prior to 1992 or clotting factor concentrates before 1987
- Health care and public safety workers after needlestick injuries or mucosal exposure to blood
- Children born to women infected with hepatitis C virus
- Past/current illicit IV/injection drug use
- Past treatment with chronic hemodialysis
- Sex with infected partner, having multiple sex partners, history of STD, unprotected sex

## HEPATITIS D VIRUS (HDV)

Hepatitis D (delta agent) occurs in some cases of hepatitis B. Because the virus requires hepatitis B surface antigen for its replication, only individuals with hepatitis B are at risk for hepatitis D. Anti-delta antibodies in the presence of HBsAg on testing confirm the diagnosis. It is also common among IV/injection drug users, hemodialysis patients, and recipients of multiple blood transfusions. Sexual contact with those with hepatitis B is considered to be an important mode of transmission of hepatitis B and D. The incubation period varies between 21 and 140 days (Bacon & Di Bisceglie, 2000).

The symptoms of hepatitis D are similar to those of hepatitis B, except that patients are more likely to develop fulminant hepatitis and to progress to chronic active hepatitis and cirrhosis. Treatment is similar to that of other forms of hepatitis; interferon as a specific treatment for hepatitis D is under investigation.

## HEPATITIS E VIRUS (HEV)

Hepatitis E is believed to be transmitted by the fecal–oral route, principally through contaminated water in areas with poor sanitation. The incubation period is variable, estimated to range between 15 and 65 days. In general, hepatitis E resembles hepatitis A. It has a self-limiting course with an abrupt onset. Jaundice is nearly always present. Chronic forms do not develop.

Avoiding contact with the virus through good hygiene, including hand washing, is the major method of prevention of hepatitis E. The effectiveness of immune globulin in protecting against hepatitis E virus is uncertain.

## HEPATITIS G (HGV) AND GB VIRUS-C

It has long been believed that there is another non-A, non-B, non-C agent causing hepatitis in humans. The incubation period for post-transfusion hepatitis is 14 to 145 days, too long for hepatitis B or C. In the United States, about 5% of chronic liver disease remains cryptogenic (does not appear to be autoimmune or viral in origin), and half the patients have previously received transfusions. Thus, a new form of hepatitis (hepatitis G or GBV-C) has been described. They are two different isolates of the same virus. Autoantibodies are absent.

The clinical significance of this virus remains uncertain. Risk factors are similar to those for hepatitis C. There is no clear relationship between GBV-C/HGV infection and progressive liver disease. Persistent infection does occur but does not affect the clinical course.

## Management of Patients With Nonviral Hepatic Disorders

Certain chemicals have toxic effects on the liver and when taken by mouth, inhaled, or injected parenterally produce acute liver cell necrosis, or toxic hepatitis. The chemicals most commonly implicated in this disease are carbon tetrachloride, phosphorus, chloroform, and gold compounds. These substances are true hepatotoxins. Many medications may induce hepatitis but are sensitizing rather than toxic. The result, drug-induced hepatitis, is similar to acute viral hepatitis, but parenchymal destruction tends to be more extensive. Some medications that can lead to hepatitis are isoniazid, halothane, acetaminophen, and certain antibiotics, antimetabolites, and anesthetic agents.

## TOXIC HEPATITIS

Toxic hepatitis resembles viral hepatitis in onset. Obtaining a history of exposure to hepatotoxic chemicals, medications, or other agents assists in early treatment and removal of the offending agent. Anorexia, nausea, and vomiting are the usual symptoms; jaundice and hepatomegaly are noted on physical assessment. Symptoms are more intense for the more severely toxic patient.

Recovery from acute toxic hepatitis is rapid if the hepatotoxin is identified early and removed or if exposure to the agent has been limited. Recovery is unlikely if there is a prolonged period between exposure and onset of symptoms. There are no effective antidotes. The fever rises; the patient becomes toxic and prostrated. Vomiting may be persistent, with the emesis containing blood. Clotting abnormalities may be severe, and hemorrhages may appear under the skin. The severe GI symptoms may lead to vascular collapse. Delirium, coma, and seizures develop, and within a few days the patient may die of fulminant hepatic failure (discussed below) unless he or she receives a liver transplant.

Short of liver transplantation, few treatment options are available. Therapy is directed toward restoring and maintaining fluid and electrolyte balance, blood replacement, and comfort and supportive measures. A few patients recover from acute toxic hepatitis only to develop chronic liver disease. If the liver heals, there may be scarring, followed by postnecrotic cirrhosis.

## DRUG-INDUCED HEPATITIS

Drug-induced hepatitis is responsible for 20% to 25% of cases of acute hepatic failure in the United States (Maddrey, Schiff & Sorrell, 2001). Manifestations of sensitivity to a medication may occur on the first day of its use or not until several months later, depending on the medication. Usually the onset is abrupt, with chills, fever, rash, pruritus, arthralgia, anorexia, and nausea. Later, there may be jaundice and dark urine and an enlarged and tender liver. When the offending medication is withdrawn, symptoms may gradually subside. However, reactions may be severe and even fatal, even though the medication is stopped. If fever, rash, or pruritus occurs from any medication, its use should be stopped immediately.

Although any medication can affect liver function, use of acetaminophen (found in many over-the-counter medications used to treat fever and pain) has been identified as the leading cause of acute liver failure (Ostapowicz, Fontana, Schiodt, et al., 2002). Others commonly associated with liver injury include but are not limited to anesthetic agents, medications used to treat rheumatic and musculoskeletal disease, antidepressants, psychotropic medications, anticonvulsants, and anti-tuberculosis agents.

Inhalational agents of the halothane family (halokanes) are metabolized by the liver and excreted in bile. These volatile anesthetics may also decrease hepatic blood flow. Halothane hepatitis is a dreaded but rare complication of halothane administration. Sevoflurane and desflurane may have less hepatotoxic effects than halokanes. Nitrous oxide, an adjunct to halokanes, is not hepatotoxic. Because it undergoes little hepatic metabolism, isoflurane is considered the anesthetic agent of choice in patients with liver disease (Bacon & Di Bisceglie, 2000).

Although its efficacy is uncertain, a short course of high-dose corticosteroids may be used in patients with severe hypersensitivity. Liver transplantation is an option for drug-induced hepatitis, but outcomes may not be as successful as with other causes of liver failure.

## FULMINANT HEPATIC FAILURE

**Fulminant hepatic failure** is the clinical syndrome of sudden and severely impaired liver function in a previously healthy person. According to the original and generally accepted definition, fulminant hepatic failure develops within 8 weeks of the first symptoms of jaundice (Maddrey et al., 2001). Patterns of the progression from jaundice to encephalopathy have been identified and have led to proposals of time-based classifications, but no agreement as to these classifications has been reached. However, three categories are frequently cited: hyperacute, acute, and subacute liver failure. In hyperacute liver failure, the duration of jaundice before the onset of encephalopathy is 0 to 7 days; in acute liver failure, it is 8 to 28 days; and in subacute liver failure, it is 28 to 72 days. The prognosis for fulminant hepatic failure is much worse than for chronic liver failure. However, in fulminant failure, the hepatic lesion is potentially reversible, with survival rates of approximately 50% to 85% (survival rates depend greatly on the etiology of liver failure). Those who do not survive die of massive hepatocellular injury and necrosis (Maddrey et al., 2001).

Viral hepatitis is a common cause of fulminant hepatic failure; other causes include toxic medications (eg, acetaminophen) and chemicals (eg, carbon tetrachloride), metabolic disturbances (Wilson's disease, a hereditary syndrome with deposition of copper in the liver), and structural changes (Budd-Chiari syndrome, an obstruction to outflow in major hepatic veins).

Jaundice and profound anorexia may be the initial reasons the patient seeks health care. Fulminant hepatic failure is often accompanied by coagulation defects, renal failure and electrolyte disturbances, infection, hypoglycemia, encephalopathy, and cerebral edema.

## Management

The key to optimizing treatment is rapid recognition of acute liver failure and intensive interventions. Treatment modalities may include plasma exchanges (plasmapheresis) or charcoal hemoperfusion for the removal (theoretically) of potentially harmful metabolites (Kaptanoglu & Blei, 2000); however, more clinical trials are needed to determine their effects or outcomes. Hepatocytes within synthetic fiber columns have been tested as liver support systems (liver assist devices) and a bridge to transplantation.

Research into interventions for acute liver failure has begun to focus on techniques that combine the efficacy of a whole liver with the convenience and biocompatibility of hemodialysis. The acronyms ELAD (extracorporeal liver assist devices) and BAL (bioartificial liver) have been used to describe these hybrid devices. These temporary devices help patients to survive until transplantation is possible. The BAL exposes separated plasma to a cartridge containing porcine liver cells after the plasma has flowed through a charcoal column that removes substances toxic to hepatocytes. The ELAD device exposes whole blood to cartridges containing human hepatoblastoma cells, resulting in removal of toxic substances. Similar extracorporeal circuits using **xenografts** will likely be studied in the near future (Maddrey et al., 2001). Although these approaches appear promising, controlled studies are required.

There is a high risk for cerebral edema, a life-threatening complication, in patients with fulminant liver failure with stage 4 encephalopathy. The cause is not fully understood, although disruption of the blood-brain barrier and plasma leaking into the cerebrospinal fluid has been proposed as one theory (Sherlock & Dooley, 2002). These patients require intracranial pressure monitoring. Measures to promote adequate cerebral perfusion include

careful fluid balance and hemodynamic assessments, a quiet environment, and diuresis with mannitol, an osmotic diuretic.

To prevent surges in intracranial pressure related to agitation, barbiturate anesthesia or pharmacologic paralysis and sedation are indicated. Other support measures include monitoring for and treating hypoglycemia, coagulopathies, and infection. Despite these treatment modalities, the mortality rate remains high. Consequently, liver transplantation (discussed later in this chapter) has become the treatment of choice for fulminant hepatic failure.

## HEPATIC CIRRHOSIS

Cirrhosis is a chronic disease characterized by replacement of normal liver tissue with diffuse fibrosis that disrupts the structure and function of the liver. There are three types of cirrhosis or scarring of the liver:

- **Alcoholic cirrhosis**, in which the scar tissue characteristically surrounds the portal areas. This is most frequently due to chronic alcoholism and is the most common type of cirrhosis.
- **Postnecrotic cirrhosis**, in which there are broad bands of scar tissue as a late result of a previous bout of acute viral hepatitis.
- **Biliary cirrhosis**, in which scarring occurs in the liver around the bile ducts. This type usually is the result of chronic biliary obstruction and infection (cholangitis); it is much less common than the other two types.

The portion of the liver chiefly involved in cirrhosis consists of the portal and the periportal spaces, where the bile canaliculi of each lobule communicate to form the liver bile ducts. These areas become the sites of inflammation, and the bile ducts become occluded with inspissated (thickened) bile and pus. The liver attempts to form new bile channels; hence, there is an overgrowth of tissue made up largely of disconnected, newly formed bile ducts and surrounded by scar tissue.

Clinical manifestations include intermittent jaundice and fever. Initially the liver is enlarged, hard, and irregular, but eventually it atrophies.

## Pathophysiology

Although several factors have been implicated in the etiology of cirrhosis, alcohol consumption is considered the major causative factor. Cirrhosis occurs with greatest frequency among alcoholics. Although nutritional deficiency with reduced protein intake contributes to liver destruction in cirrhosis, excessive alcohol intake is the major causative factor in fatty liver and its consequences. Cirrhosis, however, has also occurred in people who do not consume alcohol and in those who consume a normal diet and have a high alcohol intake.

Some people appear to be more susceptible than others to this disease, whether or not they are alcoholics or malnourished. Other factors may play a role, including exposure to certain chemicals (carbon tetrachloride, chlorinated naphthalene, arsenic, or phosphorus) or infectious schistosomiasis. Twice as many men as women are affected, although women are at greater risk of developing alcohol-induced liver disease for an as yet undiscovered reason. Most patients are between 40 and 60 years of age. Each year more than 25,000 people die of chronic liver diseases and cirrhosis in the United States (NIDDK, 2000).

Alcoholic cirrhosis is characterized by episodes of necrosis involving the liver cells, sometimes occurring repeatedly throughout

the course of the disease. The destroyed liver cells are replaced gradually by scar tissue; eventually the amount of scar tissue exceeds that of the functioning liver tissue. Islands of residual normal tissue and regenerating liver tissue may project from the constricted areas, giving the cirrhotic liver its characteristic hobnail appearance. The disease usually has an insidious onset and a protracted course, occasionally proceeding over a period of 30 or more years.

The prognosis of different forms of cirrhosis caused by various liver diseases has been investigated in several studies. Of the many prognostic indicators, the Child's classification seems most useful in predicting the outcome of patients with liver disease (Table 39-5). It is also used in choosing management approaches.

### Clinical Manifestations

Signs and symptoms of cirrhosis increase in severity as the disease progresses. The severity of the manifestations helps to categorize the disorder into two main presentations (Chart 39-10).

Compensated cirrhosis, with its less severe, often vague symptoms, may be discovered secondarily at a routine physical examination. The hallmarks of decompensated cirrhosis result from failure of the liver to synthesize proteins, clotting factors, and other substances and manifestations of portal hypertension (see the "Hepatic Dysfunction" section of this chapter for clinical manifestations and management of portal hypertension, ascites, varices, and hepatic encephalopathy).

#### LIVER ENLARGEMENT

Early in the course of cirrhosis, the liver tends to be large and its cells loaded with fat. The liver is firm and has a sharp edge noticeable on palpation. Abdominal pain may be present because of recent, rapid enlargement of the liver, producing tension on the fibrous covering of the liver (Glisson's capsule). Later in the disease, the liver decreases in size as scar tissue contracts the liver tissue. The liver edge, if palpable, is nodular.

#### PORTAL OBSTRUCTION AND ASCITES

These late manifestations are due partly to chronic failure of liver function and partly to obstruction of the portal circulation. Practically all the blood from the digestive organs is collected in the portal veins and carried to the liver. Because a cirrhotic liver does not allow the blood free passage, it backs up into the spleen and the GI tract and these organs become the seat of chronic passive congestion; that is, they are stagnant with blood and thus cannot function properly. Indigestion and altered bowel function result. Fluid rich in protein may accumulate in the peritoneal cavity, producing ascites. This can be demonstrated through percussion for shifting dullness or a fluid wave (see Fig. 39-5).

### Chart 39-10 • ASSESSMENT

#### Clinical Manifestations of Cirrhosis

##### Compensated

- Intermittent mild fever
- Vascular spiders
- Palmar erythema (reddened palms)
- Unexplained epistaxis
- Ankle edema
- Vague morning indigestion
- Flatulent dyspepsia
- Abdominal pain
- Firm, enlarged liver
- Splenomegaly

##### Decompensated

- Ascites
- Jaundice
- Weakness
- Muscle wasting
- Weight loss
- Continuous mild fever
- Clubbing of fingers
- Purpura (due to decreased platelet count)
- Spontaneous bruising
- Epistaxis
- Hypotension
- Sparse body hair
- White nails
- Gonadal atrophy

#### INFECTION AND PERITONITIS

Bacterial peritonitis may develop in cirrhotic patients with ascites in the absence of an intra-abdominal source of infection or an abscess. This condition is referred to as spontaneous bacterial peritonitis. Bacteremia is believed to be the most likely route of infection. Clinical signs may be absent; paracentesis may be necessary for diagnosis. Antibiotic therapy is effective in the treatment and prevention of recurrent episodes of spontaneous bacterial peritonitis.

#### GASTROINTESTINAL VARICES

The obstruction to blood flow through the liver resulting from the fibrotic changes also results in the formation of collateral blood vessels in the GI system and shunting of blood from the portal vessels into blood vessels with lower pressures. As a result, the patient with cirrhosis often has prominent, distended abdominal blood vessels, which are visible on abdominal inspection (caput medusae), and

distended blood vessels throughout the GI tract. The esophagus, stomach, and lower rectum are common sites of collateral blood vessels. These distended blood vessels form varices or hemorrhoids, depending on their location (see Fig. 39-6).

Because these vessels were not intended to carry the high pressure and volume of blood imposed by cirrhosis, they may rupture and bleed. Therefore, assessment must include observation for occult and frank bleeding from the GI tract. Approximately 25% of patients develop minor hematemesis; others have profuse hemorrhage from gastric and esophageal varices (Bacon & Di Bisceglie, 2000).

### EDEMA

Another late symptom of cirrhosis is edema, which is attributed to chronic liver failure. A reduced plasma albumin concentration predisposes the patient to the formation of edema. Edema is generalized but often affects lower extremities, upper extremities, and the presacral area. Facial edema is not typical. Overproduction of aldosterone occurs, causing sodium and water retention and potassium excretion.

### VITAMIN DEFICIENCY AND ANEMIA

Because of inadequate formation, use, and storage of certain vitamins (notably vitamins A, C, and K), signs of their deficiency are common, particularly hemorrhagic phenomena associated with vitamin K deficiency. Chronic gastritis and impaired GI function, together with inadequate dietary intake and impaired liver function, account for the anemia often associated with cirrhosis. The anemia and the patient's poor nutritional status and poor state of health result in severe fatigue, which interferes with the ability to carry out routine daily activities.

### MENTAL DETERIORATION

Additional clinical manifestations include deterioration of mental function with impending hepatic encephalopathy and hepatic coma. Neurologic assessment is indicated and includes the patient's general behavior, cognitive abilities, orientation to time and place, and speech patterns.

## Assessment and Diagnostic Findings

The extent of liver disease and the type of treatment are determined after reviewing the laboratory findings. Because the functions of the liver are complex, there are many diagnostic tests that may provide information about liver function (see Table 39-1). The patient needs to know why these tests are being performed and ways to cooperate.

In severe parenchymal liver dysfunction, the serum albumin level tends to decrease and the serum globulin level rises. Enzyme tests indicate liver cell damage: serum alkaline phosphatase, AST, ALT, and GGT levels increase, and the serum cholinesterase level may decrease. Bilirubin tests are performed to measure bile excretion or bile retention; elevated levels can occur with cirrhosis and other liver disorders. Prothrombin time is prolonged.

Ultrasound scanning is used to measure the difference in density of parenchymal cells and scar tissue. CT, MRI, and radioisotope liver scans give information about liver size and hepatic blood flow and obstruction. Diagnosis is confirmed by liver biopsy. Arterial blood gas analysis may reveal a ventilation-perfusion imbalance and hypoxia.

## Medical Management

The management of the patient with cirrhosis is usually based on the presenting symptoms. For example, antacids are prescribed to decrease gastric distress and minimize the possibility of GI bleeding. Vitamins and nutritional supplements promote healing of damaged liver cells and improve the general nutritional status. Potassium-sparing diuretics (spironolactone [Aldactone], triamterene [Dyrenium]) may be indicated to decrease ascites, if present; these diuretics are preferable to other diuretic agents because they minimize the fluid and electrolyte changes common with other agents. An adequate diet and avoidance of alcohol are essential. Although the fibrosis of the cirrhotic liver cannot be reversed, its progression may be halted or slowed by such measures.

Preliminary studies indicate that colchicine, an anti-inflammatory agent used to treat the symptoms of gout, may increase the length of survival in patients with mild to moderate cirrhosis. Improved survival has been observed in patients with alcoholic cirrhosis. Colchicine is believed to reverse the fibrotic processes in cirrhosis, and this has improved survival (Bacon & Di Bisceglie, 2000).

## NURSING PROCESS: THE PATIENT WITH HEPATIC CIRRHOSIS

### Assessment

Nursing assessment focuses on the onset of symptoms and the history of precipitating factors, particularly long-term alcohol abuse, as well as dietary intake and changes in the patient's physical and mental status. The patient's past and current patterns of alcohol use (duration and amount) are assessed and documented. It is also important to document any exposure to toxic agents encountered in the workplace or during recreational activities. The nurse documents and reports exposure to potentially hepatotoxic substances (medications, illicit IV/injection drugs, inhalants) or general anesthetic agents.

The nurse assesses the patient's mental status through the interview and other interactions with the patient; orientation to person, place, and time is noted. The patient's ability to carry out a job or household activities provides some information about physical and mental status. The patient's relationships with family, friends, and coworkers may give some indication about incapacitation secondary to alcohol abuse and cirrhosis. Abdominal distention and bloating, GI bleeding, bruising, and weight changes are noted.

The nurse assesses nutritional status, which is of major importance in cirrhosis, by daily weights and monitoring of plasma proteins, transferrin, and creatinine levels.

### Diagnosis

#### NURSING DIAGNOSES

Based on all the assessment data, the patient's major nursing diagnoses may include the following:

- Activity intolerance related to fatigue, general debility, muscle wasting, and discomfort
- Imbalanced nutrition, less than body requirements, related to chronic gastritis, decreased GI motility, and anorexia
- Impaired skin integrity related to compromised immunologic status, edema, and poor nutrition

- Risk for injury and bleeding related to altered clotting mechanisms

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on assessment data, potential complications may include:

- Bleeding and hemorrhage
- Hepatic encephalopathy
- Fluid volume excess

### Planning and Goals

The goals for the patient may include increased participation in activities, improvement of nutritional status, improvement of skin integrity, decreased potential for injury, improvement of mental status, and absence of complications.

### Nursing Interventions

#### PROMOTING REST

The patient with active liver disease requires rest and other supportive measures to permit the liver to reestablish its functional ability. If the patient is hospitalized, weight and fluid intake and output are measured and recorded daily. The nurse adjusts the patient's position in bed for maximal respiratory efficiency, which is especially important if ascites is marked because it interferes with adequate thoracic excursion. Oxygen therapy may be required in liver failure to oxygenate the damaged cells and prevent further cell destruction.

Rest reduces the demands on the liver and increases the liver's blood supply. Because the patient is susceptible to the hazards of immobility, efforts to prevent respiratory, circulatory, and vascular disturbances are initiated. These measures may help prevent such problems as pneumonia, thrombophlebitis, and pressure ulcers. When nutritional status improves and strength increases, the nurse encourages the patient to increase activity gradually. Activity and mild exercise, as well as rest, are planned.

#### IMPROVING NUTRITIONAL STATUS

The patient with cirrhosis who has no ascites or edema and exhibits no signs of impending hepatic coma should receive a nutritious, high-protein diet if tolerated, supplemented by vitamins of the B complex and others as indicated (including vitamins A, C, K and folic acid). Because proper nutrition is so important, the nurse makes every effort to encourage the patient to eat. This is as important as any medication. Often small, frequent meals are tolerated better than three large meals because of the abdominal pressure exerted by ascites. Protein supplements may also be indicated.

Patient preferences are considered. Patients with prolonged or severe anorexia, or those who are vomiting or eating poorly for any reason, may receive nutrients enterally or parenteral nutrition.

Patients with fatty stools (steatorrhea) should receive water-soluble forms of fat-soluble vitamins—A, D, and E (Aquisol A, D, and E). Folic acid and iron are prescribed to prevent anemia. If the patient shows signs of impending or advancing coma, the amount of protein in the diet is decreased temporarily. In the absence of hepatic encephalopathy, a moderate-protein, high-calorie intake is provided, with protein foods of high biologic value. A diet containing 1 to 1.5 g of protein per kilogram of body weight per day is required unless the patient is malnourished. Protein is restricted

if encephalopathy develops. Incorporating vegetable protein to meet protein needs may decrease the risk of encephalopathy. Sodium restriction is also indicated to prevent ascites.

A high-calorie intake should be maintained, and supplemental vitamins and minerals should be provided (eg, oral potassium if the serum potassium level is normal or low and if renal function is normal).

#### PROVIDING SKIN CARE

Providing careful skin care is important because of subcutaneous edema, the patient's immobility, jaundice, and increased susceptibility to skin breakdown and infection. Frequent position changes are necessary to prevent pressure ulcers. It is important to avoid irritating soaps and the use of adhesive tape to prevent trauma to the skin. Lotion may be soothing to irritated skin; the nurse takes measures to minimize scratching by the patient.

#### REDUCING RISK OF INJURY

The nurse protects the patient with cirrhosis from falls and other injuries. The side rails should be in place and padded with blankets in case the patient becomes agitated or restless. To minimize agitation, the nurse orients the patient to time and place and explains all procedures. The nurse instructs the patient to ask for assistance to get out of bed. The nurse carefully evaluates any injury because of the possibility of internal bleeding.

Because of the risk for bleeding from abnormal clotting, the patient should use an electric rather than a safety razor. A soft-bristled toothbrush will help to minimize bleeding gums, and pressure applied to all venipuncture sites will help to minimize bleeding.

#### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

##### Bleeding and Hemorrhage

The patient is at increased risk for bleeding and hemorrhage because of decreased production of prothrombin and decreased ability of the diseased liver to synthesize the substances necessary for blood coagulation. Precautionary measures include protecting the patient with padded side rails, applying pressure to injection sites, and avoiding injury from sharp objects. The nurse observes for melena and assesses stools for blood (signs of possible internal bleeding). Vital signs are monitored regularly. Precautions are taken to minimize rupture of esophageal varices by avoiding further increases in portal pressure (discussed previously). Dietary modification and appropriate use of stool softeners may help prevent straining during defecation. The nurse closely monitors the patient for GI bleeding and keeps readily available equipment (Sengstaken–Blakemore tube), IV fluids, and medications needed to treat hemorrhage from esophageal and gastric varices.

If hemorrhage occurs, the nurse assists the physician in initiating measures to halt the bleeding, administering fluid and blood component therapy and medications. The patient with massive hemorrhage from bleeding esophageal or gastric varices may be transferred to the intensive care unit and may require emergency surgery or other treatment modalities. The patient and family require explanations about the event and the necessary treatment.

##### Hepatic Encephalopathy

Hepatic encephalopathy and coma, possible complications of cirrhosis, may present as deteriorating mental status and dementia as well as physical signs such as abnormal voluntary and involuntary movements. Hepatic encephalopathy is mainly caused by the ac-

accumulation of ammonia in the blood and its effect on cerebral metabolism. Many factors predispose the patient with cirrhosis to hepatic encephalopathy; therefore, the patient may require extensive diagnostic testing to identify hidden sources of bleeding and ammonia.

Treatment may include the use of lactulose and nonabsorbable intestinal tract antibiotics to decrease ammonia levels, modification in medications to eliminate those that may precipitate or worsen hepatic encephalopathy, and bed rest to minimize energy expenditure.

Monitoring is an essential nursing function to identify early deterioration in mental status. The nurse monitors the patient's mental status closely and reports changes so that treatment of encephalopathy can be initiated promptly. Because electrolyte disturbances can contribute to encephalopathy, serum electrolyte levels are carefully monitored and corrected if abnormal. Oxygen is administered if oxygen desaturation occurs. The nurse monitors for fever or abdominal pain, which may signal the onset of bacterial peritonitis or other infection (see the discussion of hepatic encephalopathy in the "Hepatic Dysfunction" section of this Chapter).

### Fluid Volume Excess

Patients with advanced chronic liver disease develop cardiovascular abnormalities. These occur due to an increased cardiac output and decreased peripheral vascular resistance, possibly resulting from the release of vasodilators. A hyperdynamic circulatory state develops in patients with cirrhosis, and plasma volume increases. This increase in circulating plasma volume may be due in part to splanchnic venous congestion (Bircher et al., 1999). The greater the degree of hepatic decompensation, the more severe the hyperdynamic state. Close assessment of the cardiovascular and respiratory status is key for the nurse caring for patients with this disorder. Pulmonary compromise is always a potential complication of end-stage liver disease due to plasma volume excess, making prevention of pulmonary complications an important role for the nurse. Administering diuretics, implementing fluid restrictions, and enhancing patient positioning can optimize pulmonary function. Fluid retention may be noted in the development of ascites and lower extremity swelling and dyspnea. Monitoring intake and output, daily weight changes, changes in abdominal girth, and edema formation is part of nursing assessment in the hospital or in the home setting. Patients are also monitored for nocturia and, later, oliguria as these states indicate increasing severity of liver function (Bacon & Di Bisceglie, 2000).

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

During the patient's hospital stay, the nurse and other health care providers prepare the patient with cirrhosis for discharge, focusing on dietary instruction. Of greatest importance is the exclusion of alcohol from the diet. The patient may need referral to Alcoholics Anonymous, psychiatric care, or counseling or may benefit from support from a spiritual advisor.

Sodium restriction will continue for a considerable time, if not permanently. The patient will require written instructions, teaching, reinforcement, and support from the staff as well as the family members.

The success of treatment depends on convincing the patient of the need to adhere completely to the therapeutic plan. This includes rest, lifestyle changes, adequate dietary intake, and the elimination of alcohol. The nurse also instructs the patient and family about the symptoms of impending encephalopathy, possible bleeding tendencies, and susceptibility to infection.

Recovery is neither rapid nor easy; there are frequent setbacks and apparent lack of improvement. Many patients find it difficult to refrain from using alcohol for comfort or escape. The nurse has a significant role in offering support and encouragement to this patient.

### Continuing Care

Referral of the patient for home care may assist the patient in dealing with the transition from hospital to home, where the use of alcohol may have been an important part of normal home and social life. The home care nurse assesses the patient's progress at home and the manner in which the patient and family cope with the elimination of alcohol and the dietary restrictions. The nurse also reinforces previous teaching and answers questions that may not have occurred to the patient or family until the patient is back home and trying to establish new patterns of eating, drinking, and lifestyle. For an overall view of the nursing management of the patient with impaired liver function, refer to the Plan of Nursing Care.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Participates in activities
  - a. Plans activities and exercises to allow alternating periods of rest and activity
  - b. Reports increased strength and well-being
  - c. Participates in hygiene care
2. Increases nutritional intake
  - a. Demonstrates intake of appropriate nutrients and avoidance of alcohol as reflected by diet log
  - b. Gains weight without increased edema and ascites formation
  - c. Reports decrease in GI disturbances and anorexia
  - d. Identifies foods and fluids that are nutritious and allowed on diet or restricted from diet
  - e. Adheres to vitamin therapy regimen
  - f. Describes the rationale for small, frequent meals
3. Exhibits improved skin integrity
  - a. Has intact skin without evidence of breakdown, infection, or trauma
  - b. Demonstrates normal turgor of skin of extremities and trunk, without edema
  - c. Changes position frequently and inspects bony prominences daily
  - d. Uses lotions to decrease pruritus
4. Avoids injury
  - a. Is free of ecchymotic areas or hematoma formation
  - b. States rationale for side rails and asks for assistance to get out of bed
  - c. Uses measures to prevent trauma (eg, uses electric razor and soft toothbrush, blows nose gently, arranges furniture to prevent bumps and falls, avoids straining during defecation)
5. Is free of complications
  - a. Reports absence of frank bleeding from GI tract (ie, absence of melena and hematemesis)
  - b. Is oriented to time, place, and person and demonstrates normal attention span
  - c. Has serum ammonia level within normal limits
  - d. Identifies early, reportable signs of impaired thought processes

*(text continues on page 1113)*

## Plan of Nursing Care

### The Patient With Impaired Liver Function

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Activity intolerance related to fatigue, lethargy, and malaise

**Goal:** Patient reports decrease in fatigue and reports increased ability to participate in activities

1. Assess level of activity tolerance and degree of fatigue, lethargy, and malaise when performing routine ADLs.	1. Provides baseline for further assessment and criteria for assessment of effectiveness of interventions	• Exhibits increased interest in activities and events
2. Assist with activities and hygiene when fatigued.	2. Promotes exercise and hygiene within patient's level of tolerance	• Participates in activities and gradually increases exercise within physical limits
3. Encourage rest when fatigued or when abdominal pain or discomfort occurs.	3. Conserves energy and protects the liver	• Reports increased strength and well-being
4. Assist with selection and pacing of desired activities and exercise.	4. Stimulates patient's interest in selected activities	• Reports absence of abdominal pain and discomfort
5. Provide diet high in carbohydrates with protein intake consistent with liver function.	5. Provides calories for energy and protein for healing	• Plans activities to allow ample periods of rest
6. Administer supplemental vitamins (A, B complex, C, and K).	6. Provides additional nutrients	• Takes vitamins as prescribed

**Nursing Diagnosis:** Imbalanced nutrition: less than body requirements, related to abdominal distention and discomfort and anorexia

**Goal:** Positive nitrogen balance, no further loss of muscle mass; meets nutritional requirements

1. Assess dietary intake and nutritional status through diet history and diary, daily weight measurements and laboratory data.	1. Identifies deficits in nutritional intake and adequacy of nutritional state	• Exhibits improved nutritional status by increased weight (without fluid retention) and improved laboratory data.
2. Provide diet high in carbohydrates with protein intake consistent with liver function.	2. Provides calories for energy, sparing protein for healing	• States rationale for dietary modifications
3. Assist patient in identifying low-sodium foods.	3. Reduces edema and ascites formation	• Identifies foods high in carbohydrates and within protein requirements (moderate to high protein in cirrhosis and hepatitis, low protein in hepatic failure)
4. Elevate the head of the bed during meals.	4. Reduces discomfort from abdominal distention and decreases sense of fullness produced by pressure of abdominal contents and ascites on the stomach	• Reports improved appetite
5. Provide oral hygiene before meals and pleasant environment for meals at meal time.	5. Promotes positive environment and increased appetite; reduces unpleasant taste	• Participates in oral hygiene measures
6. Offer smaller, more frequent meals (6 per day).	6. Decreases feeling of fullness, bloating	• Reports increased appetite; identifies rationale for smaller, frequent meals
7. Encourage patient to eat meals and supplementary feedings.	7. Encouragement is essential for the patient with anorexia and gastrointestinal discomfort.	• Demonstrates intake of high-calorie diet; adheres to protein restriction
8. Provide attractive meals and an aesthetically pleasing setting at meal time.	8. Promotes appetite and sense of well-being	• Identifies foods and fluids that are nutritious and permitted on diet
9. Eliminate alcohol.	9. Eliminates "empty calories" and further damage from alcohol	• Gains weight without increased edema or ascites formation
10. Apply an ice collar for nausea.	10. May reduce incidence of nausea	• Reports increased appetite and well-being
11. Administer medications prescribed for nausea, vomiting, diarrhea, or constipation.	11. Reduces gastrointestinal symptoms and discomforts that decrease the appetite and interest in food	• Excludes alcohol from diet
12. Encourage increased fluid intake and exercise if the patient reports constipation.	12. Promotes normal bowel pattern and reduces abdominal discomfort and distention	• Takes medications for gastrointestinal disorders as prescribed
		• Reports normal gastrointestinal function with regular bowel function

(continued)

## Plan of Nursing Care

### The Patient With Impaired Liver Function (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Impaired skin integrity related to pruritus from jaundice and edema

**Goal:** Decrease potential for pressure ulcer development; breaks in skin integrity

1. Assess degree of discomfort related to pruritus and edema.	1. Assists in determining appropriate interventions	• Exhibits intact skin without redness, excoriation, or breakdown
2. Note and record degree of jaundice and extent of edema.	2. Provides baseline for detecting changes and evaluating effectiveness of interventions	• Reports relief from pruritus
3. Keep patient's fingernails short and smooth.	3. Prevents skin excoriation and infection from scratching	• Exhibits no skin excoriation from scratching
4. Provide frequent skin care; avoid use of soaps and alcohol-based lotions.	4. Removes waste products on skin while preventing dryness of skin	• Uses nondrying soaps and lotions. States rationale for use of nondrying soaps and lotions.
5. Massage every 2 hours with emollients; turn every 2 hours	5. Promotes mobilization of edema	• Turns self periodically. Exhibits reduced edema of dependent parts of the body.
6. Initiate use of alternating-pressure mattress or low air loss bed.	6. Minimizes prolonged pressure on bony prominences susceptible to breakdown	• Exhibits no areas of skin breakdown
7. Recommend avoiding use of harsh detergents.	7. May decrease skin irritation and need for scratching	• Exhibits decreased edema; normal skin turgor
8. Assess skin integrity every 4–8 hours. Instruct patient and family in this activity.	8. Edematous skin and tissue has compromised nutrient supply and is vulnerable to pressure and trauma	
9. Restrict sodium as prescribed.	9. Minimizes edema formation	
10. Perform range of motion exercises every 4 hours; elevate edematous extremities whenever possible.	10. Promotes mobilization of edema	

**Nursing Diagnosis:** High risk for injury related to altered clotting mechanisms and altered level of consciousness

**Goal:** Reduced risk of injury

1. Assess level of consciousness and cognitive level.	1. Assists in determining patient's ability to protect self and comply with required self-protective actions; may detect deterioration of hepatic function	• Is oriented to time, place, and person
2. Provide safe environment (pad side rails, remove obstacles in room, prevent falls).	2. Minimizes falls and injury if falls occur	• Exhibits no hallucinations, and demonstrates no efforts to get up unassisted or to leave hospital
3. Provide frequent surveillance to orient patient and avoid use of restraints.	3. Protects patient from harm while stimulating and orienting patient; use of restraints may disturb patient further	• Exhibits no ecchymoses (bruises), cuts, or hematoma
4. Replace sharp objects (razors) with safer items.	4. Avoids cuts and bleeding	• Uses electric razor rather than sharp-edged razor
5. Observe each stool for color, consistency, and amount.	5. Permits detection of bleeding in gastrointestinal tract	• Exhibits absence of frank bleeding from gastrointestinal tract
6. Be alert for symptoms of anxiety, epigastric fullness, weakness, and restlessness.	6. May indicate early signs of bleeding and shock	• Exhibits absence of restlessness, epigastric fullness, and other indicators of hemorrhage and shock
7. Test each stool and emesis for occult blood.	7. Detects early evidence of bleeding	• Exhibits negative results of test for occult gastrointestinal bleeding
8. Observe for hemorrhagic manifestations: ecchymosis, epistaxis, petechiae, and bleeding gums.	8. Indicates altered clotting mechanisms	• Is free of ecchymotic areas or hematoma formation
9. Record vital signs at frequent intervals, depending on patient acuity (every 1–4 hours).	9. Provides baseline and evidence of hypovolemia, and hemorrhagic shock	• Exhibits normal vital signs
10. Keep patient quiet and limit activity.	10. Minimizes risk of bleeding and straining	• Maintains rest and remains quiet if active bleeding occurs
11. Assist physician in passage of tube for esophageal balloon tamponade, if its insertion is indicated.	11. Promotes nontraumatic insertion of tube in anxious and combative patient for immediate treatment of bleeding	• Identifies rationale for blood transfusions and measures to treat bleeding
		• Uses measures to prevent trauma (eg, uses soft toothbrush, blows nose gently, avoids bumps and falls, avoids straining during defecation)
		• Experiences no side effects of medications
		• Takes all medications as prescribed

(continued)

## Plan of Nursing Care

### The Patient With Impaired Liver Function (Continued)

Nursing Interventions	Rationale	Expected Outcomes
12. Observe during blood transfusions.	12. Permits detection of transfusion reactions (risk is increased with multiple blood transfusions needed for active bleeding from esophageal varices)	<ul style="list-style-type: none"> <li>Identifies rationale for precautions with use of all medications</li> <li>Cooperates with treatment modalities</li> </ul>
13. Measure and record nature, time, and amount of vomitus.	13. Assists in evaluating extent of bleeding and blood loss	
14. Maintain patient in fasting state, if indicated.	14. Reduces risk of aspiration of gastric contents and minimizes risk of further trauma to esophagus and stomach by preventing vomiting	
15. Administer vitamin K as prescribed.	15. Promotes clotting by providing fat-soluble vitamin necessary for clotting.	
16. Remain with patient during episodes of bleeding.	16. Reassures anxious patient and permits monitoring and detection of further needs of the patient	
17. Offer cold liquids by mouth when bleeding stops (if prescribed).	17. Minimizes risk of further bleeding by promoting vasoconstriction of esophageal and gastric blood vessels	
18. Institute measures to prevent trauma: <ol style="list-style-type: none"> <li>Maintain safe environment.</li> <li>Encourage <i>gentle</i> blowing of nose.</li> <li>Provide soft toothbrush and avoid use of toothpicks.</li> <li>Encourage intake of foods with high content of vitamin C.</li> <li>Apply cold compresses where indicated.</li> <li>Record location of bleeding sites.</li> <li>Use small-gauge needles for injections.</li> </ol>	18. Promotes safety of patient <ol style="list-style-type: none"> <li>Minimizes risk of trauma and bleeding by avoiding falls and cuts, etc.</li> <li>Reduces risk of nosebleed (epistaxis) secondary to trauma and decreased clotting</li> <li>Prevents trauma to oral mucosa while promoting good oral hygiene</li> <li>Promotes healing</li> <li>Minimizes bleeding into tissues by promoting local vasoconstriction</li> <li>Permits detection of new bleeding sites and monitoring of previous sites of bleeding</li> <li>Minimizes oozing and blood loss from repeated injections</li> </ol>	
19. Administer medications carefully; monitor for side effects.	19. Reduces risk of side effects secondary to damaged liver's inability to detoxify (metabolize) medications normally	

**Nursing Diagnosis:** Disturbed body image related to changes in appearance, sexual dysfunction, and role function

**Goal:** Patient verbalizes feelings consistent with improvement of body image and self-esteem

1. Assess changes in appearance and the meaning these changes have for patient and family.	1. Provides information for assessing impact of changes in appearance, sexual function, and role on the patient and family	<ul style="list-style-type: none"> <li>Verbalizes concerns related to changes in appearance, life, and lifestyle</li> <li>Shares concerns with significant others</li> <li>Identifies past coping strategies that have been effective</li> <li>Uses past effective coping strategies to deal with changes in appearance, life, and lifestyle</li> <li>Maintains good grooming and hygiene</li> <li>Identifies short-term goals and strategies to achieve them</li> <li>Exercises an active role in decision making about self and care</li> </ul>
2. Encourage patient to verbalize reactions and feelings about these changes.	2. Enables patient to identify and express concerns; encourages patient and significant others to share these concerns	
3. Assess patient's and family's previous coping strategies.	3. Permits encouragement of those coping strategies that are familiar to patient and have been effective in the past	
4. Assist and encourage patient to maximize appearance and explore alternatives to previous sexual and role functions.	4. Encourages patient to continue safe roles and functions while encouraging exploration of alternatives	

(continued)

## Plan of Nursing Care

### The Patient With Impaired Liver Function (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<ol style="list-style-type: none"> <li>Assist patient in identifying short-term goals.</li> <li>Encourage and assist patient in decision making about care.</li> <li>Identify with patient resources to provide additional support (counselor, spiritual advisor).</li> <li>Assist patient in identifying previous practices that may have been harmful to self (alcohol and drug abuse).</li> </ol>	<ol style="list-style-type: none"> <li>Accomplishing these goals serves as positive reinforcement and increases self-esteem.</li> <li>Promotes patient's control of life and improves sense of well-being and self-esteem.</li> <li>Assists patient in identifying resources and accepting assistance from others when indicated.</li> <li>Recognition and acknowledgment of the harmful effects of these practices are necessary for identifying a healthier lifestyle.</li> </ol>	<ul style="list-style-type: none"> <li>Identifies resources that are not harmful</li> <li>Verbalizes that some of previous lifestyle practices have been harmful</li> <li>Uses healthy expressions of frustration, anger, anxiety</li> </ul>

**Nursing Diagnosis:** Chronic pain and discomfort related to enlarged tender liver and ascites

**Goal:** Increased level of comfort

<ol style="list-style-type: none"> <li>Maintain bed rest when patient experiences abdominal discomfort.</li> <li>Administer antispasmodic and sedative agents as prescribed.</li> <li>Observe, record, and report presence and character of pain and discomfort.</li> <li>Reduce sodium and fluid intake if prescribed.</li> <li>Prepare patient and assist with paracentesis.</li> </ol>	<ol style="list-style-type: none"> <li>Reduces metabolic demands and protects the liver</li> <li>Reduces irritability of the gastrointestinal tract and decreases abdominal pain and discomfort</li> <li>Provides baseline to detect further deterioration of status and to evaluate interventions</li> <li>Minimizes further formation of ascites</li> <li>Removal of ascites fluid may decrease abdominal discomfort</li> </ol>	<ul style="list-style-type: none"> <li>Reports pain and discomfort if present</li> <li>Maintains bed rest and decreases activity in presence of pain</li> <li>Takes antispasmodic and sedatives as indicated and as prescribed</li> <li>Reports decreased pain and abdominal discomfort</li> <li>Reduces sodium and fluid intake to prescribed levels if indicated to treat ascites</li> <li>Exhibits decreased abdominal girth and appropriate weight changes</li> <li>Reports decreased discomfort after paracentesis</li> </ul>
---	---	--

**Nursing Diagnosis:** Fluid volume excess related to ascites and edema formation

**Goal:** Restoration of normal fluid volume

<ol style="list-style-type: none"> <li>Restrict sodium and fluid intake if prescribed.</li> <li>Administer diuretics, potassium, and protein supplements as prescribed.</li> <li>Record intake and output every 1 to 8 hours depending on response to interventions and on patient acuity.</li> <li>Measure and record abdominal girth and weight daily.</li> <li>Explain rationale for sodium and fluid restriction.</li> <li>Prepare patient and assist with paracentesis.</li> </ol>	<ol style="list-style-type: none"> <li>Minimizes formation of ascites and edema</li> <li>Promotes excretion of fluid through the kidneys and maintenance of normal fluid and electrolyte balance</li> <li>Indicates effectiveness of treatment and adequacy of fluid intake</li> <li>Monitors changes in ascites formation and fluid accumulation</li> <li>Promotes patient's understanding of restriction and cooperation with it</li> <li>Paracentesis will temporarily decrease amount of ascites present.</li> </ol>	<ul style="list-style-type: none"> <li>Consumes diet low in sodium and within prescribed fluid restriction</li> <li>Takes diuretics, potassium, and protein supplements as indicated without experiencing side effects</li> <li>Exhibits increased urine output</li> <li>Exhibits decreasing abdominal girth</li> <li>Exhibits no rapid increase in weight</li> <li>Identifies rationale for sodium and fluid restriction</li> <li>Shows a decrease in ascites with decreased weight</li> </ul>
---	--	---

## Plan of Nursing Care

### The Patient With Impaired Liver Function (Continued)

Nursing Interventions	Rationale	Expected Outcomes
<p><b>Nursing Diagnosis:</b> Disturbed thought processes related to deterioration of liver function and increased serum ammonia level</p> <p><b>Goal:</b> Improved mental status; safety maintained</p>		
<ol style="list-style-type: none"> <li>1. Restrict dietary protein as prescribed.</li> <li>2. Give frequent, small feedings of carbohydrates.</li> <li>3. Protect from infection.</li> <li>4. Keep environment warm and draft-free.</li> <li>5. Pad the side rails of the bed.</li> <li>6. Limit visitors.</li> <li>7. Provide careful nursing surveillance to ensure patient's safety.</li> <li>8. Avoid opioids and barbiturates.</li> <li>9. Awaken at intervals (every 2–4 hours) to assess cognitive status.</li> </ol>	<ol style="list-style-type: none"> <li>1. Reduces source of ammonia (protein foods)</li> <li>2. Promotes consumption of adequate carbohydrates for energy requirements and spares protein from breakdown for energy</li> <li>3. Minimizes risk for further increase in metabolic requirements</li> <li>4. Minimizes shivering, which would increase metabolic requirements</li> <li>5. Provides protection for the patient should hepatic coma and seizure activity occur</li> <li>6. Minimizes patient's activity and metabolic requirements</li> <li>7. Provides close monitoring of new symptoms and minimizes trauma to the confused patient</li> <li>8. Prevents masking of symptoms of hepatic coma and prevents drug overdose secondary to reduced ability of the damaged liver to metabolize opioids and barbiturates</li> <li>9. Provides stimulation to the patient and opportunity for observing the patient's level of consciousness</li> </ol>	<ul style="list-style-type: none"> <li>• Adheres to protein restriction</li> <li>• Demonstrates an interest in events and activities in environment</li> <li>• Demonstrates normal attention span</li> <li>• Follows and participates in conversation appropriately</li> <li>• Is oriented to person, place, and time</li> <li>• Remains in bed when indicated</li> <li>• Reports no urinary or fecal incontinence</li> <li>• Experiences no seizures</li> </ul>

**Nursing Diagnosis:** Risk for imbalanced body temperature: hyperthermia related to inflammatory process of cirrhosis or hepatitis

**Goal:** Maintenance of normal body temperature, free from infection

<ol style="list-style-type: none"> <li>1. Record temperature regularly (every 4 hours).</li> <li>2. Encourage fluid intake.</li> <li>3. Apply cool sponges or icebag for elevated temperature.</li> <li>4. Administer antibiotics as prescribed.</li> <li>5. Avoid exposure to infections.</li> <li>6. Keep patient at rest while temperature is elevated.</li> <li>7. Assess for abdominal pain, tenderness.</li> </ol>	<ol style="list-style-type: none"> <li>1. Provides baseline to detect fever and to evaluate interventions</li> <li>2. Corrects fluid loss from perspiration and fever and increases patient's level of comfort</li> <li>3. Promotes reduction of fever and increases patient's comfort</li> <li>4. Ensures appropriate serum concentration of antibiotics to treat infection</li> <li>5. Minimizes risk of further infection and further increases in body temperature and metabolic rate</li> <li>6. Reduces metabolic rate</li> <li>7. May occur with bacterial peritonitis</li> </ol>	<ul style="list-style-type: none"> <li>• Exhibits normal temperature and reports absence of chills or sweating</li> <li>• Demonstrates adequate intake of fluids</li> <li>• Exhibits no evidence of local or systemic infection</li> </ul>

(continued)

## Plan of Nursing Care

### The Patient With Impaired Liver Function (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Ineffective breathing pattern related to ascites and restriction of thoracic excursion secondary to ascites, abdominal distention, and fluid in the thoracic cavity

**Goal:** Improved respiratory status

1. Elevate head of bed to at least 30 degrees.	1. Reduces abdominal pressure on the diaphragm and permits fuller thoracic excursion and lung expansion	<ul style="list-style-type: none"> <li>• Experiences improved respiratory status</li> <li>• Reports decreased shortness of breath</li> <li>• Reports increased strength and sense of well-being</li> <li>• Exhibits normal respiratory rate (12–18/min) with no adventitious sounds</li> <li>• Exhibits full thoracic excursion without shallow respirations</li> <li>• Exhibits normal arterial blood gases</li> <li>• Exhibits adequate oxygen saturation by pulse oximetry</li> <li>• Experiences absence of confusion or cyanosis</li> </ul>
2. Conserve patient's strength by providing rest periods and assisting with activities.	2. Reduces metabolic and oxygen requirements	
3. Change position every 2 hours.	3. Promotes expansion and oxygenation of all areas of the lungs	
4. Assist with paracentesis or thoracentesis.	4. Paracentesis and thoracentesis (performed to remove fluid from the abdominal and thoracic cavities, respectively) may be frightening to the patient.	
<ol style="list-style-type: none"> <li>a. Explain procedure and its purpose to patient.</li> <li>b. Have patient void before paracentesis.</li> <li>c. Support and maintain position during procedure.</li> <li>d. Record both the amount and the character of fluid aspirated.</li> <li>e. Observe for evidence of coughing, increasing dyspnea, or pulse rate.</li> </ol>	<ol style="list-style-type: none"> <li>a. Helps obtain patient's cooperation with procedures</li> <li>b. Prevents inadvertent bladder injury</li> <li>c. Prevents inadvertent organ or tissue injury</li> <li>d. Provides record of fluid removed and indication of severity of limitation of lung expansion by fluid</li> <li>e. Indicates irritation of the pleural space and evidence of pneumothorax or hemothorax.</li> </ol>	

**Collaborative Problem:** Gastrointestinal bleeding and hemorrhage

**Goal:** The patient will develop no episodes of gastrointestinal bleeding and hemorrhage

1. Assess patient for evidence of gastrointestinal bleeding or hemorrhage. If bleeding does occur: <ol style="list-style-type: none"> <li>a. Monitor vital signs (blood pressure, pulse, respiratory rate) every 4 hours or more frequently, depending on acuity.</li> <li>b. Assess skin temperature, level of consciousness every 4 hours or more frequently, depending on acuity.</li> <li>c. Monitor gastrointestinal secretions and output (emesis, stool for occult or obvious bleeding). Test emesis for blood once per shift and with any change. Hematest each stool.</li> <li>d. Monitor hematocrit and hemoglobin for trends and changes.</li> </ol>	1. Allows early detection of signs and symptoms of bleeding and hemorrhage	<ul style="list-style-type: none"> <li>• Experiences no episodes of bleeding and hemorrhage</li> <li>• Vital signs are within acceptable range for patient</li> <li>• No evidence of bleeding from gastrointestinal tract</li> <li>• Hematocrit and hemoglobin levels within acceptable limits</li> <li>• Turns and moves without straining and increasing intra-abdominal pressure</li> <li>• No straining with bowel movements</li> <li>• No further bleeding episodes if aggressive treatment of bleeding and hemorrhage was needed</li> <li>• Patient and family state rationale for treatments</li> <li>• Patient and family identify supports available to them</li> <li>• Patient and family describe signs and symptoms of a recurrent bleeding episode and identify needed action</li> </ul>
2. Avoid activities that increase intra-abdominal pressure (straining, turning). <ol style="list-style-type: none"> <li>a. Avoid coughing/sneezing.</li> <li>b. Assist patient to turn.</li> <li>c. Keep all needed items within easy reach.</li> <li>d. Use measures to prevent constipation such as adequate fluid intake; stool softeners.</li> <li>e. Ensure small meals.</li> </ol>	2. Minimizes increases in intra-abdominal pressure that could lead to rupture and bleeding of esophageal or gastric varices	

(continued)

## Plan of Nursing Care

### The Patient With Impaired Liver Function (Continued)

#### Nursing Interventions      Rationale      Expected Outcomes

3. Have equipment (Blakemore tube, medications, intravenous fluids) available if indicated.	3. Equipment, medications, and supplies will be readily available if patient experiences bleeding from ruptured esophageal or gastric varices.	
4. Assist with procedures and therapy needed to treat gastrointestinal bleeding and hemorrhage.	4. Gastrointestinal bleeding and hemorrhage require emergency measures (eg, insertion of Blakemore tube, administration of fluids and medications).	
5. Monitor respiratory status every hour and minimize risk of respiratory complications if esophageal tamponade is needed.	5. The patient is at high risk for respiratory complications, including asphyxiation if gastric balloon of Blakemore tube ruptures or migrates upward.	
6. Prepare patient physically and psychologically for other treatment modalities if needed.	6. The patient who experiences hemorrhage is very anxious and fearful; minimizing anxiety assists in control of hemorrhage.	
7. Monitor patient for recurrence of bleeding and hemorrhage.	7. Risk of rebleeding is high with all treatment modalities used to halt gastrointestinal bleeding.	
8. Keep family informed of patient's status.	8. Family members are likely to be anxious about the patient's status; providing information will reduce their anxiety level and promote more effective coping.	
9. Once recovered from bleeding episode, provide patient and family with information regarding signs and symptoms of gastrointestinal bleeding.	9. Risk of rebleeding is high. Subtle signs may be more quickly identified.	

#### Collaborative Problem: Hepatic encephalopathy

**Goal:** Patient will be maintained safely and without injury

1. Assess cognitive status every 4–8 hours: <ol style="list-style-type: none"> <li>Assess patient's orientation to person, place, and time.</li> <li>Monitor patient's level of activity, restlessness, and agitation. Assess for presence of flapping hand tremors (asterixis).</li> <li>Obtain and record daily sample of patient's handwriting or ability to construct a simple figure (eg, star).</li> <li>Assess neurologic signs (deep tendon reflexes, ability to follow instructions).</li> </ol>	1. Data will provide baseline of patient's cognitive status and enable detection of changes.	<ul style="list-style-type: none"> <li>Remains awake, alert, and aware of surroundings</li> <li>Is oriented to time, place, and person</li> <li>Exhibits no restlessness or agitation</li> <li>Record of handwriting demonstrates no deterioration in cognitive function</li> <li>States rationale for treatment used to prevent or treat hepatic encephalopathy</li> <li>Demonstrates stable serum ammonia level within acceptable limits</li> <li>Consumes adequate caloric intake and adheres to protein restriction</li> <li>Takes medications as prescribed</li> <li>Breath sounds are normal without adventitious sounds</li> <li>Skin and tissue intact without evidence of pressure or breaks in integrity</li> </ul>
2. Monitor medications to prevent administration of those that may precipitate hepatic encephalopathy (sedatives, hypnotics, analgesics).	2. Medications are a common precipitating factor in development of hepatic encephalopathy in patients at risk.	
3. Monitor laboratory data, especially serum ammonia level.	3. Increases in serum ammonia level are associated with hepatic encephalopathy and coma.	
4. Notify physician of even subtle changes in patient's neurologic status and cognitive function.	4. Allows early initiation of treatment of hepatic encephalopathy and prevention of hepatic coma	
5. Limit sources of protein from diet if indicated.	5. Reduces breakdown and conversion of protein to ammonia	
6. Administer medications prescribed to reduce serum ammonia level (eg, lactulose, antibiotics, glucose, benzodiazepine antagonist [Flumazaniil] if indicated).	6. Reduces serum ammonia level	
7. Assess respiratory status and initiate measures to prevent complications.	7. The patient who develops hepatic coma is at risk for respiratory complications (ie, pneumonia, atelectasis, infection).	
8. Protect patient's skin and tissue from pressure and breakdown.	8. The patient in coma is at risk for skin breakdown and pressure ulcer formation.	

## Cancer of the Liver

Hepatic tumors may be malignant or benign. Benign liver tumors were uncommon until the widespread use of oral contraceptives. With the use of oral contraceptives, benign tumors of the liver occur most frequently in women in their reproductive years.

### PRIMARY LIVER TUMORS

Few cancers originate in the liver. Primary liver tumors usually are associated with chronic liver disease, hepatitis B and C infections, and cirrhosis. Hepatocellular carcinoma (HCC) is by far the most common type of primary liver cancer, but it is rare in the United States (Bacon & Di Bisceglie, 2000). HCC is usually nonresectable because of rapid growth and metastasis. Other types of primary liver cancer include cholangiocellular carcinoma and combined hepatocellular and cholangiocellular carcinoma. If found early, resection may be possible, but early detection is unlikely. Cirrhosis, chronic infection with hepatitis B and C, and exposure to certain chemical toxins (eg, vinyl chloride, arsenic) have been implicated as causes of HCC. Cigarette smoking has also been identified as a risk factor, especially when combined with alcohol use. Some evidence suggests that aflatoxin, a metabolite of the fungus *Aspergillus flavus*, may be a risk factor for HCC. This is especially true in areas where HCC is endemic (ie, Asia and Africa). Aflatoxin and other similar toxic molds can contaminate food such as ground nuts and grains and may act as a co-carcinogen with hepatitis B. The risk of contamination is greatest when these foods are stored unrefrigerated in tropical or subtropical climates.

### LIVER METASTASES

Metastases from other primary sites are found in the liver in about half of all advanced cancer cases (Bacon & Di Bisceglie, 2000). Malignant tumors are likely to reach the liver eventually, by way of the portal system or lymphatic channels, or by direct extension from an abdominal tumor. Moreover, the liver apparently is an ideal place for these malignant cells to thrive. Often the first evidence of cancer in an abdominal organ is the appearance of liver metastases; unless exploratory surgery or an autopsy is performed, the primary tumor may never be identified.

### Clinical Manifestations

The early manifestations of malignancy of the liver include pain, a continuous dull ache in the right upper quadrant, epigastrium, or back. Weight loss, loss of strength, anorexia, and anemia may also occur. The liver may be enlarged and irregular on palpation. Jaundice is present only if the larger bile ducts are occluded by the pressure of malignant nodules in the hilum of the liver. Ascites develops if such nodules obstruct the portal veins or if tumor tissue is seeded in the peritoneal cavity.

### Assessment and Diagnostic Findings

The liver cancer diagnosis is based on clinical signs and symptoms, the history and physical examination, and the results of laboratory and x-ray studies. Increased serum levels of bilirubin, alkaline phosphatase, AST, GGT, and lactic dehydrogenase may occur. Leukocytosis (increased white blood cells), erythrocytosis (increased red blood cells), hypercalcemia, hypoglycemia, and hypocholesterolemia may also be seen on laboratory assessment.

The serum level of alpha-fetoprotein (AFP), which serves as a tumor marker, is elevated in 30% to 40% of patients with primary liver cancer. Levels of carcinoembryonic antigen (CEA), a marker of advanced cancer of the digestive tract, may be elevated. These two markers together are useful to distinguish between metastatic liver disease and primary liver cancer.

Many patients have metastases from the primary liver tumor to other sites by the time diagnosis is made; metastases occur primarily to the lung but may also occur to regional lymph nodes, adrenals, bone, kidneys, heart, pancreas, and stomach.

X-rays, liver scans, CT scans, ultrasound studies, MRI, arteriography, and laparoscopy may be part of the diagnostic workup and may be performed to determine the extent of the cancer. Positive emission tomograms (PET scans) are used to evaluate a wide range of metastatic tumors of the liver.

Confirmation of a tumor's histology can be made by biopsy under imaging guidance (CT scan or ultrasound) or laparoscopically. Local or systemic dissemination of the tumor by needle biopsy or fine-needle biopsy can occur but is rare. Some clinicians believe that these procedures should not be performed if the tumor is thought to be resectable; rather, for primary HCC diagnosis should be confirmed by frozen section at the time of laparotomy.

### Medical Management

Although surgical resection of the liver tumor is possible in some patients, the underlying cirrhosis, so prevalent in cancer of the liver, increases the risks associated with surgery. Radiation therapy and chemotherapy have been used in treating cancer of the liver with varying degrees of success. Although these therapies may prolong survival and improve quality of life by reducing pain and discomfort, their major effect is palliative.

#### RADIATION THERAPY

The use of external beam radiation for the treatment of liver tumors has been limited by the radiosensitivity of normal hepatocytes. Doses over 2,500 to 3,000 cGy may result in radiation hepatitis (O'Grady et al., 2000). More effective methods of delivering radiation to tumors of the liver include (1) intravenous or intra-arterial injection of antibodies that are tagged with radioactive isotopes and specifically attack tumor-associated antigens and (2) percutaneous placement of a high-intensity source for interstitial radiation therapy (delivering radiation directly to the tumor cells).

#### CHEMOTHERAPY

Chemotherapy has been used to improve quality of life and prolong survival; it also may be used as adjuvant therapy after surgical resection of hepatic tumors. Systemic chemotherapy and regional infusion chemotherapy are two methods used to administer antineoplastic agents to patients with primary and metastatic hepatic tumors (O'Grady et al., 2000).

An implantable pump has been used to deliver a high concentration of chemotherapy to the liver through the hepatic artery. This method provides a reliable, controlled, and continuous infusion of medication that can be carried out in the patient's home. Recent studies have begun to show some effective palliation and modestly improved survival rates (Bacon & Di Bisceglie, 2000).

#### PERCUTANEOUS BILIARY DRAINAGE

Percutaneous biliary or transhepatic drainage is used to bypass biliary ducts obstructed by liver, pancreatic, or bile duct tumors

in patients with inoperable tumors or in those considered poor surgical risks. Under fluoroscopy, a catheter is inserted through the abdominal wall and past the obstruction into the duodenum. Such procedures are used to reestablish biliary drainage, relieve pressure and pain from the buildup of bile behind the obstruction, and decrease pruritus and jaundice. As a result, the patient is made more comfortable and quality of life and survival are improved.

For several days after its insertion, the catheter is opened to external drainage. The bile is observed closely for amount, color, and presence of blood and debris. Complications of percutaneous biliary drainage include sepsis, leakage of bile, hemorrhage, and reobstruction of the biliary system by debris in the catheter or from encroaching tumor. Therefore, the patient is observed for fever and chills, bile drainage around the catheter, changes in vital signs, and evidence of biliary obstruction, including increased pain or pressure, pruritus, and recurrence of jaundice.

### OTHER NONSURGICAL TREATMENTS

Laser hyperthermia has been used to treat hepatic metastases. Heat has been directed to tumors through several methods to cause necrosis of the tumor cells while sparing normal tissue. In radiofrequency thermal ablation, a needle electrode is inserted into the liver tumor under imaging guidance. Radiofrequency energy passes through to the noninsulated needle tip, causing heat and tumor cell death from coagulation necrosis.

Immunotherapy is another treatment modality under investigation. In this therapy, lymphocytes with antitumor reactivity are administered to the patient with hepatic cancer. Regression of the tumor, the desired outcome, has been demonstrated in patients with metastatic cancer in whom standard treatment has failed.

Transcatheter arterial embolization interrupts the arterial blood flow to small tumors by injecting small particulate embolic or chemotherapeutic agents into the artery supplying the tumor. Ischemia and necrosis of the tumor occur as a result.

For multiple small lesions, ultrasound-guided injection of alcohol promotes dehydration of tumor cells and tumor necrosis (Habib, 2000; O'Grady et al., 2000).

### SURGICAL MANAGEMENT

Surgical resection is the treatment of choice when HCC is confined to one lobe of the liver and the function of the remaining liver is considered adequate for postoperative recovery. In the case of metastasis, hepatic resection can be performed when the primary site can be completely excised and the metastasis is limited. Metastases to the liver, however, are rarely limited or solitary. Capitalizing on the regenerative capacity of the liver cells, some surgeons have successfully removed 90% of the liver. However, the presence of cirrhosis limits the ability of the liver to regenerate. Staging of liver tumors aids in predicting the likelihood of surgical cure. A staging system for liver tumors is summarized in Chart 39-11.

In preparation for surgery, the patient's nutritional, fluid, and general physical status is assessed and efforts are undertaken to ensure the best physical condition possible. Support, explanation, and encouragement are provided to help the patient prepare psychologically for the surgery.

Extensive diagnostic studies may be performed. Specific studies may include liver scan, liver biopsy, cholangiography, selective hepatic angiography, percutaneous needle biopsy, peritoneoscopy, laparoscopy, ultrasound, CT scans, MRI, and blood tests, particularly determinations of serum alkaline phosphatase, AST, and GGT and its isoenzymes.

**Lobectomy.** Removal of a lobe of the liver is the most common surgical procedure for excising a liver tumor. If it is necessary to restrict blood flow from the hepatic artery and portal vein beyond 15 minutes, it is likely that hypothermia will be used. For a right-liver lobectomy or an extended right lobectomy (including the medial left lobe), a thoracoabdominal incision is used. An extensive abdominal incision is made for a left lobectomy.

**Cryosurgery.** In cryosurgery (**cryoablation**), tumors are destroyed by liquid nitrogen at  $-196^{\circ}\text{C}$ . To destroy the diseased tissue, two or three freeze-and-thaw cycles are administered via probes during open laparotomy. This technique has been used alone or as an adjunct to hepatic resection in HCC and colorectal metastases not amenable to radical surgical excision. The efficacy of cryosurgery is still being evaluated; indications and outcomes require further investigation.

**Liver Transplantation.** Removing the liver and replacing it with a healthy donor organ is another way to treat liver cancer. Recurrence of the primary liver malignancy after transplantation, however, has been reported to occur in 70% to 85% of cases, and the survival time after recurrence is brief. Metastasis and recurrence may be enhanced by the immunosuppressive therapy needed to prevent rejection. The patient with small tumors may have a good prognosis after transplantation, but recurrence is common with tumors greater than 8 cm in diameter or those that are multifocal or have vascular invasion (Bacon & Di Bisceglie, 2000). See the discussion of liver transplantation that follows.

## Nursing Management

If the patient has had surgery to treat liver cancer, potential problems related to cardiopulmonary involvement include vascular complications and respiratory and liver dysfunction. Metabolic abnormalities require careful attention. A constant infusion of 10% glucose may be required in the first 48 hours to prevent a precipitous fall in the blood glucose level resulting from decreased gluconeogenesis. Because extensive blood loss may occur as well, the patient will receive infusions of blood and IV fluids. The patient requires constant, close monitoring and care for the first 2 or 3 days, similar to postsurgical abdominal and thoracic nursing care.

The patient undergoing cryosurgery is monitored closely for hypothermia, hemorrhage, or bile leak; myoglobinuria can occur as a result of tissue necrosis and is minimized by hydration, diuresis, and at times medications (allopurinol) to bind to and aid in the excretion of toxic products.

If the patient will receive chemotherapy or radiation therapy in an effort to relieve symptoms, he or she may be discharged home while still receiving one or both of these therapies. The patient may also go home with a biliary drainage system in place. The need for teaching is great because of the need for the patient to participate in care and the family's role in care at home.

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** The nurse instructs the patient to recognize and report the complications and side effects of the chemotherapy that may occur and the actions and desired and undesirable effects of the specific chemotherapy regimen. The nurse also emphasizes the importance of follow-up visits to assess the patient and the tumor's response to chemotherapy and radiation therapy.

If the patient is receiving chemotherapy on an outpatient basis, the nurse explains the patient's and family's role in managing the chemotherapy infusion and in assessing the infusion/insertion site. The nurse encourages the patient to resume routine activities as soon as possible, while cautioning him or her to avoid activities that may damage the infusion pump or site.

The family and the patient at home with a biliary drainage system in place typically fear that the catheter will be dislodged. They need reassurance and instruction to reduce their fear that the catheter will fall out easily. The patient and family also require instruction on catheter care. They need to learn how to keep the catheter site clean and dry and how to assess the catheter and its insertion site. Irrigation of the catheter with sterile normal saline solution or water may be prescribed to keep the catheter patent and free of debris. The patient and caregivers are taught proper technique to avoid introducing bacteria into the biliary system or catheter during irrigation. They are instructed not to aspirate or draw back on the syringe during irrigation to prevent entry of irritating duodenal contents into the biliary tree or catheter. The patient and caregivers are also instructed about the signs of complications and are encouraged to notify the nurse or physician if problems or questions arise.

**Continuing Care.** In many cases, referral for home care enables the patient with liver cancer to be at home in a familiar environment with family and friends. Because of the poor prognosis associated with liver cancer, the home care nurse serves a vital role in assisting the patient and family to cope with the symptoms that may occur and the prognosis. The home care nurse assesses the

patient's physical and psychological status, the adequacy of pain relief, nutritional status, and the presence of symptoms indicating complications of treatment or progression of disease. During home visits, the nurse assesses the function of the chemotherapy pump, the infusion site, and the biliary drainage system, if indicated. The nurse collaborates with the other members of the health care team, the patient, and the family to ensure effective pain management and to manage other problems that may occur: weakness, pruritus, inadequate dietary intake, jaundice, and symptoms associated with metastasis to other sites. The home care nurse also assists the patient and family in making decisions about hospice care and assists with initiation of referrals. The patient is encouraged to discuss preferences for end-of-life care with family members and health care providers (see Chap. 17).

## Liver Transplantation

Liver transplantation is used to treat life-threatening, end-stage liver disease for which no other form of treatment is available. The transplantation procedure involves total removal of the diseased liver and its replacement with a healthy liver in the same anatomic location (**orthotopic liver transplantation [OLT]**). Removal of the liver leaves a space for the new liver and permits anatomic reconstruction of the hepatic vasculature and biliary tract as close to normal as possible.

The success of liver transplantation depends on successful immunosuppression. Immunosuppressants currently in use include cyclosporine (Neoral), corticosteroids, azathioprine (Imuran), mycophenolate mofetil (CellCept), OKT3 (a monoclonal antibody), tacrolimus (FK506, Prograf), sirolimus (formerly known as rapamycin [Rapamune]), and antithymocyte globulin. Studies are underway to find the most effective combination of immunosuppressive agents and to identify new agents with fewer side effects (Hebert et al., 1999; Watson, Friend & Jamieson, 1999).

Despite the success of immunosuppression in reducing the incidence of rejection of transplanted organs, liver transplantation is not a routine procedure and may be accompanied by complications related to the lengthy surgical procedure, immunosuppressive therapy, infection, and the technical difficulties encountered in reconstructing the blood vessels and biliary tract. Long-standing systemic problems resulting from the primary liver disease may complicate the preoperative and postoperative course. Previous surgery of the abdomen, including procedures to treat complications of advanced liver disease (ie, shunt procedures used to treat portal hypertension and esophageal varices) increase the complexity of the transplantation procedure.

The indications for liver transplantation are not as limited today as they were when the procedure was first introduced, due to advances in immunosuppressive therapy, improvements in biliary tract reconstruction, and in some cases the use of venovenous bypass. General indications for liver transplantation include irreversible advanced chronic liver disease, fulminant hepatic failure, metabolic liver diseases, and some hepatic malignancies. Examples of disorders that are indications for liver transplantation include hepatocellular liver disease (eg, viral hepatitis, drug- and alcohol-induced liver disease, and Wilson's disease) and cholestatic diseases (primary biliary cirrhosis, sclerosing cholangitis, and biliary atresia).

The patient being considered for liver transplantation frequently has many systemic problems that influence preoperative and postoperative care. Because transplantation is more

difficult when the patient has developed severe GI bleeding and hepatic coma, efforts are made to perform the procedure before this stage.

Liver transplantation is now recognized as an established therapeutic modality rather than an experimental procedure to treat these disorders. As a result, the number of centers where liver transplantation is performed is increasing. Patients requiring transplantation are often referred from distant hospitals to these sites. To prepare the patient and family for liver transplantation, nurses in all settings must understand the processes and procedures of liver transplantation.

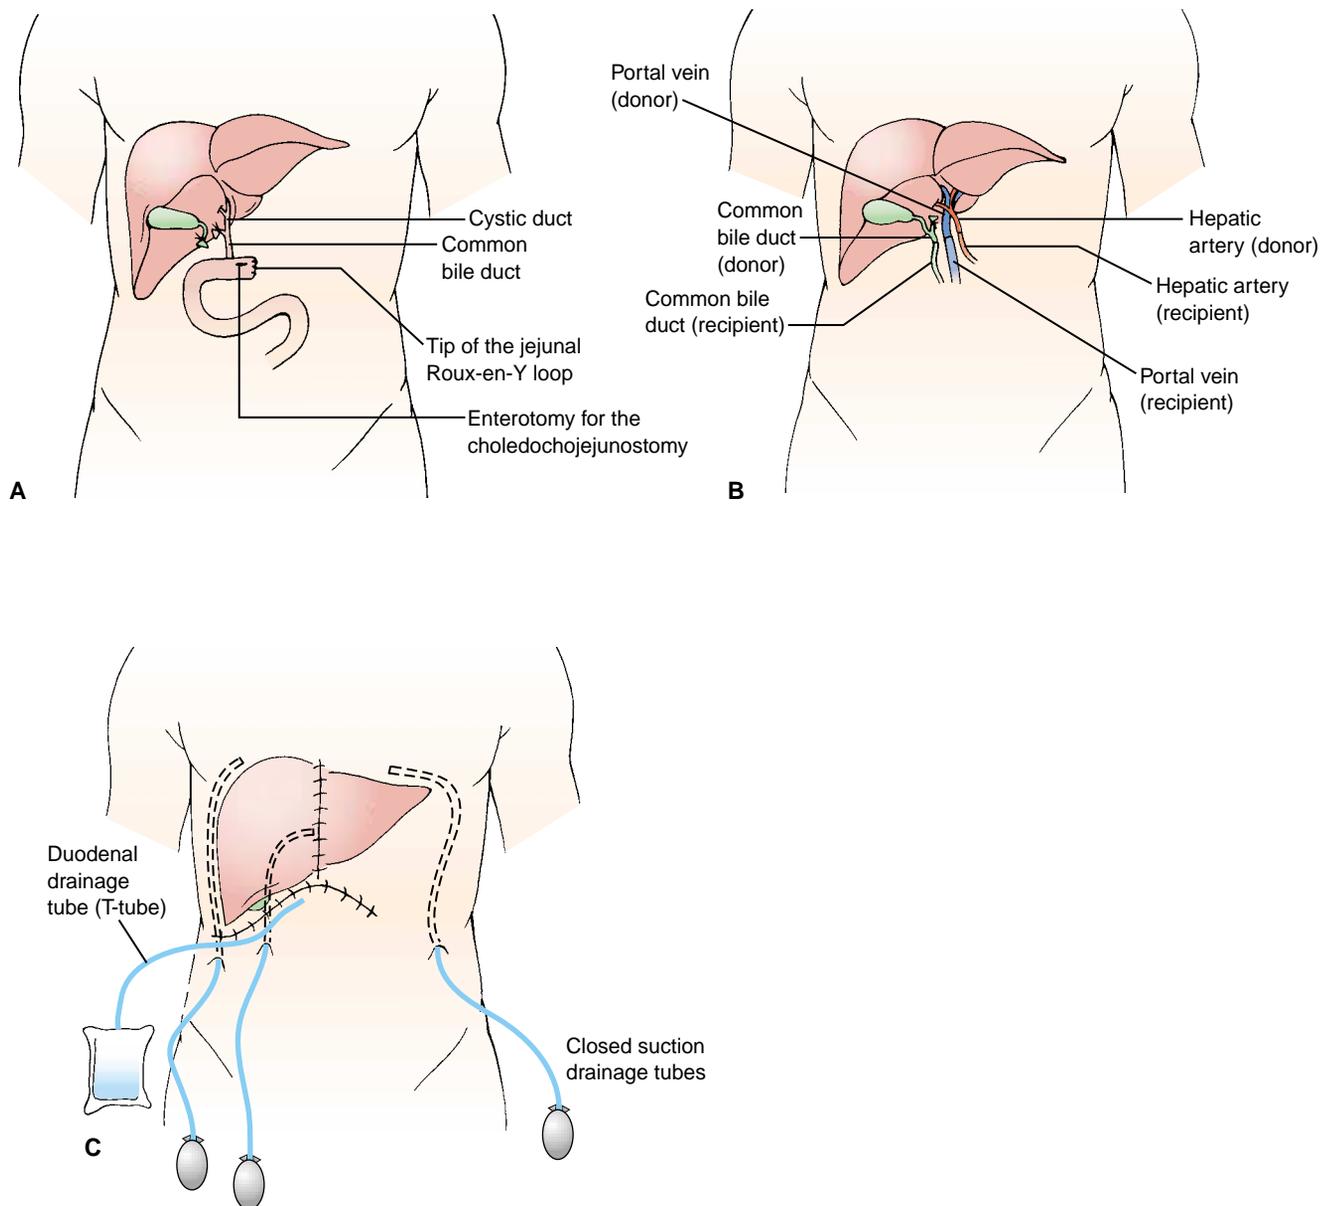

## SURGICAL PROCEDURE

The donor liver is freed from other structures, the bile is flushed from the gallbladder to prevent damage to the walls of the biliary tract, and the liver is perfused with a preservative and

cooled. Before the donor liver is placed in the recipient, it is flushed with cold lactated Ringer's solution to remove potassium and air bubbles.

Anastomoses (connections) of the blood vessels and bile duct are performed between the donor liver and the recipient liver. Biliary reconstruction is performed with an end-to-end anastomosis of the donor and recipient common bile ducts; a stented T-tube is inserted for external drainage of bile. If an end-to-end anastomosis is not possible because of diseased or absent bile ducts, an end-to-side anastomosis is made between the common bile duct of the graft and a loop (Roux-en-Y portion) of jejunum (Fig. 39-15A); in this case, bile drainage will be internal and a T-tube will not be inserted (Maddrey et al., 2001). Figure 39-15B and C illustrates the final appearance of the grafted liver and final closure and drain placement.

Liver transplantation is a long surgical procedure, partly because the patient with liver failure often has portal hypertension
