Assessing the patient's nutritional status is an important nursing role. Impaired nutritional status may contribute to disease progression, immune incompetence, increased incidence of infection, delayed tissue repair, diminished functional ability, and decreased capacity to continue antineoplastic therapy. Altered nutritional status, weight loss, and cachexia (muscle wasting, emaciation) may be secondary to decreased protein and caloric intake, metabolic or mechanical effects of the cancer, systemic disease, side effects of the treatment, or the emotional status of the patient.

The patient's weight and caloric intake are monitored on a consistent basis. Other information obtained through assessment includes diet history, any episodes of anorexia, changes in appetite, situations and foods that aggravate or relieve anorexia, and medication history. Difficulty in chewing or swallowing is determined and the occurrence of nausea, vomiting, or diarrhea is noted.

Clinical and laboratory data useful in assessing the patient's nutritional status include anthropometric measurements (triceps skin fold and middle-upper arm circumference), serum protein levels (albumin and transferrin), serum electrolytes, lymphocyte count, skin response to intradermal injection of antigens, hemoglobin levels, hematocrit, urinary creatinine levels, and serum iron levels.

### PAIN

Pain and discomfort in cancer may be related to the underlying disease, pressure exerted by the tumor, diagnostic procedures, or the cancer treatment itself. As in any other situation involving pain, cancer pain is affected by both physical and psychosocial influences.

In addition to assessing the source and site of pain, the nurse also assesses those factors that increase the patient's perception of pain, such as fear and apprehension, fatigue, anger, and social isolation. Pain assessment scales (see Chap. 13) are useful in assess-

ing the patient's pain level before pain-relieving interventions are instituted and in evaluating their effectiveness.

## FATIGUE

Acute fatigue, which occurs after an energy-demanding experience, serves a protective function; chronic fatigue, however, does not. It is often overwhelming, excessive, and not responsive to rest, and it seriously affects quality of life. Fatigue is the most commonly reported side effect in patients who receive chemotherapy and radiation therapy. The nurse assesses for feelings of weariness, weakness, lack of energy, inability to carry out necessary and valued daily functions, lack of motivation, and inability to concentrate. Patients may become less verbal and appear pallid, with relaxed facial musculature. The nurse assesses physiologic and psychological stressors that can contribute to fatigue, including pain, nausea, dyspnea, constipation, fear, and anxiety. (See Nursing Research Profile 16-2.)

## PSYCHOSOCIAL STATUS

Nursing assessment also focuses on the patient's psychological and mental status as the patient and the family face this life-threatening experience, unpleasant diagnostic tests and treatment modalities, and progression of disease. The patient's mood and emotional reaction to the results of diagnostic testing and prognosis are assessed, along with evidence that the patient is progressing through the stages of grief and can talk about the diagnosis and prognosis with the family.

## BODY IMAGE

Cancer patients are forced to cope with many assaults to body image throughout the course of disease and treatment. Entry into the health care system is often accompanied by depersonalization. Threats to self-concept are enormous as patients face the realization of illness, possible disability, and death. To accommodate treatments or because of the disease, many cancer patients are forced to alter their lifestyles. Priorities and values change when body image is threatened. Disfiguring surgery, hair loss, cachexia, skin changes, altered communication patterns, and sexual dysfunction are some of the devastating results of cancer and its treatment that threaten the patient's self-esteem and body image. The nurse identifies these potential threats and assesses the patient's ability to cope with these changes.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, nursing diagnoses of the patient with cancer may include the following:

- Impaired oral mucous membrane
- Impaired tissue integrity
- Impaired tissue integrity: alopecia
- Impaired tissue integrity: malignant skin lesions
- Imbalanced nutrition, less than body requirements
- Anorexia
- Malabsorption
- Cachexia
- Chronic pain
- Fatigue
- Disturbed body image
- Anticipatory grieving

## NURSING RESEARCH PROFILE 16-2

### Cancer-Related Fatigue

Berger, A. M., & Farr, L. (1999). The influence of daytime inactivity and nighttime restlessness on cancer-related fatigue. *Oncology Nursing Forum*, 26(10), 1663–1671.

#### Purpose

Negative, long-term consequences of chemotherapy, including fatigue, have been reported. Many women report fatigue during and following breast cancer treatment; however, perceptions of fatigue have not been objectively quantified. The purpose of this study was to identify relationships between circadian activity/rest indicators and fatigue experienced by women during the first three chemotherapy cycles for stage I/II breast cancer.

#### Study Sample and Design

A prospective, descriptive, repeated-measures study was conducted over a 12-month period. Seventy-two participants were recruited for the study; 12 withdrew, leaving a sample of 60 women. To be eligible for the study, women had to be 33 to 69 years of age, diagnosed for the first time with stage I/II breast cancer, scheduled to begin one of three intravenous chemotherapy regimens following recent modified radical mastectomy or breast-conservation surgery, English-speaking, and able to complete the research instruments.

A wrist actigraph was used for continuous monitoring of body movement over time, providing data for analysis of circadian activity/rest cycles; relative activity within days and across days; and the timing, duration, and disruption of sleep. Data were collected for 96 hours at the start of each treatment and for 72 hours at the midpoint of each chemotherapy cycle. Data from the actigraph were downloaded to a software program. The Piper Fatigue scale was used to measure participants' subjective perception of fatigue shortly after each chemotherapy treatment and on the midpoint days of each cycle coinciding with the actigraph measurements.

#### Findings

Analysis of data revealed that participants who were less active during the day and had more nighttime awakenings consistently reported higher levels of cancer-related fatigue (CRF) at the midpoint of each chemotherapy cycle. The number of night awakenings had the strongest association with CRF. Decreased daytime activity and nighttime restlessness were associated with higher CRF. Participants who were more active maintained more distinctive circadian activity/rest rhythms.

#### Nursing Implications

The findings of this study demonstrate that women whose sleep is disrupted at midpoints of chemotherapy cycles are at risk for CRF. Higher CRF levels are associated with the cumulative effects of less daytime activity, more daytime sleep, and night awakenings. Sedentary lifestyles in response to fatigue result, in turn, in increased fatigue. These findings suggest the need to assist women with developing a balance of activity and rest; advising women to “take it easy” during chemotherapy may result in decreased activity and increased fatigue.

## COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include the following:

- Infection and sepsis
- Hemorrhage
- Superior vena cava syndrome
- Spinal cord compression
- Hypercalcemia
- Pericardial effusion

- Disseminated intravascular coagulation
- Syndrome of inappropriate secretion of antidiuretic hormone
- Tumor lysis syndrome

See the later section, *Oncologic Emergencies*, for more information.

## Planning and Goals

The major goals for the patient may include management of stomatitis, maintenance of tissue integrity, maintenance of nutrition, relief of pain, relief of fatigue, improved body image, effective progression through the grieving process, and absence of complications.

## Nursing Interventions

The patient with cancer is at risk for various adverse effects of therapy and complications. The nurse in all health care settings, including the home, assists the patient and family in managing these problems.

### MANAGING STOMATITIS

**Stomatitis**, an inflammatory response of the oral tissues, commonly develops within 5 to 14 days after the patient receives certain chemotherapeutic agents, such as doxorubicin and 5-fluorouracil, and BRMs, such as IL-2 and IFN. As many as 40% of patients receiving chemotherapy experience some degree of stomatitis during treatment. Patients receiving dose-intensive chemotherapy (considerably higher doses than conventional dosing), such as those undergoing BMT, are at increased risk for stomatitis. Stomatitis may also occur with radiation to the head and neck. Stomatitis is characterized by mild redness (erythema) and edema or, if severe, by painful ulcerations, bleeding, and secondary infection. In severe cases of stomatitis, cancer therapy may be temporarily halted until the inflammation decreases.

As a result of normal everyday wear and tear, the epithelial cells that line the oral cavity undergo rapid turnover and slough off routinely. Chemotherapy and radiation interfere with the body's ability to replace those cells. An inflammatory response develops as denuded areas appear in the oral cavity. Poor oral hygiene, existing dental disease, use of other medications that dry mucous membranes, and impaired nutritional status contribute to morbidity associated with stomatitis. Radiation-induced xerostomia (dry mouth) associated with decreased function of the salivary glands may contribute to stomatitis in patients who have received radiation to the head and neck.

Myelosuppression (bone marrow depression) resulting from underlying disease or its treatment predisposes the patient to oral bleeding and infection. Pain associated with ulcerated oral tissues can significantly interfere with nutritional intake, speech, and a willingness to maintain oral hygiene.

Although multiple studies on stomatitis have been published, the optimal prevention and treatment approaches have not been identified. However, most clinicians agree that good oral hygiene that includes brushing, flossing, and rinsing is necessary to minimize the risk for oral complications associated with cancer therapies. Soft-bristled toothbrushes and nonabrasive toothpaste prevent or reduce trauma to the oral mucosa. Oral swabs with spongelike applicators may be used in place of a toothbrush for painful oral tissues. Flossing may be performed unless it causes pain or unless platelet levels are below  $40,000/\text{mm}^3$  ( $0.04 \times 10^{12}/\text{L}$ ). Oral rinses with saline solution or tap water may be nec-

essary for patients who cannot tolerate a toothbrush. Products that irritate oral tissues or impair healing, such as alcohol-based mouth rinses, are avoided. Foods that are difficult to chew or are hot or spicy are avoided to minimize further trauma. The patient's lips are lubricated to keep them from becoming dry and cracked. Topical anti-inflammatory and anesthetic agents may be prescribed to promote healing and minimize discomfort. Products that coat or protect oral mucosa are used to promote comfort and prevent further trauma. The patient who experiences severe pain and discomfort with stomatitis requires systemic analgesics.

Adequate fluid and food intake is encouraged. In some instances, parenteral hydration and nutrition are needed. Topical or systemic antifungal and antibiotic medications are prescribed to treat local or systemic infections.

### MAINTAINING TISSUE INTEGRITY

Some of the most frequently encountered disturbances of tissue integrity, in addition to stomatitis, include skin and tissue reactions to radiation therapy, alopecia, and metastatic skin lesions.

The patient who is experiencing skin and tissue reactions to radiation therapy requires careful skin care to prevent further skin irritation, drying, and damage. The skin over the affected area is handled gently; rubbing and use of hot or cold water, soaps, powders, lotions, and cosmetics are avoided. The patient may avoid tissue injury by wearing loose-fitting clothes and avoiding clothes that constrict, irritate, or rub the affected area. If blistering occurs, care is taken not to disrupt the blisters, thus reducing the risk of introducing bacteria. Moisture- and vapor-permeable dressings, such as hydrocolloids and hydrogels, are helpful in promoting healing and reducing pain. Aseptic wound care is indicated to minimize the risk for infection and sepsis. Topical antibiotics, such as 1% silver sulfadiazine cream (Silvadene), may be prescribed for use on areas of moist desquamation (painful, red, moist skin).

### ASSISTING PATIENTS TO COPE WITH ALOPECIA

The temporary or permanent thinning or complete loss of hair is a potential adverse effect of various radiation therapies and chemotherapeutic agents. The extent of alopecia depends on the dose and duration of therapy. These treatments cause alopecia by damaging stem cells and hair follicles. As a result, the hair is brittle and may fall out or break off at the surface of the scalp. Loss of other body hair is less frequent. Hair loss usually begins within 2 to 3 weeks after the initiation of treatment; regrowth begins within 8 weeks after the last treatment. Some patients who undergo radiation to the head may sustain permanent hair loss. Many health care providers view hair loss as a minor problem when compared with the potentially life-threatening consequences of cancer. For many patients, however, hair loss is a major assault on body image, resulting in depression, anxiety, anger, rejection, and isolation. To patients and families, hair loss can serve as a constant reminder of the challenges cancer places on their coping abilities, interpersonal relationships, and sexuality.

The nurse's role is to provide information about alopecia and to support the patient and family in coping with disturbing effects of therapy, such as hair loss and changes in body image. Patients are encouraged to acquire a wig or hairpiece before hair loss occurs so that the replacement matches their own hair. Use of attractive scarves and hats may make the patient feel less conspicuous. Nurses can refer patients to supportive programs, such as "Look Good, Feel Better," offered by the American Cancer Soci-

ety. Knowledge that hair usually begins to regrow after completing therapy may comfort some patients, although the color and texture of the new hair may be different.

### MANAGING MALIGNANT SKIN LESIONS

Skin lesions may occur with local extension of the tumor or embolization of the tumor into the epithelium and its surrounding lymph and blood vessels. Secondary growth of cancer cells into the skin may result in redness (erythematous areas) or can progress to wounds involving tissue necrosis and infection. The most extensive lesions tend to disintegrate and are purulent and malodorous. In addition, these lesions are a source of considerable pain and discomfort. Although this type of lesion is most often associated with breast cancer and head and neck cancers, it can also occur with lymphoma, leukemia, melanoma, and cancers of the lung, uterus, kidney, colon, and bladder. The development of severe skin lesions is usually associated with a poor prognosis for extended survival.

Ulcerating skin lesions usually indicate widely disseminated disease unlikely to be eradicated. Managing these lesions becomes a nursing priority. Nursing care includes carefully assessing and cleansing the skin, reducing superficial bacteria, controlling bleeding, reducing odor, and protecting the skin from pain and further trauma. The patient and family require assistance and guidance to care for these skin lesions at home. Referral for home care is indicated.

### PROMOTING NUTRITION

Most cancer patients experience some weight loss during their illness. Anorexia, malabsorption, and cachexia are examples of nutritional problems that commonly occur in cancer patients; special attention is needed to prevent weight loss and promote nutrition.

#### Anorexia

Among the many causes of anorexia in the cancer patient are alterations in taste, manifested by increased salty, sour, and metallic taste sensations, and altered responses to sweet and bitter flavors, leading to decreased appetite, decreased nutritional intake, and protein-calorie malnutrition. Taste alterations may result from mineral (eg, zinc) deficiencies, increases in circulating amino acids and cellular metabolites, or the administration of chemotherapeutic agents. Patients undergoing radiation therapy to the head and neck may experience “mouth blindness,” which is a severe impairment of taste.

Alterations in the sense of smell also alter taste; this is a common experience of patients with head and neck cancers. Anorexia may occur because the person feels full after eating only a small amount of food. This sense of fullness occurs secondary to a decrease in digestive enzymes, abnormalities in the metabolism of glucose and triglycerides, and prolonged stimulation of gastric volume receptors, which convey the feeling of being full. Psychological distress, such as fear, pain, depression, and isolation, throughout illness may also have a negative impact on appetite. The person may develop an aversion to food because of nausea and vomiting after treatment.

#### Malabsorption

Many cancer patients are unable to absorb nutrients from the gastrointestinal system as a result of tumor activity and cancer treatment. Tumors can affect the gastrointestinal activity in several ways. They may impair enzyme production or produce fistulas. They secrete hormones and enzymes, such as gastrin; this leads to

increased gastrointestinal irritation, peptic ulcer disease, and decreased fat digestion. They also interfere with protein digestion.

Chemotherapy and radiation can irritate and damage mucosal cells of the bowel, inhibiting absorption. Radiation therapy can cause sclerosis of the blood vessels in the bowel and fibrotic changes in the gastrointestinal tissue. Surgical intervention may change peristaltic patterns, alter gastrointestinal secretions, and reduce the absorptive surfaces of the gastrointestinal mucosa, all leading to malabsorption.

#### Cachexia

Cachexia is common in patients with cancer, especially in advanced disease. Cancer cachexia is related to inadequate nutritional intake along with increasing metabolic demand, increased energy expenditure due to anaerobic metabolism of the tumor, impaired glucose metabolism, competition of the tumor cells for nutrients, altered lipid metabolism, and a suppressed appetite. It is characterized by loss of body weight, adipose tissue, visceral protein, and skeletal muscle. Patients who are cachectic complain of loss of appetite, early satiety, and fatigue. As a result of protein losses they are often anemic and have peripheral edema.

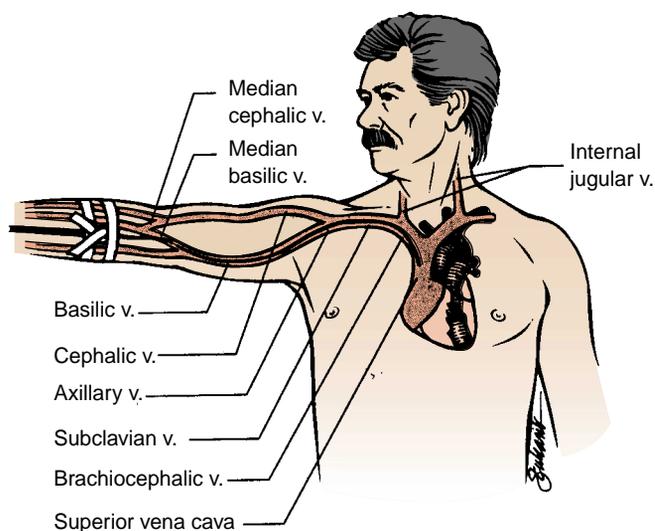

### General Nutritional Considerations

Whenever possible, every effort is used to maintain adequate nutrition through the oral route. Food should be prepared in ways that make it appealing. Unpleasant smells and unappetizing-looking foods are avoided. Family members are included in the plan of care to encourage adequate food intake. The patient's preferences, as well as physiologic and metabolic requirements, are considered when selecting foods. Small, frequent meals are provided, with supplements between meals. Patients often tolerate larger amounts of food earlier in the day rather than later, so meals can be planned accordingly. Patients should avoid drinking fluids while eating, to avoid early satiety. Oral hygiene before mealtime often makes meals more pleasant. Pain, nausea, and other symptoms that may interfere with nutrition are assessed and managed. Medications such as corticosteroids or progestational agents such as megestrol acetate have been used successfully as appetite stimulants.

If adequate nutrition cannot be maintained by oral intake, nutritional support via the enteral route may be necessary. Short-term nutritional supplementation may be provided through a nasogastric tube. However, if nutritional support is needed beyond several weeks, a gastrostomy or jejunostomy tube may be inserted. Patients and families are taught to administer enteral nutrition in the home setting.

If malabsorption is a problem, enzyme and vitamin replacement may be instituted. Additional strategies include changing the feeding schedule, using simple diets, and relieving diarrhea. If malabsorption is severe, parenteral nutrition (PN) may be necessary. PN can be administered in several ways: by a long-term venous access device, such as a right atrial catheter, an implanted venous port, or a peripherally inserted central catheter (Fig. 16-6). The nurse teaches the patient and family to care for venous access devices and to administer PN. Home care nurses may assist with or supervise PN in the home.

Interventions to reduce cachexia usually do not prolong survival but may improve the patient's quality of life. Before invasive nutritional strategies are instituted, the nurse should assess the patient carefully and discuss the options with the patient and family. Creative dietary therapies, enteral (tube) feedings, or PN may be necessary to ensure adequate nutrition. Nursing care is

**FIGURE 16-6** A peripherally inserted central catheter (PICC) is advanced through the cephalic or basilic vein to the axillary, subclavian, or brachiocephalic vein or the superior vena cava.

also directed toward preventing trauma, infection, and other complications that increase metabolic demands.

### RELIEVING PAIN

Of all patients with progressive cancer, more than 75% experience pain (Yarbro, Hansen-Frogge & Goodman, 1999). Although patients with cancer may have acute pain, their pain is more frequently characterized as chronic. (For more information on cancer-related pain, see Chap. 13.) As in other situations involving pain, the experience of cancer pain is influenced by both physical and psychosocial factors.

Cancer can cause pain in various ways (Table 16-9). Pain is also associated with various cancer treatments. Acute pain is linked with trauma from surgery. Occasionally, chronic pain syndromes, such as postsurgical neuropathies (pain related to nerve tissue injury), occur. Some chemotherapeutic agents cause tissue necrosis, peripheral neuropathies, and stomatitis—all potential sources of pain—whereas radiation therapy can cause pain secondary to skin or organ inflammation. Cancer patients may have other sources of pain, such as arthritis or migraine headaches, that are unrelated to the underlying cancer or its treatment.

In today's society, most people expect pain to disappear or resolve quickly, and in fact it usually does. Although controllable, cancer pain is commonly irreversible and not quickly resolved.

For many patients, pain is a signal that the tumor is growing and that death is approaching. As the patient anticipates the pain and anxiety increases, pain perception heightens, producing fear and further pain. Chronic cancer pain, then, can be best described as a cycle progressing from pain to anxiety to fear and back to pain again.

Pain tolerance, the point past which pain can no longer be tolerated, varies among people. Pain tolerance is decreased by fatigue, anxiety, fear of death, anger, powerlessness, social isolation, changes in role identity, loss of independence, and past experiences. Adequate rest and sleep, diversion, mood elevation, empathy, and medications such as antidepressants, antianxiety agents, and analgesics enhance tolerance to pain.

Inadequate pain management is most often the result of misconceptions and insufficient knowledge about pain assessment and pharmacologic interventions on the part of patients, families, and health care providers. Successful management of cancer pain is based on thorough and objective pain assessment that examines physical, psychosocial, environmental, and spiritual factors. A multidisciplinary team approach is essential to determine optimal management of the patient's pain. Unlike instances of chronic nonmalignant pain, systemic analgesics play a central role in managing cancer pain.

The World Health Organization (Dalton & Youngblood, 2000) advocates a three-step approach to treating cancer pain (see Chap. 13). Analgesics are administered based on the patient's level of pain. Nonopioid analgesics (eg, acetaminophen) are used for mild pain; weak opioid analgesics (eg, codeine) are used for moderate pain; and strong opioid analgesics (eg, morphine) are used for severe pain. If the patient's pain escalates, the strength of the analgesic medication is increased until the pain is controlled. Adjuvant medications are also administered to enhance the effectiveness of analgesics and to manage other symptoms that may contribute to the pain experience. Examples of adjuvant medications include antiemetics, antidepressants, anxiolytics, antiseizure agents, stimulants, local anesthetics, radiopharmaceuticals (radioactive agents that may be used to treat painful bone tumors), and corticosteroids.

Preventing and reducing pain help to decrease anxiety and break the pain cycle. This can be accomplished best by administering analgesics on a regularly scheduled basis as prescribed (the preventive approach to pain management), with additional analgesics administered for breakthrough pain as needed and as prescribed.

Various pharmacologic and nonpharmacologic approaches offer the best methods of managing cancer pain. No reasonable approaches, even those that may be invasive, should be over-

**Table 16-9 • Sources of Cancer Pain**

SOURCE	DESCRIPTIONS	UNDERLYING CANCER
Bone metastasis	Throbbing, aching	Breast, prostate, myeloma
Nerve compression, infiltration	Burning, sharp, tingling	Breast, prostate, lymphoma
Lymphatic or venous obstruction	Dull, aching, tightness	Lymphoma, breast, Kaposi's sarcoma
Ischemia	Sharp, throbbing	Kaposi's sarcoma
Organ obstruction	Dull, crampy, gnawing	Colon, gastric
Organ infiltration	Distention, crampy	Liver, pancreatic
Skin inflammation, ulceration, infection, necrosis	Burning, sharp	Breast, head and neck, Kaposi's sarcoma

looked because of a poor or terminal prognosis. Nurses help patients and families to take an active role in managing pain. Nurses provide education and support to correct fears and misconceptions about opioid use. Inadequate pain control leads to suffering, anxiety, fear, immobility, isolation, and depression. Improving a patient's quality of life is as important as preventing a painful death.

### DECREASING FATIGUE

In recent years, fatigue has been recognized as one of the most significant and frequent symptoms experienced by patients receiving cancer therapy. Nurses help the patient and family to understand that fatigue is usually an expected and temporary side effect of the cancer process and of many treatments used. Fatigue also stems from the stress of coping with cancer. It does not always signify that the cancer is advancing or that the treatment is failing. Potential sources of fatigue are summarized in Chart 16-7.

Nursing strategies are implemented to minimize fatigue or assist the patient to cope with existing fatigue. Helping the patient to identify sources of fatigue aids in selecting appropriate and individualized interventions. Ways to conserve energy are developed to help the patient plan daily activities. Alternating periods of rest and activity are beneficial. Regular, light exercise may decrease fatigue and facilitate coping, whereas lack of physical activity and "too much rest" can actually contribute to deconditioning and associated fatigue.

Patients are encouraged to maintain as normal a lifestyle as possible by continuing with those activities they value and enjoy. Prioritizing necessary and valued activities can assist patients in planning for each day. Both patients and families are encouraged to plan to reallocate responsibilities, such as attending to child care, cleaning, and preparing meals. Patients who are employed full-time may need to reduce the number of hours worked each week. The nurse assists the patient and family in coping with these changing roles and responsibilities.

Nurses also address factors that contribute to fatigue and implement pharmacologic and nonpharmacologic strategies to manage pain. Nutrition counseling is provided to patients who are not eating enough calories or protein. Small, frequent meals require less energy for digestion. Serum hemoglobin and hematocrit levels are monitored for deficiencies, and blood products or EPO are administered as prescribed. Patients are monitored for alterations in oxygenation and electrolyte balances. Physical ther-

apy and assistive devices are beneficial for patients with impaired mobility.

### IMPROVING BODY IMAGE AND SELF-ESTEEM

A positive approach is essential when caring for the patient with an altered body image. To help the patient retain control and positive self-esteem, it is important to encourage independence and continued participation in self-care and decision making. The patient should be assisted to assume those tasks and participate in those activities that are personally of most value. Any negative feelings that the patient has or threats to body image should be identified and discussed. The nurse serves as a listener and counselor to both the patient and the family. Referral to a support group can provide the patient with additional assistance in coping with the changes resulting from cancer or its treatment. In many cases, a cosmetologist can provide ideas about hair or wig styling, make-up, and the use of scarves and turbans to help with body image concerns.

Patients who experience alterations in sexuality and sexual function are encouraged to discuss concerns openly with their partner. Alternative forms of sexual expression are explored with the patient and partner to promote positive self-worth and acceptance. The nurse who identifies serious physiologic, psychological, or communication difficulties related to sexuality or sexual function is in a key position to assist the patient and partner to seek further counseling if necessary.

### ASSISTING IN THE GRIEVING PROCESS

A cancer diagnosis need not indicate a fatal outcome. Many forms of cancer are curable; others may be cured if treated early. Despite these facts, many patients and their families view cancer as a fatal disease that is inevitably accompanied by pain, suffering, debility, and emaciation. Grieving is a normal response to these fears and to the losses anticipated or experienced by the patient with cancer. These may include loss of health, normal sensations, body image, social interaction, sexuality, and intimacy. The patient, family, and friends may grieve for the loss of quality time to spend with others, the loss of future and unfulfilled plans, and the loss of control over one's own body and emotional reactions.

The patient and family just informed of the cancer diagnosis frequently respond with shock, numbness, and disbelief. It is often during this stage that the patient and family are called on to make important initial decisions about treatment. They require the support of the physician, nurse, and other health care team members to make these decisions. An important role of the nurse is to answer any questions the patient and family have and clarify information provided by the physician.

In addition to assessing the response of the patient and family to the diagnosis and planned treatment, the nurse assists them in framing their questions and concerns, identifying resources and support people (eg, spiritual advisor, counselor), and communicating their concerns with each other. Support groups for patients and families are available through hospitals and various community organizations. These groups provide direct assistance, advice, and emotional support.

As the patient and family progress through the grieving process, they may express anger, frustration, and depression. During this time, the nurse encourages the patient and family to verbalize their feelings in an atmosphere of trust and support. The nurse continues to assess their reactions and provides assistance and support as they confront and learn to deal with new problems.

If the patient enters the terminal phase of disease, the nurse may realize that the patient and family members are at different stages of grief. In such cases, the nurse assists the patient and family to ac-

Chart  
16-7

#### Sources of Fatigue in Cancer Patients

- Pain, pruritus
- Imbalanced nutrition related to anorexia, nausea, vomiting, cachexia
- Electrolyte imbalance related to vomiting, diarrhea
- Ineffective protection related to neutropenia, thrombocytopenia, anemia
- Impaired tissue integrity related to stomatitis, mucositis
- Impaired physical mobility related to neurologic impairments, surgery, bone metastasis, pain, and analgesic use
- Deficient knowledge related to disease process, treatment
- Anxiety related to fear, diagnosis, role changes, uncertainty of future
- Ineffective breathing patterns related to cough, shortness of breath, and dyspnea
- Disturbed sleep pattern related to cancer therapies, anxiety, and pain

knowledge and cope with their reactions and feelings. Nurses also assist patients and families to explore preferences for issues related to end-of-life care such as withdrawal of active disease treatment, desire for the use of life support measures, and symptom management. Support, which can be as simple as holding the patient's hand or just being with the patient at home or at the bedside, often contributes to peace of mind. Maintaining contact with the surviving family members after the death of the cancer patient may help them to work through their feelings of loss and grief. See Chapter 17 for further discussion of end-of-life issues.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Despite advances in cancer care, infection remains the leading cause of death. In the cancer patient, defense against infection is compromised in many different ways. The integrity of the skin and mucous membrane, the body's first line of defense, is challenged by multiple invasive diagnostic and therapeutic procedures, by adverse effects of radiation and chemotherapy, and by the detrimental effects of immobility.

Impaired nutrition resulting from anorexia, nausea, vomiting, diarrhea, and the underlying disease alters the body's ability to combat invading organisms. Medications such as antibiotics disturb the balance of normal flora, allowing the overgrowth of pathogenic organisms. Other medications can also alter the immune response (see Chap. 50). Cancer itself may be immunosuppressive. Cancers such as leukemia and lymphoma are often associated with defects in cellular and humoral immunity. Advanced cancer can lead to obstruction by the tumor of the hollow viscera (such as the intestines), blood vessels, and lymphatic vessels, creating a favorable environment for proliferation of pathogenic organisms. In some patients, tumor cells infiltrate bone marrow and prevent normal production of WBCs. Most often, however, a decrease in WBCs is a result of bone marrow suppression after chemotherapy or radiation therapy.

The use of the hematopoietic growth factors, also called colony-stimulating factors (see the previous discussion of BRM therapy), has reduced the severity and duration of neutropenia associated with myelosuppressive chemotherapy and radiation therapy. The administration of these factors assists in reducing the risk for infection and, possibly, in maintaining treatment schedules, drug dosages, treatment effectiveness, and the quality of life.

### Infection

Gram-positive organisms, such as *Streptococcus* and *Staphylococcus* species, are the most frequently isolated causes of infection. Gram-negative organisms, such as *Escherichia coli* and *Pseudomonas aeruginosa*, and fungal organisms, such as *Candida albicans*, also contribute to the incidence of serious infection.

Fever is probably the most important sign of infection in the immunocompromised patient. Although fever may be related to a variety of noninfectious conditions, including the underlying cancer, any temperature of 38.3°C (101°F) or higher is reported and dealt with promptly.

Antibiotics may be prescribed to treat infections after cultures of wound drainage, exudate, sputum, urine, stool, or blood are obtained. Patients with neutropenia are treated with broad-spectrum antibiotics before the infecting organism is identified because of the high incidence of mortality associated with untreated infection. Broad-spectrum antibiotic coverage or empiric therapy most often includes a combination of medications to

defend the body against the major pathogenic organisms. An important component of the nurse's role is to administer these medications promptly according to the prescribed schedule to achieve adequate blood levels of the medications.

Strict asepsis is essential when handling intravenous lines, catheters, and other invasive equipment. Exposure of the patient to others with an active infection and to crowds is avoided. Patients with profound immunosuppression, such as BMT recipients, may need to be placed in a protective environment where the room and its contents are sterilized and the air is filtered. These patients may also receive low-bacteria diets, avoiding fresh fruits and vegetables. Hand hygiene and appropriate general hygiene are necessary to reduce exposure to potentially harmful bacteria and to eliminate environmental contaminants. Invasive procedures, such as injections, vaginal or rectal examinations, rectal temperatures, and surgery, are avoided. The patient is encouraged to cough and perform deep-breathing exercises frequently to prevent atelectasis and other respiratory problems. Prophylactic antimicrobial therapy may be used for patients who are expected to be profoundly immunosuppressed and at risk for certain infections. The nurse teaches the patient and family to recognize signs and symptoms of infection to report, perform effective hand hygiene, use antipyretics, maintain skin integrity, and administer hematopoietic growth factors when indicated.

### Septic Shock

The nurse assesses the patient frequently for infection and inflammation throughout the course of the disease. Septicemia and septic shock are life-threatening complications that must be prevented or detected and treated promptly. Patients with signs and symptoms of impending sepsis and septic shock require immediate hospitalization and aggressive treatment.

Signs and symptoms of septic shock (see Chap. 15) include altered mental status, either subnormal or elevated temperature, cool and clammy skin, decreased urine output, hypotension, dysrhythmias, electrolyte imbalances, and abnormal arterial blood gas values. The patient and family members are instructed about signs of septicemia, methods for preventing infection, and actions to take if infection or septicemia occurs.

Septic shock is most often associated with overwhelming gram-negative bacterial infections. The nurse monitors the blood pressure, pulse rate, respirations, and temperature of the patient with shock every 15 to 30 minutes. Neurologic assessments are carried out to detect changes in orientation and responsiveness. Fluid and electrolyte status is monitored by measuring fluid intake and output and serum electrolytes. Arterial blood gas values and pulse oximetry are monitored to determine tissue oxygenation. The nurse administers intravenous fluids, blood products, and vasopressors as prescribed to maintain the patient's blood pressure and tissue perfusion. Supplemental oxygen is often necessary. Broad-spectrum antibiotics are administered as prescribed to combat the underlying infection (see Chap. 15).

### Bleeding and Hemorrhage

Thrombocytopenia, a decrease in the circulating platelet count, is the most common cause of bleeding in cancer patients and is usually defined as a count of less than 100,000/mm<sup>3</sup> (0.1 × 10<sup>12</sup>/L). When the count falls between 20,000 and 50,000/mm<sup>3</sup> (0.02 to 0.05 × 10<sup>12</sup>/L), the risk for bleeding increases. Counts under 20,000/mm<sup>3</sup> (0.02 × 10<sup>12</sup>/L) are associated with an increased risk for spontaneous bleeding, for which the patient requires a platelet transfusion. Platelets are essential for normal blood clotting and coagulation (hemostasis).

Thrombocytopenia often results from bone marrow depression after certain types of chemotherapy and radiation therapy. Tumor infiltration of the bone marrow can also impair the normal production of platelets. In some cases, platelet destruction is associated with an enlarged spleen (hypersplenism) and abnormal antibody function that occur with leukemia and lymphoma.

In addition to monitoring laboratory values, the nurse continues to assess the patient for bleeding. The nurse also takes steps to prevent trauma and minimize the risk for bleeding by encouraging the patient to use a soft, not stiff, toothbrush and an electric, not straight-edged, razor. Additionally, the nurse avoids unnecessary invasive procedures (eg, rectal temperatures, intramuscular injections, and catheterization) and assists the patient and family to identify and remove environmental hazards that may lead to falls or other trauma. Soft foods, increased fluid intake, and stool softeners, if prescribed, may be indicated to reduce trauma to the gastrointestinal tract. The joints and extremities are handled and moved gently to minimize the risk for spontaneous bleeding. The nurse may administer IL-11, which has been approved by the FDA (Rust, Wood & Battiato, 1999) to prevent severe thrombocytopenia and to reduce the need for platelet transfusions following myelosuppressive chemotherapy in patients with nonmyeloid malignancies. In some instances, the nurse teaches the patient or family member to administer IL-11 in the home.

Hemorrhage may be related to various underlying abnormalities, such as thrombocytopenia and coagulation disorders. These clinical situations are often associated with the cancer itself or the adverse effects of cancer treatments. Sites of hemorrhage may include the gastrointestinal, respiratory, and genitourinary tracts and the brain. Blood pressure and pulse and respiratory rates are monitored every 15 to 30 minutes when hospitalized patients experience bleeding.

Serum hemoglobin and hematocrit are monitored carefully for changes indicating blood loss. The nurse tests all urine, stool, and emesis for occult blood. Neurologic assessments are performed to detect changes in orientation and behavior. The nurse administers fluids and blood products as prescribed to replace any losses. Vasopressor agents are administered as prescribed to maintain blood pressure and ensure tissue oxygenation. Supplemental oxygen is used as necessary.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

Patients with cancer usually return home from acute care facilities or receive treatment in the home or outpatient area rather than acute care facilities. The shift from the acute care setting also shifts the responsibility for care to the patient and family. As a result, families and friends must assume increased involvement in patient care, which requires teaching that enables them to provide care. Teaching initially focuses on providing information needed by the patient and family to address the most immediate care needs likely to be encountered at home.

Side effects of treatments and changes in the patient's status that should be reported are reviewed verbally and reinforced with written information. Strategies to deal with side effects of treatment are discussed with the patient and family. Other learning needs are identified based on the priorities conveyed by the patient and family as well as on the complexity of care provided in the home.

Technological advances allow home administration of chemotherapy, PN, blood products, parenteral antibiotics, and par-

enteral analgesics; management of symptoms; and care of vascular access devices. Although home care nurses provide care and support for patients receiving this advanced technical care, the patient and family need instruction and ongoing support that allow them to feel comfortable and proficient in managing these treatments at home. Follow-up visits and telephone calls from the nurse are often reassuring to the patient and family and increase their comfort in dealing with complex and new aspects of care. Continued contact facilitates evaluation of the patient's progress and ongoing needs.

### Continuing Care

Referral for home care is often indicated for the patient with cancer. The responsibilities of the home care nurse include assessing the home environment, suggesting modifications in the home or in care to assist the patient and family in addressing the patient's physical needs, providing physical care, and assessing the psychological and emotional impact of the illness on the patient and family.

Assessing changes in the patient's physical status and reporting relevant changes to the physician help to ensure that appropriate and timely modifications in therapy are made. The home care nurse also assesses the adequacy of pain management and the effectiveness of other strategies to prevent or manage the side effects of treatment modalities.

The patient's and family's understanding of the treatment plan and management strategies is assessed, and previous teaching is reinforced. The nurse often facilitates the coordination of patient care by maintaining close communication with all health care providers involved in the patient's care. The nurse may make referrals and coordinate available community resources (eg, local office of the American Cancer Society, home aides, church groups, parish nurses, and support groups) to assist patients and caregivers.

## Evaluation

### EXPECTED PATIENT OUTCOMES

For specific patient outcomes, see the Plan of Nursing Care. Expected patient outcomes may include:

1. Maintains integrity of oral mucous membranes
2. Maintains adequate tissue integrity
3. Maintains adequate nutritional status
4. Achieves relief of pain and discomfort
5. Demonstrates increased activity tolerance and decreased fatigue
6. Exhibits improved body image and self-esteem
7. Progresses through the grieving process
8. Experiences no complications, such as infection, or sepsis, and no episodes of bleeding or hemorrhage

## Cancer Rehabilitation

Many cancer patients, including those who receive primary surgical treatment and adjuvant chemotherapy or radiation therapy, return to work and their usual activities of daily living. These patients may encounter a variety of problems, including changes in their functional abilities and in the attitudes of employers, coworkers, and family members who still view cancer as a terminal, debilitating disease. Nurses play an important role in the re-

habilitation of the cancer patient. Both the patient and family are included as part of any rehabilitation effort because cancer affects not only the patient but also the family members. In addition, with the shift away from inpatient care, many families are caring for patients at home. To maximize beneficial outcomes, evaluation of the patient's needs related to cancer rehabilitation begins early in cancer treatment (Table 16-10).

Assessment for body image changes as a result of disfiguring treatments is necessary to facilitate the patient's adjustment to changes in appearance or functional abilities. The nurse can refer the patient and family to a variety of support groups sponsored by the American Cancer Society, such as those for people who have had laryngectomies or mastectomies. Nurses also collaborate with physical, occupational, and enterostomal therapists in improving the patient's abilities in the use of prosthetic and assistive devices, and in altering the home environment as needed.

Patients often experience distress (eg, pain, nausea) related to the underlying cancer or treatments. These symptoms may interfere with work and quality of life. Nurses assess for these problems and assist the patient in identifying strategies for coping with them. For patients with gastrointestinal disturbances after chemotherapy, altering work hours or receiving treatments in the

evenings may prove helpful. Collaboration with physicians and pharmacists is helpful in identifying appropriate interventions.

Nurses collaborate with dietitians to help patients plan meals that will be acceptable and meet nutritional requirements. Nurses are also involved in the ongoing assessment of patients to detect any long-term consequences of cancer treatment.

Although the Americans With Disabilities Act of 1990 was intended to protect patients with disabling disorders against discrimination, recovering cancer patients have reported instances of unfair practices and discrimination in the workplace. Some employers do not understand that different kinds of cancers have different prognoses and different effects on functional ability. As a result, employers may hesitate to hire or continue to employ people with cancer, especially if ongoing treatment regimens require adjustments in work schedules. Employers, coworkers, and families may continue to view the person as "sick" despite ongoing recovery or completion of treatment. Attitudes of coworkers can be a problem when the patient has a communication impairment, as may occur in some head and neck cancers. The patient may benefit from vocational rehabilitation services of the American Cancer Society or other agencies.

Nurses can participate in efforts to educate employers and the public in general to ensure that the rights of patients with cancer are maintained. Whenever possible, nurses assist patients and families to resume preexisting roles. Psychologists and clergy or spiritual advisors are consulted to assist with psychosocial and spiritual concerns. Rehabilitation shifts the focus from what has been lost to what can be done with existing strengths and abilities. In that spirit, nurses encourage patients to regain the highest level of function and independence possible.

**Table 16-10 • Assessing Patient Needs for Cancer Rehabilitation**

AREA OF NEED	FACTORS TO ASSESS
<b>Functional</b>	
Activities of daily living	Mobility Cognitive impairment Sensory impairments Communication barriers
<b>Physiologic</b>	
Nutrition	Need for enteral or parenteral nutrition
Elimination	Alterations in bowel and bladder function
Symptoms related to disease or treatment	Pain Nausea, vomiting, diarrhea Dyspnea, fatigue Skin impairment, alopecia
<b>Psychosocial Resources</b>	
Family	Availability of caregiver, home physical environment Availability of private transportation; affordability of transportation
Community	Availability of public transportation; affordability of transportation Availability and access to community organizations for assistance and support
Personal	Spiritual concerns Family relationships Body image Coping abilities Sexuality
Financial	Job security for patient and family members Need for vocational training

### **Gerontologic Considerations**

As a result of an increased life expectancy and an increased risk for cancer with age, nurses are providing cancer-related care for growing numbers of elderly patients. More than 58% of all cancers occur in people older than 65 years of age, and about two thirds of all cancer deaths occur in people 65 years of age and older. Nursing care of this population addresses special needs, including physical, psychosocial, and financial concerns.

Oncology nurses working with the elderly population need to understand the normal physiologic changes that occur with aging. These changes include decreased skin elasticity; decreased skeletal mass, structure, and strength; decreased organ function and structure; impaired immune system mechanisms; alterations in neurologic and sensory functions; and altered drug absorption, distribution, metabolism, and elimination. These changes ultimately influence the elderly patient's ability to tolerate cancer treatment. In addition, many elderly patients have other chronic diseases and associated treatments that may limit tolerance to cancer treatments (Table 16-11).

Potential chemotherapy-related toxicities, such as renal impairment, myelosuppression, fatigue, and cardiomyopathy, may increase as a result of declining organ function and diminished physiologic reserves. The recovery of normal tissues after radiation therapy may be delayed, and the patient may experience more severe adverse effects, such as mucositis, nausea and vomiting, and myelosuppression. Because of decreased tissue healing capacity and declining pulmonary and cardiovascular functioning, the older patient is slower to recover from surgery. Elderly patients are also at increased risk for complications such as atelectasis, pneumonia, and wound infections.

**Table 16-11 • Age-Related Changes and Their Effects on Patients with Cancer**

AGE-RELATED CHANGES	IMPLICATIONS
Impaired immune system	Use special precautions to avoid infection; monitor for atypical signs and symptoms of infection.
Altered drug absorption, distribution, metabolism, and elimination	Mandates careful calculation of chemotherapy and frequent assessment for drug response and side effects.
Increased prevalence of other chronic diseases	Monitor for effect of cancer or its treatment on patient's other chronic diseases; monitor patient's tolerance for cancer treatment.
Diminished renal, respiratory, and cardiac reserve	Be proactive in prevention of decreased renal function, atelectasis, pneumonia, and cardiovascular compromise.
Decreased skin and tissue integrity; reduction in body mass; delayed healing	Prevent pressure ulcers secondary to immobility. Monitor skin and mucous membranes for changes related to radiation or chemotherapy. Prevent wound infection.
Decreased musculoskeletal strength	Prevent falls; encourage use of hip protectors if indicated.
Decreased neurosensory functioning; loss of vision, hearing, and distal extremity tactile senses	Provide teaching and instructions modified for patient's hearing and vision loss; provide instruction concerning safety and skin care for distal extremities.
Potential changes in cognitive and emotional capacity	Provide teaching and support modified for patient's level of functioning.

Access to cancer care for elderly patients may be limited by discriminatory or fatalistic attitudes of health care providers, caregivers, and patients themselves. Issues such as the gradual loss of supportive resources, declining health or loss of a spouse, and unavailability of relatives or friends may result in limited access to care and unmet needs for assistance with activities of daily living. In addition, the economic impact of health care may be difficult for those living on fixed incomes.

The nurse must be aware of the special needs of the aging population. Cancer prevention, detection, and screening efforts are directed toward the elderly as well as the younger population. Nurses carefully monitor elderly patients receiving cancer treatments for signs and symptoms of adverse effects. In addition, the elderly patient is instructed to report all symptoms to the physician. It is not uncommon for the elderly patient to delay reporting symptoms, attributing them to "old age." Many elderly people do not want to report illness for fear of losing their independence or financial security. Sensory losses (eg, hearing and visual losses) and memory deficits are considered when planning patient education because they may affect the patient's ability to process and retain information. In such cases, the nurse needs to act as a patient advocate, encouraging independence and identifying resources for support when indicated.

## Care of the Patient with Advanced Cancer

The patient with advanced cancer is likely to experience many of the problems previously described, but all to a greater degree. Symptoms of gastrointestinal disturbances, nutritional problems, weight loss, and cachexia make the patient more susceptible to skin breakdown, fluid and electrolyte problems, and infection.

Although not all cancer patients experience pain, those who do commonly fear that it will not be adequately treated. Although treatment at this stage of illness is likely to be palliative rather than curative, prevention and appropriate management of prob-

lems can improve the quality of the patient's life considerably. For example, use of analgesia at set intervals rather than on an "as needed" basis usually breaks the cycle of tension and anxiety associated with waiting until pain becomes so severe that pain relief is inadequate once the analgesic is given. Working with the patient and family, as well as with other health care providers, on a pain-management program based on the patient's requirements frequently increases the patient's comfort and sense of control. In addition, the dose of opioid analgesic required is often reduced as pain becomes more manageable and other medications (eg, sedatives, tranquilizers, muscle relaxants) are added to assist in relieving pain.

If the patient is a candidate for radiation therapy or surgical intervention to relieve severe pain, the consequences of these procedures (eg, percutaneous nerve block, cordotomy) are explained to the patient and family, and measures are taken to prevent complications resulting from altered sensation, immobility, and changes in bowel and bladder function.

With the appearance of each new symptom, the patient may experience dread and fear that the disease is progressing. However, one cannot assume that all symptoms are related to the cancer. The new symptoms and problems are evaluated and treated aggressively if possible to increase the patient's comfort and improve quality of life.

Weakness, immobility, fatigue, and inactivity typically occur in the advanced stages of cancer as a result of the tumor, treatment, inadequate nutritional intake, or shortness of breath. The nurse works with the patient to set realistic goals and to provide rest balanced with planned activities and exercise. Other measures include assisting the patient in identifying energy-conserving methods for accomplishing tasks and promoting activities that the patient values the most.

Efforts are made throughout the course of the disease to provide the patient with as much control and independence as desired, but with assurance that support and assistance are available when needed. Additionally, the health care team works with the

patient and family to ascertain and comply with the patient's wishes about treatment methods and care as the terminal phase of illness and death approach.

## HOSPICE

For many years, society was unable to cope appropriately with patients in the most advanced stages of cancer, and patients died in acute care settings rather than at home or in facilities designed to meet their needs. The needs of patients with terminal illnesses are best met by a comprehensive multidisciplinary program that focuses on quality of life, palliation of symptoms, and provision of psychosocial and spiritual support for the patient and family when cure and control of the disease are no longer possible. The concept of hospice, which originated in Great Britain, best addresses these needs. Most important, the focus of care is on the family, not just the patient. Hospice care can be provided in several settings: free-standing, hospital-based, and community or home-based settings.

Because of the high costs associated with maintaining free-standing hospices, care is often delivered by coordinating services provided by both the hospital and community. Although physi-

cians, social workers, clergy, dietitians, pharmacists, physical therapists, and volunteers are involved in patient care, nurses are most often the coordinators of all hospice activities. It is essential that home care and hospice nurses possess advanced skills in assessing and managing pain, nutrition, dyspnea, bowel dysfunction, and skin impairments.

In addition, hospice programs facilitate clear communication among family members and health care providers. Most patients and families are informed of the prognosis and are encouraged to participate in decisions regarding pursuing or terminating cancer treatment. Through collaboration with other support disciplines, nurses assist patients and families to cope with changes in role identity, family structure, grief, and loss. Hospice nurses are actively involved in bereavement counseling. In many instances, family support for survivors continues for about 1 year. See Chapter 17 for detailed discussion of end-of-life care.

## Oncologic Emergencies

For information about these emergencies, see Table 16-12.

**Table 16-12 • Oncologic Emergencies: Manifestations and Management**

EMERGENCY	CLINICAL MANIFESTATIONS AND DIAGNOSTIC FINDINGS	MANAGEMENT
<p><b>Superior Vena Cava Syndrome (SVCS)</b>            Compression or invasion of the superior vena cava by tumor, enlarged lymph nodes, intraluminal thrombus that obstructs venous circulation, or drainage of the head, neck, arms, and thorax. Typically associated with lung cancer, SVCS can also occur with lymphoma and metastases. If untreated, SVCS may lead to cerebral anoxia (because not enough oxygen reaches the brain), laryngeal edema, bronchial obstruction, and death.</p>	<p><i>Clinical</i>            Gradually or suddenly impaired venous drainage giving rise to</p> <ul style="list-style-type: none"> <li>• Progressive shortness of breath (dyspnea), cough, and facial swelling</li> <li>• Edema of the neck, arms, hands, and thorax and reported sensation of skin tightness and difficulty swallowing</li> <li>• Possibly engorged and distended jugular, temporal, and arm veins</li> <li>• Dilated thoracic vessels causing prominent venous patterns on the chest wall</li> <li>• Increased intracranial pressure, associated visual disturbances, headache, and altered mental status</li> </ul> <p><i>Diagnostic</i>            Diagnosis is confirmed by</p> <ul style="list-style-type: none"> <li>• Clinical findings</li> <li>• Chest x-ray</li> <li>• Thoracic CT scan</li> <li>• MRI</li> </ul> <p>Intraluminal thrombosis is identified by venogram.</p>	<p><i>Medical</i></p> <ul style="list-style-type: none"> <li>• Radiation therapy to shrink tumor size and relieve symptoms</li> <li>• Chemotherapy for radiation-resistant tumor (eg, lymphoma or small cell lung cancer) or when the mediastinum has been irradiated to maximum tolerance</li> <li>• Anticoagulant or thrombolytic therapy for intraluminal thrombosis</li> <li>• Surgery (less common), eg, vena cava bypass graft (synthetic or autologous) to redirect blood flow around the obstruction</li> <li>• Supportive measures such as oxygen therapy, corticosteroids, and diuretics</li> </ul> <p><i>Nursing</i></p> <ul style="list-style-type: none"> <li>• Identify patients at risk for SVCS.</li> <li>• Monitor and report clinical manifestations of SVCS.</li> <li>• Monitor cardiopulmonary and neurologic status.</li> <li>• Facilitate breathing by positioning the patient properly. This helps to promote comfort and reduce anxiety produced by difficulty breathing resulting from progressive edema.</li> <li>• Promote energy conservation to minimize shortness of breath.</li> <li>• Monitor the patient's fluid volume status and administer fluids cautiously to minimize edema.</li> <li>• Assess for thoracic radiation-related problems such as dysphagia (difficulty swallowing) and esophagitis.</li> <li>• Monitor for chemotherapy-related problems, such as myelosuppression.</li> <li>• Provide postoperative care as appropriate.</li> </ul>

(continued)

Table 16-12 • Oncologic Emergencies: Manifestations and Management (Continued)

EMERGENCY	CLINICAL MANIFESTATIONS AND DIAGNOSTIC FINDINGS	MANAGEMENT
<p><b>Spinal Cord Compression</b></p> <p>Potentially leading to permanent neurologic impairment and associated morbidity and mortality, compression of the cord and its nerve roots may result from tumor, lymphomas, or intervertebral collapse.</p> <p>The prognosis depends on the severity and rapidity of onset. About 70% of compressions occur at the thoracic level, 20% in the lumbosacral level, and 10% in the cervical region. Metastatic cancers (breast, lung, kidney, prostate, myeloma, lymphoma) and related bone erosion are associated with spinal cord compression.</p>	<p><i>Clinical</i></p> <ul style="list-style-type: none"> <li>• Local inflammation, edema, venous stasis, and impaired blood supply to nervous tissues</li> <li>• Local or radicular pain along the dermatomal areas innervated by the affected nerve root (eg, thoracic radicular pain extends in a band around the chest or abdomen)</li> <li>• Pain exacerbated by movement, coughing, sneezing, or the Valsalva maneuver</li> <li>• Neurologic dysfunction, and related motor and sensory deficits (numbness, tingling, feelings of coldness in the affected area, inability to detect vibration, loss of positional sense)</li> <li>• Motor loss ranging from subtle weakness to flaccid paralysis</li> <li>• Bladder and/or bowel dysfunction depending on level of compression (above S2, overflow incontinence; from S3 to S5, flaccid sphincter tone and bowel incontinence)</li> </ul> <p><i>Diagnostic</i></p> <ul style="list-style-type: none"> <li>• Percussion tenderness at the level of compression</li> <li>• Abnormal reflexes</li> <li>• Sensory and motor abnormalities</li> <li>• MRI, myelogram, spinal cord x-rays, bone scans, and CT scan</li> </ul>	<p><i>Medical</i></p> <ul style="list-style-type: none"> <li>• Radiation therapy to reduce tumor size to halt progression and corticosteroid therapy to decrease inflammation and swelling at the compression site</li> <li>• Surgery only if symptoms progress despite radiation therapy or if vertebral fracture leads to additional nerve damage</li> <li>• Chemotherapy as adjuvant to radiation therapy for patients with lymphoma or small cell lung cancer</li> <li>• <i>Note:</i> Despite treatment, patients with poor neurologic function before treatment are less likely to regain complete motor and sensory function; patients who develop complete paralysis usually do not regain all neurologic function.</li> </ul> <p><i>Nursing</i></p> <ul style="list-style-type: none"> <li>• Perform ongoing assessment of neurologic function to identify existing and progressing dysfunction.</li> <li>• Control pain with pharmacologic and non-pharmacologic measures.</li> <li>• Prevent complications of immobility resulting from pain and decreased function (eg, skin breakdown, urinary stasis, thrombophlebitis, and decreased clearance of pulmonary secretions).</li> <li>• Maintain muscle tone by assisting with range-of-motion exercises in collaboration with physical and occupational therapists.</li> <li>• Institute intermittent urinary catheterization and bowel training programs for patients with bladder or bowel dysfunction.</li> <li>• Provide encouragement and support to patient and family coping with pain and altered functioning, lifestyle, roles, and independence.</li> </ul>
<p><b>Hypercalcemia</b></p> <p>In patients with cancer, hypercalcemia is a potentially life-threatening metabolic abnormality resulting when the calcium released from the bones is more than the kidneys can excrete or the bones can reabsorb. It may result from:</p> <ul style="list-style-type: none"> <li>• Bone destruction by tumor cells and subsequent release of calcium</li> <li>• Production of prostaglandins and osteoclast-activating factor, which stimulate bone breakdown and calcium release</li> <li>• Tumors that produce parathyroid-like substances that promote calcium release</li> <li>• Excessive use of vitamins and minerals and conditions unrelated to cancer, such as dehydration, renal impairment, primary hyperparathyroidism, thyrotoxicosis, thiazide diuretics, and hormone therapy</li> </ul>	<p><i>Clinical</i></p> <p>Fatigue, weakness, confusion, decreased level of responsiveness, hyporeflexia, nausea, vomiting, constipation, polyuria (excessive urination), polydipsia (excessive thirst), dehydration, and dysrhythmias</p> <p><i>Diagnostic</i></p> <p>Serum calcium level exceeding 11 mg/dL (2.74 mmol/L)</p>	<p><i>Medical</i></p> <p>See Chapter 14.</p> <p><i>Nursing</i></p> <ul style="list-style-type: none"> <li>• Identify patients at risk for hypercalcemia and assess for signs and symptoms of hypercalcemia.</li> <li>• Educate patient and family; prevention and early detection can prevent fatality.</li> <li>• Teach at-risk patients to recognize and report signs and symptoms of hypercalcemia.</li> <li>• Encourage patients to consume 2 to 3 L of fluid daily unless contraindicated by existing renal or cardiac disease.</li> <li>• Explain the use of dietary and pharmacologic interventions such as stool softeners and laxatives for constipation.</li> <li>• Advise patients to maintain nutritional intake without restricting normal calcium intake.</li> <li>• Discuss antiemetic therapy if nausea and vomiting occur.</li> <li>• Promote mobility by emphasizing its importance in preventing demineralization and breakdown of bones.</li> </ul>

(continued)

Table 16-12 • Oncologic Emergencies: Manifestations and Management (Continued)

EMERGENCY	CLINICAL MANIFESTATIONS AND DIAGNOSTIC FINDINGS	MANAGEMENT
<p><b>Pericardial Effusion and Cardiac Tamponade</b></p> <p>Cardiac tamponade is an accumulation of fluid in the pericardial space. The accumulation compresses the heart and thereby impedes expansion of the ventricles and cardiac filling during diastole. As ventricular volume and cardiac output fall, the heart pump fails, and circulatory collapse develops. With gradual onset, fluid accumulates gradually, and the outer layer of the pericardial space stretches to compensate for rising pressure. Large amounts of fluid accumulate before symptoms of heart failure occur. With rapid onset, pressures rise too quickly for the pericardial space to compensate. Cancerous tumors, particularly from adjacent thoracic tumors (lung, esophagus, breast cancers), and cancer treatment are the most common causes of cardiac tamponade. Radiation therapy of 4,000 cGy or more to the mediastinal area has also been implicated in pericardial fibrosis, pericarditis, and resultant cardiac tamponade. Untreated pericardial effusion and cardiac tamponade lead to circulatory collapse and cardiac arrest.</p>	<p><i>Clinical</i></p> <ul style="list-style-type: none"> <li>• Neck vein distention during inspiration (Kussmaul's sign)</li> <li>• Pulsus paradoxus (systolic blood pressure decrease exceeding 10 mm Hg during inspiration; pulse gets stronger on expiration)</li> <li>• Distant heart sounds, rubs and gallops, cardiac dullness</li> <li>• Compensatory tachycardia (heart beats faster to compensate for decreased cardiac output)</li> <li>• Increased venous and vascular pressures</li> </ul> <p><i>Diagnostic</i></p> <ul style="list-style-type: none"> <li>• ECG helps diagnose pericardial effusion.</li> <li>• In small effusion, chest x-rays show small amounts of fluid in the pericardium; in large effusions, x-ray films disclose "water-bottle" heart (obliteration of vessel contour and cardiac chambers).</li> <li>• ECG and CT scans help diagnose pleural effusions and evaluate effect of treatment.</li> <li>• Narrow pulse pressure</li> <li>• Shortness of breath and tachypnea</li> <li>• Weakness, chest pain, orthopnea, anxiety, diaphoresis, lethargy, and altered consciousness from decreased cerebral perfusion</li> </ul>	<p><i>Medical</i></p> <ul style="list-style-type: none"> <li>• Pericardiocentesis (the aspiration or withdrawal of the pericardial fluid by a large-bore needle inserted into the pericardial space). In malignant effusions, pericardiocentesis provides only temporary relief; fluid usually reaccumulates. Windows or openings in the pericardium can be created surgically as a palliative measure to drain fluid into the pleural space. Catheters may also be placed in the pericardial space and sclerosing agents (such as tetracycline, talc, bleomycin, 5-fluorouracil, or thiotepa) injected to prevent fluid from reaccumulating.</li> <li>• Radiation therapy or antineoplastic agents, depending on how sensitive the primary tumor is to these treatments. In mild effusions, prednisone and diuretic medications may be prescribed and the patient's status carefully monitored.</li> </ul> <p><i>Nursing</i></p> <ul style="list-style-type: none"> <li>• Monitor vital signs and oxygen saturation frequently.</li> <li>• Assess for pulsus paradoxus.</li> <li>• Monitor ECG tracings.</li> <li>• Assess heart and lung sounds, neck vein filling, level of consciousness, respiratory status, and skin color and temperature.</li> <li>• Monitor and record intake and output.</li> <li>• Review laboratory findings (eg, arterial blood gas and electrolyte levels).</li> <li>• Elevate the head of the patient's bed to ease breathing.</li> <li>• Minimize patient's physical activity to reduce oxygen requirements; administer supplemental oxygen as prescribed.</li> <li>• Provide frequent oral hygiene.</li> <li>• Reposition and encourage the patient to cough and take deep breaths every 2 hours.</li> <li>• As needed, maintain patent IV access, reorient the patient, and provide supportive measures and appropriate patient instruction.</li> </ul>
<p><b>Disseminated Intravascular Coagulation (DIC, also called consumption coagulopathy)</b></p> <p>Complex disorder of coagulation or fibrinolysis (destruction of clots), which results in thrombosis or bleeding. DIC is most commonly associated with hematologic cancers (leukemia); cancer of prostate, GI tract, and lungs; chemotherapy (methotrexate, prednisone, L-asparaginase, vincristine, and 6-mercaptopurine), and disease processes, such as sepsis, hepatic failure, and anaphylaxis. Blood clots form when normal coagulation mechanisms are triggered. Once activated, the clotting cascade continues to consume clotting factors and platelets faster than the body can re-</p>	<p><i>Clinical</i></p> <p><i>Chronic DIC:</i> Few or no observable symptoms or easy bruising, prolonged bleeding from venipuncture and injection sites, bleeding of the gums, and slow GI bleeding</p> <p><i>Acute DIC:</i> life-threatening hemorrhage and infarction; clinical symptoms of this syndrome are varied and depend on the organ system involved in thrombus and infarction or bleeding episodes</p> <p><i>Diagnostic</i></p> <ul style="list-style-type: none"> <li>• Prolonged prothrombin time (PT or protime)</li> <li>• Prolonged partial thromboplastin time (PTT)</li> <li>• Prolonged thrombin time (TT)</li> <li>• Decreased fibrinogen level</li> <li>• Decreased platelet level</li> <li>• Decrease in clotting factors</li> </ul>	<p><i>Medical</i></p> <ul style="list-style-type: none"> <li>• Chemotherapy, biologic response modifier therapy, radiation therapy, or surgery is used to treat the underlying cancer.</li> <li>• Antibiotic therapy is used for sepsis.</li> <li>• Anticoagulants, such as heparin or antithrombin III, decrease the stimulation of the coagulation pathways.</li> <li>• Transfusion of fresh-frozen plasma or cryoprecipitates (which contain clotting factors and fibrinogen), packed red blood cells, and platelets may be used as replacement therapy to prevent or control bleeding.</li> <li>• Although controversial, antifibrinolytic agents such as aminocaproic acid (Amicar), which is associated with increased thrombus formation, may be used.</li> </ul>

(continued)

Table 16-12 • Oncologic Emergencies: Manifestations and Management (Continued)

EMERGENCY	CLINICAL MANIFESTATIONS AND DIAGNOSTIC FINDINGS	MANAGEMENT
<p>place them. Clots are deposited in the microvasculature, placing the patient at great risk for impaired circulation, tissue hypoxia, and necrosis. In addition, fibrinolysis occurs, breaking down clots and increasing the circulating levels of anticoagulant substances, thereby placing the patient at risk for hemorrhage.</p>	<ul style="list-style-type: none"> <li>• Decreased hemoglobin</li> <li>• Decreased hematocrit</li> <li>• Elevated fibrin split products</li> <li>• Positive protamine sulfate precipitation test (thrombin activation test)</li> </ul>	<p><i>Nursing</i></p> <ul style="list-style-type: none"> <li>• Monitor vital signs.</li> <li>• Measure and document intake and output.</li> <li>• Assess skin color and temperature; lung, heart, and bowel sounds; level of consciousness, headache, visual disturbances, chest pain, decreased urine output, and abdominal tenderness.</li> <li>• Inspect all body orifices, tube insertion sites, incisions, and bodily excretions for bleeding.</li> <li>• Review laboratory test results.</li> <li>• Minimize physical activity to decrease injury risks and oxygen requirements.</li> <li>• Prevent bleeding; apply pressure to all venipuncture sites, and avoid nonessential invasive procedures; provide electric rather than straight-edged razors; avoid tape on the skin and advise gentle but adequate oral hygiene.</li> <li>• Assist the patient to turn, cough, and take deep breaths every 2 hours.</li> <li>• Reorient the patient, if needed; maintain a safe environment; and provide appropriate patient education and supportive measures.</li> </ul>
<p><b>Syndrome of Inappropriate Secretion of Antidiuretic Hormone (SIADH)</b></p> <p>The continuous, uncontrolled release of antidiuretic hormone (ADH), produced by tumor cells or by the abnormal stimulation of the hypothalamic–pituitary network, leads to increased extracellular fluid volume, water intoxication, hyponatremia, and increased excretion of urinary sodium. As fluid volume increases, stretch receptors in the right atrium respond by releasing a second hormone, atrial natriuretic factor (ANF). The release of ANF causes increased renal excretion of sodium, which worsens hyponatremia.</p> <p>The most common cause of SIADH is cancer, especially small cell cancers of the lung. Antineoplastics—vincristine, vinblastine, cisplatin, and cyclophosphamide—and morphine also stimulate ADH secretion, which promotes conservation and reabsorption of water by the kidneys. As more fluid is absorbed, the circulatory volume increases, ANF is released, and sodium is actively excreted by the kidneys in compensation.</p>	<p><i>Clinical</i></p> <p><i>Serum sodium levels below 120 mEq/L (SI: 120 mmol/L):</i> symptoms of hyponatremia including personality changes, irritability, nausea, anorexia, vomiting, weight gain, fatigue, muscular pain (myalgia), headache, lethargy, and confusion.</p> <p><i>Serum sodium levels below 110 mEq/L (SI: 110 mmol/L):</i> seizure, abnormal reflexes, papilledema, coma, and death. Edema is rare.</p> <p><i>Diagnostic</i></p> <ul style="list-style-type: none"> <li>• Decreased serum sodium level</li> <li>• Increased urine osmolality</li> <li>• Increased urinary sodium level</li> <li>• Decreased BUN, creatinine, and serum albumin levels secondary to dilution</li> <li>• Abnormal water load test results</li> </ul>	<p><i>Medical</i></p> <p>Fluid intake range limited to 500 to 1,000 mL/day to increase the serum sodium level and decrease fluid overload. If water restriction alone is not effective in correcting or controlling serum sodium levels, demeclocycline is often prescribed to interfere with the antidiuretic action of ADH and ANF. When neurologic symptoms are severe, parenteral sodium replacement and diuretic therapy are indicated. Electrolyte levels are monitored carefully to detect secondary magnesium, potassium, and calcium imbalances. After the symptoms of SIADH are controlled, the underlying cancer is treated. If water excess continues despite treatment, pharmacologic intervention (urea and furosemide) may be indicated.</p>
<p><b>Tumor Lysis Syndrome</b></p> <p>Potentially fatal complication associated with radiation- or chemotherapy-induced cell destruction of large or rapidly growing cancers such as leukemia, lymphoma, and small cell lung cancer. The release of intracellular contents from the tumor cells, leads to electrolyte imbalances—hyperkalemia,</p>	<p><i>Clinical</i></p> <p>Clinical manifestations depend on the extent of metabolic abnormalities.</p> <ul style="list-style-type: none"> <li>• Neurologic: Fatigue, weakness, memory loss, altered mental status, muscle cramps, tetany, paresthesias (numbness and tingling), seizures</li> <li>• Cardiac: Elevated blood pressure, shortened QT complexes, widened QRS waves, dysrhythmias, cardiac arrest</li> </ul>	<p><i>Nursing</i></p> <ul style="list-style-type: none"> <li>• Maintain intake and output measurements.</li> <li>• Assess level of consciousness, lung and heart sounds, vital signs, daily weight, and urine specific gravity; also assess for nausea, vomiting, anorexia, edema, fatigue, and lethargy.</li> <li>• Monitor laboratory test results, including serum electrolyte levels, osmolality, and blood urea nitrogen, creatinine, and urinary sodium levels.</li> <li>• Minimize the patient's activity; provide appropriate oral hygiene; maintain environmental safety; and restrict fluid intake if necessary.</li> <li>• Reorient the patient and provide instruction and encouragement as needed.</li> </ul> <p><i>Medical</i></p> <ul style="list-style-type: none"> <li>• To prevent renal failure and restore electrolyte balance, aggressive fluid hydration is initiated 48 hours before and after the initiation of cytotoxic therapy to increase urine volume and eliminate uric acid and electrolytes. Urine is alkalinized by adding sodium bicarbonate to IV fluid to maintain a urine pH of 7 or more; this prevents renal failure secondary to uric acid precipitation in the kidneys.</li> </ul>

(continued)

Table 16-12 • Oncologic Emergencies: Manifestations and Management (Continued)

EMERGENCY	CLINICAL MANIFESTATIONS AND DIAGNOSTIC FINDINGS	MANAGEMENT
<p>hypocalcemia, hyperphosphatemia, and hyperuricemia—because the kidneys can no longer excrete large volumes of the released intracellular metabolites.</p>	<ul style="list-style-type: none"> <li>• GI: Anorexia, nausea, vomiting, abdominal cramps, diarrhea</li> <li>• Renal: Flank pain, oliguria, anuria, renal failure, acidic urine pH</li> </ul> <p><i>Diagnostic</i> Electrolyte imbalances identified by laboratory test results</p>	<ul style="list-style-type: none"> <li>• Diuretic therapy, with a carbonic anhydrase inhibitor or acetazolamide, to alkalinize the urine</li> <li>• Allopurinol therapy to inhibit the conversion of nucleic acids to uric acid</li> <li>• Administration of a cation-exchange resin, such as sodium polystyrene sulfonate (Kayexalate) to treat hyperkalemia by binding and eliminating potassium through the bowel</li> <li>• Administration of hypertonic dextrose and regular insulin temporarily shifts potassium into cells and lowers serum potassium levels.</li> <li>• Administration of phosphate-binding gels, such as aluminum hydroxide, to treat hyperphosphatemia by promoting phosphate excretion in the feces.</li> <li>• Hemodialysis when patients are unresponsive to the standard approaches for managing uric acid and electrolyte abnormalities</li> </ul> <p><i>Nursing</i></p> <ul style="list-style-type: none"> <li>• Identify at-risk patients, including those in whom tumor lysis syndrome may develop up to 1 week after therapy has been completed.</li> <li>• Institute essential preventive measures (eg, fluid hydration and allopurinol).</li> <li>• Assess patient for signs and symptoms of electrolyte imbalances.</li> <li>• Assess urine pH to confirm alkalization.</li> <li>• Monitor serum electrolyte and uric acid levels for evidence of fluid volume overload secondary to aggressive hydration.</li> <li>• Instruct patients to report symptoms indicating electrolyte disturbances.</li> </ul>

### Critical Thinking Exercises

1. You are seeing a married couple in their 70s in the clinic for blood pressure checks. What questions regarding cancer screening are appropriate for them? How would you respond if your suggestions for cancer screening are met with the answer that they are too old to worry about cancer? What special considerations are there if the woman has a physical disability that requires her to use a wheelchair?
2. A 54-year-old woman with bone metastases secondary to breast cancer has been admitted to the hospital with a diagnosis of hypercalcemia. Describe the underlying cause of hypercalcemia and the medical and nursing management strategies that are anticipated. What patient monitoring would be essential before and after treatment of hypercalcemia?
3. One of your home care patients, a 42-year-old executive of a major corporation, has a nonresectable malignant brain tumor for which she is receiving radiation therapy. She is being discharged from the hospital and will continue therapy as an outpatient. She and her husband are concerned about her future and survival and are also concerned about

the impact of the diagnosis on the couple's 10-year-old twins. She is also concerned about her ability to carry out her executive responsibilities. What assessment by the nurse is indicated at this point, and what actions would be warranted by the nurse to help the patient and her husband deal with their concerns?

4. A 70-year-old man with advanced cancer living at home with his wife has been experiencing increasingly severe pain for which an oral opioid analgesic has recently been prescribed. What nursing assessments are essential for the home care nurse? What teaching will be indicated for the patient and family? How would you modify your teaching if the patient and his wife understand little English?

# ● End-of-Life Care

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Discuss the historical, legal, and sociocultural perspectives of palliative and end-of-life care in the United States.
2. Define palliative care.
3. Compare and contrast the settings where palliative care and end-of-life care are provided.
4. Describe the principles and components of hospice care.
5. Identify barriers to improving care at the end of life.
6. Reflect on personal experience with and attitudes toward death and dying.
7. Apply skills for communicating with terminally ill patients and their families.
8. Provide culturally and spiritually sensitive care to terminally ill patients and their families.
9. Implement nursing measures to manage physiologic responses to terminal illness.
10. Support actively dying patients and their families.
11. Identify components of uncomplicated grief and mourning and implement nursing measures to support the patient and family.

## Nursing and End-of-Life Care

One of the most difficult realities that nurses face is that, despite our very best efforts, some patients will die. Although we cannot change this fact, we can have a significant and lasting effect on the way in which patients live until they die, the manner in which the death occurs, and the enduring memories of that death for the families. Nursing has a long history of holistic, person- and family-centered care. Indeed, the definition of nursing offered by the American Nurses Association (ANA) highlights nursing's commitment to the diagnosis and treatment of human responses to illness (ANA, 1995). There is perhaps no setting or circumstance in which care—that is, attention to the human responses—is more important than in caring for the dying patient.

Knowledge about end-of-life decisions and principles of care is essential to supporting patients during decision making and in end-of-life closure in ways that recognize their unique responses to illness and that support their values and goals. Education, clinical practice, and research concerning end-of-life care are evolving, and the need to prepare nurses and other health care professionals to care for the dying has emerged as a priority. The National Institute for Nursing Research has taken the lead in coordinating research related to end-of-life care within the National Institutes of Health (Grady, 1999). At no time in nursing's history has there been a greater opportunity to bring research, education, and practice together to change the culture of dying, bringing much-needed improvement to care that is relevant across practice settings, age groups, cultural backgrounds, and illnesses.

### THE CONTEXT FOR DEATH AND DYING IN AMERICA

In the past three decades there has been a surge of interest in the care of the dying, with an emphasis on the settings in which death occurs, the technologies used to sustain life, and the challenges of trying to improve end-of-life care. The focus on care of the dying has been motivated by the aging of the population, the prevalence of and publicity surrounding life-threatening illnesses such as cancer and AIDS, and the efforts of health care providers to build a continuum of service that spans the lifetime from birth until death (Lesparre & Matherlee, 1998). Although there are more

opportunities than ever before to allow a peaceful death, the knowledge and technologies available to health care providers have made the process of dying anything but peaceful. According to Callahan (1993a), Americans view death as what happens when medicine fails, an attitude that often places the study of death and improvement of the dying process outside of the focus of modern medicine and health care. Numerous initiatives aimed at improving end-of-life care have been launched in recent years, spurred by a widespread call for substantive change in the way Americans deal with death.

The Palliative Care Task Force of the Last Acts Campaign (Last Acts, 1997) identified the following as precepts or principles underlying a more comprehensive and humane approach to care of the dying:

- Respecting patients' goals, preferences, and choices
- Attending to the medical, emotional, social, and spiritual needs of the dying person
- Using strengths of interdisciplinary resources
- Acknowledging and addressing caregiver concerns
- Building mechanisms and systems of support

### TECHNOLOGY AND END-OF-LIFE CARE

In the last century, chronic, degenerative diseases replaced communicable diseases as the major causes of death. Although technological advances in health care have extended and improved the quality of life for many, the ability of technologies to prolong life beyond the point that some would consider meaningful has raised troubling ethical issues. In particular, the use of technology to sustain life has raised perplexing issues with regard to quality of life, prolongation of dying, adequacy of pain relief and symptom management, and allocation of scarce resources. The major ethical question that has emerged concerning the use of technology to extend life is: Because we can prolong life through a particular intervention, does it necessarily follow that we must do so? In the latter half of the 20th century a "technological imperative" practice pattern among health care professionals emerged, along with an expectation among patients and families that every available means to extend life must be tried.

Decisions to apply every available technology to extend life have contributed to the shift in the place of death from the home to the hospital or extended care facility. In the earlier part of the last

## Glossary

**assisted suicide:** use of pharmacological agents to hasten the death of a terminally ill patient; illegal in most states

**autonomy:** self-determination; in the health care context, the right of the individual to make choices about the use and discontinuation of medical treatment

**bereavement:** period during which mourning for a loss takes place

**euthanasia:** Greek for "good death;" has evolved to mean the intentional killing by act or omission of a dependent human being for his or her alleged benefit

**grief:** the personal feelings that accompany an anticipated or actual loss

**hospice:** a coordinated program of interdisciplinary care and services provided pri-

marily in the home to terminally ill patients and their families

**interdisciplinary collaboration:** members of diverse health care disciplines jointly plan, implement, and evaluate care

**Medicare Hospice Benefit:** a Medicare entitlement that provides for comprehensive, interdisciplinary palliative care and services for eligible beneficiaries who have a terminal illness and a life expectancy of less than 6 months

**mourning:** individual, family, group, and cultural expressions of grief and associated behaviors

**palliative care:** comprehensive care for patients whose disease is not responsive to cure; care also extends to patients' families

**palliative sedation:** use of pharmacological agents, at the request of the terminally ill patient, to induce sedation when symptoms have not responded to other management measures. The purpose is not to hasten the patient's death but to relieve intractable symptoms.

**spirituality:** personal belief systems that focus on a search for meaning and purpose in life, intangible elements that impart meaning and vitality to life, and a connectedness to a higher or transcendent dimension

**terminal illness:** progressive, irreversible illness that despite cure-focused medical treatment will result in the patient's death

century, most deaths occurred at home. Because of this, most families had direct experience “being with” death, providing care to family members at the end of life and mourning for the loss of loved ones. As the place of death shifted to the hospital, families became increasingly distanced from the death experience. By the early 1970s, when hospice care was just beginning in this country, technology had become the expected companion of the critically and terminally ill (Wentzel, 1981). The implications of technological intervention at the end of life continue to be profound, affecting a societal view of death that influences how clinicians care for the dying, how family and friends participate in care, how patients and families understand and choose among end-of-life care options, how families prepare for **terminal illness** and death, and how they heal following the death of a loved one.

## SOCIOCULTURAL CONTEXT

Although each individual experiences terminal illness uniquely, such illness is also shaped substantially by the social and cultural contexts in which it occurs. In the United States, life-threatening illness, life-sustaining treatment decisions, dying, and death occur in a social environment where illness is largely considered a foe and where battles are either lost or won (Benoliel, 1993). A care/cure dichotomy has emerged in which health care providers may view cure as the ultimate good and care as second best, a good only when cure is no longer possible (Benoliel, 1993; Gadow, 1988). In such a model of health or medical care, alleviating suffering is not as valued as curing disease, and patients who cannot be cured feel distanced from the health care team, concluding that when treatment has failed, they too have failed. Patients and families who have internalized the socially constructed meaning of care as second best may fear that any shift from curative goals in the direction of comfort-focused care will result in no care or poorer-quality care, and that the clinicians on whom they have come to rely will abandon them if they withdraw from the battle for cure.

The reduction of patients to their diseases is exemplified in the frequently relayed message in late-stage illness that “nothing more can be done.” This all-too-frequently used statement communicates the belief of many clinicians that there is nothing of value to offer patients who are beyond cure. In a care-focused perspective, mind, body, and spirit are inextricable, and treating the body without attending to the other components is considered inadequate to evoke true healing (Upledger, 1989; Wendler, 1996). This expanded notion of healing as care, along with and beyond cure, implies that healing can take place throughout life and outside the boundaries of contemporary medicine. In this expanded definition, healing is transcendent and its boundaries are unlimited, even as body systems begin to fail at the end of life (Byock, 1997).

## Clinicians’ Attitudes Toward Death

Clinicians’ attitudes toward the terminally ill and dying remain the greatest barrier to improving care at the end of life. Kübler-Ross illuminated the concerns of the seriously ill and dying in her seminal work *On Death and Dying*, published in 1969. At that time, it was common for patients to be kept uninformed about life-threatening diagnoses, particularly cancer, and for physicians and nurses to avoid open discussion of death and dying with their patients (Krisman-Scott, 2000; Seale, 1991). Kübler-Ross taught the health care community that having open discussion about life and death issues did not harm patients, and that the patients in

fact welcomed such openness. She was openly critical of what she called “a new but depersonalized science in the service of prolonging life rather than diminishing human suffering” (Kübler-Ross, 1969, p. 20). She taught the health care community that healing could not take place in a conspiracy of silence, and that as clinicians break the silence and enter the patient’s world, they too can be healed by their struggles and strengths. Her work revealed that, given adequate time and some help in working through the process, patients could reach a stage of acceptance where they were neither angry nor depressed about their fate (Kübler-Ross, 1969).

Clinicians’ reluctance to discuss disease and death openly with patients stems from their own anxieties about death as well as misconceptions about what and how much patients want to know about their illnesses. In an early study of care of the dying in hospital settings, sociologists Glaser and Strauss (1965) discovered that health care professionals in hospital settings avoided direct communication about dying in hope that the patient would discover it on his or her own. They identified four “awareness contexts,” described as the patient’s, physician’s, family’s, and other health care professionals’ awareness of the patient’s status and their recognition of each other’s awareness:

1. Closed awareness: The patient is unaware of his or her terminal state while others are aware. Closed awareness may be characterized by families and health care professionals conspiring to guard the “secret,” fearing that the patient would not be able to cope with full disclosure about his or her status, and the patient’s acceptance of others’ accounts of his or her “future biography” as long as they give him or her no reason to be suspicious.
2. Suspected awareness: The patient suspects what others know and attempts to find out. Suspected awareness may be triggered by inconsistencies in families’ and clinicians’ communication and behavior, discrepancies between clinicians’ accounts of the seriousness of the patient’s illness, or a decline in the patient’s condition or other environmental cues.
3. Mutual pretense awareness: The patient, the family, and the health care professionals are aware that the patient is dying but all pretend otherwise.
4. Open awareness: All are aware that the patient is dying and are able to openly acknowledge that reality.

Glaser and Strauss (1965) also identified a pattern of clinician behavior in which those who feared or were uncomfortable discussing death developed and substituted “personal mythologies” for appraisals of what level of disclosure patients actually wanted. For example, clinicians avoided direct communication with patients about the seriousness of their illness based on their beliefs that (1) patients already knew the truth or would ask if they wanted to know, or (2) patients would subsequently lose all hope, give up, or be psychologically harmed by disclosure.

Glaser and Strauss’ findings were published more than 35 years ago, yet their observations remain valid today. Although a growing number of health care providers are becoming comfortable with assessing patients’ and families’ information needs and disclosing honest information about the seriousness of illness, many still avoid the topic of death in hopes that the patient will ask or find out on his or her own. Despite progress on many health care fronts, those who work with dying patients have identified the persistence of a “conspiracy of silence” about dying (Stanley, 2000, p. 34).

## Patient and Family Denial

Denial on the part of the patient and family about the seriousness of terminal illness also has been cited as a barrier to discussion about end-of-life treatment options. Kübler-Ross (1969) was one of the first to examine patient denial and expose it as a useful coping mechanism that enables patients to gain temporary emotional distance from something that is too painful to contemplate fully. Patients who are characterized as being in denial may be using that strategy to preserve important interpersonal relationships, to protect others from the emotional effects of their illness, or to protect themselves because of fears of abandonment.

Connor (1992) studied a small group of terminally ill cancer patients who were characterized by their use of denial as a coping mechanism. Participants in the experimental group were questioned in structured interviews about their perceptions of the most difficult aspects of having cancer and those actions that they or others take that make these difficulties easier or more difficult to bear. They were offered psychosocial intervention that consisted largely of therapeutic communication followed by a postintervention assessment of their use of denial as a defense mechanism. The use of denial by patients in a control group was also assessed, but these patients did not receive the psychosocial intervention. The researcher concluded that terminally ill patients using denial respond favorably to sensitive psychosocial intervention, as indicated by decreased scores on an instrument to measure denial. Connor acknowledged, however, that additional research is needed to gauge the timing of such interventions according to some measure of patient readiness.

In a more recent study, researchers reported that while the majority of a sample of 200 patients with advanced cancer in their final weeks of life were completely aware of their medical prognosis, a combined total of 26.5% were either unaware or only partially aware (Chochinov, Tataryn, Wilson, Ennis & Lander, 2000). Depression was nearly three times greater in those patients who were unaware of their prognosis. The researchers concluded that denial of prognosis is more likely in patients with underlying psychological or emotional distress. Similarly, Chow and colleagues (2001) reported that many patients surveyed about their understanding of palliative radiation therapy for advanced cancer believed that their disease was curable, that the radiation therapy would cure their cancer, or that the therapy would prolong their lives. Importantly, most also reported that they were unfamiliar with the concept of radiation therapy, were not given information, or were not satisfied with the information their physicians had provided. Clearly, further research is needed to examine the complex interplay between patients' misconceptions about advanced illness, their underlying psychological states, and clinicians' persistent lack of candor in discussing treatment expectations and prognosis.

The question of how to communicate with patients in a way that acknowledges where they are on the continuum of acceptance, while providing them with unambiguous information, remains a challenge. Zerwekh (1994) analyzed stories from 32 hospice nurses and concluded that nurses in a hospice setting were adept at interventions deemed important in care of the dying, namely truth telling and encouraging patient **autonomy**. Although she acknowledged that each individual views "truth" differently, she observed that hospice nurses participating in the study used communication skills to assist the patient and family to discuss end-of-life issues. Hospice nurses deliberately spoke about sensitive matters that were usually avoided and gave patients and families truthful representations of their status when patients were in tran-

sition from curative to palliative care. Although timing of the questions takes experience, speaking the truth can be a relief to patients and families, enhancing their autonomy by making way for truly informed consent as the basis for decision making.

## Assisted Suicide

The assisted suicide debate has aimed a spotlight on the adequacy and quality of end-of-life care in the United States. **Assisted suicide** refers to providing another person the means to end his or her own life. Physician-assisted suicide involves the prescription by a physician of a lethal dose of medication for the purpose of ending someone's life (not to be confused with the ethically and legally supported practices of withholding or withdrawing medical treatment in accordance with the wishes of the terminally ill individual).

Judeo-Christian beliefs support the view that suicide is a violation of natural law and the law of God (Helm, 1984; Sorenson, 1991). However, there have recently been calls for the legalization of assisted suicide. Although the preference to take one's own life over awaiting death has been evident through the ages, these recent efforts to legalize assisted suicide underscore the need for changes in the ways individuals with terminal illnesses are cared for and treated at the end of their lives. This is further emphasized by the efforts of groups such as the Hemlock Society to have physician-assisted suicide legalized and the Hemlock Society's publication of information to the public describing methods for ending one's own life when such assistance from physicians is not available.

Although assisted suicide is expressly prohibited under statutory or common law in the majority of states, the calls for legalized assisted suicide have highlighted inadequacies in the care of the dying. In 1990, Dr. Jack Kevorkian, a retired pathologist, assisted a 54-year-old woman with early Alzheimer's disease to end her life using a device that he had devised to allow a patient to control the infusion of a lethal dose of potassium chloride. In 1999, after 130 deaths and nine trials, Kevorkian was convicted on second-degree murder charges in the death of a 52-year-old man with amyotrophic lateral sclerosis and is currently serving a 10- to 25-year prison sentence in Michigan. In a telephone poll conducted the week following the conviction, 55% of respondents disagreed with the verdict (Langer, 1999).

Meanwhile, public support for physician-assisted suicide has resulted in a number of state ballot initiatives. In 1994, voters approved the Oregon Death with Dignity Act, the first such legislative initiative to pass. This law provides for terminally ill patients' access to physician-assisted suicide under very controlled circumstances. After numerous challenges, a majority of Oregonians voted against an attempted repeal, and the law was implemented in 1997. The most recent challenges to the law included the 1999 federal Pain Relief Promotion Act, a bill designed to derail the implementation of the Oregon law by prohibiting the use of federally controlled substances for physician-assisted suicide, and a 2001 directive from Attorney General John Ashcroft to the Drug Enforcement Agency to track and prosecute physicians who prescribe under the Oregon law. There is an ongoing battle in the courts over this issue, and while Oregon is currently the only state with a statute legalizing physician-assisted suicide, it is likely that the issue will be pursued in the courts and through ballot measures in other states.

Whereas proponents of physician-assisted suicide argue that terminally ill individuals should have a legally sanctioned right to make independent decisions about the value of their lives and the

timing and circumstances of their deaths, its opponents argue for greater access to symptom management and psychosocial support for individuals approaching the end of life. Numerous ethical and legal issues have been raised, including voluntariness and authenticity of requests in relation to the mental competence and decision-making capacity of patients who request physician-assisted suicide, the existence of underlying untreated clinical depression or other suffering, and issues of overt or perceived coercion. Assisted suicide is opposed by nursing and medical organizations as a violation of the ethical traditions of nursing and medicine. The ANA Position Statement on Assisted Suicide acknowledges the complexity of the assisted suicide debate but clearly states that nursing participation in assisted suicide is a violation of the Code for Nurses. The ANA Position Statement further stresses the important role of the nurse in supporting effective symptom management, contributing to the creation of environments for care that honor the patient's and family's wishes, and ascertaining and addressing their concerns and fears (ANA, 1994).

## Settings for End-of-Life Care: Palliative Care Programs and Hospice

### PALLIATIVE CARE

As concerns have grown about the poor quality of life patients experience during progressive illness, broadening the concept of palliative care beyond the hospice has begun to take hold in health care settings across the country (Jones, 1997). **Palliative care** is an approach to care for the seriously ill that has long been a part of cancer care. Both palliative care and hospice have been recognized as important bridges between the compulsion for cure-oriented care and physician-assisted suicide (Saunders & Kastenbaum, 1997). Advocates for improved care for the dying have stated that acceptance, management, and understanding of death should become fully integrated concepts in mainstream health care (Callahan, 1993a; Morrison, Siu, Leipzig et al., 2000). Increasingly, palliative care is being offered to patients with noncancer chronic illnesses, where comprehensive symptom management and psychosocial and spiritual support can enhance the patient's and family's quality of life.

While hospice care is considered by many to be the “gold standard” for palliative care, the term **hospice** is generally associated with palliative care that is delivered at home or in special facilities to patients who are approaching the end of life. Palliative care is conceptually broader than hospice care, defined as the active, total care of patients whose disease is not responsive to treatment (World Health Organization, 1990).

Palliative care emphasizes management of psychological, social, and spiritual problems in addition to control of pain and other physical symptoms. As the definition suggests, palliative care is not care that begins when cure-focused treatment ends. The goal of palliative care is to improve the patient's and family's quality of life, and many aspects of this type of comprehensive, comfort-focused approach to care are applicable earlier in the process of life-threatening disease in conjunction with cure-focused treatment. However, definitions of palliative care, the services that are part of it, and the clinicians who provide it are evolving steadily.

Some would argue that palliative care is no different from comprehensive nursing, medical, social, and spiritual care and that patients should not have to be labeled as “dying” to receive

person-focused care and symptom management. In addition to a focus on the multiple dimensions of the illness experience for both patients and their families, palliative care emphasizes the interdisciplinary collaboration that is necessary to bring about the desired outcomes for patients and their families. **Interdisciplinary collaboration** is distinguished from multidisciplinary practice in that the former is based on communication and cooperation among the various disciplines; each member of the team contributes to a single care plan that addresses the needs of the patient and family.

### Palliative Care at the End of Life

As discussed above, palliative care is broadly conceptualized as comprehensive, person- and family-centered care when disease is not responsive to treatment. The broadening of the concept of palliative care actually followed the development of hospice services in the United States. Hospice care is in fact palliative care. The difference is that hospice care is associated with the end of life, and although it focuses on quality of life, hospice care by necessity usually includes realistic emotional, social, spiritual, and financial preparation for death. In the mid-1970s, when hospice care was introduced in the United States, it was more broadly conceived as care that addressed the whole person—physical, social, emotional, and spiritual—and was available to patients earlier in the process of life-threatening illness. After hospice care was recognized as a distinct program of services under Medicare in the early 1980s, organizations providing hospice care were able to receive Medicare reimbursement if they could demonstrate that the hospice program met the Medicare “conditions of participation,” or regulations, for hospice providers.

While Medicare reimbursement resulted in new rules for hospices, it also defined when Medicare beneficiaries are able to use their **Medicare Hospice Benefit**. In most programs, the Medicare definitions for patient eligibility are used to guide all enrollment decisions. According to Medicare, the patient who wishes to use his or her Medicare Hospice Benefit must be certified by a physician as terminally ill, with a life expectancy of 6 months or less if the disease follows its natural course. Thus, hospice has come to be defined as care provided to terminally ill persons and their families in the last 6 months of the patient's life. Because of additional Medicare rules concerning completion of all cure-focused medical treatment before the Medicare Hospice Benefit may be accessed, many patients delay enrollment in hospice programs until very close to the end of life.

The reasons for late referral to hospice and the underuse of hospice services are complex. They may include values and attitudes of health care providers, the inadequate dissemination of existing knowledge about pain and symptom management, health care providers' difficulties in effectively communicating with terminally ill individuals, and insufficient attention to palliative care concepts in health care providers' education and training.

Hospices care for approximately 29% of patients who are eligible (National Hospice and Palliative Care Organization, 2001). For the most part, the remainder of terminally ill patients die in hospitals and long-term care facilities. It is clear that better care for the dying is urgently needed in hospitals, long-term care facilities, home care agencies, and outpatient settings. At the same time, many chronic diseases do not have a predictable “end stage” that fits hospice eligibility criteria, meaning that many patients die after a long, slow, and often painful decline, without the benefit of the coordinated palliative care that is unique to hospice programs. The palliative approach to care could benefit many

more patients if it were available across settings for care and earlier in the disease process. In an attempt to make this valuable approach to care more widely available, palliative care programs are being developed in other settings for patients who are either not eligible for hospice or are “not ready” to enroll in a formal hospice program. As yet, there is no dedicated reimbursement to providers for palliative care services when they are delivered outside of the hospice setting, making the sustainability of such programs challenging.

### Palliative Care in the Hospital Setting

Since the advent of diagnosis-related groups (DRGs) as the basis for prospective payment for hospital services in the 1980s, there has been a financial incentive for hospitals to transfer patients with terminal illnesses who were no longer in need of acute-level care to other settings, such as long-term care facilities and home, to receive care (Field & Cassel, 1997). Despite the economic and human costs associated with death in the hospital setting, as many as 50% of all deaths occur in acute care settings (Hogan et al., 2000). The landmark Study to Understand Prognoses and Preferences for Outcomes and Risks of Treatments (SUPPORT, 1995) documented troubling deficiencies in the care of the dying in hospital settings:

- Many patients received unwanted care at the end of life.
- Clinicians were not aware of patient preferences for life-sustaining treatment, even when preferences were documented in the clinical record.
- Pain was often poorly controlled at the end of life.
- Efforts to enhance communication were ineffective.

It is clear that many patients will continue to opt for hospital care or by default will find themselves in hospital settings at the end of life. Increasingly, hospitals are conducting system-wide assessments of end-of-life care practices and outcomes and are developing innovative models for delivering high-quality, person-centered care to patients approaching the end of life. Hospitals cite considerable financial barriers to providing high-quality palliative care in an acute care setting (Cassel, Ludden & Moon, 2000). Public policy changes have been called for that would provide reimbursement to hospitals for care delivered via designated hospital-wide palliative care beds, clustered palliative care units, or palliative care consultation services in acute care settings.

### Palliative Care in Long-Term Care Facilities

The place of death for a growing number of Americans after the age of 65 is the long-term care facility (Alliance for Aging Research, 1997). As many as one third of all Medicare beneficiaries who die in any given year spend all or part of their last year of life in a long-term care facility (Hogan et al., 2000). The trend favoring care of dying patients in long-term care facilities will continue as the population ages and as managed care payors pressure health care providers to minimize costs (Field & Cassel, 1997). Yet residents of long-term care facilities reportedly have poor access to high-quality palliative care. Regulations that govern how care in these facilities is organized and reimbursed tend to emphasize restorative measures and fail to reward palliative care (Zerzan, Stearns & Hanson, 2000). Although home hospice programs have been permitted since 1986 to enroll long-term care facility residents in hospice programs and provide interdisciplinary services to residents who qualify for hospice care, the Office of the Inspector General, an oversight arm of the federal govern-

ment, has questioned whether such services are an unnecessary duplication of services already provided by facility staff (Office of the Inspector General, 1997). While there has been regulatory scrutiny on the one hand, long-term care facilities of all types are under increasing public pressure to improve care of the dying and are beginning to develop palliative care units or services, contract with home hospice programs to provide hospice care in the facilities, and educate staff, residents, and their families about pain and symptom management and end-of-life care.

### HOSPICE CARE

Hospice in the United States is not a place, but a concept of care in which the end of life is viewed as a developmental stage. The root of the word hospice is *hospes*, meaning “host.” Historically, hospice has referred to a shelter or way station for weary travelers on a pilgrimage (Bennahum, 1996). In the years that followed Kübler-Ross’s groundbreaking work, the concept of hospice care as an alternative to depersonalized death in institutions began as a grassroots movement. Her work, and the development of the concept of hospice in England by Dr. Cicely Saunders, resulted in recognition of gaps in the existing system of care for the terminally ill (Amenta, 1986). Hospice care began in response to “noticeable gaps . . . (1) between treating the disease and treating the person, (2) between technological research and psycho-social support, and (3) between the general denial of the fact of death in our society and the acceptance of death by those who face it” (Wentzel, 1981, p. 11). According to Saunders, who founded the world-renowned St. Christopher’s Hospice in London (Bennahum, 1996), the principles underlying hospice are as follows:

- Death must be accepted.
- The patient’s total care is best managed by an interdisciplinary team whose members communicate regularly with each other.
- Pain and other symptoms of terminal illness must be managed.
- The patient and family should be viewed as a single unit of care.
- Home care of the dying is necessary.
- Bereavement care must be provided to family members.
- Research and education should be ongoing.

### Hospice Care in the United States

Although the concept dates to ancient times, hospice as a way of caring for those at the end of life did not emerge in the United States until the 1960s (Hospice Association of America, 2001). The hospice movement in the United States is based on the belief that meaningful living is achievable during terminal illness, and that it is best supported in the home, free from technological interventions to prolong physiologic dying (Amenta, 1986). After the first U.S. hospice was founded in Connecticut in 1974, the concept quickly spread and the number of hospice programs in the United States has grown dramatically. In the years between 1984 and 1996, which followed the creation of the Medicare Hospice Benefit, there was a 70-fold increase in the number of hospices participating in Medicare (Hospice Association of America, 2001).

Despite more than 25 years of existence in the United States, hospice remains an option for end-of-life care that has not been fully integrated into mainstream health care. Although hospice care is available to persons with any life-limiting condition, it has primarily been used by patients with advanced cancer, where the disease staging and trajectory lend themselves to more reliable

prediction about the end of life (Boling & Lynn, 1998; Christakis & Lamont, 2000). Many reasons have been proposed for the reluctance of physicians to refer patients to hospice and the reluctance of patients to accept this form of care. These include the difficulties in making a terminal prognosis, the strong association of hospice with death, advances in “curative” treatment options in late-stage illness, and financial pressures on health care providers that may cause them to retain rather than refer hospice-eligible patients. The result is that patients who could benefit from the comprehensive, interdisciplinary support offered by hospice programs frequently do not enter hospice care until their final days (or hours) of life (Christakis & Lamont, 2000).

Hospice is a coordinated program of interdisciplinary services provided by professional caregivers and trained volunteers to patients with serious, progressive illnesses that are not responsive to cure. In hospice settings, the patient and family together are the unit of care. The goal of hospice care is to enable the patient to remain at home, surrounded by the people and objects that have been important to him or her throughout life. Hospice care does not seek to hasten death, nor does it encourage the prolongation of life through artificial means. Hospice care hinges on the competent patient’s full or “open” awareness of dying; it embraces a realism about death, such that the patient and family are assisted to understand the dying process and can live each moment as fully as possible.

Although most hospice care is provided in the patient’s own home, some hospice programs have developed inpatient facilities or residences where terminally ill patients without family support or those who desire inpatient care may receive hospice services.

Eligibility criteria for hospice vary depending on the hospice program, but generally patients must have a progressive, irreversible illness and limited life expectancy and have opted for palliative care rather than cure-focused treatment. Although hospices have historically served cancer patients, patients with any life-limiting illness are eligible.

## Medicare Hospice Benefit

In 1983, the Medicare Hospice Benefit was implemented to cover hospice care for Medicare beneficiaries. State Medical Assistance (Medicaid) also provides coverage for hospice care, as do most commercial insurers. Federal reimbursement for hospice care ushered in a new era in hospice in which program standards developed and published by the federal government codified what had formerly been a grassroots, loosely organized and defined ideal for care at the end of life. To receive Medicare dollars for hospice services, programs are required to comply with conditions of participation promulgated by the Centers for Medicare and Medicaid Services. Medicare standards have come to largely define hospice philosophy and services. Eligibility criteria for hospice coverage under the Medicare Hospice Benefit are specified in Chart 17-1. Federal rules for hospices require that the patient’s continuing eligibility for hospice care is reviewed periodically. There is no limit to the length of time that an eligible patient may continue to receive hospice care. Patients who live longer than 6 months under hospice care are not discharged if their physician and the hospice medical director continue to certify that the patient is terminally ill with a life expectancy of 6 months or less, assuming that the disease continues its expected course. The hospice certification and review process and the open-ended benefit structure are intended to address the difficulty physicians face in predicting how long a patient will live, so that patients are not restricted to a lifetime limit on the number of hospice days they may receive.

Chart  
17-1

## Eligibility Criteria for Hospice Care

### General

- Serious, progressive illness
- Limited life expectancy
- Informed choice of palliative care over cure-focused treatment

### Hospice-Specific

- Presence of a family member or other caregiver continuously in the home when the patient is no longer able to safely care for him/herself (some hospices have created special services within their programs for patients who live alone, but this varies widely)

### Medicare and Medicaid Hospice Benefits

- Medicare Part A; Medical Assistance eligibility
- Waiver of traditional Medicare/Medicaid benefits for the terminal illness
- Life expectancy of 6 months or less
- Physician certification of terminal illness
- Care must be provided by a Medicare-certified hospice program

To use hospice benefits under Medicare or Medicaid, the patient must meet eligibility criteria and “elect” to use the hospice benefit in place of traditional Medicare or Medicaid benefits for the terminal illness. Once the patient elects the benefit, the Medicare-certified hospice program assumes responsibility for providing and paying for the care and treatment related to the underlying illness for which hospice care was elected. The Medicare-certified hospice is paid a predetermined dollar amount for each day of hospice care each patient receives. Four levels of hospice care are covered under Medicare and Medicaid hospice benefits:

- Routine home care: All services provided are included in the daily rate to the hospice.
- Inpatient respite care: A 5-day inpatient stay, provided on an occasional basis to relieve the family caregivers
- Continuous care: Continuous nursing care provided in the home for management of a medical crisis. Care reverts to the routine home care level when the crisis is resolved. (For example, the patient develops seizure activity and a nurse is placed in the home continuously to monitor the patient and administer medications. After 72 hours the seizure activity is under control, the family has been instructed how to care for the patient, and the continuous nursing care is stopped.)
- General inpatient care: Inpatient stay for symptom management that cannot be provided in the home; not subject to the guidelines for a standard hospital inpatient stay.

Most hospice care is provided at the “routine home care” level and includes the services depicted in Chart 17-2. According to federal guidelines, hospices may provide no more than 20% of the aggregate annual patient days at the inpatient level. Patients may “revoke” their hospice benefits at any time, resuming traditional coverage under Medicare or Medicaid for the terminal illness. They may also re-elect their hospice benefits at a later time after reassessment for eligibility according to these criteria

## Nursing Care of the Terminally Ill Patient

Many patients suffer unnecessarily when they do not receive adequate attention for the symptoms accompanying serious illness. Careful evaluation of the patient should include not only the physical problems but also the psychosocial and spiritual dimen-

Chart  
17-2

### Home Hospice Services Covered Under the Medicare / Medicaid Hospice Benefit Routine Home Care Level

- Nursing care: Provided by or under the supervision of a registered nurse, available 24 hours a day
- Medical social services
- Physician's services
- Counseling services, including dietary counseling
- Home health aide/homemaker
- Physical/occupational/speech therapists
- Volunteers
- Bereavement follow-up (for up to 13 months following the death of the patient)
- Medical supplies for the palliation of the terminal illness
- Medical equipment for the palliation of the terminal illness
- Medications for the palliation of the terminal illness

sions of the patient's and family's experience of serious illness. This approach contributes to a more comprehensive understanding of how the patient's and family's life has been affected by the illness and will lead to nursing care that addresses the needs in every dimension.

## PSYCHOSOCIAL ISSUES

Nurses are responsible for educating patients about the possibilities and probabilities inherent in their illness and their life with the illness, and for supporting them as they conduct life review, values clarification, treatment decision making, and end-of-life closure. The only way to do this effectively is to try to appreciate and understand the illness from the patient's perspective.

Kübler-Ross's (1969) work revealed that patients in the final stages of life can and will talk openly about their experiences, exposing as a myth the view that patients will be harmed by honest discussion with their caregivers about death. Despite the continued reluctance of health care providers to engage in open discussion about end-of-life issues, studies have confirmed that patients want information about their illness and end-of-life choices are not harmed by open discussion about death (McSkimming, Super, Driever et al., 1997; Virmani, Schneiderman & Kaplan, 1994).

At the same time, nurses need to be both culturally aware and sensitive in their approaches to communication with patients and families about death. Attitudes toward open disclosure about terminal illness vary widely among different cultures, and direct communication to the patient about such matters may be viewed as harmful (Blackhall, Murphy, Frank et al., 1995). To provide effective patient- and family-centered care at the end of life, nurses must be willing to set aside their assumptions so that they can discover what type and amount of disclosure is most meaningful to each patient and family within their unique belief systems.

The social and legal evolution of advance directive documents represents some progress in our willingness to both contemplate and communicate our wishes surrounding the end of life (Chart 17-3). Now legally sanctioned in every state and federally sanctioned through the Patient Self-Determination Act (PSDA) of 1990, advance directives are written documents that allow the individual who is of sound mind to document his or her preferences regarding the use or nonuse of medical treatment at the end of life, specify the preferred setting for care, and communicate other valuable insights into his or her values and beliefs. The addition

Chart  
17-3

### Methods of Stating End-of-Life Preferences

**Advance directives**—Written documents that allow the individual of sound mind to document preferences regarding end-of-life care that should be followed when the signer is terminally ill and unable to verbally communicate his/her wishes. The documents are generally completed in advance of or during serious illness. The most common types are the living will (also known as a medical directive) and a proxy directive (also known as a durable power of attorney for health care).

**Proxy directive**—The appointment and authorization of another individual to make medical decisions on behalf of the person who created an advance directive when he/she is no longer able to speak for him/herself. This is also known as a health care power of attorney or durable power of attorney for health care.

**Living will**—Also known as a medical directive. A type of advance directive in which the individual of sound mind documents treatment preferences. Provides instructions for care in the event that the signer is terminally ill and not able to communicate wishes directly. Often accompanied by a proxy directive (also known as a health care power of attorney).

**Durable power of attorney for health care**—A legal document that enables the signer to designate another individual to make health care decisions on his/her behalf when he/she is unable to do so.

of a proxy directive (the appointment and authorization of another individual to make medical decisions on behalf of the person who created the advance directive when he or she can no longer speak for himself or herself) is an important addition to the "living will" or medical directive that specifies the signer's preferences. Although these documents are widely available from health care providers, community organizations, bookstores, and the Internet, their underuse reflects society's continued discomfort with openly confronting the subject of death. Further, the existence of a properly executed advance directive does not reduce the complexity of end-of-life decisions. The advance directive should not be considered an adequate substitute for ongoing communication between health care provider, patient, and family as the end of life approaches (Lynn, 1991).

## COMMUNICATION

As has been discussed, remarkable strides have been made in the ability to prolong life, but attention to care for the dying lags behind (Callahan, 1993b). On one level, this comes as no surprise. Each of us will eventually face death, and most would agree that one's own demise is a subject he or she would prefer not to contemplate. Indeed, Glaser and Strauss (1965) noted that unwillingness in our culture to talk about the process of dying is tied to our discomfort with the notion of particular deaths—those of our patients' and our own—rather than talking about death in the abstract, which is more comfortable. Finucane (1999) observed that our struggle to stay alive is a prerequisite to being human. Confronting death in our patients uncovers our own deeply rooted fears.

To develop a level of comfort and expertise in communicating with seriously and terminally ill patients and their families, nurses and other clinicians need to first consider their own experiences with and values concerning illness and death. Reflection, reading, and talking with family members, friends, and colleagues can assist the nurse to examine beliefs about death and dying. Talking with individuals from differing cultural backgrounds can

assist the nurse to view personally held beliefs through a different lens, and can help to sensitize the nurse to death-related beliefs and practices in other cultures. Discussion with nursing and non-nursing colleagues can also be useful to reveal the values shared by many health care professions and identify diversity in the values of patients in their care. Values clarification and personal death awareness exercises can provide a starting point for self-discovery and discussion.

### Skills for Communicating With the Seriously Ill

Nurses need to develop skill and comfort in assessing patients' and families' responses to serious illness and planning interventions that will support their values and choices throughout the continuum of care. Patients and families need ongoing assistance: telling a patient something once is not teaching, and hearing the patient's words is not the same as active listening. Throughout the course of a serious illness, patients and their families will encounter complicated treatment decisions, bad news about disease progression, and recurring emotional responses. In addition to the time of initial diagnosis, lack of response to the treatment course, decisions to continue or withdraw particular interventions, and decisions about hospice care are examples of critical points on the treatment continuum that demand patience, empathy, and honesty from the nurse. Discussing sensitive issues such as serious illness, hopes for survival, and fears associated with death is never easy. However, the art of therapeutic communication can be learned and, like other skills, must be practiced to gain expertise. Similar to other skills, communication should be practiced in a "safe" setting, such as a classroom or clinical skills laboratory with other students or clinicians.

Although communication with each patient and family should be tailored to their level of understanding and values concerning disclosure, general guidelines for the nurse include the following (Addington, 1991):

- Deliver and interpret the technical information necessary for making decisions without hiding behind medical terminology.
- Realize that the best time for the patient to talk may be when it is least convenient for you.
- Being fully present during any opportunity for communication is often the most helpful form of communication.
- Allow the patient and family to set the agenda regarding the depth of the conversation.

### Nursing Interventions When the Patient and Family Receive Bad News

Communicating about a life-threatening diagnosis or about disease progression is best accomplished by the interdisciplinary team in any setting—a physician, nurse, and social worker should be present whenever possible to provide information, facilitate discussion, and address concerns. Most importantly, the presence of the team conveys caring and respect for the patient and family. Creating the right setting is particularly important. If the patient wishes to have family present for the discussion, arrangements should be made to have the discussion at a time that is best for the patient and family. A quiet area with a minimum of disturbances should be used. Each clinician who is present should turn off beepers or other communication devices for the duration of the meeting and should allow sufficient time for the patient and family to

absorb and respond to the news. Finally, the space in which the meeting takes place should be conducive to seating all of the participants at eye level. It is difficult enough for patients and families to be the recipients of bad news without having an array of clinicians standing uncomfortably over them at the foot of the patient's bed.

After an initial discussion of a life-threatening illness or progression of a disease, patients and their families will have many questions and may need to be reminded of factual information. Coping with news about a serious diagnosis or poor prognosis is an ongoing process. The nurse needs to be sensitive to these ongoing needs and may need to repeat previously provided information or simply be present while the patient and family react emotionally. The most important intervention the nurse can provide is listening empathetically. Seriously ill patients and their families need time and support to cope with the changes brought about by serious illness and the prospect of impending death. The nurse who is able to sit comfortably with another's suffering, time and time again, without judgment and without the need to solve the patient's and family's problems provides an intervention that is a gift beyond measure. Keys to effective listening include the following:

- Resist the impulse to fill the "empty space" in communication with talk.
- Allow the patient and family sufficient time to reflect and respond after asking a question.
- Prompt gently: "Do you need more time to think about this?"
- Avoid distractions (noise, interruptions).
- Avoid the impulse to give advice.
- Avoid canned responses: "I know just how you feel."
- Ask questions.
- Assess understanding—your own and the patient's—by restating, summarizing, and reviewing.

### Responding With Sensitivity To Difficult Questions

Patients will often direct questions or concerns to nurses before they have been able to fully discuss the details of their diagnosis and prognosis with the physician or the entire health care team. Using open-ended questions allows the nurse to elicit the patient's and family's concerns, explore misconceptions and needs for information, and form the basis for collaboration with the physician and other team members. For example, the seriously ill patient may ask the nurse, "Am I dying?" The nurse should avoid making unhelpful responses that dismiss the patient's real concerns or defer the issue to another care provider. Nursing assessment and intervention are always possible, even when a need for further discussion with the physician is clearly indicated. Whenever possible, discussions in response to the patient's concerns should occur when the patient expresses a need, although it may be the least convenient time for the nurse (Addington, 1991). Creating an uninterrupted space of just 5 minutes can do much to identify the source of the concern, allay anxieties, and plan for follow-up. For example, in response to the question, "Am I dying?" the nurse could establish eye contact and follow with a statement acknowledging the patient's fears ("This must be very difficult for you") and an open-ended statement or question ("Tell me more about what is on your mind."). The nurse then needs to listen intently, ask additional questions for clarification, and provide reassurance only when it is realistic. In this example,

the nurse might quickly ascertain that the patient's question emanates from a need for specific information—about diagnosis and prognosis from the physician, about the physiology of the dying process from the nurse, or perhaps about financial implications for the family from the social worker. The chaplain may also be called upon to talk with the patient about existential concerns.

### NURSING RESEARCH PROFILE 17-1

#### Decision Making at the End of Life

Tilden, V. P., Tolle, S. W., Nelson, C. A., & Fields, J. (2001). Family decision-making to withdraw life-sustaining treatments from hospitalized patients. *Nursing Research*, 50(2), 105–115.

#### Purpose

Although participation of family members in end-of-life decision making is increasing, little is known about the stress associated with their participation. Further, it is not known how families' reasoning processes compare to those of clinicians. The purpose of this study was to assess factors that affect family stress associated with withdrawal of life-sustaining treatment from their dying, hospitalized relatives. Investigators also compared family members and clinicians on their reasoning about the decision.

#### Study Sample and Design

A descriptive quantitative study was conducted in four large tertiary-care centers. Family members who had participated in the decision to withdraw life-sustaining treatment from patients who had been unable to make their own decisions were invited to participate.

Seventy-four family members of 51 patients participated in the study and were interviewed for data collection 1 to 2 months after the death of the patient; 65 family members were interviewed again 7 to 8 months later. Clinician data about the families' decision making were obtained from physicians ( $n = 21$ ) and nurses ( $n = 24$ ) 2 months after patients' deaths.

The Horowitz Impact of Events Scale and the mental/emotional state scale of the Rand 36-item Health Survey 1.0 was used to measure family stress. The researchers measured the importance of each of three factors (quality of life, patient preference, and prolongation of life) to family and clinician reasoning about treatment decisions by single-item indicators scaled on a 0 to 100-mm visual analog scale (VAS). The VAS scores indicated the likelihood that the respective factors would be considered in reaching a decision.

#### Findings

High levels of family stress were found 1 month and 7 to 8 months after the death, although stress levels at 7 to 8 months were lower. Patient/family characteristics that were associated with increased stress included the absence of advance directives (ADs), being an ethnic minority, and having a longer commuting distance to the hospital during the decedent's hospitalization. Families were more likely than clinicians to prioritize life prolongation over quality of life, particularly in the absence of an AD. Family members described their participation in decision making about withdrawing life support as one of the most difficult things they had ever had to do.

#### Nursing Implications

It is important for health care providers to recognize the impact of participation in end-of-life decision making on family members and to support them at this time. The study underscores the importance of assisting families to identify patients' preferences for end-of-life care and the importance of ADs in easing the process for family members. Further research is needed to compare the effect of having a written AD to guide family members versus patients' informal conversations about treatment preferences on family stress levels.

As a member of the interdisciplinary team caring for the patient at the end of life, the nurse fills an important role in facilitating the team's understanding of the patient's values and preferences, the family dynamics concerning decision making, and the patient's and family's response to treatment and changing health status. Many dilemmas in patient care at the end of life are related to poor communication between team members and the patient and family and failure of team members to communicate effectively with each other. Regardless of the care setting, the nurse can ensure a proactive approach to the psychosocial care of the patient and family. Periodic, structured assessments provide an opportunity for all parties to consider their priorities and plan for an uncertain future. The nurse can assist the patient and family to clarify their values and preferences concerning end-of-life care by using a structured approach. Sufficient time must be devoted to each step, so that the patient and family have time to process new information, formulate questions, and consider their options. The nurse may need to plan several meetings to accomplish the four steps described in Table 17-1.

## PROVIDING CULTURALLY SENSITIVE CARE AT THE END OF LIFE

Although death, grief, and mourning are universally accepted aspects of living, values, expectations, and practices during serious illness, as death approaches, and following death are culturally bound and expressed. Health care providers may share very similar values concerning end-of-life care and may find that they are inadequately prepared to assess for and implement care plans that support culturally diverse perspectives. Historical mistrust of the health care system and unequal access to even basic medical care may underlie the beliefs and attitudes among ethnically diverse populations (Crawley, Payne, Bolden et al., 2000; Phipps, True & Pomerantz, 2000). In addition, lack of education or knowledge concerning end-of-life care treatment options and language barriers influence decisions among many socioeconomically disadvantaged groups.

Much of the formal structure concerning health care decisions in the United States is rooted in the Western notions of autonomy, truth telling, and the acceptability of withdrawing or withholding life-prolonging medical treatment at the end of life. Yet in many cultures, interdependence is valued over autonomy, leading to decision and communication styles that favor relinquishment of decision making to family members or to a perceived authority figure, such as the physician (Blackhall et al., 1995; Ersek, Kagawa-Singer, Barnes et al., 1998). In addition, there is variation in preference regarding the use of life-prolonging medical treatments such as cardiopulmonary resuscitation and artificially provided nutrition and hydration at the end of life; some groups are less likely to agree with withholding or withdrawing such life support in terminal illness (Caralis, Davis, Wright et al., 1993).

The nurse's role is to assess the values, preferences, and practices of every patient, regardless of ethnicity, socioeconomic status, or background. The nurse can share knowledge about the patient's and family's cultural beliefs and practices with the health care team and facilitate the adaptation of the care plan to accommodate these practices. For example, the nurse may find that a patient prefers to have his eldest son make all of his care decisions. Institutional practices and laws governing informed consent are also rooted in the Western notion of autonomous decision making

Table 17-1 • Discussing End-of-Life Care

1. Initiate discussion	<ul style="list-style-type: none"> <li>• Establish a supportive relationship with patient and family</li> <li>• State the purposes of the patient/family–health care team conference:               <ul style="list-style-type: none"> <li>• To ensure that the plan of care is consistent with patient and family values and preferences</li> <li>• To find out how best to support this patient and family</li> </ul> </li> <li>• Inquire if the patient or family have questions or concerns that they want to express</li> <li>• Elicit values and preferences concerning:               <ul style="list-style-type: none"> <li>• Patient and family decision-making roles                   <ul style="list-style-type: none"> <li>• How have major decisions been made in the past?</li> <li>• How have treatment/care decisions been made during the course of the illness?</li> <li>• Has the patient appointed a surrogate?                       <ul style="list-style-type: none"> <li>• Formal (Durable Power of Attorney)</li> <li>• Informal</li> </ul> </li> <li>• How does the patient/family want decisions to be structured from this point on?</li> </ul> </li> <li>• Setting for receiving care at the end of life                   <ul style="list-style-type: none"> <li>• Home</li> <li>• Home with hospice care</li> <li>• Assisted living or long-term care with/without hospice</li> <li>• Disposition when unable to care for self independently (plan for how and where the patient prefers to receive care when he/she can no longer live independently)</li> </ul> </li> <li>• Family involvement in care provision</li> </ul> </li> </ul>
2. Clarify understanding of the medical treatment plan and prognosis	<ul style="list-style-type: none"> <li>• Identify what the patient and family understand</li> <li>• Identify gaps in knowledge, need for consultation with other members of the health care team</li> <li>• Use simple, everyday language</li> </ul>
3. Identify end-of-life priorities	<ul style="list-style-type: none"> <li>• Facilitate open discussion about priorities               <ul style="list-style-type: none"> <li>• “What is most important to you now?”</li> <li>• “How can (I/we) best help you to meet your goals?”</li> </ul> </li> <li>• Allow sufficient time for emotional response</li> </ul>
4. Contribute to the interdisciplinary care plan	<ul style="list-style-type: none"> <li>• Provide guidance and/or referral for understanding medical options</li> <li>• Make recommendations for referrals to other disciplines or services (eg, spiritual care, support groups, community resources)</li> <li>• Identify need for patient/family teaching</li> <li>• Develop a plan for follow-up:               <ul style="list-style-type: none"> <li>• Schedule (frequency, time, place)</li> <li>• Participants</li> <li>• Tasks/assignments</li> <li>• Communication that needs to occur before the next meeting</li> <li>• Family member responsible for coordination</li> </ul> </li> </ul>

Adapted with permission from Balaban, R. B. (2000). A physician's guide to talking about end-of-life care. *Journal of General Internal Medicine*, 15(3), 195–200. Oxford: Blackwell Science Ltd.

and informed consent. If a patient who wishes to defer decisions to his son, the nurse can work with the team to negotiate informed consent, respecting the patient's right not to participate in decision making and honoring his family's cultural practices (Ersek et al., 1998).

The nurse should assess and document the patient's and family's specific beliefs, preferences, and practices regarding end-of-life care, preparation for death, and after-death rituals. Chart 17-4 identifies topics that the nurse should cover and questions that the nurse may use to elicit the information. The nurse must use judgment and discretion about the timing and setting for eliciting this information. Some patients may wish to have a family member speak for them or because of advanced illness may be unable to provide information. The nurse should give the patient and family a context for the discussion, such as “It is very important to us to provide care that addresses your needs and the needs

of your family. We want to honor and support your wishes, and want you to feel free to tell us how we are doing, and what we could do to better meet your needs. I'd like to ask you some questions; what you tell me will help me to understand and support what is most important to you at this time. You don't need to answer anything that makes you uncomfortable. Is it all right to ask some questions?” The assessment of end-of-life beliefs, preferences, and practices will probably need to be carried out in short segments over a period of time (for example, across multiple days of an inpatient hospital stay or in conjunction with multiple patient visits to an outpatient setting). The novice nurse's discomfort with asking questions and discussing this type of sensitive content can be reduced by prior practice in a classroom or clinical skills laboratory, observation of interviews conducted by experienced nurses, and partnering with an experienced nurse during the first few assessments.

### Chart 17-4 • ASSESSMENT

#### Nursing Assessment of End-of-Life Care Beliefs, Preferences, and Practices

- *Disclosure/truth telling:* “Tell me how you/your family talk about very sensitive or serious matters.”
- *Content:* “Are there any topics that you or your family are uncomfortable discussing?”
- *Person responsible for disclosure:* “Is there one person in the family who assumes responsibility for obtaining and sharing information?”
- *Disclosure practices regarding children:* “What kind of information may be shared with children in your family, and who is responsible for communicating with the children?”
- *Sharing of information within the family or community group:* “What kind/how much information should be shared with your immediate family? Your extended family? Others in the community (for example, members of a religious community)?”
- *Decision-making style:* “How are decisions made in your family? Who would you like to be involved in decisions about your treatment or care?”
  - Individual
  - Family-centered
  - Family elder or patriarch/matriarch
  - Deference to authority (such as the physician)
- *Symptom management:* “How would you like us to help you to manage the physical effects of your illness?”
  - Acceptability of medications used for symptom relief
  - Beliefs regarding expression of pain and other symptoms
  - Degree of symptom management desired
- *Life-sustaining treatment expectations:* “Have you thought about what type of medical treatment you/your loved one want(s) as the end of life is nearing? Do you have an advanced directive (living will and/or durable power of attorney)?”
  - Nutrition/hydration at the end of life
  - Cardiopulmonary resuscitation
  - Ventilator
  - Dialysis
  - Antibiotics
  - Medications to treat infection
- *Desired location of dying:* “Do you have a preference about being at home or in some other location when you die?”
  - Desired role for family members in providing care: “Who do you want to be involved in caring for you at the end of life?”
  - Gender-specific prohibitions: “Are you uncomfortable having either males or females provide your care or your loved one’s personal care?”
- *Spiritual/religious practices and rituals:* “Is there anything that we should know about your spiritual or religious beliefs about death? Are there any practices that you would like us to observe as death is nearing?”
- *Care of the body after the death:* “Is there anything that we should know about how a body/your body should be treated after death?”
- *Expression of grief:* “What types of losses have you and your family experienced? How do you and your family express grief?”
- *Funeral and burial practices:* “Are there any rituals or practices associated with funerals or burial that are especially important to you?”
- *Mourning practices:* “How have you and your family carried on after a loss in the past? Are their particular behaviors or practices that are expected or required?”

## GOAL SETTING IN PALLIATIVE CARE AT THE END OF LIFE

As the treatment goals begin to shift in the direction of comfort care over aggressive disease-focused treatment, symptom relief and patient/family-defined quality of life assume greater prominence in treatment decision making. Patient, family, and clinicians may all be accustomed to an almost automatic tendency to pursue exhaustive diagnostic testing to locate and treat the source of the patient’s illness or symptoms. Each decision to withdraw treatment or discontinue diagnostic testing will be an extremely emotional one for the patient and family. They may fear that the support from health care providers on which they have come to rely will be withdrawn along with the treatment.

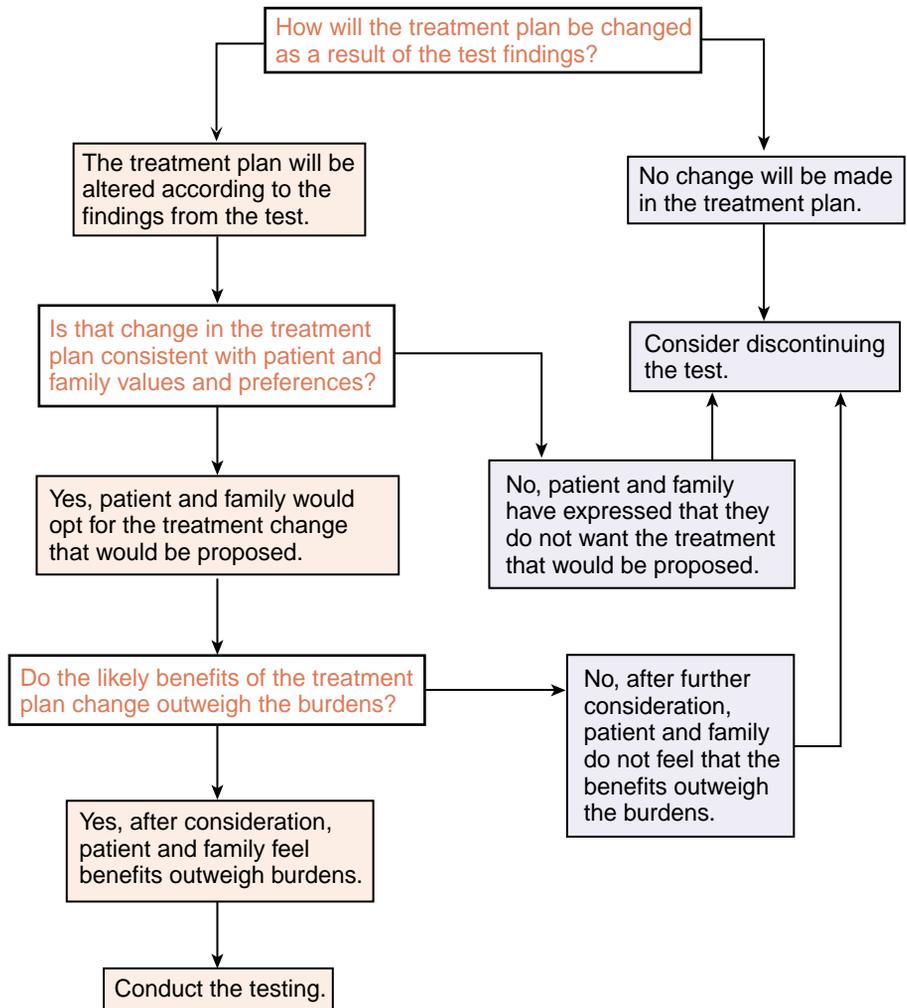

Throughout the course of the illness, and especially as the patient’s functional status and symptoms indicate approaching death, clinicians need to assist the patient and family to weigh the benefits of continued diagnostic testing and disease-focused medical treatment against the burdens of those activities. Patients and their families may be extremely reluctant to forego monitoring that has become routine throughout the illness (such as blood testing, x-rays) but that may contribute little to a primary focus on comfort. Likewise, health care providers from other disciplines may have difficulty discontinuing such diagnostic testing or medical treatment. The nurse should collaborate with other members of the interdisciplinary team to share assessment findings and develop a coordinated plan of care (Fig. 17-1). In addition, the nurse may assist the patient and family to clarify their goals, expected outcomes, and values as they consider treatment options

(Chart 17-5). The nurse needs to work with interdisciplinary colleagues to ensure that the patient and family are referred for continuing psychosocial support, symptom management, and assistance with other care-related challenges (eg, arranging for home care or hospice support, referrals for financial assistance).

## SPIRITUAL CARE

Attention to the spiritual component of the patient’s and family’s illness experience is not new within the context of nursing care, yet many nurses lack the comfort or skills to assess and intervene in this dimension. **Spirituality** contains features of religiosity, but the two concepts are not interchangeable (Highfield, 2000). Spirituality involves the “search for meaning and purpose in life and relatedness to a transcendent dimension” (Hermann, 2001, p. 67). For most people, contemplating their own deaths raises many issues, such as the meaning of existence, the purpose of suffering, and the existence of an afterlife. In a national survey on spiritual beliefs and the dying process conducted by Gallup for the Nathan Cummings Foundation and Fetzer Institute in 1996 and published in 1997, respondents’ greatest worries about death included the following:

- The medical matter of greatest worry was the possibility of being vegetable-like for some period of time (73%).
- The emotional matter of greatest worry was not having the chance to say goodbye to someone (73%) or the possibility of having great physical pain before death (67%).
- The practical matter of greatest worry was how family or loved ones will be cared for (65%) or thinking that death

**FIGURE 17-1** An algorithm for decision making about diagnostic testing at the end of life.

will be a cause of inconvenience and stress for those who love them (64%).

- The spiritual matter of greatest worry was not being forgiven by God (56%) or dying when removed or cut off from God or a higher power (51%).

The spiritual assessment is a key component of comprehensive nursing assessment for terminally ill patients and their families. Although the nursing assessment should include religious affiliation, spiritual assessment is conceptually much broader than religion and thus is relevant regardless of the patient's expression of religious

preference or affiliation. In addition to assessment of the role of religious faith and practices, important religious rituals, and connection to a religious community, the nurse should further explore:

- The harmony or discord between the patient's and family's beliefs
- Other sources of meaning, hope, and comfort
- The presence or absence of a sense of peace of mind and purpose in life
- Spiritually or religiously based beliefs about illness, medical treatment, care of the sick

### Chart 17-5 • ASSESSMENT

#### Nursing Assessment of the Patient and Family Perspective: Goal Setting in Palliative Care

- Patient and family
  - Awareness of diagnosis, illness stage, and prognosis
    - "Tell me your understanding of your illness right now."
  - Values
    - "Tell me what is most important to you as you are thinking about the treatment options available to you/your loved one."
  - Preferences
    - "You've said that being comfortable and pain-free is most important to you right now. Where would you like to receive
- care (home, hospital, long-term care facility, doctor's office), and how can I help?"
- Expected/desired outcomes
  - "What are your hopes and expectations for this (diagnostic test [eg, CT scan] or treatment)?"
- Benefits and burdens
  - "Is there a point at which you would say that the testing or treatment is outweighed by the burdens it is causing you (eg, getting from home to the hospital, pain, nausea, fatigue, interference with other important activities)?"

Maugans (1996) created the useful mnemonic “SPIRIT” to assist health care professionals to include spiritual assessment in their practice:

- Spiritual belief system
- Personal spirituality
- Integration and involvement with others in a spiritual community
- Ritualized practices and restrictions
- Implications for medical care
- Terminal events planning

## HOPE

Kübler-Ross maintained that hope persisted across every stage of terminal illness, noting that “even the most accepting, the most realistic patients left the possibility open for some cure, for the discovery of a new drug, or the ‘last-minute success in a research project’ ” (1969, p. 139). Viktor Frankl (1984), a survivor of the Holocaust, described a human capacity for optimism that can be maintained in spite of the possibility or even certainty of pain and death. In terminal illness, hope represents patients’ imagined future, forming the basis of a positive, accepting attitude and providing their lives with meaning, direction and optimism (Hickey, 1986). When hope is viewed this way, it is not limited to cure of the disease, and instead focuses on what is achievable in the time remaining. Many patients find hope in working on important relationships and creating legacies. The terminally ill patient can be extremely resilient, reconceptualizing hope repeatedly as he or she approaches the end of life.

The concept of hope has been delineated and studied by numerous nurse researchers, and its presence has been related to concepts such as spirituality, quality of life, and transcendence. Morse and Doberneck (1995) defined hope as a multidimensional construct that provides comfort to the individual as he or she endures life threats and personal challenges. These authors identified seven universal components of hope from their study of patients who had survived serious illness:

- Realistic initial assessment of the threat
- Envisioning alternatives and setting goals
- Bracing for negative outcomes
- Realistic assessment of resources
- Solicitation of mutually supportive relationships
- Continuous evaluation for signs reinforcing the goals
- Determination to endure

The nurse can support the patient and family by using effective listening and communication skills and encouraging realistic hope that is specific to the patient’s and family’s needs for information, expectations for the future, and values and preferences concerning the end of life. It is important for the nurse to engage in self-reflection and identify her or his own biases and fears concerning illness, life, and death. As nurses become more skilled in working with seriously ill patients, they can become less determined to “fix” and more willing to listen, more comfortable with silence, grief, anger, and sadness, and more fully present with patients and their families.

Nursing interventions for enabling and supporting hope include:

- Listening attentively
- Encouraging sharing of feelings
- Providing accurate information
- Encouraging and supporting patient control over his or her circumstances, choices, and environment whenever possible

- Assisting the patient to explore ways for finding meaning in his or her life
- Encouraging realistic goals
- Facilitating effective communication within the family
- Making referrals for psychosocial and spiritual counseling
- Assisting with the development of supports in the home or community when none exist

## MANAGING PHYSIOLOGIC RESPONSES TO ILLNESS

Patients approaching the end of life experience many of the same symptoms, regardless of their underlying disease processes. Symptoms in terminal illness may be caused by the disease, either directly (eg, dyspnea due to chronic obstructive lung disease) or indirectly (eg, nausea and vomiting related to pressure in the gastric area), by the treatment for the disease, or by a coexisting disorder that is unrelated to the disease. Chapter 13 presents assessment principles for pain that include identifying the effect of the pain on the patient’s life, the importance of believing the patient’s report of the pain and its effect, and the importance of systematic assessment of pain. Similarly, symptoms such as dyspnea, nausea, weakness, and anxiety should be as carefully and systematically assessed and managed. Questions that guide the assessment of symptoms are listed in Chart 17-6.

The goals of symptom management at the end of life are to completely relieve the symptom when possible, or to decrease the symptom to a level that the patient can tolerate when it cannot be completely relieved. Medical interventions may be aimed at treating the underlying causes of the symptoms. Pharmacologic and nonpharmacologic methods for symptom management may be used in combination with medical interventions to modify the physiologic causes of symptoms. For example, some patients who develop pleural effusion secondary to metastatic cancer may experience temporary relief of the associated dyspnea following thoracentesis, an invasive medical procedure in which fluid is drained from the pleural space. In addition, pharmacologic management with low-dose oral morphine is very effective in relieving dyspnea, and guided relaxation may reduce the anxiety associated with the sensation of breathlessness. As with pain, the principles

of pharmacologic symptom management are the smallest dose of the medication to achieve the desired effect, avoidance of polypharmacy, anticipation and management of medication side effects, and creation of a therapeutic regimen that is acceptable to the patient based on his or her goals for maximizing quality of life.

As with pain management, patients may elect to tolerate higher symptom levels in exchange for greater independence, mobility, alertness, or other priorities. Anticipating and planning interventions for symptoms that have not yet occurred is a cornerstone of end-of-life care. Both patients and family members cope more effectively with new symptoms and exacerbations of existing symptoms when they know what to expect and how to manage it. Hospice programs typically provide “emergency kits” containing ready-to-administer doses of a variety of medications that are useful to treat symptoms in advanced illness. Family members can be instructed to administer a prescribed dose from the emergency kit, often avoiding prolonged suffering for the patient as well as rehospitalization for symptom management.

## Pain

Pain and suffering are among the most feared consequences of cancer (Roth & Breitbart, 1996). Pain is a significant symptom for many cancer patients throughout their treatment and disease course; it results both from the disease and the modalities used to treat it. Numerous studies have indicated that patients with advanced illness, particularly cancer, experience considerable pain (Field & Cassel, 1997; Jacox, Carr, & Payne, 1994). While the means to relieve pain have existed for many years, the continued, pervasive undertreatment of pain has been well documented (American Pain Society, 1999; Jacox et al., 1994). It is estimated that as many as 70% of patients with advanced cancer experience severe pain (Jacox et al., 1994; World Health Organization, 1990). The impact of poorly managed pain on patients’ psychological, emotional, social, and financial well-being has attracted considerable research interest, but practice has been slow to change (Spross, 1992).

Patients who have an established regimen of analgesics should continue to receive those medications as they approach the end of life. Inability to communicate pain should not be equated with the absence of pain. While most pain can be managed effectively using the oral route, as the end of life nears patients may be less able to swallow oral medications due to somnolence or nausea. Patients who have been receiving opioids should continue to receive equianalgesic doses via the rectal or sublingual routes. Concentrated morphine solution can be very effectively delivered by the sublingual route, as the small liquid volume is well tolerated even when the patient cannot swallow. As long as the patient continues to receive opioids, a regimen to combat constipation must be implemented. If the patient cannot swallow laxatives or stool softeners, rectal suppositories or enemas may be necessary.

The nurse should teach the family about continuation of comfort measures as the patient approaches the end of life, how to administer analgesics via alternate routes, and how to assess for pain when the patient cannot verbally report pain intensity. Because the analgesics administered orally or rectally are short-acting, typically scheduled as frequently as every 3 to 4 hours around the clock, there is always a strong possibility that the patient approaching the end of life will die in close proximity to the time of analgesic administration. If the patient is at home, family members administering analgesics need to be prepared for this possibility. They will need reassurance that they did not “cause” the death of the patient by administering a dose of analgesic medication (see Chart 13-3).

## Dyspnea

Dyspnea is an uncomfortable awareness of breathing that is common in patients approaching the end of life (Brant, 1998). Dyspnea is a highly subjective symptom that often is not associated with visible signs of distress, such as tachypnea, diaphoresis, or cyanosis. Patients with primary lung tumors, lung metastases, pleural effusion, and restrictive lung disease may experience significant dyspnea. Although the underlying cause of the dyspnea can be identified and treated in some cases, the burdens of additional diagnostic evaluation and treatment aimed at the physiological problem may outweigh the benefits. The treatment of dyspnea varies depending on the patient’s general physical condition and imminence of death. For example, a blood transfusion may provide temporary symptom relief for the anemic patient earlier in the disease process; however, as the patient approaches the end of life the benefits are typically short-lived or absent.

## NURSING ASSESSMENT AND INTERVENTION

As is true in pain assessment and management, the patient’s report of dyspnea must be believed. Also like the experience of physical pain, the meaning of the dyspnea to the patient may increase his or her suffering. For example, the patient may interpret increasing dyspnea as a sign that death is approaching. For some patients, sensations of breathlessness may invoke frightening images of drowning or suffocation, and the resulting cycle of fear and anxiety may create even greater sensations of breathlessness. Therefore, the nurse should conduct a careful assessment of the psychosocial and spiritual components of the symptom (see Chart 17-5). Physical assessment parameters include:

- Symptom intensity, distress, and interference with activities (scale of 0 to 10)
- Auscultation of lung sounds
- Assessment of fluid balance
- Measurement of dependent edema (circumference of lower extremities)
- Measurement of abdominal girth
- Temperature
- Skin color
- Sputum quantity and character
- Cough

To determine the intensity of the symptom and its interference with daily activities, patients can be asked to self-report using a scale of 0 to 10, where 0 is no dyspnea and 10 is the worst imaginable dyspnea. Measurement of the patient’s baseline before treatment and subsequent measures during exacerbation of the symptom, periodically during treatment, and whenever the treatment plan changes will provide ongoing objective evidence for the efficacy of the treatment plan. In addition, physical assessment findings may assist in locating the source of the dyspnea and selecting nursing interventions to relieve the symptom. The components of the assessment will change as the patient’s condition changes. For example, when the patient who has been on daily weights can no longer get out of bed, the goal of comfort may outweigh the benefit of continued weights. Like other symptoms at the end of life, dyspnea can be managed effectively in the absence of assessment and diagnostic data (ie, arterial blood gases) that are standard when the patient’s illness or symptom is reversible.

Nursing management of dyspnea at the end of life is directed toward administering medical treatment for the underlying pathology, monitoring the patient’s response to treatment, assisting the patient and family to manage anxiety (which exacerbates dyspnea),

altering the perception of the symptom, and conserving energy (Chart 17-7). Pharmacologic intervention is aimed at modifying lung physiology and improving performance as well as altering the perception of the symptom. Bronchodilators and corticosteroids are examples of medications used to treat underlying obstructive pathology, thereby improving overall lung function. Low doses of opioids are very effective in relieving dyspnea, although the mechanism of relief is not entirely clear. Although dyspnea in terminal illness is typically not associated with diminished blood oxygen saturation, low-flow oxygen often provides psychological comfort to the patient and the family, particularly in the home setting.

As discussed above, dyspnea may be exacerbated by anxiety, and anxiety may trigger episodes of dyspnea, setting off a respiratory crisis in which patient and family may panic. For patients receiving care at home, patient and family instruction should include anticipation and management of crisis situations and a clearly communicated emergency plan. Patients and families should be instructed about medication administration, condition changes that should be reported to the physician and nurse, and strategies for coping with diminished reserves and increasing symptomatology as the disease progresses. The patient and family need reassurance that the symptom can be effectively managed at home without the need for activation of the emergency medical services or hospitalization and that a nurse will be available at all times via telephone or to conduct a visit.

## Nutrition and Hydration at the End of Life

### ANOREXIA

Anorexia and cachexia are common problems in the seriously ill. The profound changes in the patient's appearance and his or her

concomitant lack of interest in the socially important rituals of mealtime are particularly disturbing to families. The approach to the problem varies depending on the patient's stage of illness, level of disability associated with the illness, and desires. The anorexia-cachexia syndrome is characterized by disturbances in carbohydrate, protein, and fat metabolism, endocrine dysfunction, and anemia. The syndrome results in severe asthenia (loss of energy). Although causes of anorexia may be controlled for a period of time, progressive anorexia is an expected and natural part of the dying process. Anorexia may be related to or exacerbated by situational variables (eg, the ability to have meals with the family versus eating alone in the "sick room"), progression of the disease, treatment for the disease, or psychological distress. The patient and family should be instructed in strategies to manage the variables associated with anorexia. Table 17-2 summarizes nursing measures and patient and family teaching for managing anorexia.

### USE OF PHARMACOLOGIC AGENTS TO STIMULATE APPETITE IN THE TERMINALLY ILL

A number of pharmacologic agents are commonly used to stimulate appetite in anorectic patients. Commonly used medications for appetite stimulation include dexamethasone (Decadron), cyproheptadine (Periactin), megestrol acetate (Megace), and dronabinol (Marinol). Dexamethasone initially increases appetite and may provide short-term weight gain in some patients. However, therapy may need to be discontinued in the patient with a longer life expectancy, as after 3 to 4 weeks corticosteroids interfere with the synthesis of muscle protein. Cyproheptadine may be used when corticosteroids are contraindicated, such as when the patient is diabetic. It promotes mild appetite increase but no appreciable weight gain. Megestrol acetate produces temporary weight gain of primarily fatty tissue, with little effect on protein balance. Because of the time required to see any effect from this agent, therapy should not be initiated if life expectancy is less than 30 days. Finally, dronabinol is a psychoactive compound found in cannabis that may be helpful in reducing nausea and vomiting, appetite loss, pain, and anxiety, thereby improving intake in some patients. However, dronabinol is not as effective as the other agents for appetite stimulation in most patients. Although the use of these agents may cause temporary weight gain, their use is not associated with an increase in lean body mass in the terminally ill. Therapy should be tapered or discontinued after 4 to 8 weeks if there is no response (Wrede-Seaman, 1999).

### CACHEXIA

Cachexia refers to severe muscle wasting and weight loss associated with illness. Although anorexia may exacerbate cachexia, it is not the primary cause. Cachexia is associated with changes in metabolism that include hypertriglyceridemia, lipolysis, and accelerated protein turnover, leading to depletion of fat and protein stores (Plata-Salaman, 1997). However, the pathophysiology of cachexia in terminal illness is not well understood. In terminal illness, the severity of tissue wasting is greater than would be expected from reduced food intake alone, and typically increasing appetite or food intake does not reverse cachexia in the terminally ill.

Anorexia and cachexia differ from starvation (simple food deprivation) in several important ways. Appetite is lost early in the process, the body becomes catabolic in a dysfunctional way, and supplementation by gastric feeding (tube feeding) or parenteral nutrition in advanced disease does not replenish lost lean body mass. At one time it was believed that cancer patients with rapidly growing tumors developed cachexia because the

Chart  
17-7

### Palliative Nursing Interventions for Dyspnea

#### Decrease Anxiety

- Administer prescribed anxiolytic medications as indicated for anxiety or panic associated with dyspnea.
- Assist with relaxation techniques, guided imagery.
- Provide patient with a means to call for assistance (call bell/light within reach in a hospital or long-term care facility; hand-held bell or other device for home).

#### Treat Underlying Pathology

- Administer prescribed bronchodilators and corticosteroids (obstructive pathology).
- Administer blood products, erythropoietin as prescribed (typically not beneficial in advanced disease).
- Administer prescribed diuretics and monitor fluid balance.

#### Alter Perception of Breathlessness

- Administer prescribed oxygen therapy via nasal cannula, if tolerated; masks may not be well tolerated.
- Administer prescribed low-dose opioids via oral route (morphine sulfate is used most commonly).
- Provide air movement in the patient's environment with a portable fan.

#### Reduce Respiratory Demand

- Teach patient and family to implement energy conservation measures.
- Place needed equipment, supplies, and nourishment within reach.
- For home or hospice care, offer bedside commode, electric bed (with head that elevates).

**Table 17-2 • Measures for Managing Anorexia**

NURSING INTERVENTIONS	PATIENT AND FAMILY TEACHING TIPS
<p>Initiate measures to ensure adequate dietary intake without adding stress to the patient at mealtimes.</p> <p>Assess the impact of medications (eg, chemotherapy, antiretrovirals) or other therapies (radiation therapy, dialysis) that are being used to treat the underlying illness.</p> <p>Administer and monitor effects of prescribed treatment for nausea, vomiting, and delayed gastric emptying.</p> <p>Encourage patient to eat when effects of medications have subsided.</p>	<p>Reduce the focus on “balanced” meals; offer the same food as often as the patient desires it.</p> <p>Increase the nutritional value of meals. For example, add dry milk powder to milk, and use this fortified milk to prepare cream soups, milkshakes, and gravies.</p>
<p>Assess and modify environment to eliminate unpleasant odors and other factors that cause nausea, vomiting, and anorexia.</p> <p>Remove items that may reduce appetite (soiled tissues, bedpans, emesis basins, clutter).</p> <p>Assess and manage anxiety and depression to the extent possible.</p>	<p>Allow and encourage the patient to eat when hungry, regardless of usual meal times.</p> <p>Eliminate or reduce noxious cooking odors, pet odors, or other odors that may precipitate nausea, vomiting, or anorexia.</p> <p>Keep patient’s environment clean, uncluttered, and comfortable.</p>
<p>Position to enhance gastric emptying.</p>	<p>Make mealtime a shared experience away from the “sick” room whenever possible.</p> <p>Reduce stress at mealtimes.</p> <p>Avoid confrontations about the amount of food consumed.</p> <p>Reduce or eliminate routine weighing of the patient.</p> <p>Encourage patient to eat in a sitting position; elevate the head of the patient’s bed.</p> <p>Plan meals (food selection and portion size) that the patient desires.</p> <p>Provide small frequent meals if they are easier for patient to eat.</p>
<p>Assess for constipation and/or intestinal obstruction.</p>	<p>Ensure that patient and family understand that prevention of constipation is essential, even when the patient’s intake is minimal.</p> <p>Encourage adequate fluid intake, dietary fiber, and use of bowel program to prevent constipation.</p>
<p>Prevent and manage constipation on an ongoing basis, even when the patient’s intake is minimal.</p> <p>Provide frequent mouth care, particularly following nourishment.</p>	<p>Assist the patient to rinse after every meal. Avoid mouthwashes that contain alcohol or glycerine, which dry mucous membranes.</p> <p>Weight loss may cause dentures to loosen and cause irritation.</p> <p>Remove them to inspect the gums and to provide oral care.</p>
<p>Ensure that dentures fit properly.</p>	<p>Patient’s comfort may be enhanced if pain medications given on an as-needed basis for breakthrough pain are administered before mealtimes.</p>
<p>Administer and monitor effects of topical and systemic treatment for oropharyngeal pain.</p>	

tumor created an excessive nutritional demand and diverted nutrients from the rest of the body. Recent research links cytokines produced by the body in response to a tumor to a complex inflammatory-immune response present in patients whose tumors have metastasized, leading to anorexia, weight loss, and altered metabolism. An increase in cytokines occurs not only in cancer but also in AIDS and many other chronic diseases (Plata-Salaman, 1997).

### ARTIFICIAL NUTRITION AND HYDRATION IN TERMINAL ILLNESS

Along with breathing, eating and drinking are essential to survival throughout one’s lifetime. As patients near the end of life, their bodies’ nutritional needs change, their desire for food and fluid may diminish, and they may no longer be able to use, eliminate, or store nutrients and fluids adequately. Eating, feeding, and sharing meals are important social activities in families and communities, and food preparation and enjoyment are linked to happy memories, strong emotions, and hopes for survival. For the patient with serious illness, food preparation and mealtimes often become battlegrounds where well-meaning family members argue, plead, and cajole to encourage the ill person to eat. It is not unusual for seriously ill patients to lose their appetites entirely, to develop

strong aversions for foods they have enjoyed in the past, or to crave a particular food to the exclusion of all other foods.

Although nutritional supplementation may be an important part of the treatment plan in early or chronic illness, unintended weight loss and dehydration are expected sequelae of progressive illness. As illness progresses, patients, families, and clinicians may believe that without artificial nutrition and hydration, the terminally ill patient will “starve,” causing profound suffering and hastened death. However, starvation should not be viewed as the failure to implant tubes for nutritional supplementation or hydration of terminally ill patients with irreversible progression of disease. Studies have demonstrated that terminally ill patients who were hydrated had neither improved biochemical parameters nor improved states of consciousness (Waller, Hershkowitz & Adunsky, 1994). Similarly, survival was not increased when terminally ill patients with advanced dementia received enteral feeding (Meier, Ahronheim, Morris et al., 2001). Further, in patients who are close to death there are beneficial effects to withholding or withdrawing artificial nutrition and hydration, such as decreased urine output and incontinence, decreased gastric fluids and emesis, decreased pulmonary secretions and respiratory distress, and decreased edema and pressure discomfort (Zerwekh, 1987).

As the patient approaches the end of life, families and health care providers should offer the patient what he or she desires and can most easily tolerate. Nurses should instruct the family how to separate feeding from caring by demonstrating love, sharing, and caring by being with the loved one in other ways. Preoccupation with appetite, feeding, and weight loss diverts energy and time that the patient and family could use in other meaningful activities. The following are tips to promote nutrition for the terminally ill patient:

- Offer small portions of favorite foods.
- Do not be overly concerned about a “balanced” diet.
- Cool foods may be better tolerated than hot foods.
- Offer cheese, eggs, peanut butter, mild fish, chicken, or turkey. Meat (especially beef) may taste bitter and unpleasant.
- Add milkshakes, “Instant Breakfast” drinks, or other liquid supplements.
- Add dry milk powder to milkshakes and cream soups to increase protein and calorie content.
- Place nutritious foods at the bedside (fruit juices, milkshakes in insulated drink containers with straws).
- Schedule meals when family members can be present to provide company and stimulation.
- Avoid arguments at mealtime.
- Assist the patient to maintain a schedule of oral care. Rinse the mouth after each meal or snack. Avoid mouthwashes that contain alcohol. Use a soft toothbrush. Treat ulcers or lesions. Make sure dentures fit well.
- Treat pain and other symptoms.
- Offer ice chips made from frozen fruit juices.
- Allow the patient to refuse foods and fluids.

## Delirium

Many patients may remain alert, arousable, and able to communicate until very close to death. Others may sleep for long intervals and awaken only intermittently, with eventual somnolence until death. Delirium refers to concurrent disturbances in level of consciousness, psychomotor behavior, memory, thinking, attention, and sleep-wake cycle (Brant, 1998). In some patients, a period of agitated delirium may precede death, sometimes causing families to be hopeful that the suddenly active patient may be getting better. Confusion may be related to underlying, treatable conditions such as medication side effects or interactions, pain or discomfort, hypoxia or dyspnea, a full bladder or impacted stool. In patients with cancer, confusion may be secondary to brain metastases. Delirium may also be related to metabolic changes, infection, and organ failure.

The patient with delirium may become hypoactive or hyperactive, restless, irritable, and fearful. Sleep deprivation and hallucinations may occur. If treatment of the underlying factors contributing to these symptoms bring no relief, a combination of pharmacologic intervention with neuroleptics or benzodiazepines may be effective in decreasing distressing symptoms. Haloperidol (Haldol) may reduce hallucinations and agitation. Benzodiazepines (eg, lorazepam [Ativan]) can reduce anxiety but will not clear the sensorium and may contribute to worsening cognitive impairment if used alone.

Nursing interventions are aimed at identifying the underlying causes of delirium, acknowledging the family’s distress over its occurrence, reassuring them about what is normal, teaching the family how to interact with and ensure safety for the patient with delirium, and monitoring the effects of medications used to treat severe agitation, paranoia, or fear. Confusion may mask the pa-

tient’s unmet spiritual needs and fears about dying. Spiritual intervention, music therapy, gentle massage, and therapeutic touch may provide some relief. Reducing environmental stimuli, avoiding harsh lighting or very dim lighting (which may produce disturbing shadows), the presence of familiar faces, and gentle reorientation and reassurance are also helpful.

## Depression

Clinical depression should not be accepted as an inevitable consequence of dying, nor should it be confused with sadness and anticipatory grieving, which are normal reactions to the losses associated with impending death. Emotional and spiritual support and control of disturbing physical symptoms are appropriate interventions for situational depression associated with terminal illness. The psychological sequelae of cancer pain have been linked to suicidal thought and less frequently to carrying out a planned suicide (Ripamonti, Filiberti, Totis et al., 1999). Cancer patients with advanced disease are especially vulnerable to delirium, depression, suicidal ideation, and severe anxiety (Roth & Breitbart, 1996). Higher levels of debilitation predict higher levels of pain and depressive symptoms, and the presence of pain doubles the likelihood of developing major psychiatric complications of illness (Roth & Breitbart, 1996). Patients and their families must be given space and time to experience sadness and to grieve, but patients should not have to endure untreated depression at the end of their lives. An effective combined approach to clinical depression includes relief of physical symptoms, attention to emotional and spiritual distress, and pharmacologic intervention with psychostimulants, selective serotonin reuptake inhibitors (SSRIs), and tricyclic antidepressants (Block, 2000).

## PALLIATIVE SEDATION AT THE END OF LIFE

Effective control of symptoms can be achieved under most conditions, but some patients may experience distressing, intractable symptoms. Although its use remains controversial, **palliative sedation** is offered in some settings to patients who are close to death, who have symptoms that do not respond to conventional pharmacologic and nonpharmacologic approaches, and as a result are experiencing unrelieved suffering. Palliative sedation is distinguished from **euthanasia** or physician-assisted suicide in that the intent of palliative sedation is to palliate the symptoms, not to hasten the patient’s death. Palliative sedation is most commonly used when the patient exhibits intractable pain, dyspnea, seizures, or delirium. It is generally considered appropriate in only the most difficult cases. Before implementing palliative sedation, the care team should assess for the presence of underlying and treatable causes of suffering, such as depression or spiritual pain. Finally, patients and families should be fully informed about the use of this treatment and alternatives.

Palliative sedation is accomplished through infusion of a benzodiazepine or barbiturate in doses adequate to induce sleep and eliminate signs of discomfort (Quill & Byock, 2000). The nurse acts as a collaborating member of the interdisciplinary team, providing emotional support to the patient and family, facilitating clarification of values and preferences, and providing comfort-focused physical care. Once sedation has been induced, the nurse will need to continue comfort care, monitor the physiologic effects of the sedation, support the family during the final hours or days of the patient’s life, and ensure communication within the care team and between the team and family.

## Nursing Care of the Patient Who Is Close to Death

Providing care to the patient who is close to death and being present at the time of death can be one of the most rewarding experiences a nurse can have. Patients and their families are understandably fearful of the unknown, and the approach of death may prompt new concerns or cause previous fears or issues to resurface. It has often been said that as we age and as we approach death, we do not become different people, just more like ourselves. Families that have always had difficulty communicating or in which there are old resentments and hurts may experience heightened difficulty as their loved one nears death. In contrast, the time at the end of life can also afford the family the opportunity to resolve old hurts and learn new ways of being a family. Regardless of the setting, dying patients can be made comfortable, space can be made for their loved ones to remain present when they wish, and the opportunity to experience growth and healing can be facilitated by skilled practitioners. Likewise, regardless of setting, patients' and families' apprehension surrounding the time of death may be diminished if they know what to expect as death nears and how to respond.

### EXPECTED PHYSIOLOGIC CHANGES WHEN THE PATIENT IS CLOSE TO DEATH

Observable, expected changes in the body take place as the patient approaches death and organ systems begin to fail. Nursing care measures aimed at patient comfort should be continued: pain medications (administered rectally or sublingually), turning, mouth care, eye care, positioning to facilitate draining of secretions, and measures to protect the skin from incontinence should be continued. The nurse should consult with the physician about discontinuing measures that no longer contribute to patient comfort such as drawing blood, administering tube feedings, suctioning (in most cases), and invasive monitoring. The nurse should prepare the family for the normal, expected changes that accompany the period immediately preceding death. Although the exact time of death cannot be predicted, it is often possible to identify when a patient is very close to death. Hospice programs frequently provide written information for families so they know what to expect and what to do as death nears (Chart 17-8).

If they have been prepared for the time of death, families are less likely to panic and will be better able to be with their loved one in a meaningful way. Noisy, gurgling breathing or moaning is generally most distressing to the family. In most cases, the sounds of breathing at the end of life are related to oropharyngeal relaxation and diminished awareness. Family members may have difficulty believing that the patient is not in pain or that his or her breathing could not be improved by suctioning secretions. Patient positioning and family reassurance are the most helpful responses to these symptoms.

#### Terminal “Bubbling”

When death is imminent, the patient may become increasingly somnolent and unable to clear sputum or oral secretions, which may lead to further impairment of breathing from pooled and/or dried and crusted secretions. The sound and appearance of the secretions are often more distressing to the family than is the presence of the secretions to the patient. Family distress over the changes in patient condition may be eased by supportive nursing

care. Continuation of comfort-focused interventions and reassurance that the patient is not in any distress can do much to ease family concerns. Gentle mouth care with a moistened swab or very soft toothbrush will help to maintain the integrity of the patient's mucous membranes. In addition, gentle oral suctioning, positioning to enhance drainage of secretions, and sublingual or transdermal administration of anticholinergic drugs (Table 17-3) to reduce the production of secretions will provide comfort to the patient and support to the family. Deeper suctioning may cause significant discomfort to the dying patient and is rarely of any benefit, as secretions will reaccumulate rapidly.

### THE DEATH VIGIL

Although every death is unique, it is often possible for the experienced clinician to assess that the patient is “actively” or imminently dying and to prepare the family in the final days or hours leading to death. As death nears, the patient may withdraw, sleep for longer intervals, or become somnolent. The family should be encouraged to be with the patient, to speak and reassure him or her of their presence, to stroke or touch him or her, or to lie alongside him or her (even in the hospital or long-term care facility) if they are comfortable with this degree of closeness and can do so without causing discomfort to the patient.

Family members may have gone to great lengths to ensure that their loved one will not die alone. However, despite the best intentions and efforts of families and clinicians, the patient's death may occur at a time when no one is present. In any setting, it is unrealistic for family members to be at the patient's bedside 24 hours a day, and it is not unusual for patients to die when the family has stepped away from the bedside just briefly. Experienced hospice clinicians have observed and reported that some patients appear to “wait” until family members are away from the bedside to die, perhaps to spare their loved ones the pain of being present at the time of death. The nurse can reassure family members throughout the death vigil by being present intermittently or continuously, modeling behaviors (such as touching and speaking to the patient), providing encouragement in relation to family caregiving, providing reassurance about normal physiologic changes, and encouraging family rest breaks. When the patient dies while the family is away from the bedside, the family may express feelings of guilt and profound grief and will need emotional support.

### AFTER-DEATH CARE

The time of death is generally preceded by a period of gradual diminishment of bodily functions in which increasing intervals between respirations, a weakened and irregular pulse, diminishing blood pressure, and skin color changes or mottling may be observed. For the patient who has received adequate management of symptoms and for the family who has received adequate preparation and support, the actual time of death is commonly peaceful and occurs without struggle. The nurse may or may not be present at the time of the patient's death. In many states, the certifying physician may authorize the nurse to make the pronouncement of death and sign the death certificate. The determination of death is made through a physical examination that includes auscultation for the absence of breathing and heart sounds. Home care or hospice programs in which the nurse makes the time-of-death visit and pronouncement of death will have policies and procedures to guide the nurse's actions during this visit. Immediately upon cessation of vital functions the body will begin

Chart  
17-8

## Signs of Approaching Death

**The person will show less interest in eating and drinking.** For many patients, refusal of food is an indication that they are ready to die. Fluid intake may be limited to that which will keep their mouths from feeling too dry.

- What you can do: Offer, but do not force, fluids and medication. Sometimes, pain or other symptoms that have required medication in the past may no longer be present. For most patients, pain medications will still be needed, and can be provided by concentrated oral solutions placed under the tongue or by rectal suppository.

**Urinary output may decrease in amount and frequency.**

- What you can do: No response is needed unless the patient expresses a desire to urinate and cannot. Call the hospice nurse for advice if you are not sure.

**As the body weakens, the patient will sleep more and begin to detach from the environment.** He or she may refuse your attempts to provide comfort.

- What you can do: Allow your loved one to sleep. You may wish to sit with him or her, play soft music, or hold hands. Your loved one's withdrawal is normal and is not a rejection of your love.

**Mental confusion may become apparent,** as less oxygen is available to supply the brain. The patient may report strange dreams or visions.

- What you can do: As he or she awakens from sleep, remind him or her of the day and time, where he or she is, and who is present. This is best done in a casual, conversational way.

**Vision and hearing may become somewhat impaired and speech may be difficult to understand.**

- What you can do: Speak clearly but no more loudly than necessary. Keep the room as light as the patient wishes, even at night. Carry on all conversations as if they can be heard, since hearing may be the last of the senses to cease functioning. Many patients are able to talk until minutes before death and are reassured by the exchange of a few words with a loved one.

**Secretions may collect in the back of the throat and rattle or gurgle as the patient breathes through the mouth.** He or she may try to cough, and his or her mouth may become dry and encrusted with secretions.

- What you can do: if the patient is trying to cough up secretions and is experiencing choking or vomiting, call the hospice nurse for assistance. Secretions may drain from the mouth if you place the patient on his/her side and provide support with pillows.

Cleansing the mouth with moistened mouth swabs will help to relieve the dryness that occurs with mouth breathing.

Offer water in small amounts to keep the mouth moist. A straw with one finger placed over the end can be used to transfer sips of water to the patient's mouth.

**Breathing may become irregular with periods of no breathing (apnea).**

The patient may be working very hard to breathe and may make a moaning sound with each breath. As the time of death nears, the breathing remains irregular and may become more shallow and mechanical.

- What you can do: Raising the head of the bed may help the patient to breathe more easily. The moaning sound does not mean that the patient is in pain or other distress; it is the sound of air passing over very relaxed vocal cords.

**As the oxygen supply to the brain decreases, the patient may become restless.** It is not unusual to pull at the bed linens, to have visual hallucinations, or even to try to get out of bed at this point.

- What you can do: Reassure the patient in a calm voice that you are there. Prevent him/her from falling by trying to get out of bed. Soft music or a back rub may be soothing.

**The patient may feel hot one moment and cold the next as the body loses its ability to control the temperature.**

As circulation slows, the arms and legs may become cool and bluish. The underside of the body may darken. It may be difficult to feel a pulse at the wrist.

- What you can do: Provide and remove blankets as needed. Avoid using electric blankets, which may cause burns because the patient cannot tell you if he or she is too warm. Sponge the patient's head with a cool cloth if this provides comfort.

**Loss of bladder and bowel control may occur around the time of death.**

- What you can do: Protect the mattress with waterproof padding and change the padding as needed to keep the patient comfortable.

**As people approach death, many times they report seeing gardens, libraries, or family or friends who have died.** They may ask you to pack their bags and find tickets or a passport. Sometimes they may become insistent and attempt to do these chores themselves. They may try getting out of bed (even if they have been confined to bed for a long time) so that they can "leave."

- What you can do: Reassure the patient that it is all right; he or she can "go" without getting out of bed. Stay close, share stories, and be present.

Used with permission from the Family Home Hospice of the Visiting Nurse Association of Greater Philadelphia.

to change. The body will become dusky or bluish, waxen-appearing, and cool, blood will darken and pool in dependent areas of the body (such as the back and sacrum if the body is in a supine position), and urine and stool may be evacuated.

Immediately following the death, the family should be allowed and encouraged to spend time with the deceased. Nor-

mal responses of family members at the time of death vary widely and range from quiet expressions of grief to overt expressions that include wailing and prostration. Families' desires for privacy during their time with the deceased should be honored. Family members may wish to independently manage or assist with care of the body after death. If the death occurs in a

long-term care facility, the nurse follows the facility's procedure for preparation of the body and transportation to the facility's morgue. However, the family's needs to remain with the deceased, to wait until other family members arrive before the body is moved, and to perform after-death rituals should be honored. When an expected death occurs in the home setting, the body is often transported directly to the funeral home by the funeral director.

## GRIEF, MOURNING, AND BEREAVEMENT

A wide range of feelings and behaviors are normal, adaptive, and healthy reactions to the loss of a loved one. **Grief** refers to the personal feelings that accompany an anticipated or actual loss. **Mourning** reflects the individual, family, group, and cultural expressions of grief and associated behaviors. **Bereavement** refers to the period of time during which mourning takes place. Both grief reactions and mourning behaviors change over time as the individual learns to live with the loss. Although the pain of the loss may be tempered by the passage of time, recent conceptualizations of loss as an ongoing developmental process maintain that time does not heal the bereaved individual completely (Silverman, 2001); that is, the bereaved do not get over a loss entirely, nor do they return to who they were before the loss. Rather, they develop a new sense of who they are and where they fit in a world that has changed dramatically and permanently.

## Anticipatory Grief and Mourning

Denial, sadness, anger, fear, and anxiety are normal grief reactions in the individual with life-threatening illness and those close to him or her. Kübler-Ross (1969) described five common emotional reactions to dying that are applicable to the experience of any loss (Table 17-4). Although useful in understanding the overall experience of the dying process, the stages that Kübler-Ross described have been misinterpreted as following a linear, expected trajectory. Not every patient or family member experiences every stage, many patients never reach a stage of acceptance, and patients and families fluctuate on a sometimes day-to-day basis in their emotional responses. Further, while impending loss stresses the patient, those who are close to him or her, and the functioning of the family unit, awareness of dying also provides a unique opportunity for family members to reminisce, resolve relationships, plan for the future, and say goodbye.

Individual and family coping with the anticipation of death is complicated by the varied and conflicting trajectories that grief and mourning may assume in the family. For example, while the patient may be experiencing sadness while contemplating role changes that have been brought about by the illness, the patient's spouse or partner may be expressing or holding in feelings of anger about the current changes in role and impending loss of the relationship; others in the family may be engaged in denial (eg, "Dad will get better; he just needs to eat more."), fear ("Who will take care of us?" or "Will I get sick too?"), or profound sadness

**Table 17-4 • Kübler-Ross's Five Stages of Dying**

STAGE	NURSING IMPLICATIONS
<p><b>Denial:</b> "This cannot be true." Feelings of isolation. May search for another health care professional who will give a more favorable opinion. May seek unproven therapies.</p>	<p>Denial can be an adaptive response, providing a buffer after bad news. It allows time to mobilize defenses, but can be maladaptive when it prevents the patient or family from seeking help and when denial behaviors cause more pain or distress than the illness or interfere with everyday functions. Nurses should assess the patient's and family's coping style, information needs, and understanding of the illness and treatment to establish a basis for empathetic listening, education, and emotional support. Rather than confronting the patient with information he or she is not ready to hear, the nurse can encourage him or her to share fears and concerns. Open-ended questions or statements such as "Tell me more about how you are coping with this new information about your illness" can provide a springboard for expression of concerns.</p>
<p><b>Anger:</b> "Why me?" Feelings of rage, resentment or envy directed at God, health care professionals, family, others.</p>	<p>Anger can be very isolating, and loved ones or clinicians may withdraw. Nurses should allow the patient and family to express anger, treating them with understanding, respect, and knowledge that the root of the anger is grief over impending loss.</p>
<p><b>Bargaining:</b> "I just want to see my grandchild's birth, then I'll be ready. . . ." Patient and/or family plead for more time to reach an important goal. Promises are sometimes made with God.</p>	<p>Terminally ill patients are sometimes able to outlive prognoses and achieve some future goal. Nurses should be patient, allow expression of feelings, and support realistic and positive hope.</p>
<p><b>Depression:</b> "I just don't know how my kids are going to get along after I'm gone." Sadness, grief, mourning for impending losses.</p>	<p>Normal and adaptive response. Clinical depression should be assessed and treated when present. Nurses should encourage the patient and family to express their sadness fully. Insincere reassurance or encouragement of unrealistic hopes should be avoided.</p>
<p><b>Acceptance:</b> "I've lived a good life, and I have no regrets." Patient and/or family are neither angry nor depressed.</p>	<p>The patient may withdraw as his or her circle of interest diminishes. The family may feel rejected by the patient. Nurses need to support the family's expression of emotions and encourage them to continue to be present for the patient.</p>

and withdrawal. Although each of these behaviors is normal, tension may arise when one or more family members perceive that others are less caring, too emotional, or too detached.

The nurse needs to assess the characteristics of the family system and intervene in a manner that supports and enhances the cohesion of the family unit. Parameters for assessing the family facing life-threatening illness are identified in Chart 17-9. The nurse can patiently guide family members to talk about their feelings and understand them in the broader context of anticipatory grief and mourning. Acknowledging and expressing feelings, continuing to interact with the patient in meaningful ways, and planning for the time of death and bereavement are adaptive family behaviors. Professional support provided by grief counselors in the community, at a local hospital, in the long-term care facility, or associated with a hospice program can help both the patient and family to sort out and acknowledge feelings and make the end of life as meaningful as possible.

## Grief and Mourning After Death

When a loved one dies, the family members enter a new phase of grief and mourning as they begin to accept the loss, feel the pain of permanent separation, and prepare to live a life without the deceased. Even if the loved one died after a long illness, preparatory grief experienced during the terminal illness will not preclude the

grief and mourning that follow the death. Following the patient's death after a long or difficult illness, family members may experience conflicting feelings of relief that the loved one's suffering has ended, compounded by guilt and grief related to unresolved issues or the circumstances of death. Grief work may be especially difficult if the patient's death was painful, prolonged, accompanied by unwanted interventions, or unattended. Families who had no preparation or support during the period of imminence and death may have a more difficult time finding a place for the painful memories.

Although some family members may experience prolonged or complicated mourning, most grief reactions fall within a "normal" range. The feelings are often profound, but the bereaved individual eventually reconciles the loss and finds a way to re-engage with his or her life. Grief and mourning are affected by individual characteristics, coping skills, and experiences with illness and death; the nature of the relationship to the deceased; factors surrounding the illness and the death; family dynamics; social support; and cultural expectations and norms. After-death rituals, including preparation of the body, funeral practices, and burial rituals, are socially and culturally significant ways that members of a family begin to accept the reality and finality of death. Preplanning of funerals is becoming increasingly common, and hospice professionals in particular assist families to make plans for death, often involving the patient who may wish to take an active planning role. Preplanning the funeral relieves the family of the decision burden in the intensely emotional period following a death. Uncomplicated grief and mourning are characterized by emotional feelings of sadness, anger, guilt, and numbness; physical sensations such as hollowness in the stomach and tightness in the chest, weakness, and lack of energy; cognitions that include preoccupation with the loss and a sense of the deceased as still present; and behaviors such as crying, visiting places that are reminders of the deceased, social withdrawal, and restless overactivity (Worden, 1991).

In general, the period of mourning is an adaptive response to loss during which the mourner comes to accept the loss as real and permanent, acknowledges and experiences the painful emotions that accompany the loss, experiences life without the deceased, overcomes impediments to adjustment, and finds a new way of living in a world without the loved one. Particularly immediately following the death, the mourner begins to recognize the reality and permanence of the loss by talking about the deceased and telling and retelling the story of the illness and death. Societal norms in the United States are frequently at odds with the normal grieving processes of individuals, where time excused from work obligations is typically measured in days and mourners are often expected to get over the loss quickly and get on with life.

In reality, the work of grief and mourning takes time, and avoiding grief work following the death often leads to long-term adjustment difficulties. According to Rando (2000), mourning for a loss involves the "undoing" of psychosocial ties that bind the mourner to the deceased, personal adaptation to the loss, and learning to live in the world without the deceased. Six key processes of mourning allow the individual to accommodate to the loss in a healthy way: recognition of the loss; reaction to the separation, experiencing and expressing the pain of the loss; recollection and re-experiencing the deceased, the relationship, and the associated feelings; relinquishing old attachments to the deceased; readjustment to adapt to the new world without forgetting the old; and reinvestment (Rando, 2000). Similarly, Worden (1991) described four tasks of mourning: acceptance of the reality of the loss, working through the pain of grief, adjusting to the environment in which the deceased is gone, and emotional "relocation" of the deceased in order to move on with life.

Chart  
17-9

### Assessing Anticipatory Mourning in the Family Facing Life-Threatening Illness

- Family constellation
  - Identify the members who constitute the patient's family.
    - Who is important to the patient?
  - Identify roles and relationships among the family members.
    - Who is the primary caregiver?
    - By what authority is this person the primary caregiver?
- Cohesion and boundaries
  - How autonomous/interdependent are family members?
    - Degree of involvement with each other as individuals and as a family
    - Degree of bonding between family members
    - Degree of "teamwork" in the family
    - Degree of reliance on individual family members for specific tasks/roles
  - How do family members differ in:
    - Personality?
    - World view?
    - Priorities?
  - What are the implicit and explicit expectations or "rules" for behavior within the family?
- Flexibility and adaptability
  - What is the family's ability to integrate new information?
  - How does the family manage change?
  - How able are the family members to assume new roles and responsibilities?
- Communication
  - What is the style of communication in the family, in terms of:
    - Openness?
    - Directness?
    - Clarity?
  - What are the constraints on communication?
  - What topics are avoided?

Although many individuals complete the work of mourning with the informal support of family and friends, many find that talking with others who have had a similar experience, such as in formal support groups, normalizes the feelings and experiences and provides a framework for learning new skills to cope with the loss and create a new life. Bereavement support groups are often sponsored by hospitals, hospices, and other community organizations. Groups for parents who have lost a child, children who have lost a parent, widows, widowers, and gay men and lesbians who have lost a life partner are some examples of specialized support groups available in many communities. Nursing interventions for those experiencing grief and mourning are identified in Chart 17-10.

## Complicated Grief and Mourning

Complicated grief and mourning are characterized by prolonged feelings of sadness and feelings of general worthlessness or hopelessness that persist long after the death, prolonged symptoms that interfere with activities of daily living (anorexia, insomnia, fatigue, panic), or self-destructive behaviors such as alcohol or substance abuse and suicidal ideation or attempts. Complicated grief and mourning require professional assessment and can be treated with pharmacologic and psychological interventions.

## Coping With Death and Dying: Professional Caregiver Issues

Whether practicing in the trauma center, intensive care unit or other acute care setting, home care, hospice, long-term care, or the many locations where patients and their families receive ambulatory services, nurses are closely involved with complex and emotionally laden issues surrounding loss of life. To be most effective and satisfied with the care they provide, nurses need to at-

tend to their own emotional responses to the losses they witness every day. Well before the nurse exhibits symptoms of stress or burnout, he or she should acknowledge the difficulty of coping with others' pain on a daily basis and put healthy practices in place that will guard against emotional exhaustion. In hospice settings, where death, grief, and loss are expected outcomes of patient care, interdisciplinary colleagues rely on each other for support, using meeting time to express frustration, sadness, anger, and other emotions; to learn coping skills from each other; and to speak about how they were affected by the lives of those patients who have died since the last meeting. In many settings, staff members organize or attend memorial services to support families and other caregivers, who find comfort in joining each other to remember and celebrate the lives of patients. Finally, healthy personal habits, including diet, exercise, stress reduction activities (such as dance, yoga, t'ai chi, meditation), and sleep, will help guard against the detrimental effects of stress.

### Critical Thinking Exercises

1. Your patient, age 70, has metastatic prostate cancer and is receiving home hospice care. In the past, he has received transfusions of packed red blood cells to treat anemia associated with bone marrow involvement. He has received only temporary benefit from the transfusions. The patient's wife has asked that her husband's hemoglobin continue to be checked weekly because she is concerned about his increasing weakness and exertional dyspnea. The interdisciplinary team is meeting to discuss the patient's treatment plan. The team consensus is that he is unlikely to live more than a few days or weeks. What additional assessment data are needed to determine the wishes and expectations of the patient? Of the wife? What are the team's options for intervention? What are the pros and cons associated with each option?
2. You are conducting your first home care visit to an 88-year-old woman who has been hospitalized three times in the last 4 months with heart failure. She is short of breath, although she uses oxygen continuously. She is confined to bed and is incontinent and has a stage III pressure ulcer on her coccyx. She is not interested in eating and has lost 30 lb in the last 4 months. She is becoming progressively weaker. Her husband, also 88, has limited mobility due to arthritis. He has a history of colon cancer and has had a colostomy for the last 10 years. Although he tries to take care of her, it is becoming increasingly difficult for him to do so. They have been married for almost 70 years and are very devoted to each other. What assessments would you carry out and what strategies would you implement to (1) relieve some of the patient's symptoms and discomfort, (2) assist her husband in management of her care, and (3) prepare both of them for her inevitable death?
3. You have been assigned to care for a 34-year-old father of three in the end stages of ALS. He was discharged home from the hospital yesterday and is being admitted to the local visiting nurse association's home palliative care program. During the admission assessment, when you ask him about his religion and beliefs as part of the spiritual assessment that is performed at the time of admission, he says to

Chart  
17-10

### Nursing Interventions for Grief and Mourning

- Support the expression of feelings.
  - Encourage the telling of the story using open-ended statements or questions (eg, "Tell me about your husband").
  - Assist the mourner to find an outlet for his/her feelings: talking, attending a support group, keeping a journal, finding a safe outlet for angry feelings (writing letters that will not be mailed, physical activity)
  - Assess emotional affect and reinforce the normalcy of feelings.
  - Assess for guilt and regrets.
    - Are you especially troubled by a certain memory or thought?
    - How do you manage those memories?
  - Assess for the presence of social support.
    - Do you have someone to whom you can talk about your husband?
    - Can I help you to find someone you can talk to?
  - Assess coping skills.
    - How are you managing day to day?
    - Have you experienced other losses? How did you manage those?
    - Are there things you are having trouble doing?
    - Do you have/need help with specific tasks?
  - Assess for signs of complicated grief and mourning and offer professional referral.

you, “I don’t go to church anymore and I really don’t have time for people who want to talk about religion.” Should you respond to his comment? If not, why? If so, what will you say? Should you continue with part or all of a spiritual assessment? Explain your rationale. If you continue with the spiritual assessment, what questions would you use in the assessment? Discuss your plan for follow-up.

# ● Preoperative Nursing Management

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Define the three phases of the perioperative period.
2. Describe a comprehensive preoperative assessment to identify surgical risk factors.
3. Identify the causes of preoperative anxiety and describe nursing measures to alleviate it.
4. Identify legal and ethical considerations related to informed consent.
5. Describe preoperative nursing measures that decrease the risk for infection and other postoperative complications.
6. Describe the immediate preoperative preparation of the patient.
7. Develop a preoperative teaching plan designed to promote the patient's recovery from anesthesia and surgery, thus preventing postoperative complications.

Surgery, whether elective or emergent, is a stressful, complex event. Today, as a result of advances in surgical techniques and instrumentation as well as in anesthesia, many surgical procedures that were once performed in an inpatient setting now take place in an ambulatory or outpatient setting. Approximately 60% of elective surgeries are now performed in an ambulatory or outpatient setting (Russell, Williams & Bulstrode, 2000). This trend has increased the acuity and complexity of surgical patients and procedures. The number of surgical patients admitted for overnight hospital stays is expected to continue to decrease.

In the past, the patient scheduled for elective surgery would be admitted to the hospital at least 1 day before surgery for evaluation and preparation; these activities are now completed before the patient is admitted to the hospital. Today, many patients arrive at the hospital the morning of surgery and go home after recovering in the postanesthesia care unit (PACU) from the anesthesia. Often, surgical patients who require hospital stays are trauma patients, acutely ill patients, patients undergoing major surgery, patients who require emergency surgery, and patients with a concurrent medical disorder. Although each setting offers its own unique advantages for the delivery of patient care, all require a comprehensive preoperative nursing assessment and nursing intervention to prepare the patient and family before surgery.

Today's technology has led to more complex procedures, more complicated microsurgical and laser technology, more sophisticated bypass equipment, increased use of laparoscopic surgery, and more sensitive monitoring devices. Surgery might now involve the transplantation of multiple human organs, the implantation of mechanical devices, the reattachment of body parts, and the use of robots and minimally invasive procedures in the operating room (Mack, 2002). Advances in anesthesia have kept pace with these surgical technologies. More sophisticated monitoring and new pharmacologic agents, such as short-acting anesthetics and more effective antiemetics, have improved postoperative pain management, reduced postoperative nausea and vomiting, and shortened procedure and recovery times.

Concurrent with technologic advances have been changes in the delivery of and payment for health care. Pressure to reduce hospital stays and contain costs has resulted in patients undergoing diagnostic **preadmission testing (PAT)** and preoperative preparation before admission to the hospital. Many facilities have a presurgical services department to facilitate testing and to initiate the nursing assessment process, which may focus on patient demographics, health history, and other information pertinent to the surgical procedure. The increasing use of **ambulatory or same-day surgery** means that patients leave the hospital sooner, which increases the need for teaching, discharge planning, preparation for self-care, and referral for home care and rehabilitation

services. Competent care of ambulatory or same-day surgical patients requires a sound knowledge of all aspects of perioperative and perianesthesia nursing practice.

## Perioperative and Perianesthesia Nursing

The special field known as perioperative and perianesthesia nursing includes a wide variety of nursing functions associated with the patient's surgical experience during the perioperative period. **Perioperative** and perianesthesia nursing addresses the nursing roles relevant to the three phases of the surgical experience: **preoperative**, **intraoperative**, and **postoperative**. As shown in Chart 18-1, each phase begins and ends at a particular point in the sequence of events that constitutes the surgical experience, and each includes a wide range of activities the nurse performs using the nursing process and based on the standards of practice (American Society of PeriAnesthesia Nurses, 2000; Litwack, 1999; Quinn, 1999).

### PREOPERATIVE PHASE

The **preoperative phase** begins when the decision to proceed with surgical intervention is made and ends with the transfer of the patient onto the operating room table. The scope of nursing activities during this time can include establishing a baseline evaluation of the patient before the day of surgery by carrying out a preoperative interview (which includes not only a physical but also an emotional assessment, previous anesthetic history, and identification of known allergies or genetic problems that may affect the surgical outcome), ensuring that necessary tests have been or will be performed (preadmission testing), arranging appropriate consultative services, and providing preparatory education about recovery from anesthesia and postoperative care. On the day of surgery, patient teaching is reviewed, the patient's identity and the surgical site are verified, informed consent is confirmed, and an intravenous infusion is started. If the patient is going home the same day, the availability of safe transport and the presence of an accompanying responsible adult is verified. Depending on when the preadmission evaluation and testing were done, the nursing activities on the day of surgery may be as basic as performing or updating the preoperative patient assessment and addressing questions the patient or family may have.

### INTRAOPERATIVE PHASE

The **intraoperative phase** begins when the patient is transferred onto the operating room table and ends when he or she is admitted to the postanesthesia care unit (PACU). In this

## Glossary

**ambulatory surgery:** may include *outpatient (or same-day)* surgery that does not require an overnight hospital stay or *short stay*, with admission to an inpatient hospital setting for less than 24 hours

**informed consent:** the patient's autonomous decision about whether to undergo a surgical procedure; based on the nature of the condition, the treatment options, and the risks and benefits involved

**intraoperative phase:** period of time from when the patient is transferred to the operating room table to when he or she is admitted to the postanesthesia care unit (PACU)

**perioperative phase:** period of time that constitutes the surgical experience; includes the preoperative, intraoperative, and postoperative phases of nursing care

**postoperative phase:** period of time that begins with the admission of the patient

to the PACU and ends after a follow-up evaluation in the clinical setting or home

**preadmission testing (PAT):** diagnostic testing performed before admission to the hospital

**preoperative phase:** period of time from when the decision for surgical intervention is made to when the patient is transferred to the operating room table

Chart  
18-1

## Examples of Perioperative Nursing Activities

**Preoperative Phase***Preadmission Testing*

1. Initiates initial preoperative assessment
2. Initiates teaching appropriate to patient's needs
3. Involves family in interview
4. Verifies completion of preoperative testing
5. Verifies understanding of surgeon-specific preoperative orders (eg, bowel preparation, preoperative shower)
6. Assesses patient's need for postoperative transportation and care

*Admission to Surgical Center or Unit*

1. Completes preoperative assessment
2. Assesses for risks for postoperative complications
3. Reports unexpected findings or any deviations from normal
4. Verifies that operative consent has been signed
5. Coordinates patient teaching with other nursing staff
6. Reinforces previous teaching
7. Explains phases in perioperative period and expectations
8. Answers patient's and family's questions
9. Develops a plan of care

*In the Holding Area*

1. Assesses patient's status; baseline pain and nutritional status
2. Reviews chart
3. Identifies patient
4. Verifies surgical site and marks site per institutional policy
5. Establishes intravenous line
6. Administers medications if prescribed
7. Takes measures to ensure patient's comfort
8. Provides psychological support
9. Communicates patient's emotional status to other appropriate members of the health care team

**Intraoperative Phase***Maintenance of Safety*

1. Maintains aseptic, controlled environment
2. Effectively manages human resources, equipment, and supplies for individualized patient care
3. Transfers patient to operating room bed or table
4. Positions the patient
  - Functional alignment
  - Exposure of surgical site
5. Applies grounding device to patient
6. Ensures that the sponge, needle, and instrument counts are correct
7. Completes intraoperative documentation

*Physiologic Monitoring*

1. Calculates effects on patient of excessive fluid loss or gain
2. Distinguishes normal from abnormal cardiopulmonary data
3. Reports changes in patient's vital signs
4. Institutes measures to promote normothermia

*Psychological Support (Before Induction and When Patient Is Conscious)*

1. Provides emotional support to patient
2. Stands near or touches patient during procedures and induction
3. Continues to assess patient's emotional status

**Postoperative Phase***Transfer of Patient to Postanesthesia Care Unit*

1. Communicates intraoperative information
  - Identifies patient by name
  - States type of surgery performed
  - Identifies type of anesthetic used
  - Reports patient's response to surgical procedure and anesthesia
  - Describes intraoperative factors (eg, insertion of drains or catheters; administration of blood, analgesic agents, or other medications during surgery; occurrence of unexpected events)
  - Describes physical limitations
  - Reports patient's preoperative level of consciousness
  - Communicates necessary equipment needs
  - Communicates presence of family and/or significant others

**Postoperative Assessment Recovery Area**

1. Determines patient's immediate response to surgical intervention
2. Monitors patient's physiologic status
3. Assesses patient's pain level and administers appropriate pain relief
4. Maintains patient's safety (airway, circulation, prevention of injury)
5. Administers medications, fluid, and blood component therapy, if prescribed
6. Provides oral fluids if prescribed for ambulatory surgery patient
7. Assesses patient's readiness for transfer to in-hospital unit or for discharge home based on institutional policy (eg, Alderete score, see Chap. 20)

*Surgical Unit*

1. Continues close monitoring of patient's physical and psychological response to surgical intervention
2. Assesses patient's pain level and administers appropriate pain relief measures
3. Provides teaching to patient during immediate recovery period
4. Assists patient in recovery and preparation for discharge home
5. Determines patient's psychological status
6. Assists with discharge planning

*Home or Clinic*

1. Provides follow-up care during office or clinic visit or by telephone contact
2. Reinforces previous teaching and answers patient's and family's questions about surgery and follow-up care
3. Assesses patient's response to surgery and anesthesia and their effects on body image and function
4. Determines family's perception of surgery and its outcome

phase, the scope of nursing activity can include providing for the patient's safety, maintaining an aseptic environment, ensuring proper function of equipment, providing the surgeon with specific instruments and supplies for the surgical field, and completing appropriate documentation. In some instances, the nursing activities can encompass providing emotional support by holding the patient's hand during general anesthesia induction, assisting in positioning the patient on the operating room table using basic principles of body alignment, or acting as scrub nurse, circulating nurse, or registered nurse first assistant (RNFA).

**POSTOPERATIVE PHASE**

The **postoperative phase** begins with the admission of the patient to the PACU and ends with a follow-up evaluation in the clinical setting or at home. The scope of nursing care covers a wide range of activities during this period. In the immediate postoperative phase, the focus includes maintaining the patient's airway, monitoring vital signs, assessing the effects of the anesthetic agents, assessing the patient for complications, and providing comfort and pain relief. Nursing activities then focus on promoting the patient's recovery and initiating the teaching, follow-up

## GENETICS IN NURSING PRACTICE—Perioperative Nursing

Nurses who are caring for patients undergoing surgery need to take various genetic considerations into account when assessing patients throughout the perioperative experience. For example, surgical outcomes may be altered by genetic conditions that may cause complications with anesthesia, including the following:

- Malignant hyperthermia
- Central core disease (CCD)
- Duchenne muscular dystrophy
- Hyperkalemic periodic paralysis
- King-Denborough

### NURSING ASSESSMENTS

#### PREOPERATIVE FAMILY HISTORY ASSESSMENT

- Obtain a thorough assessment of personal and family history, inquiring about prior problems with surgery or anesthesia with specific attention to complications such as fever, rigidity, dark urine, unexpected reactions.
- Inquire about any history of musculoskeletal complaints, history of heat intolerance, fevers of unknown origin, or unusual drug reaction.
- Assess for family history of any sudden or unexplained death, especially during participation in athletic events.

#### PHYSICAL ASSESSMENT

- Assess for subclinical muscle weakness.
- Assess for other physical features suggestive of an underlying genetic condition, such as contractures, kyphoscoliosis, and pterygium with progressive weakness.

#### MANAGEMENT ISSUES SPECIFIC TO GENETICS

- Inquire whether DNA mutation or other genetic testing has been performed on an affected family member.
- If indicated, refer for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, availability of diagnostic/genetic testing.
- Offer appropriate genetics information and resources.
- Assess patient's understanding of genetics information.
- Provide support to families with newly diagnosed malignant hyperthermia.
- Participate in management and coordination of care of patients with genetic conditions and individuals predisposed to develop or pass on a genetic condition.

#### GENETICS RESOURCES FOR NURSES AND THEIR PATIENTS ON THE WEB

Genetic Alliance: <http://www.geneticalliance.org>—a directory of support groups for patients and families with genetic conditions

Gene Clinics: <http://www.geneclinics.org>—a listing of common genetic disorders with up-to-date clinical summaries, genetic counseling and testing information

International Council of Nurses [http://www.icn.ch/matters\\_genetics.htm](http://www.icn.ch/matters_genetics.htm)—ICN's statement re: genetics and nursing.

National Organization of Rare Disorders: <http://www.rarediseases.org>—a directory of support groups and information for patients and families with rare genetic disorders

OMIM: Online Mendelian Inheritance in Man: <http://www.ncbi.nlm.nih.gov/omim/stats/html>—a complete listing of inherited genetic conditions

care, and referrals essential for recovery and rehabilitation after discharge. Each phase is reviewed in more detail in the three chapters of this unit.

Historically, the perioperative nurse's practice environment has been isolated, consisting of the area behind the double doors of the surgical suite. Although the nursing process guided nursing care, the fundamentals of assessment, diagnosis, planning, intervention, and evaluation were often misunderstood by practitioners unfamiliar with the delivery of surgical care. In recent years, the acceptance of a conceptual model for patient care, published by the Association of Perioperative Registered Nurses, formerly known as the Association of Operating Room Nurses (still abbreviated AORN), has helped to delineate the relationship of various components of nursing practice and the effect on patient outcomes (Beyea, 2000). The Perioperative Nursing Data Set (PNDS) is a language that describes the practice of perioperative nursing practice in four domains: safety, physiologic responses, behavioral responses, and health care systems (Fig. 18-1). The first three domains reflect phenomena of concern to perioperative nurses and are composed of nursing diagnoses, interventions, and outcomes that surgical patients and their families experience. The fourth domain, the health care system, comprises structural data elements and focuses on clinical processes and outcomes. The model is used to depict the relationship of nursing process components to the achievement of optimal patient outcomes.

## Surgical Classifications

Surgery may be performed for various reasons. A surgical procedure may be diagnostic (eg, biopsy or exploratory laparotomy). It may be curative (eg, excision of a tumor or an inflamed appendix) or reparative (eg, multiple wound repair). Surgery may be reconstructive or cosmetic (eg, mammoplasty or a facelift), or it may be palliative (eg, to relieve pain or correct a problem; for instance, a gastrostomy tube may be inserted to compensate for the inability to swallow food). Surgery may also be classified according to the degree of urgency involved: emergent, urgent, required, elective, and optional. These terms are defined in Table 18-1.

## Preparation for Surgery

### INFORMED CONSENT

Voluntary and written **informed consent** from the patient is necessary before nonemergent surgery can be performed. Such written consent protects the patient from unsanctioned surgery and protects the surgeon from claims of an unauthorized operation. In the best interests of all parties concerned, sound medical, ethical, and legal principles are followed. The nurse may ask the patient to sign the form and may witness the patient's signature. It is the physician's responsibility to provide appropriate information. Chart 18-2 lists the criteria for a valid informed consent.

Many ethical principles are integral to informed consent (see Chap. 3). Before the patient signs the consent form, the surgeon must provide a clear and simple explanation of what the surgery will entail. The surgeon must also inform the patient of the benefits, alternatives, possible risks, complications, disfigurement, disability, and removal of body parts as well as what to expect in the early and late postoperative periods. If the patient needs additional information to make his or her decision, the nurse notifies the physician about this. Also, the nurse ascertains that the consent form has been signed before administering psychoactive premedication, because the consent may not be valid if it was obtained while the patient was under the influence of medications that can affect judgment and decision-making

Chart  
18-2

### Criteria for Valid Informed Consent

#### Voluntary Consent

Valid consent must be freely given, without coercion.

#### Incompetent Patient

Legal definition: individual who is *not* autonomous and cannot give or withhold consent (eg, individuals who are mentally retarded, mentally ill, or comatose)

#### Informed Subject

Informed consent should be in writing. It should contain the following:

- Explanation of procedure and its risks
- Description of benefits and alternatives
- An offer to answer questions about procedure
- Instructions that the patient may withdraw consent
- A statement informing the patient if the protocol differs from customary procedure

#### Patient Able to Comprehend

Information must be written and delivered in language understandable to the patient. Questions must be answered to facilitate comprehension if material is confusing.

capacity. Informed consent is necessary in the following circumstances:

- Invasive procedures, such as a surgical incision, a biopsy, a cystoscopy, or paracentesis
- Procedures requiring sedation and/or anesthesia (see Chap. 19 for a discussion of levels of sedation and anesthesia)
- A nonsurgical procedure, such as an arteriography, that carries more than slight risk to the patient
- Procedures involving radiation

The patient personally signs the consent if he or she is of legal age and is mentally capable. When the patient is a minor or unconscious or incompetent, permission must be obtained from a responsible family member (preferably next of kin) or legal guardian. An emancipated minor (married or independently earning his or her own living) may sign his or her own consent form. State regulations and agency policy must be followed. In

Table 18-1 • Categories of Surgery Based on Urgency

CLASSIFICATION	INDICATIONS FOR SURGERY	EXAMPLES
I. Emergent—Patient requires immediate attention; disorder may be life-threatening	Without delay	Severe bleeding Bladder or intestinal obstruction Fractured skull Gunshot or stab wounds Extensive burns
II. Urgent—Patient requires prompt attention	Within 24–30 h	Acute gallbladder infection Kidney or ureteral stones
III. Required—Patient needs to have surgery	Plan within a few weeks or months	Prostatic hyperplasia without bladder obstruction Thyroid disorders Cataracts
IV. Elective—Patient should have surgery	Failure to have surgery not catastrophic	Repair of scars Simple hernia Vaginal repair
V. Optional—Decision rests with patient	Personal preference	Cosmetic surgery

an emergency, it may be necessary for the surgeon to operate as a lifesaving measure without the patient's informed consent. Every effort, however, must be made to contact the patient's family. In such a situation, contact can be made by telephone, telegram, fax, or other electronic means.

When the patient has doubts and has not had the opportunity to investigate alternative treatments, a second opinion may be requested. No patient should be urged or coerced to sign an operative permit. Refusing to undergo a surgical procedure is a person's legal right and privilege. However, such information must be documented and relayed to the surgeon so that other arrangements can be made. For example, additional explanations may be provided to the patient and family, or the surgery may be rescheduled.

The consent process can be improved by providing audiovisual materials to supplement discussion, by ensuring that the wording of the consent form is understandable, and by using other strategies and resources as needed to help the patient understand its content.

**NURSING ALERT** The signed consent form is placed in a prominent place on the patient's chart and accompanies the patient to the operating room.

## ASSESSMENT OF HEALTH FACTORS THAT AFFECT PATIENTS PREOPERATIVELY

The overall goal in the preoperative period is for the patient to have as many positive health factors as possible. Every attempt is made to stabilize those conditions that otherwise hinder a smooth recovery. When negative factors dominate, the risks of surgery and postoperative complications increase.

Before any surgical treatment is initiated, a health history is obtained, a physical examination is performed during which vital signs are noted, and a database is established for future comparisons (Meeker & Rothrock, 1999). During the physical examination, many factors are considered that have the potential to affect the patient undergoing surgery. Health care providers should be alert for signs of abuse that can occur at all ages and to men and women from all socioeconomic, ethnic, and cultural groups (Little, 2000; Marshall, Benton & Brazier, 2000). Findings need to be reported accordingly (see Chap. 5 for further discussion of signs of abuse).

Blood tests, x-rays, and other diagnostic tests are prescribed when specifically indicated by information obtained from a thorough history and physical examination (King, 2000). These preliminary contacts with the health care team provide the patient with opportunities to ask questions and to become acquainted with those who may be providing care during and after surgery.

### Nutritional and Fluid Status

Optimal nutrition is an essential factor in promoting healing and resisting infection and other surgical complications (Braunschweig, Gomez & Sheean, 2000). Assessment of a patient's nutritional status provides information on obesity, undernutrition, weight loss, malnutrition, deficiencies in specific nutrients, metabolic abnormalities, the effects of medications on nutrition, and special problems of the hospitalized patient (Quinn, 1999). Nutritional needs may be determined by measurement of body mass index and waist circumference (National Institutes of Health, 2000). See Chapter 5 for further discussion of nutritional assessment.

Any nutritional deficiency, such as malnutrition, should be corrected before surgery so that enough protein is available for tissue repair (King, 2000; Russell, Williams & Bulstrode, 2000). The nutrients needed for wound healing are summarized in Table 18-2.

Dehydration, hypovolemia, and electrolyte imbalances can lead to significant problems in patients with comorbid medical conditions or in elderly patients. The severity of fluid and electrolyte imbalances is often difficult to determine. Mild volume deficits may be treated during surgery; however, additional time may be needed to correct pronounced fluid and electrolyte deficits to promote the best possible preoperative condition.

### Drug or Alcohol Use

People who abuse drugs or alcohol frequently deny or attempt to hide it. In such situations, the nurse who is obtaining the patient's health history needs to ask frank questions with patience, care, and a nonjudgmental attitude. See Chapter 5 for an assessment of alcohol and drug use.

Because acutely intoxicated persons are susceptible to injury, surgery is postponed in these patients if possible. If emergency surgery is required, local, spinal, or regional block anesthesia is used for minor surgery. Otherwise, to prevent vomiting and potential aspiration, a nasogastric tube is inserted before administering general anesthesia.

The person with a history of chronic alcoholism often suffers from malnutrition and other systemic problems that increase the surgical risk. Additionally, alcohol withdrawal delirium (delirium tremens) may be anticipated up to 72 hours after alcohol withdrawal. Delirium tremens is associated with a significant mortality rate when it occurs postoperatively.

Chart 18-3 gives more information about risk factors that may lead to complications.

### Respiratory Status

The goal for potential surgical patients is optimal respiratory function. Patients are taught breathing exercises and use of an incentive spirometer if indicated. Because adequate ventilation is potentially compromised during all phases of surgical treatment, surgery is usually postponed when the patient has a respiratory infection. Patients with underlying respiratory disease (eg, asthma, chronic obstructive pulmonary disease) are assessed carefully for current threats to their pulmonary status. Patients' use of medications that may affect recovery is also assessed (King, 2000; Smetana, 1999).

Patients who smoke are urged to stop 2 months before surgery (King, 2000), although many do not do so. These patients should be counseled to stop smoking at least 24 hours prior to surgery. Research suggests that counseling has a positive effect on the patient's smoking behavior 24 hours preceding surgery, helping reduce the potential for adverse effects associated with smoking such as increased airway reactivity, decreased mucociliary clearance, as well as physiologic changes in the cardiovascular and immune systems (Shannon-Cain, Webster & Cain, 2002).

### Cardiovascular Status

The goal in preparing any patient for surgery is to ensure a well-functioning cardiovascular system to meet the oxygen, fluid, and nutritional needs of the perioperative period. If the patient has

Table 18-2 • Nutrients Important for Wound Healing

NUTRIENT	RATIONALE FOR INCREASED NEED	POSSIBLE DEFICIENCY OUTCOME
Protein	To replace the lean body mass lost during the catabolic phase after stress To restore blood volume and plasma proteins lost through exudates, bleeding from the wound, and possible hemorrhage To replace losses resulting from immobility (increased excretion) To meet the increased needs for tissue repair and resistance to infection	Significant weight loss Impaired/delayed wound healing Shock related to decreased blood volume Edema related to decreased serum albumin Diarrhea related to decreased albumin Anemia Increased risk of infection related to decreased antibodies, impaired tissue integrity Decreased lipoprotein synthesis → fatty infiltration of the liver → liver damage Increased mortality
Calories	To replace losses related to lack of oral intake and hypermetabolism during catabolic phase after stress To spare protein To restore normal weight	Signs and symptoms of protein deficiency due to use of protein to meet energy requirements Extensive weight loss
Water	To replace fluid lost through vomiting, hemorrhage, exudates, fever, drainage, diuresis To maintain homeostasis	Signs, symptoms, and complications of dehydration, such as poor skin turgor, dry mucous membranes, oliguria, anuria, weight loss, increased pulse rate, decreased central venous pressure
Vitamin C	Important for capillary formation, tissue synthesis, and wound healing through collagen formation Needed for antibody formation	Impaired/delayed wound healing related to impaired collagen formation and increased capillary fragility and permeability Increased risk of infection related to decreased antibodies
Thiamine, niacin, riboflavin Folic acid, vitamin B <sub>12</sub>	Requirements increase with increased metabolic rate Needed for cell proliferation and therefore tissue synthesis Important for maturation of red blood cells Impaired folic acid synthesis associated with the use of some antibiotics; impaired vitamin B <sub>12</sub> absorption associated with the use of some antibiotics	Decreased enzymes available for energy metabolism Decreased or arrested cell division Megaloblastic anemia
Vitamin A	Important for tissue synthesis, wound healing, and immune function Enhances resistance to infection	Impaired/delayed wound healing related to decreased collagen synthesis; impaired immune function Increased risk of infection
Vitamin K	Important for normal blood clotting Impaired intestinal synthesis associated with the use of antibiotics	Prolonged prothrombin time
Iron	To replace iron lost through blood loss	Signs, symptoms, and complications of iron deficiency anemia, such as fatigue, weakness, pallor, anorexia, dizziness, headaches, stomatitis, glossitis, cardiovascular and respiratory changes, possible cardiac failure
Zinc	Needed for protein synthesis and wound healing Needed for normal lymphocyte and phagocyte response	Impaired/delayed wound healing Impaired immune response

Reproduced with permission from Dudek, S. G. (Ed.). (2001). *Nutrition essentials for nursing practice* (4th ed.). Philadelphia: Lippincott Williams & Wilkins.

uncontrolled hypertension, surgery may be postponed until the blood pressure is under control.

Because cardiovascular disease increases the risk for complications, patients with these conditions require greater-than-usual diligence during all phases of nursing management and care (King, 2000). Depending on the severity of the symptoms, surgery may be deferred until medical treatment can be instituted to improve the patient's condition. At times, surgical treatment can be modified to meet the cardiac tolerance of the patient. For example, in a patient with obstruction of the descending colon and coronary artery disease, a temporary simple colostomy may be performed rather than a more extensive colon resection that would require a prolonged period of anesthesia.

## Hepatic and Renal Function

The presurgical goal is optimal function of the liver and urinary systems so that medications, anesthetic agents, body wastes, and toxins are adequately processed and removed from the body.

The liver is important in the biotransformation of anesthetic compounds. Therefore, any disorder of the liver has an effect on how anesthetic agents are metabolized. Because acute liver disease is associated with high surgical mortality, preoperative improvement in liver function is a goal. Careful assessment is made with the help of various liver function tests (see Chap. 39).

Because the kidneys are involved in excreting anesthetic drugs and their metabolites and because acid–base status and metabolism

### Chart 18-3 Risk Factors for Surgical Complications

Hypovolemia  
 Dehydration or electrolyte imbalance  
 Nutritional deficits  
 Extremes of age (very young, very old)  
 Extremes of weight (emaciation, obesity)  
 Infection and sepsis  
 Toxic conditions  
 Immunologic abnormalities  
 Pulmonary disease  
   Obstructive disease  
   Restrictive disorder  
   Respiratory infection  
 Renal or urinary tract disease  
   Decreased renal function  
   Urinary tract infection  
   Obstruction  
 Pregnancy  
   Diminished maternal physiologic reserve  
 Cardiovascular disease  
   Coronary artery disease or previous myocardial infarction  
   Cardiac failure  
   Dysrhythmias  
   Hypertension  
   Prosthetic heart valve  
   Thromboembolism  
   Hemorrhagic disorders  
   Cerebrovascular disease  
 Endocrine dysfunction  
   Diabetes mellitus  
   Adrenal disorders  
   Thyroid malfunction  
 Hepatic disease  
   Cirrhosis  
   Hepatitis  
 Preexisting mental or physical disability

are also important considerations in anesthesia administration, surgery is contraindicated when a patient has acute nephritis, acute renal insufficiency with oliguria or anuria, or other acute renal problems. The exception is surgery that is performed as a lifesaving measure or that is necessary to improve urinary function, as in the case of an obstructive uropathy.

## Endocrine Function

The patient with diabetes who is undergoing surgery is at risk for hypoglycemia and hyperglycemia. Hypoglycemia may develop during anesthesia or postoperatively from inadequate carbohydrates or from excessive administration of insulin. Hyperglycemia, which may increase the risk for surgical wound infection, may result from the stress of surgery, which may trigger increased levels of catecholamine. Other risks are acidosis and glucosuria. Although the surgical risk in the patient with controlled diabetes is no greater than in the nondiabetic patient, the goal is to maintain the blood glucose level at less than 200 mg/dL. Frequent monitoring of blood glucose levels is important before, during, and after surgery (see Chap. 41 for discussion of the patient with diabetes undergoing surgery).

Patients who have received corticosteroids are at risk for adrenal insufficiency. Therefore, the use of corticosteroids for any purpose during the preceding year must be reported to the anesthesiologist or anesthesiologist and surgeon. Additionally, the patient is monitored for signs of adrenal insufficiency.

Patients with uncontrolled thyroid disorders are at risk for thyrotoxicosis (with hyperthyroid disorders) and respiratory failure (with hypothyroid disorders). Therefore, the patient is assessed for a history of these disorders.

## Immune Function

An important function of the preoperative assessment is to determine the existence of allergies, including the nature of previous allergic reactions. It is especially important to identify and document any sensitivity to medications and past adverse reactions to these agents. The patient is asked to identify any substances that precipitated previous allergic reactions, including medications, blood transfusions, contrast agents, latex, and food products, and to describe the signs and symptoms produced by these substances. A sample latex allergy screening questionnaire is shown in Figure 18-2.

Immunosuppression is common with corticosteroid therapy, renal transplantation, radiation therapy, chemotherapy, and disorders affecting the immune system, such as acquired immunodeficiency syndrome (AIDS) and leukemia. The mildest symptoms or slightest temperature elevation must be investigated. Because patients who are immunosuppressed are highly susceptible to infection, great care is taken to ensure strict asepsis.

## Previous Medication Use

A medication history is obtained from each patient because of the possible effects of medications on the patient's perioperative and perianesthesia course and the possibility of drug interactions (Quinn, 1999). Any medication the patient is using or has used in the past is documented, including over-the-counter (OTC) preparations and herbal agents and the frequency with which they are used. Potent medications have an effect on physiologic functions; interactions of such medications with anesthetic agents can cause serious problems, such as arterial hypotension and circulatory collapse.

The potential effects of prior medication therapy are evaluated by the anesthesiologist or anesthesiologist, who considers the length of time the patient has used the medications, the physical condition of the patient, and the nature of the proposed surgery. Medications that cause particular concern are listed in Table 18-3.

Many patients take self-prescribed or OTC medications in addition to those listed in Table 18-3. Aspirin is a common OTC medication prescribed by physicians or taken independently by patients to prevent myocardial infarction, stroke, and other disorders (Karch, 2002). Because of the effects of aspirin or other OTC medications and possible interactions with other medications and anesthetic agents, it is important to ask a patient about their use. The information is noted in the patient's chart and conveyed to the anesthesiologist or anesthesiologist and surgeon.

The use of herbal medications is widespread among patients. Approximately 15 million Americans report their use (Ang-Lee, Moss & Yuan, 2001; Karch, 2002; Lyons, 2002). Patients with chronic illnesses may be using herbal medications to supplement their prescribed medications or in place of them. Certain herbal medications, such as echinacea, ephedra, garlic (*Allium sativum*), ginkgo, ginseng, kava kava (*Piper methysticum*), St. John's wort

Ask the patient the following questions. Check "Yes" or "No" in the box.	YES	NO
1. Has a doctor ever told you that you are allergic to latex?		
2. Do you have on-the-job exposure to latex?		
3. Were you born with problems involving your spinal cord?		
4. Have you ever had allergies, asthma, hay fever, eczema or problems with rashes?		
5. Have you ever had respiratory distress, rapid heart rate or swelling?		
6. Have you ever had swelling, itching, hives or other symptoms after contact with a balloon?		
7. Have you ever had swelling, itching, hives or other symptoms after a dental examination or procedure?		
8. Have you ever had swelling, itching, hives or other symptoms following a vaginal or rectal examination or after contact with a diaphragm or condom?		
9. Have you ever had swelling, itching, hives or other symptoms during or within one hour after wearing rubber gloves?		
10. Have you ever had a rash on your hands that lasted longer than one week?		
11. Have you ever had swelling, itching, hives, runny nose, eye irritation, wheezing, or asthma after contact with any latex or rubber product?		
12. Have you ever had swelling, itching, hives or other symptoms after being examined by someone wearing rubber or latex gloves?		
13. Are you allergic to bananas, avocados, kiwi or chestnuts?		
14. Have you ever had an unexplained anaphylactic episode?

Procedure: \_\_\_\_\_

**FIGURE 18-2** Example of a latex allergy assessment form. Courtesy of Inova Fairfax Hospital, Falls Church, VA.

(*Hypericum perforatum*), licorice (*Glycyhiza glabra*), and valerian (*Valeriana officinalis*) have been identified as the most commonly used herbal medications that may cause concern during the perioperative period (Ang-Lee, Moss & Yuan, 2001; Kuhn, 1999; Lyons, 2002). Because of the potential effects of herbal medications on coagulation and potential interactions with other medications, the nurse must ask surgical patients explicitly about the use of these agents, document their use, and inform the surgical team and anesthesiologist or anesthesiologist (Brumly, 2000).

**NURSING ALERT** Because of possible adverse interactions, the nurse must assess and document the patient's use of prescription medications, OTC medications (especially aspirin), and herbal medications. The nurse must clearly communicate this information to the anesthesiologist or anesthesiologist.

## Psychosocial Factors

All patients have some type of emotional reaction before any surgical procedure, be it obvious or hidden, normal or abnormal. For example, preoperative anxiety may be an anticipatory response to an experience the patient views as a threat to his or her customary role in life, body integrity, or life itself. Psychological distress directly influences body functioning. Therefore, it is imperative to identify any anxiety the patient is experiencing.

By taking a careful health history, the nurse elicits patient concerns that can have a bearing on the course of the surgical experience (Quinn, 1999). Undoubtedly, a patient about to undergo surgery is faced with various fears, including fears of the unknown, of death, of anesthesia, pain, or cancer. Concerns about loss of work time, loss of job, increased responsibilities or burden on family members, and the threat of permanent incapacity further

**Table 18-3 • Medications With the Potential to Affect the Surgical Experience**

AGENT (GENERIC AND TRADE EXAMPLE)	EFFECT OF INTERACTION WITH ANESTHETICS
<b>Corticosteroids</b> Prednisone (Deltasone)	Cardiovascular collapse can occur if discontinued suddenly. Therefore, a bolus of corticosteroid may be administered intravenously immediately before and after surgery.
<b>Diuretics</b> Hydrochlorothiazide (HydroDIURIL)	During anesthesia, may cause excessive respiratory depression resulting from an associated electrolyte imbalance
<b>Phenothiazines</b> Chlorpromazine (Thorazine)	May increase the hypotensive action of anesthetics
<b>Tranquilizers</b> Diazepam (Valium)	May cause anxiety, tension, and even seizures if withdrawn suddenly
<b>Insulin</b>	Interaction between anesthetics and insulin must be considered when a patient with diabetes is undergoing surgery.
<b>Antibiotics</b> Erythromycin (Ery-Tab)	When combined with a curariform muscle relaxant, nerve transmission is interrupted and apnea from respiratory paralysis may result.
<b>Anticoagulants</b> Warfarin (Coumadin)	Can increase the risk of bleeding during the intraoperative and postoperative periods; should be discontinued in anticipation of elective surgery. The surgeon will determine how long before the elective surgery the patient should stop taking an anticoagulant, depending on the type of planned procedure and the medical condition of the patient.
<b>Antiseizure Medications</b> Phenytoin (Dilantin)	An intravenous route of medication may need to be administered to keep the patient seizure-free in the intraoperative and postoperative periods.
<b>Monoamine Oxidase (MAO) Inhibitors</b> Phenelzine sulfate (Nardil)	May increase the hypotensive action of anesthetics

contribute to the emotional strain created by the prospect of surgery. Less obvious concerns may occur because of previous experiences with the health care system and people the patient has known with the same condition.

People express fear in different ways. For example, one patient may repeatedly ask a lot of questions, even though answers were given previously. Another person may withdraw, deliberately avoiding communication, perhaps by reading or watching television. Still others may talk about trivialities. Consequently, the nurse must be empathetic, listen well, and provide information that helps alleviate concerns.

An important outcome of the psychosocial assessment is the determination of the extent and role of the patient's support network. The value and reliability of all available support systems are assessed. Other information, such as usual level of functioning and typical daily activities, may assist in the patient's care and rehabilitation plans. Assessing the patient's readiness to learn and determining the best approach to maximize comprehension will provide the basis for preoperative patient education.

## Spiritual and Cultural Beliefs

Spiritual beliefs play an important role in how people cope with fear and anxiety. Regardless of the patient's religious affiliation, spiritual beliefs can be as therapeutic as medication. Every attempt must be made to help the patient obtain the spiritual help that he or she requests. Faith has great sustaining power. Thus, the beliefs of each patient should be respected and supported. Some

nurses avoid the subject of a clergy visit lest the suggestion alarm the patient. Asking if the patient's spiritual advisor knows about the impending surgery is a caring, nonthreatening approach.

Showing respect for a patient's cultural values and beliefs facilitates rapport and trust. Some areas of assessment include identifying the ethnic group to which the patient relates and the customs and beliefs the patient holds about illness and health care providers. For example, patients from some cultural groups are unaccustomed to expressing feelings openly. Nurses need to consider this pattern of communication when assessing pain. As a sign of respect, people from other cultural groups may not make direct eye contact with others. The nurse needs to know that this lack of eye contact is not avoidance or a lack of interest.

Perhaps the most valuable skill at the nurse's disposal is listening carefully to the patient, especially when obtaining the history. Invaluable information and insights may be gained by engaging in conversation and using communication and interviewing skills. An unhurried, understanding, and caring nurse invites confidence on the part of the patient.

## Special Considerations

In the preoperative period, attention needs to be paid to patients with special considerations. These may include the patient who is undergoing ambulatory surgery, the geriatric patient, the patient who is obese, the patient with a disability, and the patient undergoing emergency surgery.

## THE AMBULATORY SURGERY PATIENT

The brief time the patient and family spend in the ambulatory setting is an important factor in the preoperative period. The nurse must quickly and comprehensively assess and anticipate the patient's needs and at the same time begin planning for discharge and follow-up home care.

The nurse needs to be sure that the patient and family understand that the patient will go first to the preoperative holding area before going to the operating room for the surgical procedure and then will spend some time in the PACU before being discharged home with the family later that day. Other preoperative teaching content should also be verified (see the section later in this chapter on instructing the ambulatory surgery patient) and reinforced as needed. The nurse should ensure that any plans for follow-up home care are in place if needed (Quinn, 1999).

## ELDERLY PATIENTS

The older person undergoing surgery may have a combination of chronic illnesses and health problems in addition to the specific one for which surgery is indicated. Elderly people frequently do not report symptoms, perhaps because they fear a serious illness may be diagnosed or because they accept such symptoms as part of the aging process. Subtle clues alert the nurse to underlying problems.

Health care staff must remember that the hazards of surgery for the aged are proportional to the number and severity of co-existing health problems and the nature and duration of the operative procedure. The underlying principle that guides the preoperative assessment, surgical care, and postoperative care is that the aged patient has less physiologic reserve (the ability of an organ to return to normal after a disturbance in its equilibrium) than the younger patient. Cardiac reserves are lower; renal and hepatic functions are depressed; and gastrointestinal activity is likely to be reduced. Dehydration, constipation, and malnutrition may be evident. Sensory limitations, such as impaired vision or hearing and reduced tactile sensitivity, are often the reasons for falls and burns. Therefore, the nurse must be alert to maintaining a safe environment. Arthritis is common in older people and may affect mobility, making it difficult for the patient to turn from one side to the other or ambulate without discomfort. Protective measures include adequate padding for tender areas, moving the patient slowly, protecting bony prominences from prolonged pressure, and providing gentle massage to promote circulation.

The condition of the mouth is important to assess. Dental caries, dentures, and partial plates are particularly significant to the anesthesiologist or anesthetist because decayed teeth or dental prostheses may become dislodged during intubation and occlude the airway.

An additional area to assess in elderly patients is the preoperative level of activity. Research suggests that elderly patients who had hip replacement surgery and who reported performing greater physical activities (including heavy chores) preoperatively can walk greater distances postoperatively than elderly patients who are less physically active prior to surgery (Whitney & Parkman, 2002).

As the body ages, its ability to perspire decreases. Because decreased perspiration leads to dry, itchy skin, which becomes fragile and is easily abraded, precautions are taken when moving an elderly person. Decreased subcutaneous fat makes older people more susceptible to temperature changes. A lightweight cotton

blanket is an appropriate cover when an elderly patient is moved to and from the operating room.

Most elderly people have experienced personal illnesses and possibly life-threatening illnesses of friends and family. Such experiences may result in fears about the surgery and about the future. Providing the patient with an opportunity to express these fears enables the patient to gain some peace of mind and a sense of being understood.

Preoperative pain assessment and teaching are important with elderly patients. It is important for nurses to incorporate pain management information and pain communication skills when teaching elderly persons how to obtain greater postoperative pain relief (McDonald, Freeland, Thomas & Moore, 2001).

Because the elderly patient may have greater risks during the perioperative period, the following are critical: (1) skillful preoperative assessment and treatment, (2) skillful anesthesia and surgery, and (3) meticulous and competent postoperative and postanesthesia management.

## OBESE PATIENTS

Like age, obesity increases the risk and severity of complications associated with surgery (National Institutes of Health, 2000). During surgery, fatty tissues are especially susceptible to infection. Additionally, obesity increases technical and mechanical problems related to surgery. Therefore, dehiscence (wound separation) and wound infections are more common. Moreover, the obese patient may be more difficult to care for because of the added weight; the patient tends to breathe poorly when supine, which increases the risk of hypoventilation and postoperative pulmonary complications. In addition, abdominal distention, phlebitis, and cardiovascular, endocrine, hepatic, and biliary diseases occur more readily in obese patients (Dudek, 2001). It has been estimated that for each 30 pounds of excess weight, about 25 additional miles of blood vessels are needed, and this places increased demands on the heart.

## PATIENTS WITH DISABILITIES

Special considerations for patients with a mental or physical disability include the need for assistive devices, modifications in preoperative teaching, additional assistance with and attention to positioning or transferring, and the effects of the disability on surgery and anesthesia (Quinn, 1999).

Assistive devices include hearing aids, eyeglasses, braces, prostheses, and other devices. Individuals who are hearing-impaired may need a translator or some alternative communication system perioperatively. If they rely on signing or speech (lip) reading, and if their eyeglasses or contact lenses are removed or if health care staff wear surgical masks, these patients will need an alternative method of communication. These needs must be identified as a factor in the preoperative evaluation and clearly communicated to personnel. Specific strategies for accommodating the patient's needs must be identified ahead of time. Ensuring the safety of assistive devices is important; these devices are expensive and likely to be lost.

Most patients are directed to move from the stretcher to the operating room table and back again. In addition to being unable to see or hear instructions, patients with a disability may be unable to move without special devices or a great deal of assistance. The patient with a disability that affects body position (eg, cerebral

palsy, post-polio syndrome, and other neuromuscular disorders) may need special positioning during surgery to prevent pain and injury. Moreover, these patients may be unable to sense whether their extremities are positioned incorrectly.

Patients with respiratory problems related to a disability (eg, multiple sclerosis, muscular dystrophy) may experience difficulties unless the problems are made known to the anesthesiologist or anesthetist and adjustments are made. These factors need to be clearly identified in the preoperative period and communicated to the appropriate personnel.

## PATIENTS UNDERGOING EMERGENCY SURGERY

Emergency surgeries are unplanned and occur with little time for preparation (Meeker & Rothrock, 1999). The unpredictable nature of trauma and emergency surgery poses unique challenges to the nurse throughout the perioperative period.

All of the previously discussed factors that affect patients preparing to undergo surgery apply to these patients, usually in a very condensed time frame. The preoperative assessment may actually coincide with resuscitation efforts in the emergency department (Meeker & Rothrock, 1999). For the unconscious patient, informed consent and essential information, such as pertinent past medical history and allergies, need to be obtained from a family member, if one is available. A quick visual survey of the patient is essential to identify all sites of injury when the emergency surgery is due to trauma (see Chap. 71 for more information).

The psychological status of the patient undergoing emergency surgery should be assessed quickly if the patient is awake (Meeker & Rothrock, 1999). The patient may have undergone a very frightening experience and may need extra support and explanation of the surgery.

## Preoperative Nursing Interventions

### PREOPERATIVE TEACHING

Nurses have long recognized the value of preoperative instruction (Fitzpatrick, 1998). Each patient is taught as an individual, with consideration for any unique concerns or needs; the program of instruction should be based on the individual's learning needs (Quinn, 1999). Multiple teaching strategies should be used (eg, verbal, written, return demonstration), depending on the patient's needs and abilities. Preoperative teaching is initiated as soon as possible. It should start in the physician's office and continue until the patient arrives in the operating room.

### When and What to Teach

Ideally, instruction is spaced over a period of time to allow the patient to assimilate information and ask questions as they arise. Frequently, teaching sessions are combined with various preparation procedures to allow for an easy and timely flow of information. The nurse should guide the patient through the experience and allow ample time for questions. Some patients may feel too many descriptive details will increase their anxiety level, and the nurse should respect their wish for less detail.

Teaching should go beyond descriptions of the procedure and should include explanations of the sensations the patient will experience. For example, telling the patient only that preoperative medication will relax him or her before the operation is not as effective as also noting that the medication may result in light-

headedness and drowsiness. Knowing what to expect will help the patient anticipate these reactions and thus attain a higher degree of relaxation than might otherwise be expected.

The ideal timing for preoperative teaching is not on the day of surgery but during the preadmission visit when diagnostic tests are performed. At this time, the nurse or resource person answers questions and provides important patient teaching. During this visit, the patient can meet and ask questions of the perioperative nurse, view audiovisuals, receive written materials, and be given the telephone number to call as questions arise closer to the date of surgery. Most institutions provide written instructions (designed to be copied and given to patients) about many types of surgery (Economou & Economou, 1999).

### Deep-Breathing, Coughing, and Incentive Spirometers

One goal of preoperative nursing care is to teach the patient how to promote optimal lung expansion and consequent blood oxygenation after anesthesia. The patient assumes a sitting position to enhance lung expansion. The nurse then demonstrates how to take a deep, slow breath and how to exhale slowly. After practicing deep breathing several times, the patient is instructed to breathe deeply, exhale through the mouth, take a short breath, and cough from deep in the lungs (Chart 18-4). The nurse also demonstrates how to use an incentive spirometer, a device that provides measurement and feedback related to breathing effectiveness. In addition to enhancing respiration, these exercises may help the patient to relax.

If there will be a thoracic or abdominal incision, the nurse demonstrates how the incision line can be splinted to minimize pressure and control pain. The patient should put the palms of both hands together, interlacing the fingers snugly. Placing the hands across the incisional site acts as an effective splint when coughing. Additionally, the patient is informed that medications are available to relieve pain and should be taken regularly for pain relief so that effective deep-breathing and coughing exercises can be performed. The goal in promoting coughing is to mobilize secretions so they can be removed. Deep breathing before coughing stimulates the cough reflex. If the patient does not cough effectively, atelectasis (lung collapse), pneumonia, and other lung complications may occur.

### Mobility and Active Body Movement

The goals of promoting mobility postoperatively are to improve circulation, prevent venous stasis, and promote optimal respiratory function.

The nurse explains the rationale for frequent position changes after surgery and then shows the patient how to turn from side to side and how to assume the lateral position without causing pain or disrupting intravenous lines, drainage tubes, or other equipment. Any special position the individual patient will need to maintain after surgery (eg, adduction or elevation of an extremity) is discussed, as is the importance of maintaining as much mobility as possible despite restrictions. Reviewing the process before surgery is helpful because the patient may be too uncomfortable after surgery to absorb new information.

Exercises of the extremities include extension and flexion of the knee and hip joints (similar to bicycle riding while lying on the side). The foot is rotated as though tracing the largest possible circle with the great toe (see illustrations in Chart 18-4). The elbow and shoulder are also put through range of motion. At first,

### Chart 18-4 • PATIENT EDUCATION

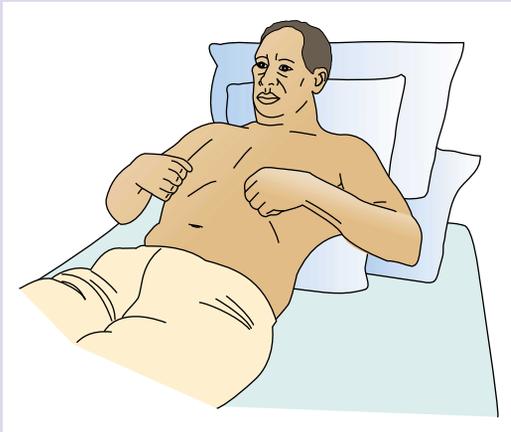

#### Preoperative Instructions to Prevent Postoperative Complications

Preoperative teaching for patients undergoing surgery includes instruction in breathing and leg exercises used to prevent postoperative complications, such as pneumonia and deep vein thrombosis. These exercises may be performed in the hospital or at home.

#### Diaphragmatic Breathing

Diaphragmatic breathing refers to a flattening of the dome of the diaphragm during inspiration, with resultant enlargement of the upper abdomen as air rushes in. During expiration, the abdominal muscles contract.

1. Practice in the same position you would assume in bed after surgery: a semi-Fowler's position, propped in bed with the back and shoulders well supported with pillows.
2. With your hands in a loose-fist position, allow the hands to rest lightly on the front of the lower ribs, with your fingertips against lower chest to feel the movement.

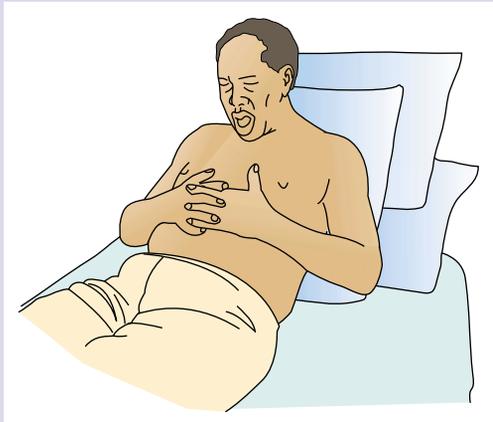

Diaphragmatic breathing

3. Breathe out gently and fully as the ribs sink down and inward toward midline.
4. Then take a deep breath through your nose and mouth, letting the abdomen rise as the lungs fill with air.
5. Hold this breath for a count of five.
6. Exhale and let out *all* the air through your nose and mouth.
7. Repeat this exercise 15 times with a short rest after each group of five.
8. Practice this twice a day preoperatively.

#### Coughing

1. Lean forward slightly from a sitting position in bed, interlace your fingers together, and place your hands across the incisional site to act as a splintlike support when coughing.

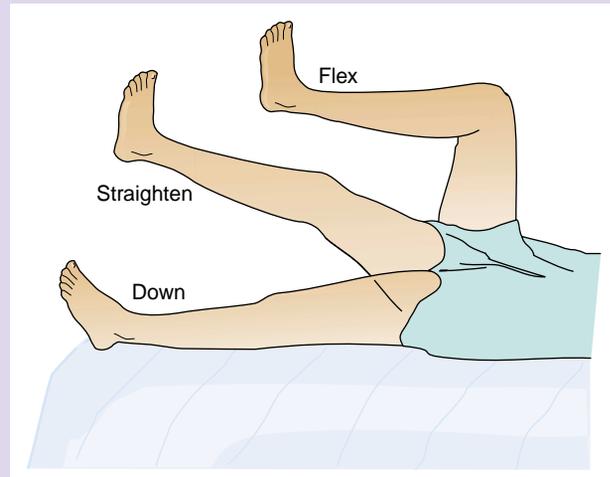

Splinting when coughing

2. Breathe with the diaphragm as described under "Diaphragmatic Breathing."
3. With your mouth slightly open, breathe in fully.
4. "Hack" out sharply for three short breaths.
5. Then, keeping your mouth open, take in a quick deep breath and immediately give a strong cough once or twice. This helps clear secretions from your chest. It may cause some discomfort but will not harm your incision.

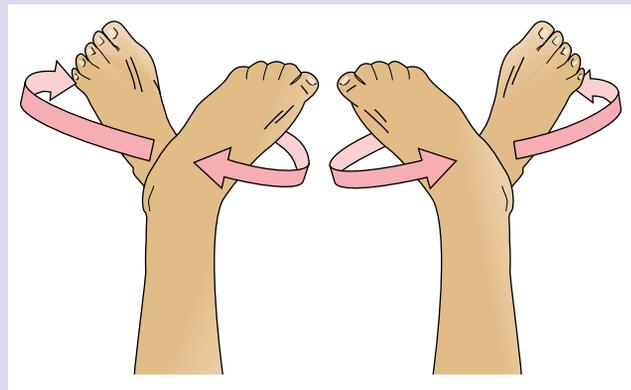

#### Leg Exercises

1. Lie in a semi-Fowler's position and perform the following simple exercises to improve circulation.
2. Bend your knee and raise your foot—hold it a few seconds, then extend the leg and lower it to the bed.

Leg exercises

3. Do this five times with one leg, then repeat with the other leg.
4. Then trace circles with the feet by bending them down, in toward each other, up, and then out.
5. Repeat these movements five times.

Foot exercises

#### Turning to the Side

1. Turn on your side with the uppermost leg flexed most and supported on a pillow.
2. Grasp the side rail as an aid to maneuver to the side.
3. Practice diaphragmatic breathing and coughing while on your side.

#### Getting Out of Bed

1. Turn on your side.
2. Push yourself up with one hand as you swing your legs out of bed.

the patient is assisted and reminded to perform these exercises. Later, the patient is encouraged to do them independently. Muscle tone is maintained so that ambulation will be easier.

The nurse should remember to use proper body mechanics and to instruct the patient to do the same. Whenever the patient is positioned, his or her body needs to be properly aligned.

## Pain Management

An assessment should include a determination between acute and chronic pain so that the patient may differentiate postoperative pain from a chronic condition. It is at this point that a pain scale should be introduced and its use explained to the patient. Chapter 13 contains several examples of pain scales.

Postoperatively, medications are administered to relieve pain and maintain comfort without increasing the risk for inadequate air exchange. The patient is instructed to take the medication as frequently as prescribed during the initial postoperative period for pain relief. Anticipated methods of administration of analgesic agents for inpatients include patient-controlled analgesia (PCA), epidural catheter bolus or infusion, or patient-controlled epidural analgesia (PCEA). A patient who is expected to go home would receive oral analgesic agents. These are discussed with the patient before surgery, and the patient's interest and willingness to use those methods are assessed. The patient is instructed in use of a pain intensity rating scale to promote effective postoperative pain management.

## Cognitive Coping Strategies

Cognitive strategies may be useful for relieving tension, overcoming anxiety, decreasing fear, and achieving relaxation. Examples of such strategies include the following:

- Imagery—The patient concentrates on a pleasant experience or restful scene.
- Distraction—The patient thinks of an enjoyable story or recites a favorite poem or song.
- Optimistic self-recitation—The patient recites optimistic thoughts (“I know all will go well”).

## Instruction for Ambulatory Surgical Patients

Preoperative education for the same-day or ambulatory surgical patient comprises all the material presented earlier in this chapter as well as collaborative planning with the patient and family for discharge and follow-up home care. The major difference in outpatient preoperative education is the teaching environment (Quinn, 1999).

Preoperative teaching content may be presented in a group meeting, on a videotape, during night classes, at preadmission testing, or by telephone in conjunction with the preoperative interview. In addition to answering questions and describing what to expect, the nurse tells the patient when and where to report, what to bring (insurance card, list of medications and allergies), what to leave at home (jewelry, watch, medications, contact lenses), and what to wear (loose-fitting, comfortable clothes; flat shoes). The nurse in the surgeon's office may initiate teaching before the perioperative telephone contact.

The last preoperative phone call is designed to remind the patient not to eat or drink as directed. A fasting period of 8 hours or more is recommended for a meal that includes fried or fatty foods or meat (Crenshaw, Winslow & Jacobson, 1999). The anesthesiologist or anesthesiologist may restrict foods and fluids for

longer periods of time depending on the patient's fluid status, age, and pulmonary status and the nature of the surgical procedure.

The purpose of withholding food before surgery is to prevent aspiration. Aspiration occurs when food or fluid is regurgitated from the stomach and enters the pulmonary system. Such inhaled material, which is a foreign substance, is irritating and causes an inflammatory reaction that interferes with adequate air exchange. Aspiration is a serious problem, and mortality is high (60% to 70%). If the patient is assessed as being at high risk for aspiration, the anesthesiologist or anesthesiologist prescribes more stringent food and fluid restrictions. Fluids may be administered intravenously

### NURSING RESEARCH PROFILE 18-1

#### Preoperative Fasting Guidelines

Crenshaw, J., & Winslow, E. (2002). Preoperative fasting: Old habits die hard. *American Journal of Nursing*, 102(5), 36–44.

#### Purpose

In 1999 the American Society of Anesthesiologists (ASA) made the “NPO after Midnight” rule obsolete with revised practice guidelines that support much more liberal preoperative fasting in healthy adults. This study sought to determine if these guidelines had changed preoperative fasting practices.

#### Study Sample and Design

This was a descriptive study conducted in a 935-bed medical center in the United States. The center did not have a fasting policy. A convenience sample of 155 patients were interviewed about their preoperative fasting, comparing instructed, actual, and ASA-recommended fasting durations for liquids and solids. A semi-structured interview was used by trained staff nurses to collect the data. Subjects were all over 18 years old, admitted to the hospital from home for an elective, nonobstetric or nongastrointestinal surgery. All were in stable condition, had been without an IV infusion for more than 4 hours prior to surgery, were admitted to a noncritical care unit after surgery, and consented to participate. The patients all spoke and understood English; 87% were Caucasian, 7% were African American, and 9.6% were Hispanic, Asian, or of other ethnic origin.

#### Findings

The patients interviewed fasted from liquids and solids for an average of 12 to 14 hours, with some patients fasting for as long as 20 hours from liquids and 37 hours from solid foods. Ninety-seven percent of the 155 patients fasted from liquids for more than 6 hours. Actual fasting durations were found (using paired t-tests) to be significantly longer than both the instructed fasting durations (mean 10 hours) and the ASA recommendations. Most patients (91%) were instructed to maintain NPO status after midnight. A nurse participated in the preoperative fasting instruction with 63% of the patients. Almost half of the patients rated thirst and worry at a 5 on a 0-to-10 scale.

#### Nursing Implications

Nurses are an important part of the surgical team and are involved in preoperative fasting instruction with the majority of patients. Therefore, they share the responsibility for recommending excessively long and unnecessary fasting for patients and for patients' lack of understanding of instructions demonstrated in this study. Clear and specific instructions must be given to patients about fasting time for liquids and solids. The rationale for the fasting should also be clearly explained. Patients should be warned that they will feel thirsty and should be taught strategies (as permitted) for coping with thirst, such as brushing teeth, rinsing the mouth, and chewing gum.

in some patients to ensure an adequate fluid volume when oral fluids are restricted.

## PREOPERATIVE PSYCHOSOCIAL INTERVENTIONS

### Reducing Preoperative Anxiety

Cognitive strategies useful for reducing anxiety were addressed previously in this chapter. In addition to these strategies, music therapy is an easy-to-administer, inexpensive, noninvasive intervention that can reduce anxiety in the perioperative patient. The patient should be allowed to choose his or her own music and be provided with quiet uninterrupted listening time (White, 2000).

The general preoperative teaching addressed earlier in this section will also help decrease anxiety in many patients. Knowing ahead of time about the possible need for a ventilator, drainage tubes, or other types of equipment will help decrease anxiety in the postoperative period.

### Decreasing Fear

During the preoperative assessment the nurse should assist the patient to identify coping strategies that he or she has previously used to decrease fear. The patient benefits from knowing when family and friends will be able to visit after surgery and that a spiritual advisor will be available if desired. Research suggests that hypnosis may be a useful strategy for reducing fear and overcoming the anxiety associated with surgery (Hernandez & Tatarunis, 2000).

### Respecting Cultural, Spiritual, and Religious Beliefs

Psychosocial interventions include identifying and showing respect for cultural, spiritual, and religious beliefs. In some cultures, for example, individuals are stoic in regard to pain, whereas others are more expressive. These responses should be recognized as normal for those patients and families and respected by perioperative personnel. When patients decline blood transfusions for religious reasons (Jehovah's Witnesses), this information needs to be clearly identified in the preoperative period, documented, and communicated to the appropriate personnel.

## GENERAL PREOPERATIVE NURSING INTERVENTIONS

### Managing Nutrition and Fluids

The major purpose of withholding food and fluid before surgery is to prevent aspiration. However, studies demonstrate that in patients who do not have a compromised airway or coexisting diseases or disorders that affect gastric emptying or fluid volume (eg, pregnancy, obesity, diabetes, gastroesophageal reflux, enteral tube feeding, ileus or bowel obstruction), lengthy restriction of fluid and food is unnecessary (Crenshaw & Winslow, 2002; Pandit, Loberg & Pandit, 2000). Until recently, fluid and food were restricted preoperatively overnight and often longer. However, recent review of this practice by the American Society of Anesthesiologists has resulted in new recommendations for persons undergoing elective surgery who are otherwise healthy (ASA Task Force on Preoperative Fasting, 1999). The recommendations depend on the age of the patient and type of food eaten. For ex-

ample, adults are advised to fast for 8 hours after eating fatty food and 4 hours after ingesting milk products (Crenshaw, Winslow & Jacobson, 1999; Crenshaw & Winslow, 2002). Most patients are currently allowed clear liquids up to 2 hours before an elective procedure (Crenshaw & Winslow, 2002).

### Preparing the Bowel for Surgery

Enemas are not commonly ordered preoperatively unless the patient is undergoing abdominal or pelvic surgery. In this case, a cleansing enema or laxative may be prescribed the evening before surgery and may be repeated the morning of surgery. The goals of this preparation are to allow satisfactory visualization of the surgical site and to prevent trauma to the intestine or contamination of the peritoneum by feces. Unless the condition of the patient presents some contraindication, the toilet or bedside commode, rather than the bedpan, is used for evacuating the enema if the patient is hospitalized during this time. Additionally, antibiotics may be prescribed to reduce intestinal flora.

### Preparing the Skin

The goal of preoperative skin preparation is to decrease bacteria without injuring the skin. If the surgery is not performed as an emergency, the patient may be instructed to use a soap containing a detergent-germicide to cleanse the skin area for several days before surgery to reduce the number of skin organisms; this preparation may be carried out at home.

Generally, hair is not removed preoperatively unless the hair at or around the incision site is likely to interfere with the operation. If hair must be removed, electric clippers are used for safe hair removal immediately before the operation.

## IMMEDIATE PREOPERATIVE NURSING INTERVENTIONS

The patient changes into a hospital gown that is left untied and open in the back. The patient with long hair may braid it, remove hairpins, and cover the head completely with a disposable paper cap.

The mouth is inspected, and dentures or plates are removed. If left in the mouth, these items could easily fall to the back of the throat during induction of anesthesia and cause respiratory obstruction.

Jewelry is not worn to the operating room; wedding rings and jewelry of body piercings should be removed to prevent injury (Fogg, 2001). If a patient objects to removing a ring, some institutions allow the ring to be securely fastened to the finger with tape. All articles of value, including assistive devices, dentures, glasses, and prosthetic devices, are given to family members or are labeled clearly with the patient's name and stored in a safe place according to the institution's policy.

All patients (except those with urologic disorders) should void immediately before going to the operating room to promote continence during low abdominal surgery and to make abdominal organs more accessible. Urinary catheterization is performed in the operating room as necessary.

### Administering Preanesthetic Medication

The use of preanesthetic medication is minimal with ambulatory or outpatient surgery. If prescribed, it is usually administered in the preoperative holding area. If a preanesthetic medication is

administered, the patient is kept in bed with the side rails raised because the medication can cause lightheadedness or drowsiness. During this time, the nurse observes the patient for any untoward reaction to the medications. The immediate surroundings are kept quiet to promote relaxation.

Often, surgery is delayed or operating room schedules are changed, and it becomes impossible to request that a medication be given at a specific time. In these situations, the preoperative medication is prescribed “on call from operating room.” The nurse can have the medication ready to give and administer it as soon as a call is received from the operating room staff. It usually takes 15 to 20 minutes to prepare the patient for the operating room. If the nurse gives the medication before attending to the other details of preoperative preparation, the patient will have at least partial benefit from the preoperative medication and will have a smoother anesthetic and operative course.

## Maintaining the Preoperative Record

A preoperative checklist contains critical elements that need to be checked preoperatively (Meeker & Rothrock, 1999). An example is shown in Figure 18-3. The completed chart accompanies the patient to the operating room with the surgical consent form attached, along with all laboratory reports and nurses' records. Any unusual last-minute observations that may have a bearing on anesthesia or surgery are noted at the front of the chart in a prominent place.

## Transporting the Patient to the Presurgical Area

The patient is transferred to the holding area or presurgical suite in a bed or on a stretcher about 30 to 60 minutes before the anesthetic is to be given. The stretcher should be as comfortable as possible, with a sufficient number of blankets to prevent

chilling in air-conditioned rooms. A small head pillow is usually provided.

The patient is taken to the preoperative holding area, greeted by name, and positioned comfortably on the stretcher or bed. The surrounding area should be kept quiet if the preoperative medication is to have maximal effect. Unpleasant sounds or conversation should be avoided because a sedated patient who overhears them might misinterpret them.

Patient safety in the preoperative area is a priority. Using a process to verify patient identification, the surgical procedure, and the surgical site maximizes patient safety and allows for early identification and intervention if any discrepancies are identified (Brown, Riippa & Shaneberger, 2001).

**NURSING ALERT** It is important for someone to be with the preoperative patient at all times. Someone must be present to provide reassurance as well as to ensure safety. Facial expression, or the warm grasp of a hand can communicate reassurance nonverbally.

## Attending to Family Needs

Most hospitals and ambulatory surgery centers have a waiting room where the family and significant others can wait while the patient is undergoing surgery. This room may be equipped with comfortable chairs, television, telephones, and facilities for light refreshment. Volunteers may remain with the family, offer them coffee, and keep them informed of the patient's progress. After surgery, the surgeon may meet the family in the waiting room and discuss the outcome.

The family and significant others should never judge the seriousness of an operation by the length of time the patient is in the operating room. A patient may be in surgery much longer than the actual operating time for several reasons:

- Patients are routinely transported well in advance of the actual operating time.
- The anesthesiologist or anesthetist often makes additional preparations that may take 30 to 60 minutes.
- The surgeon may take longer than expected with the preceding case, which delays the start of the next surgical procedure.

After surgery, the patient is taken to the PACU to ensure safe emergence from anesthesia.

Family members and significant others waiting to see the patient after surgery should be informed that the patient may have certain equipment or devices (eg, intravenous lines, indwelling urinary catheter, nasogastric tube, oxygen lines, monitoring equipment, and blood transfusion lines) in place when he or she returns from surgery. When the patient returns to the room, the nurse provides explanations regarding the frequent postoperative observations that will be made. However, it is the responsibility of the surgeon, not the nurse, to relay the surgical findings and the prognosis, even when the findings are favorable.

## NURSING PROCESS: CARE OF THE PATIENT IN THE PREOPERATIVE PERIOD

Preoperative assessment of the surgical patient involves evaluating the elements addressed in the previous section on the factors that affect the patient undergoing surgery. A variety of patient problems or nursing diagnoses can be anticipated or identified on the basis of the assessment data.

## Assessment

During the preoperative phase of care, nursing assessment usually addresses the following parameters:

- Physical condition, including respiratory, cardiac, and other major body systems as discussed earlier in this chapter
- Results of blood tests, x-ray studies, and other diagnostic tests
- Nutritional and fluid status
- Medication use, as previously described
- Psychological preparedness for surgery (anxiety, fear, spiritual and cultural beliefs)
- Special considerations, including the ambulatory surgery patient, gerontologic considerations, obesity, the patient with a disability, or the patient undergoing emergency surgery, as discussed earlier in this chapter

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, major preoperative nursing diagnoses of the surgical patient may include the following:

- Anxiety related to the surgical experience (anesthesia, pain) and the outcome of surgery
- Fear related to perceived threat of the surgical procedure and separation from support system
- Knowledge deficit of preoperative procedures and protocols and postoperative expectations

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Failure to identify and communicate pertinent preoperative risk factors may lead to complications.

## Planning and Goals

The major goals for the preoperative surgical patient may include relief of preoperative anxiety, decreased fear, increased knowledge of perioperative expectations, and absence of preoperative complications.

## Nursing Interventions

### REDUCING PREOPERATIVE ANXIETY

Specific nursing interventions are discussed in detail under psychosocial interventions and preoperative teaching in the previous sections.

### DECREASING FEAR

Nursing management is discussed under psychosocial interventions in the previous section.

### PROVIDING PATIENT EDUCATION

Specific nursing interventions pertaining to preoperative patient education are discussed in detail in earlier sections of this chapter.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Nursing interventions to prevent preoperative complications include identification and documentation of factors that affect patients preparing to undergo surgery (discussed earlier in this chapter).

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Reports relief of anxiety
  - a. Discusses with anesthesiologist or anesthesiologist concerns related to types of anesthesia and induction
  - b. Verbalizes an understanding of the preanesthetic medication and general anesthesia
  - c. Discusses last-minute concerns with nurse or physician
  - d. Discusses financial concerns with social worker, when appropriate
  - e. Requests visit with member of clergy when appropriate
  - f. Relaxes quietly after being visited by health care team members
2. Reports that fear is decreased
  - a. Discusses fears with health care professionals
  - b. Verbalizes an understanding of the location of family members or significant others during procedure
3. Voices understanding of surgical intervention
  - a. Participates in preoperative preparation
  - b. Demonstrates and describes exercises he or she is expected to perform postoperatively
  - c. Reviews information about postoperative care
  - d. Accepts preanesthetic medication, if prescribed
  - e. Remains in bed once premedicated
  - f. Relaxes during transportation to operating room or unit
  - g. States rationale for use of side rails
  - h. Discusses postoperative expectations
4. Shows no evidence of preoperative complications.

### Critical Thinking Exercises

1. During the preoperative assessment of a man scheduled for hand surgery in an ambulatory setting, you think that the patient's responses indicate that he does not understand the procedure and that he has not made plans for postoperative care. What further assessment and teaching is indicated? What nursing interventions are warranted?
2. A patient with a long history of the use of several herbal supplements is scheduled for major surgery. What effect would this information have on your preoperative care of this patient?
3. Two patients are admitted to the same-day surgery unit for bilateral knee replacements. One patient is a 30-year-old who ambulates with crutches and the other is a 75-year-old who lives alone. How would your assessments, preoperative teaching, and preparation differ for these two patients?

# ● Intraoperative Nursing Management

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Describe the interdisciplinary approach to the care of the patient during surgery.
2. Describe the principles of surgical asepsis.
3. Describe various nursing roles as well as the role of the anesthesiologist or anesthetist in the intraoperative phase of care.
4. Identify adverse effects of surgery and anesthesia.
5. Identify the surgical risk factors related to age-specific populations and nursing interventions to reduce those risks.
6. Compare various types of anesthesia with regard to uses, advantages, disadvantages, and nursing responsibilities.
7. Identify the use of the nursing process for optimizing patient outcomes during the intraoperative period.

Anesthesia and surgery place the patient at risk for several complications or adverse events. Consciousness or full awareness, mobility, protective biologic functions, and personal control are totally or partially relinquished by the patient when entering the operating room. Staff from the departments of anesthesia, nursing, and surgery work collaboratively to implement professional standards of care, to control iatrogenic and individual risks, and to promote high-quality patient outcomes.

## The Surgical Team

The surgical team consists of the patient, the anesthesiologist or anesthetist, the surgeon, the intraoperative nurses, and the surgical technologists. The anesthesiologist or nurse anesthetist administers the **anesthetic** agent and monitors the patient's physical status throughout the surgery. The surgeon and assistants scrub and perform the surgery. The individual in the scrub role, either a nurse or surgical technologist, provides sterile instruments and supplies to the surgeon during the procedure. The circulating nurse coordinates the care of the patient in the operating room. Care provided by the circulating nurse includes assisting with patient positioning, preparing the patient's skin for surgery, managing surgical specimens, and documenting intraoperative events.

## THE PATIENT

As the patient enters the operating room, he or she may feel relaxed and prepared, or fearful and highly stressed. These feelings depend very much on the amount and timing of preoperative sedation and the patient's level of fear and anxiety. Fears about loss of control, the unknown, pain, death, changes in body structure or function, and disruption of lifestyle all may contribute to a generalized anxiety. These fears can increase the amount of anesthetic needed, the level of postoperative pain, and overall recovery time.

The patient is also subject to several risks. Infection, failure of the surgery to relieve symptoms, temporary or permanent complications related to the procedure or the anesthetic, and death are uncommon but potential outcomes of the surgical experience (Chart 19-1). In addition to fears and risks, the patient undergoing sedation and anesthesia temporarily loses both cognitive function and biologic self-protective mechanisms. Loss of pain sense, reflexes, and ability to communicate subjects the intraoperative patient to possible injury.

Chart  
19-1

## Potential Adverse Effects of Surgery and Anesthesia

Anesthesia and surgery disrupt all major body systems. Although most patients can compensate for surgical trauma and the effects of anesthesia, all patients are at risk during the operative procedure. These risks include the following:

- Cardiac dysrhythmia from electrolyte imbalance or adverse effect of anesthetic agents
- Myocardial depression, bradycardia, and circulatory collapse from toxic levels of local anesthetics
- Central nervous system agitation, seizures, and respiratory arrest from toxic levels of local anesthetics
- Oversedation or undersedation during moderate sedation
- Agitation or disorientation, especially in elderly patients
- Hypoxemia or hypercarbia from hypoventilation and inadequate respiratory support during anesthesia
- Laryngeal trauma, oral trauma, and broken teeth from difficult intubation
- Hypothermia from cool operating room temperatures, exposure of body cavities, and impaired thermoregulation secondary to anesthetic agents
- Hypotension from blood loss or adverse effect of anesthesia
- Infection
- Thrombosis from compression of blood vessels or stasis
- Malignant hyperthermia secondary to adverse effect of anesthesia
- Nerve damage, skin breakdown from prolonged or inappropriate positioning
- Electrical shock or burns
- Laser burns
- Drug toxicity, faulty equipment, and human error

## Gerontologic Considerations

Elderly patients face higher risks from anesthesia and surgery than younger adult patients (Polanczyk et al., 2001). Statistically, perioperative risk increases with each decade over 60 years, often because of the increased incidence of coexisting disease. Modifications tailored to the biologic changes of later life and the application of research findings for this population can reduce the risks.

## Glossary

**anesthesia:** a state of narcosis, analgesia, relaxation, and loss of reflexes

**anesthesiologist:** physician trained to deliver anesthesia and to monitor the patient's condition during surgery

**anesthetic:** the substance, such as a chemical or gas, used to induce anesthesia

**anesthetist:** health care professional, such as a nurse anesthetist, who is trained to deliver anesthesia and to monitor the patient's condition during surgery

**circulating nurse (or circulator):** registered nurse who coordinates and documents patient care in the operating room

**moderate sedation:** use of sedation to depress the level of consciousness without altering the patient's ability to maintain a patent airway and to respond to physical stimuli and verbal commands

**restricted zone:** area in the operating room where scrub attire and surgical masks are required; includes operating room and sterile core areas

**scrub role:** registered nurse, licensed practical nurse, or surgical technologist who scrubs and dons sterile surgical attire, prepares instruments and supplies, and hands

instruments to the surgeon during the procedure

**semirestricted zone:** area in the operating room where scrub attire is required; may include areas where surgical instruments are processed

**surgical asepsis:** absence of microorganisms in the surgical environment to reduce the risk for infection

**unrestricted zone:** area in the operating room that interfaces with other departments; includes patient reception area and holding area

Biologic variations of particular importance include age-related cardiovascular and pulmonary changes (Townsend, 2002). The aging heart and blood vessels have decreased ability to respond to stress. Reduced cardiac output and limited cardiac reserve make the elderly patient vulnerable to changes in circulating volume and blood oxygen levels. Excessive or rapid administration of intravenous solutions may cause pulmonary edema. A sudden or prolonged drop in blood pressure may lead to cerebral ischemia, thrombosis, embolism, infarction, and anoxia. Reduced gas exchange can lead to cerebral hypoxia.

The elderly patient needs fewer anesthetics to produce anesthesia and eliminates the anesthetic agent over a longer time than a younger patient. As people age, the percentage of lean body tissue decreases and fatty tissue steadily increases (from age 20 years to 90 years). Anesthetic agents that have an affinity for fatty tissue concentrate in body fat and the brain (Dudek, 2001). Lower doses of anesthetic are appropriate for another reason. The older patient, particularly when malnourished, may have low plasma protein levels. With decreased plasma proteins, more of the anesthetic agent remains free or unbound, and the result is more potent action.

Also in elderly adults, body tissues made up predominantly of water and those with a rich blood supply, such as skeletal muscle, liver, and kidneys, shrink. Reduced liver size decreases the rate at which the liver can inactivate many anesthetics, whereas decreased kidney function slows elimination of waste products and anesthetics. Other factors affecting the elderly surgical patient in the intraoperative period include the following:

- Impaired ability to increase metabolic rate and impaired thermoregulatory mechanisms increase susceptibility to hypothermia.
- Bone loss (25% in women, 12% in men) necessitates careful manipulation and positioning during surgery.
- Reduced ability to adjust rapidly to emotional and physical stress influences surgical outcomes and requires meticulous observation of vital functions.

As expected, mortality is higher with emergency surgery (commonly required for traumatic injuries) than with elective surgery, making continuous and careful monitoring and prompt intervention especially important for older surgical patients (Phippen & Wells, 2000).

## Nursing Care

Throughout surgery, nursing responsibilities include providing for the safety and well-being of the patient, coordinating the operating room personnel, and performing scrub and circulating activities. Because the patient's emotional state remains a concern, the care begun by preoperative nurses is continued by the intraoperative nursing staff, who provide the patient with information and realistic reassurance. The nurse supports coping strategies and reinforces the patient's ability to influence outcomes by encouraging his or her active participation in the plan of care.

In the role of patient advocate, intraoperative nurses monitor factors that can cause injury, such as patient position, equipment malfunction, and environmental hazards, and they protect patients' dignity and interests while they are anesthetized. Additional responsibilities include maintaining surgical standards of care, identifying existing patient risk factors, and assisting in modifying complicating factors to help reduce operative risk (Phippen & Wells, 2000).

## THE CIRCULATING NURSE

The **circulating nurse** (also known as the **circulator**) must be a registered nurse. He or she manages the operating room and protects the patient's safety and health by monitoring the activities of the surgical team, checking the operating room conditions, and continually assessing the patient for signs of injury and implementing appropriate interventions. The main responsibilities include verifying consent, coordinating the team, and ensuring cleanliness, proper temperature, humidity, and lighting; the safe functioning of equipment; and the availability of supplies and materials. The circulating nurse monitors aseptic practices to avoid breaks in technique while coordinating the movement of related personnel (medical, radiography, and laboratory) as well as implementing fire safety precautions (Phippen & Wells, 2000). The circulating nurse monitors the patient and documents specific activities throughout the operation to ensure the patient's safety and well-being. Nursing activities directly relate to preventing complications and achieving optimal patient outcomes.

## THE SCRUB ROLE

Activities of the **scrub role** include performing a surgical hand scrub; setting up the sterile tables; preparing sutures, ligatures, and special equipment (such as a laparoscope); and assisting the surgeon and the surgical assistants during the procedure by anticipating the instruments that will be required, such as sponges, drains, and other equipment (Phippen & Wells, 2000). As the surgical incision is closed, the scrub person and the circulator count all needles, sponges, and instruments to be sure they are accounted for and not retained as a foreign body in the patient. Tissue specimens obtained during surgery must also be labeled by the scrub person and sent to the laboratory by the circulator.

## THE SURGEON

The surgeon performs the surgical procedure and heads the surgical team. He or she is a licensed physician (MD), osteopath (DO), oral surgeon (DDS or DMD), or podiatrist (DPM) who is specially trained and qualified. Qualifications may include certification by a specialty board, adherence to Joint Commission on Accreditation of Healthcare Organizations (JCAHO) standards, and adherence to hospital standards and admitting practices and procedures (Fortunato, 2000).

## THE REGISTERED NURSE FIRST ASSISTANT

The registered nurse first assistant (RNFA) is another member of the operating room staff. Although the scope of practice of the RNFA depends on each state's nurse practice act, the RNFA practices under the direct supervision of the surgeon. RNFA responsibilities may include handling tissue, providing exposure at the operative field, suturing, and providing hemostasis. The entire process requires a thorough understanding of anatomy and physiology, tissue handling, and the principles of **surgical asepsis**. The competent RNFA needs to be aware of the objectives of the surgery, needs to have the knowledge and ability to anticipate needs and to work as a skilled member of a team, and needs to be able to handle any emergency situation in the operating room (Fortunato, 2000; Rothrock, 1999).

## THE ANESTHESIOLOGIST AND ANESTHETIST

An **anesthesiologist** is a physician specifically trained in the art and science of anesthesiology. An **anesthetist** is a qualified health care professional who administers anesthetics. Most anesthetists are nurses who have graduated from an accredited nurse anesthesia program and have passed examinations sponsored by the American Association of Nurse Anesthetists to become a certified registered nurse anesthetist (CRNA). The anesthesiologist or anesthetist interviews and assesses the patient prior to surgery, selects the anesthesia, administers it, intubates the patient if necessary, manages any technical problems related to the administration of the anesthetic agent, and supervises the patient's condition throughout the surgical procedure. Before the patient enters the operating room, often at preadmission testing, the anesthesiologist or anesthetist visits the patient to provide information and answer questions. The type of anesthetic to be administered, previous reactions to anesthetics, and known anatomic abnormalities that would make airway management difficult are discussed. The anesthesiologist or anesthetist uses the American Society of Anesthesiologists (ASA) Physical Status Classification System to determine the patient's status (Chart 19-2).

When the patient arrives in the operating room, the anesthesiologist or anesthetist reassesses the patient's physical condition immediately prior to initiating anesthesia. The anesthetic is administered, and the patient's airway is maintained either through a laryngeal mask airway (LMA) or an endotracheal tube. During surgery, the anesthesiologist or anesthetist monitors the patient's blood pressure, pulse, and respirations as well as the electrocardiogram (ECG), blood oxygen saturation level, tidal volume, blood gas levels, blood pH, alveolar gas concentrations, and body temperature. Monitoring by electroencephalography is some-

times required. Levels of anesthetics in the body can also be determined; a mass spectrometer can provide instant readouts of critical concentration levels on display terminals. The device also assesses the patient's ability to breathe unassisted and indicates the need for mechanical assistance when ventilation is poor and the patient is not breathing well independently.

## The Surgical Environment

The surgical environment is known for its stark appearance and cool temperature. The surgical suite is behind double doors, and access is limited to authorized personnel. External precautions include adhering to principles of surgical asepsis; strict control of the operating room (OR) environment is required, including traffic pattern restrictions. Policies governing this environment address such issues as the health of the staff; the cleanliness of the rooms; the sterility of equipment and surfaces; processes for scrubbing, gowning, and gloving; and OR attire.

To provide the best possible conditions for surgery, the OR is situated in a location that is central to all supporting services (eg, pathology, radiology, laboratory). The OR has special air filtration devices to screen out contaminating particles, dust, and pollutants. The temperature, humidity, and airflow patterns are controlled (Meeker et al., 1999).

Electrical hazards, emergency exit clearances, and storage of equipment and anesthetic gases are monitored periodically by official entities, such as state agencies and JCAHO. To help decrease microbes, the surgical area is divided into three zones: the **unrestricted zone**, where street clothes are allowed; the **semi-restricted zone**, where attire consists of scrub clothes and caps; and the **restricted zone**, where scrub clothes, shoe covers, caps, and masks are worn. The surgeons and other surgical team members wear additional sterile clothing and protective devices during the operation.

The Association of Perioperative Registered Nurses, formerly known as the Association of Operating Room Nurses (and still abbreviated as AORN), recommends specific practices for those wearing surgical attire to promote a high level of cleanliness in a particular practice setting (AORN, 2002). OR attire includes close-fitting cotton dresses, pantsuits, jumpsuits, and gowns. Knitted cuffs on sleeves and pant legs prevent organisms shed from the perineum, legs, and arms from being released into the immediate surroundings. Shirts and waist drawstrings should be tucked inside the pants to prevent accidental contact with sterile areas and to contain skin shedding. Wet or soiled garments should be changed.

Masks are worn at all times in the restricted zone of the OR. High-filtration masks decrease the risk for postoperative wound infection by containing and filtering microorganisms from the oropharynx and nasopharynx. Masks should fit tightly, should cover the nose and mouth completely, and should not interfere with breathing, speech, or vision. Masks must be adjusted to prevent venting from the sides. Disposable masks have a filtration efficiency exceeding 95%. Masks are changed between patients and should not be worn outside the surgical department. The mask must be either on or off; it must not be allowed to hang around the neck.

Headgear should completely cover the hair (head and neckline, including beard) so that single strands of hair, bobby pins, clips, and particles of dandruff or dust do not fall on the sterile field.

Shoes should be comfortable and supportive. Shoes worn in from the outside must be covered with disposable shoe covers for protection from soiling. Shoe covers are worn one time only and are removed upon leaving the restricted area.

Chart  
19-2

### American Society of Anesthesiologists Physical Status Classification System

Anesthetists and anesthesiologists use the American Society of Anesthesiologists Physical (P) Status Classification System to describe the patient's general status and identify potential risks during surgery. There are five classes of physical status.

- **P 1.** A normally healthy patient  
*Example:* No systemic abnormality, localized infection without fever, benign tumor, hernia
- **P 2.** A patient with mild systemic disease  
*Example:* Well-controlled hypertension, well-controlled diabetes mellitus, chronic bronchitis, obesity, age over 80 yr
- **P 3.** A patient with severe systemic disease that is not incapacitating  
*Example:* Severe disease, compensated heart failure, myocardial infarction more than 6 mo ago, angina pectoris, severe dysrhythmia, cirrhosis, poorly controlled diabetes or hypertension, ileus
- **P 4.** A patient with an incapacitating systemic disease that is a constant threat to life  
*Example:* Severe heart failure, myocardial infarction less than 6 mo ago, severe respiratory failure, advanced liver or renal failure
- **P 5.** A moribund patient who is not expected to survive for 24 hours with or without operation  
*Example:* Unconscious patient with traumatic head injury and agonal cardiac rhythm

Barriers such as scrub attire and masks do not entirely protect the patient from microorganisms. Upper respiratory tract infections, sore throats, and skin infections in staff and patients are sources of pathogens and must be reported.

**NURSING ALERT** Good health is essential for any person in the OR, and any perioperative team member with an infectious disease (eg, an upper respiratory tract infection or infected skin lesion) should not have direct patient contact. Until the infectious process has resolved, the perioperative team member should not work in the OR.

Because artificial fingernails harbor microorganisms and may cause nosocomial infections (Winslow & Jacobson, 2000), a ban on artificial nails by OR personnel is supported by the Centers for Disease Control and Prevention (CDC), AORN, and the Association of Professionals in Infection Control. Short, natural fingernails are encouraged (Winslow & Jacobson, 2000).

## PRINCIPLES OF SURGICAL ASEPSIS

Surgical asepsis prevents the contamination of surgical wounds. The patient's natural skin flora or a previously existing infection may cause postoperative wound infection. Rigorous adherence to the principles of surgical asepsis by OR personnel is the foundation of preventing surgical site infections.

All surgical supplies, any instruments, needles, sutures, dressings, gloves, covers, and solutions that may come in contact with the surgical wound and exposed tissues, must be sterilized before use (Meeker & Rothrock, 1999; Townsend, 2002). Traditionally, the surgeon, surgical assistants, and nurses prepared themselves by scrubbing their hands and arms with antiseptic soap and water, but this traditional practice is being challenged by research investigating the optimal length of time to scrub and the best preparation to use (Larsen et al., 2001). (See Nursing Research Profile 19-1.)

Surgical team members wear long-sleeved sterile gowns and gloves. Head and hair are covered with a cap, and a mask is worn

over the nose and mouth to minimize the possibility that bacteria from the upper respiratory tract will enter the wound. During surgery, the personnel who have scrubbed, gloved, and gowned touch only sterilized objects. Nonscrubbed personnel refrain from touching or contaminating anything sterile.

An area of the patient's skin considerably larger than that requiring exposure during the surgery is meticulously cleansed, and an antimicrobial agent is applied. If hair needs to be removed, it is done immediately prior to the procedure to minimize the risk of wound infection (Townsend, 2002). The remainder of the patient's body is covered with sterile drapes.

## Environmental Controls

In addition to the protocols described previously, surgical asepsis requires meticulous cleaning and maintenance of the OR environment. Floors and horizontal surfaces are cleaned frequently with detergent, soap, and water, or a detergent germicide. Sterilizing equipment is inspected regularly to ensure optimal operation and performance.

All equipment that comes into direct contact with the patient must be sterile (Townsend, 2002). Sterilized linens, drapes, and solutions are used. Instruments are cleaned and sterilized in a unit near the operating room. Individually wrapped sterile items are used when additional individual items are needed.

Airborne bacteria are a concern. To decrease the amount of bacteria in the air, standard OR ventilation provides 15 air exchanges per hour (Meeker & Rothrock, 1999). Staff members shed skin scales, resulting in about 1,000 bacteria-carrying particles (or colony-forming units [CFUs]) per cubic foot per minute. With the standard air exchanges, air counts of bacteria are reduced to 50 to 150 CFUs per cubic foot per minute. The number of personnel and unnecessary physical movements may be restricted to minimize bacteria in the air and achieve an OR infection rate no greater than 3% to 5% in clean, infection-prone surgery.

### NURSING RESEARCH PROFILE 19-1

#### New Techniques for Surgical Hand Preparation

Larsen, E., Aiello, A., Heilman, J., Lyle, C., Cronquist, A., Stahl, J., & Dello-Latta, P. (2001). Comparison of different regimens for surgical hand preparation. *AORN Journal*, 73(2), 412-432.

#### Purpose

Staff members traditionally perform a lengthy regimen of scrubbing with an antiseptic agent before surgery, mostly due to concerns about reducing the risk for infection. The purpose of this study was to compare the traditional scrubbing technique in the operating room to a waterless hand preparation in terms of antimicrobial effectiveness, effect on skin condition, and time requirements.

#### Study Sample and Design

This was a 6-week, single-center, prospective clinical trial. Twenty surgical staff members used the waterless hand preparation for 3 weeks, had a 1-week hiatus, then used the traditional surgical scrub for 3 consecutive weeks. A reference group of five subjects was also included in the study, which was conducted at a 2,000-bed medical center in three operating suites. The participants were full-time surgical staff members who performed an average of at least 10 scrubs per week and ranged in age from 18 to 65 years of age. The three tools used to measure skin condition consisted of the visual scoring of skin, erythema grading scale, and the hand skin assessment. A total

of 13 microbial skin counts were taken of each subject's hands during the study.

#### Findings

The waterless hand preparation was associated with less skin damage and lower microbial skin counts on days 5 and 19 compared to the traditional scrub. The researchers suggest that a lengthy scrub, as well as the use of a brush or sponge, appears to be counterproductive, causing skin damage and increased skin shedding. The waterless hand preparation protocol had shorter contact time (mean 80.7 seconds) compared to the traditional protocol (mean 145 seconds) and was preferred by the participants. They reported that it was easier, faster, milder on the hands, and conducive to donning gloves.

#### Nursing Implications

The waterless hand preparation performed better compared to the traditional surgical scrub, but nurses should keep in mind that this was a small study. The results of this study warrant evaluation of this new technique in a larger clinical trial before consideration for widespread implementation.

Some ORs have laminar airflow units. These units provide 400 to 500 air exchanges per hour. When used appropriately, laminar airflow units result in less than 10 CFUs per cubic foot per minute during surgery. The goal for a laminar flow-equipped OR is an infection rate under 1%. An OR equipped with this unit is frequently used for total joint replacement or organ transplant surgery.

Despite all these precautions, wound contamination may occur during surgery but may only become apparent days or weeks later in the form of an incisional infection or abscess. Constant surveillance and conscientious technique in carrying out aseptic practices is necessary to reduce the risk for contamination and infection.

## Basic Guidelines for Maintaining Surgical Asepsis

All practitioners involved in the intraoperative phase have a responsibility to provide and maintain a safe environment. Adherence to aseptic practice is part of this responsibility. The eight basic principles of aseptic technique follow:

- All materials in contact with the surgical wound and used within the sterile field must be sterile. Sterile surfaces or articles may touch other sterile surfaces or articles and remain sterile; contact with unsterile objects at any point renders a sterile area contaminated.
- Gowns of the surgical team are considered sterile in front from the chest to the level of the sterile field. The sleeves are also considered sterile from 2 inches above the elbow to the stockinette cuff.
- Sterile drapes are used to create a sterile field. Only the top surface of a draped table is considered sterile. During draping of a table or patient, the sterile drape is held well above the surface to be covered and is positioned from front to back.
- Items should be dispensed to a sterile field by methods that preserve the sterility of the items and the integrity of the sterile field. After a sterile package is opened, the edges are considered unsterile. Sterile supplies, including solutions, are delivered to a sterile field or handed to a scrubbed person in such a way that the sterility of the object or fluid remains intact.
- The movements of the surgical team are from sterile to sterile areas and from unsterile to unsterile areas. Scrubbed persons and sterile items contact only sterile areas; circulating nurses and unsterile items contact only unsterile areas.
- Movement around a sterile field must not cause contamination of the field. Sterile areas must be kept in view during movement around the area. At least a 1-foot distance from the sterile field must be maintained to prevent inadvertent contamination.
- Whenever a sterile barrier is breached, the area must be considered contaminated. A tear or puncture of the drape permitting access to an unsterile surface underneath renders the area unsterile. Such a drape must be replaced.
- Every sterile field should be constantly monitored and maintained. Items of doubtful sterility are considered unsterile. Sterile fields should be prepared as close as possible to the time of use.

## HEALTH HAZARDS ASSOCIATED WITH THE SURGICAL ENVIRONMENT

Safety issues in the OR include exposure to blood and body fluids, hazards associated with laser beams, and exposure to latex, radiation, and toxic agents. Internal monitoring of the OR includes

the analysis of surface swipe samples and air samples for infectious and toxic agents. In addition, policies and procedures for minimizing exposure to body fluids and reducing the dangers associated with lasers and radiation have been established.

## Laser Risks

The AORN has recommended practices for laser safety (AORN, 2002). While lasers are in use, warning signs should be clearly posted to alert personnel. Among the safety issues are the following: reducing the possibility of exposing the eyes and skin to laser beams, preventing inhalation of the laser plume (smoke and particulate matter), and protecting the patient and personnel from fire and electrical hazards. Because several types of lasers are available for clinical use, perioperative personnel should be familiar with the unique features, specific operation, and safety measures for each type of laser used in the practice setting (Townsend, 2002).

Nurses and other intraoperative personnel working with lasers must have a thorough eye examination before participating in procedures involving lasers. Special protective goggles, specific to the type of laser used in the procedure, are worn. There is controversy about the protection needed to avoid the laser plume and effects of its inhalation. Smoke evacuators are used in some procedures to remove the laser plume from the operative field. In recent years this technology has been applied to protect the surgical team from the hazards associated with the generalized smoke plume generated by standard electrocautery units.

## Exposure to Blood and Body Fluids

Since the advent of the acquired immunodeficiency syndrome (AIDS) epidemic, OR attire has changed dramatically. Double gloving is routine, at least in trauma surgery where sharp bone fragments are present. In addition to the routine scrub suit and double gloves, some surgeons wear rubber boots, a waterproof apron, and sleeve protectors. Goggles, or a wrap-around face shield, are worn to protect against splashing when the surgical wound is irrigated or when bone drilling is performed. In hospitals where numerous total joint procedures are performed, a full bubble mask may be used. This mask provides full barrier protection from bone fragments and splashes. Safe ventilation is accomplished through an accompanying hood with a separate air-filtration system.

## Latex Allergy

Both the AORN and the American Society of Perianesthesia Nurses (ASPAN) have recommended standards of care for the patient with latex allergy (AORN, 2002; ASPAN, 2000). These recommendations include early identification of the patient with a latex allergy, preparation of a latex allergy supply cart, and maintenance of latex allergy precautions throughout the perioperative period. Due to the increased number of patients with latex allergies, many latex-free products are now available. For safety, manufacturers and hospital material managers need to take responsibility for identifying the latex content in items used by patients and health care personnel. (see Chaps. 18 and 53 for assessment for latex allergy).

**NURSING ALERT** It is the responsibility of all nurses, and particularly perianesthesia and perioperative nurses, to be aware of latex allergies, necessary precautions, and products that are latex-free (Meeker & Rothrock, 1999). Hospital staff are also at risk for developing a latex allergy secondary to repeated exposure to latex products.

## The Surgical Experience

During the surgical procedure, the patient will need sedation, anesthesia, or a combination of these.

### SEDATION AND ANESTHESIA

Sedation and anesthesia have four levels: minimal sedation, moderate sedation, deep sedation, and anesthesia. Standards of care for each level have been set by JCAHO. A surgical procedure may also be performed using anesthetic agents that suspend sensation in parts of the body (local, regional, epidural, or spinal anesthesia).

For the patient, the anesthesia experience consists of having an intravenous line inserted, if it was not inserted earlier; receiving a sedating agent prior to induction with an anesthetic agent; losing consciousness; being intubated, if indicated; and then receiving a combination of anesthetic agents. Typically the experience is a smooth one and the patient has no recall of the events.

#### Minimal Sedation

The minimal sedation level is a drug-induced state during which the patient can respond normally to verbal commands. Cognitive function and coordination may be impaired, but ventilatory and cardiovascular functions are not affected (JCAHO, 2001; Patterson, 2000a, b).

#### Moderate Sedation

**Moderate sedation** is a form of anesthesia that may be produced intravenously. It is defined as a depressed level of consciousness that does not impair the patient's ability to maintain a patent airway and to respond appropriately to physical stimulation and verbal command. Its goal is a calm, tranquil, amnesic patient who, when sedation is combined with analgesic agents, is relatively pain-free during the procedure but able to maintain protective reflexes (JCAHO, 2001; Patterson, 2000a, b). Sedation can be administered by an anesthesiologist, anesthesiologist, other physician, or nurse. When administered by an anesthesiologist or anesthesiologist, moderate sedation is referred to as monitored anesthesia care. The medications permitted for use in moderate sedation vary with the credentials of the person administering the sedative. In addition, state departments of health are very specific about who may administer moderate sedation and about the training required for those individuals. These regulations vary greatly from state to state.

Midazolam (Versed) or diazepam (Valium) is used frequently for intravenous sedation. In some states, the physician must administer the first dose; a nurse with special training can administer subsequent doses. Other medications used include analgesic agents (eg, morphine, fentanyl) and reversal agonists, such as naloxone (Narcan). A nurse who is knowledgeable and skilled in detecting dysrhythmias, administering oxygen, and performing resuscitation must continuously monitor the patient who receives sedation. The patient receiving this form of anesthesia is never left alone and is closely monitored for respiratory, cardiovascular, and central nervous system depression using such methods as pulse oximetry, ECG, and frequent measurement of vital signs (Patterson, 2000a, b). The level of sedation is monitored by the patient's ability to maintain a patent airway and to respond to verbal commands.

Moderate sedation may be used alone or in combination with local, regional, or spinal anesthesia. Its use is increasing as more surgical procedures and diagnostic studies are performed in am-

bulatory and same-day settings with the expectation that the patient will be discharged home a few hours after the procedure.

### Deep Sedation

Deep sedation is a drug-induced state during which a patient cannot be easily aroused but can respond purposefully after repeated stimulation (JCAHO, 2001). The difference between deep sedation and anesthesia is that the anesthetized patient is not arousable. Deep sedation and anesthesia are achieved when an anesthetic agent is inhaled or administered intravenously. Inhaled anesthetic agents include volatile liquid agents and gases (Aranda & Hanson, 2000; Townsend, 2002). Volatile liquid anesthetics produce anesthesia when their vapors are inhaled. Included in this group are halothane (Fluothane), enflurane (Ethrane), isoflurane (Forane), sevoflurane (Ultrane), and desflurane (Suprane). All are administered with oxygen, and usually with nitrous oxide as well.

Gas anesthetics are administered by inhalation and are always combined with oxygen. Nitrous oxide is the most commonly used gas anesthetic. When inhaled, the anesthetics enter the blood through the pulmonary capillaries and act on cerebral centers to produce loss of consciousness and sensation. When anesthetic administration is discontinued, the vapor or gas is eliminated through the lungs. Table 19-1 lists the advantages, disadvantages, and implications of the different volatile liquid and gas anesthetics.

### Anesthesia

General anesthesia consists of four stages, each associated with specific clinical manifestations. When opioid agents (narcotics) and neuromuscular blockers (relaxants) are administered, several of the stages are absent. The anesthesia level consists of general anesthesia and spinal or major regional anesthesia but does not include local anesthesia (JCAHO, 2001). **Anesthesia** is a state of narcosis (severe central nervous system depression produced by pharmacologic agents), analgesia, relaxation, and reflex loss. Patients under general anesthesia are not arousable, even to painful stimuli. They lose the ability to maintain ventilatory function and require assistance in maintaining a patent airway. Cardiovascular function may be impaired as well (JCAHO, 2001).

#### STAGE I: BEGINNING ANESTHESIA

As the patient breathes in the anesthetic mixture, warmth, dizziness, and a feeling of detachment may be experienced. The patient may have a ringing, roaring, or buzzing in the ears and, though still conscious, may sense an inability to move the extremities easily. During this stage, noises are exaggerated; even low voices or minor sounds seem loud and unreal. For this reason, the nurse avoids making unnecessary noises or motions when anesthesia begins.

#### STAGE II: EXCITEMENT

The excitement stage, characterized variously by struggling, shouting, talking, singing, laughing, or crying, is often avoided if the anesthetic is administered smoothly and quickly. The pupils dilate, but contract if exposed to light; the pulse rate is rapid, and respirations may be irregular.

Because of the possibility of uncontrolled movements of the patient during this stage, the anesthesiologist or anesthesiologist must always be assisted by someone ready to help restrain the patient. A strap may be in place across the patient's thighs, and the hands may be secured to an armboard. The patient should not be touched except for purposes of restraint, but restraints should not be applied over the operative site. Manipulation increases circulation to the operative site and thereby increases the potential for bleeding.

Table 19-1 • Inhalation Anesthetic Agents

AGENT	ADMINISTRATION	ADVANTAGES	DISADVANTAGES	IMPLICATIONS/ CONSIDERATIONS
<b>Volatile Liquids</b>				
halothane (Fluothane)	Inhalation; special vaporizer	Not explosive or flammable Induction rapid and smooth Useful in almost every type of surgery Low incidence of postoperative nausea and vomiting	Requires skillful administration to prevent overdose May cause liver damage May produce hypotension Requires special vaporizer for administration	In addition to observation of pulse and respiration postoperatively, blood pressure must be monitored frequently.
methoxyflurane (Penthrane)	Inhalation; special vaporizer	Nonflammable Seldom causes postoperative nausea and vomiting Analgesic action continues several hours after surgery Excellent muscle relaxation	Requires skillful administration Renal damage may occur. Unpleasant odor	Prolonged postoperative depressant action calls for careful observation by PACU personnel.
enflurane (Ethrane)	Inhalation	Rapid induction and recovery Potent analgesic Not explosive or flammable	Respiratory depression may develop rapidly, along with ECG abnormalities. Not compatible with epinephrine	Observe for possible respiratory depression. Administration with epinephrine may cause ventricular fibrillation.
isoflurane (Forane)	Inhalation	Rapid induction and recovery Muscle relaxants are markedly potentiated.	A profound respiratory depressant	Respirations must be monitored closely and supported when necessary.
sevoflurane (Ultran)	Inhalation	Rapid induction and excretion; minimal side effects	Coughing and laryngospasm; trigger for malignant hyperthermia	Monitor for malignant hyperthermia.
desflurane (Suprane)	Inhalation	Rapid induction and emergence; rare organ toxicity	Respiratory irritation; trigger for malignant hyperthermia	Monitor for malignant hyperthermia, dysrhythmias.
<b>Gases</b>				
nitrous oxide (N <sub>2</sub> O)	Inhalation (semiclosed method)	Induction and recovery rapid Nonflammable Useful with oxygen for short procedures Useful with other agents for all types of surgery	Poor relaxant Weak anesthetic May produce hypoxia	Most useful in conjunction with other agents with longer action Monitor for chest pain, hypertension, and stroke.

### STAGE III: SURGICAL ANESTHESIA

Surgical anesthesia is reached by continued administration of the anesthetic vapor or gas. The patient is unconscious and lies quietly on the table. The pupils are small but contract when exposed to light. Respirations are regular, the pulse rate and volume are normal, and the skin is pink or slightly flushed. With proper administration of the anesthetic, this stage may be maintained for hours in one of several planes, ranging from light (1) to deep (4), depending on the depth of anesthesia needed.

### STAGE IV: MEDULLARY DEPRESSION

This stage is reached when too much anesthesia has been administered. Respirations become shallow, the pulse is weak and thready, and the pupils become widely dilated and no longer contract when exposed to light. Cyanosis develops and, without prompt intervention, death rapidly follows. If this stage develops, the anesthetic is discontinued immediately and respiratory and circulatory support is initiated to prevent death. Stimulants,

although rarely used, may be administered; narcotic antagonists can be used if overdose is due to opioids.

During smooth administration of an anesthetic, there is no sharp division between the first three stages, and there is no stage IV. The patient passes gradually from one stage to another, and it is only by close observation of the signs exhibited by the patient that an anesthesiologist or anesthetist can control the situation. The responses of the pupils, the blood pressure, and the respiratory and cardiac rates are probably the most reliable guides to the patient's condition.

## METHODS OF ANESTHESIA ADMINISTRATION

Anesthetics produce anesthesia because they are delivered to the brain at a high partial pressure that enables them to cross the blood–brain barrier. Relatively large amounts of anesthetic must be administered during induction and the early maintenance

phases because the anesthetic is recirculated and deposited in body tissues. As these sites become saturated, smaller amounts of the anesthetic agent are required to maintain anesthesia because equilibrium or near equilibrium has been achieved between brain, blood, and other tissues.

Anything that diminishes peripheral blood flow, such as vasoconstriction or shock, may reduce the amount of anesthetic required. Conversely, when peripheral blood flow is unusually high, as in the muscularly active or the apprehensive patient, induction is slower and greater quantities of anesthetic are required because the brain receives a smaller quantity of anesthetic.

## Inhalation

Liquid anesthetics may be administered by mixing the vapors with oxygen or nitrous oxide–oxygen and then having the patient inhale the mixture (Townsend, 2002). The vapor is administered to the patient through a tube or a mask. The inhalation anesthetic may also be administered through a laryngeal mask (Fig. 19-1), a flexible tube with an inflatable silicone ring and cuff that can be inserted into the larynx (Fortunato, 2000). The endotracheal technique for administering anesthetics consists of introducing a soft rubber or plastic endotracheal tube into the trachea, usually by means of a laryngoscope. The endotracheal tube may be inserted through either the nose or mouth. When in place, the tube seals off the lungs from the esophagus so that if the patient vomits, stomach contents do not enter the lungs.

## Intravenous

General anesthesia can also be produced by the intravenous injection of various substances, such as barbiturates, benzodiazepines, nonbarbiturate hypnotics, dissociative agents, and opioid agents (Aranda & Hanson, 2000; Townsend, 2002). These medications may be administered for induction (initiation) or maintenance of anesthesia. They are often used along with inhalation anesthetics but may be used alone. They can also be used to produce moderate sedation. Intravenous anesthetics are presented in Table 19-2.

An advantage of intravenous anesthesia is that the onset of anesthesia is pleasant; there is none of the buzzing, roaring, or dizziness known to follow administration of an inhalation anes-

thetic. For this reason, induction of anesthesia usually begins with an intravenous agent and is often preferred by patients who have experienced various methods. The duration of action is brief, and the patient awakens with little nausea or vomiting. Thiopental is usually the agent of choice, and it is often administered with other anesthetic agents in prolonged procedures.

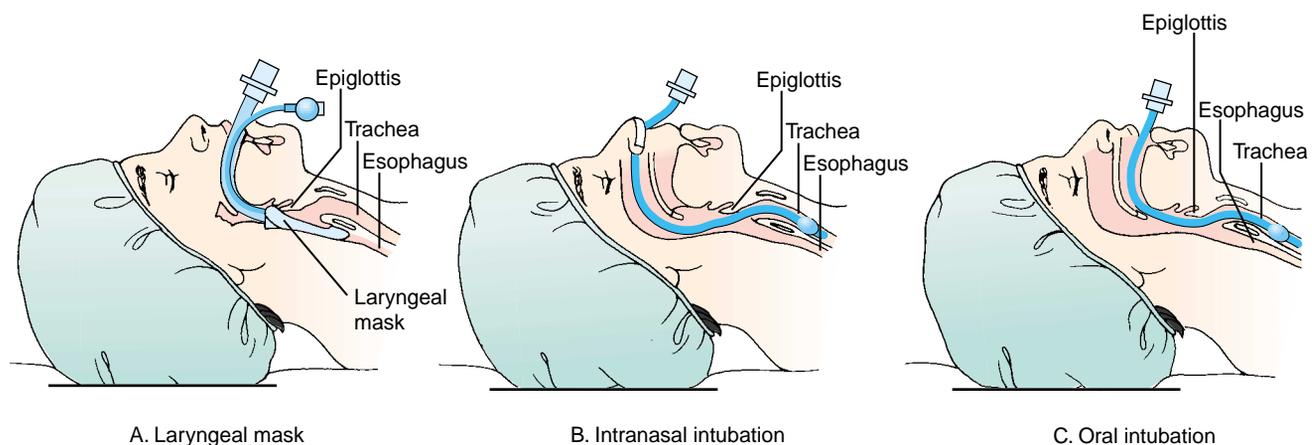

Intravenous anesthetic agents are nonexplosive, they require little equipment, and they are easy to administer. The low incidence of postoperative nausea and vomiting makes the method useful in eye surgery because vomiting would increase intraocular pressure and endanger vision in the operated eye. Intravenous anesthesia is useful for short procedures but is used less often for the longer procedures of abdominal surgery. It is not indicated for children, who have small veins and require intubation because of their susceptibility to respiratory obstruction.

A disadvantage of an intravenous anesthetic such as thiopental is its powerful respiratory depressant effect. It must be administered by a skilled anesthesiologist or anesthetist and only when some method of oxygen administration is available immediately in case of difficulty. Sneezing, coughing, and laryngospasm are sometimes noted with its use.

Intravenous neuromuscular blockers (muscle relaxants) block the transmission of nerve impulses at the neuromuscular junction of skeletal muscles. Muscle relaxants are used to relax muscles in abdominal and thoracic surgery, relax eye muscles in certain types of eye surgery, facilitate endotracheal intubation, treat laryngospasm, and assist in mechanical ventilation.

Purified curare was the first widely used muscle relaxant; tubocurarine was isolated as the active ingredient. Succinylcholine was later introduced because it acts more rapidly than curare. Several other agents are also used (Table 19-3). The ideal muscle relaxant has the following characteristics:

- It is nondepolarizing (noncompetitive agent), with an onset and duration of action similar to succinylcholine but without its problems of bradycardia and cardiac dysrhythmias (Townsend, 2002).
- It has a duration of action between those of succinylcholine and pancuronium.
- It lacks cumulative and cardiovascular effects.
- It can be metabolized and does not depend on the kidneys for its elimination.

**FIGURE 19-1** Anesthetic delivery methods: (A) laryngeal mask, (B) nasal endotracheal catheter (in position), and (C) oral endotracheal intubation (tube is in position with cuff inflated).

Table 19-2 • Intravenous Anesthetic Agents

AGENT	ADMINISTRATION	ADVANTAGES	DISADVANTAGES	IMPLICATIONS/CONSIDERATIONS
<b>Tranquilizers and Sedative-Hypnotics</b>				
<i>Benzodiazepines</i>				
midazolam (Versed)	IV	Short acting; has antianxiety, sedative, amnesic, muscle relaxant effects	Increased sensitivity to its effects in chronic obstructive pulmonary disease patients	Monitor respiratory status closely.
diazepam (Valium)	IV Orally	Preoperative sedation Intraoperative tranquilization during regional anesthesia	Absorbed unpredictably when given IM	IV administration may produce thrombophlebitis (central vein is therefore preferred).
chlordiazepoxide (Librium)	IM	Production of hypnosis during anesthetic induction		
droperidol (Inapsine)	IM	Long duration of action	Weak antihistaminic action and $\alpha$ -adrenergic blocking action; inhibition of basic ganglionic dopaminergic pathways may lead to extrapyramidal rigidity resembling parkinsonism	Major tranquilizer Keep IV fluids and vasopressors available to treat hypotension.
lorazepam (Ativan)	IV	Long duration of action	Used with caution in patients with renal and liver impairment	Monitor laboratory values.
<b>Opioids</b>				
morphine (high doses)	IV	Not a myocardial depressant	Can depress arterial blood pressure by decreasing systemic vascular resistance Does not provide good amnesia Does not promote adequate muscular relaxation	Orthostatic hypotension may occur.
meperidine hydrochloride (Demerol)	IV Subcutaneously IM	Prompt onset Because of spasmolytic effect, it is drug of choice for surgery of bile duct, distal colon, and rectum; easily detoxified and excreted	May slow rate of respirations Adverse reactions: dizziness, nausea, and vomiting	In some patients, histamine may be released; treatment is diphenhydramine (Benadryl).
<b>Neuroleptanalgesics</b>				
The term <i>neuroleptanalgesic</i> refers to the combination of a short-acting synthetic opioid agent (fentanyl) and a butyrophenone (droperidol). Patient becomes very drowsy; responds to voice command, although analgesia is profound. Of significance, the combination produces peripheral vasodilation followed by a decrease in arterial blood pressure. If administered rapidly, it may cause skeletal muscular rigidity and possibly respiratory impairment. These agents are also called narcotic agonist analgesics.				
fentanyl (Sublimaze)	IV Transdermally	75–100 times more potent than morphine and about 25% of duration of morphine (IV) Little effect on cardiovascular system	In very high dosage, an $\alpha$ -adrenergic blocking effect Respiratory depression	Short duration of action is due to its more rapid redistribution and more active metabolism by liver than other opioids.
sufentanil (Sufenta)	Injection	Onset extremely rapid		Duration is only about one third that of fentanyl.
<b>Dissociative Agents</b>				
When under dissociative analgesia, the patient appears not to be asleep or anesthetized, but rather dissociated from the surroundings.				
ketamine (Ketalar; Ketaject)	IV IM	Rapid induction and short action; often used to supplement nitrous oxide Useful when hypotension may be hazardous; can be administered as analgesic or anesthetic	May cause elevated blood pressure and depressed respirations Patient may experience hallucinations. Vomiting and aspiration may occur.	Avoid verbal, visual, or tactile stimulation because this may trigger psychic aberration. Droperidol or diazepam (see below) may eliminate such psychic phenomena. Observe for signs of respiratory depression. Keep resuscitation equipment nearby.

(continued)

Table 19-2 • Intravenous Anesthetic Agents (Continued)

AGENT	ADMINISTRATION	ADVANTAGES	DISADVANTAGES	IMPLICATIONS/CONSIDERATIONS
<b>Barbiturates</b>				
thiopental sodium (Pentothal)	IV injection (or rectal)	Rapid induction Nonexplosive Requires little equipment Low incidence of post-operative nausea and vomiting	Powerful depressant of breathing Poor relaxant May produce coughing, sneezing, and laryngospasm Not useful for children because of small veins	Requires close observation because of potency and rapidity of drug action
methohexital sodium (Brevital)	IV	Rapid onset	Respiratory depression, involuntary muscle movement, seizures; may cause necrosis if IV infiltrates	Monitor respiratory status closely, monitor for seizure activity, ensure IV in vein.
<b>Nonbarbiturate Hypnotics</b>				
etomidate (Amidate)	IV	Few cardiovascular and respiratory effects; useful for frail patients	Transient adrenal suppression; involuntary muscle movements	
propofol (Diprivan)	IV	Rapid induction with minimal excitatory effects; may have antiemetic effect	Myocardial depression; hypotension; pain on injection	Monitor cardiac function and blood pressure closely; contraindicated in patients with allergy to eggs and soybean oil.

## Regional Anesthesia

Regional anesthesia is a form of local anesthesia in which an anesthetic agent is injected around nerves so that the area supplied by these nerves is anesthetized. The effect depends on the type of nerve involved. Motor fibers are the largest fibers and have the thickest myelin sheath. Sympathetic fibers are the smallest and have a minimal covering. Sensory fibers are intermediate. Thus, a local anesthetic blocks motor nerves least readily and sympathetic nerves most readily. An anesthetic cannot be regarded as having worn off until all three systems (motor, sensory, and autonomic) are no longer affected.

The patient receiving spinal or local anesthesia is awake and aware of his or her surroundings unless medications are given to produce mild sedation or to relieve anxiety. The nurse must avoid careless conversation, unnecessary noise, and unpleasant odors; these may be noticed by the patient in the OR and may contribute to a negative view of the surgical experience. A quiet environment is therapeutic. The diagnosis must not be stated aloud if the patient is not to know it at this time.

## Conduction Blocks and Spinal Anesthesia

There are many types of conduction blocks, depending on the nerve groups affected by the injection. Epidural anesthesia is achieved by injecting a local anesthetic into the spinal canal in the space surrounding the dura mater (Fig. 19-2). Epidural anesthesia also blocks sensory, motor, and autonomic functions, but it is differentiated from spinal anesthesia by the injection site and the amount of anesthetic used. Epidural doses are much higher because the epidural anesthetic does not make direct contact with the cord or nerve roots.

An advantage of epidural anesthesia is the absence of headache that occasionally results from subarachnoid injection. A dis-

advantage is the greater technical challenge of introducing the anesthetic into the epidural rather than the subarachnoid space. If inadvertent subarachnoid injection occurs during epidural anesthesia and the anesthetic travels toward the head, high spinal anesthesia can result; this can produce severe hypotension and respiratory depression and arrest. Treatment of these complications includes airway support, intravenous fluids, and use of vasopressors. Other types of nerve blocks include:

- Brachial plexus block, which produces anesthesia of the arm
- Paravertebral anesthesia, which produces anesthesia of the nerves supplying the chest, abdominal wall, and extremities
- Transsacral (caudal) block, which produces anesthesia of the perineum and, occasionally, the lower abdomen

Spinal anesthesia is a type of extensive conduction nerve block that is produced when a local anesthetic is introduced into the subarachnoid space at the lumbar level, usually between L4 and L5 (see Fig. 19-2). It produces anesthesia of the lower extremities, perineum, and lower abdomen. For the lumbar puncture procedure, the patient usually lies on the side in a knee–chest position. Sterile technique is used as a spinal puncture is made and the medication is injected through the needle. As soon as the injection has been made, the patient is positioned on his or her back. If a relatively high level of block is sought, the head and shoulders are lowered.

The spread of the anesthetic agent and the level of anesthesia depend on the amount of fluid injected, the speed with which it is injected, the positioning of the patient after the injection, and the specific gravity of the agent. If the specific gravity is greater than that of cerebrospinal fluid (CSF), the agent moves to the dependent position of the subarachnoid space. If the specific gravity is less than that of CSF, the anesthetic moves away from the dependent position. The anesthesiologist or anesthetist controls the spread of the agent. Generally, the agents used are procaine,

Table 19-3 • Neuromuscular Blocking Agents

MUSCLE RELAXANT	ACTION	ADVANTAGES	DISADVANTAGES	USES AND COMMENTS
<b>Nondepolarizing Neuromuscular Blocking Agents</b>				
tubocurarine chloride (Tubarine)	Peaks at 30–60 min	50%–70% excreted unchanged in 3–6 h	Histamine-like reaction Hypotension Increased airway resistance Skin erythema	Contraindicated with history of allergy, asthma
gallamine (Flaxedil)	20% as potent as curare Lasts 25% shorter time than curare Blocks vagal ganglia in heart	All excreted unchanged	Tachycardia	Used with cyclopropane or halothane
pancuronium bromide (Pavulon)	Similar to curare but 5 times more potent Duration: 60–85 min	Safe; stable Good muscle relaxant Reversible by neostigmine and atropine		Excellent for situations requiring complete relaxation Avoid with myasthenia gravis or renal disease. Avoid with patients sensitive to bromide.
vecuronium bromide (Norcuron)	Blocks depolarization	Facilitates endotracheal intubation; good muscle relaxant	Prolonged dose-related apnea	Related to Pavulon Well tolerated in patients with renal failure
<b>Depolarizing Neuromuscular Blocking Agents</b>				
These mimic the action of acetylcholine at the neuromuscular junction. Acetylcholine is discharged almost immediately on release, then repolarization of muscle takes place. When depolarizing neuromuscular blocking agents are used, skeletal muscle depolarizes.				
succinylcholine (Anectine; Sucostrin)	Onset is rapid: 1 min Duration: 4–8 min	Ideal for endotracheal intubation, fracture reduction; treatment of laryngospasm	Contraindicated in patients with low pseudocholinesterase On second IV injection, bradycardia and various dysrhythmias May cause fasciculations of the muscles and pain	Used to treat laryngospasm, status asthmaticus, and toxic reactions to local anesthetic drugs
decamethonium bromide (Sincurine)	Onset: 30–40 sec Duration: 15–20 min	Excreted unchanged by kidney	Some fasciculation of muscle: jaw masseter muscles; posterior calf muscles Difficult to reverse its action	Produces depolarization of end-plate region

tetracaine (Pontocaine), lidocaine (Xylocaine), and bupivacaine (Marcaine) (Table 19-4).

A few minutes after induction of a spinal anesthetic, anesthesia and paralysis affect the toes and perineum and then gradually the legs and abdomen. If the anesthetic reaches the upper thoracic and cervical spinal cord in high concentrations, a temporary partial or complete respiratory paralysis results. Paralysis of the respiratory muscles is managed by mechanical ventilation until the effects of the anesthetic on the respiratory nerves have worn off.

Nausea, vomiting, and pain may occur during surgery when spinal anesthesia is used. As a rule, these reactions result from manipulation of various structures, particularly those within the abdominal cavity. The simultaneous intravenous administration of a weak solution of thiopental and inhalation of nitrous oxide may prevent such reactions.

Headache may be an after-effect of spinal anesthesia. Several factors are involved in the incidence of headache: the size of the spinal needle used, the leakage of fluid from the subarachnoid space through the puncture site, and the patient's hydration status. Measures that increase cerebrospinal pressure are helpful in

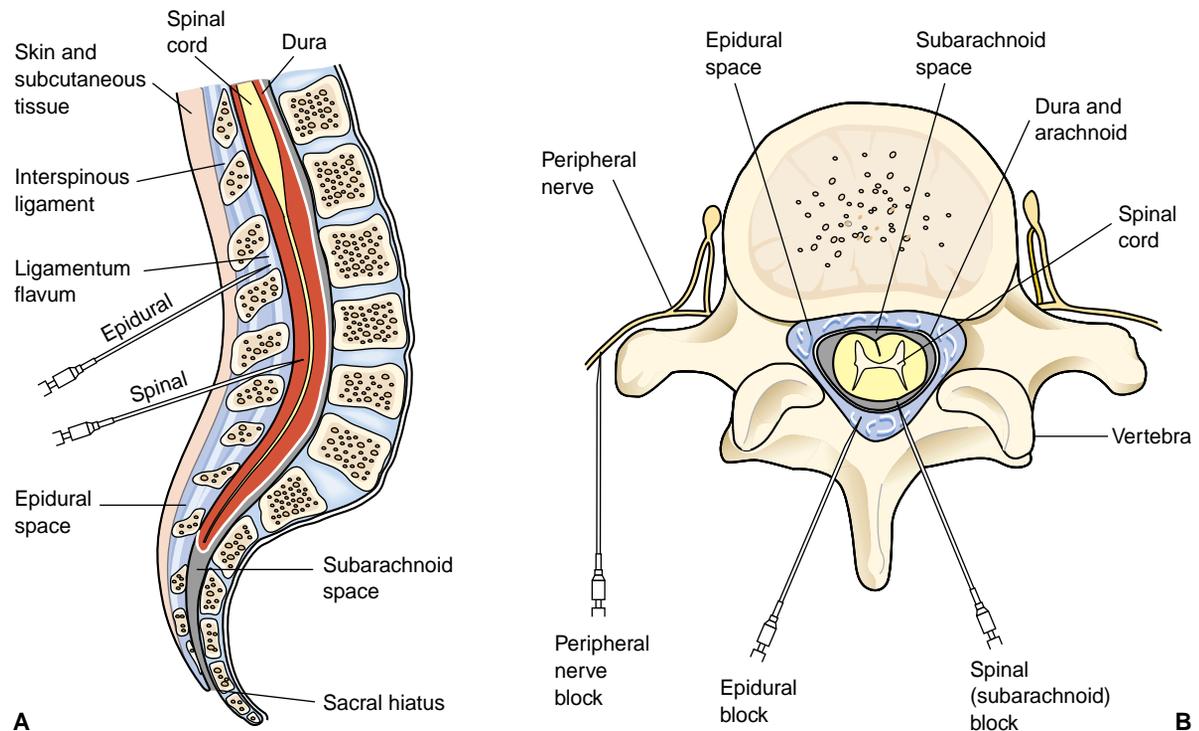

relieving headache. These include keeping the patient lying flat, quiet, and well hydrated.

In continuous spinal anesthesia, the tip of a plastic catheter remains in the subarachnoid space during the surgical procedure so that more anesthetics may be injected as needed. This technique allows greater control of the dosage, but there is greater potential for postanesthetic headache because of the large-gauge needle used.

### Local Infiltration Anesthesia

Infiltration anesthesia is the injection of a solution containing the local anesthetic into the tissues at the planned incision site. Often it is combined with a local regional block by injecting the nerves immediately supplying the area. The advantages of local anesthesia are as follows:

- It is simple, economical, and nonexplosive.
- Equipment needed is minimal.
- Postoperative recovery is brief.
- Undesirable effects of general anesthesia are avoided.
- It is ideal for short and superficial surgical procedures.

**FIGURE 19-2** (A) Injection sites for spinal and epidural anesthesia. (B) Cross-section of injection sites for peripheral nerve, epidural, and spinal blocks.

Local anesthesia is often administered in combination with epinephrine. Epinephrine constricts blood vessels, which prevents rapid absorption of the anesthetic agent and thus prolongs its local action. Rapid absorption of the anesthetic agent into the bloodstream, which could cause seizures, is also prevented. Types of local anesthetic agents are listed in Table 19-5.

Local anesthesia is the anesthesia of choice in any surgical procedure in which it can be used. However, contraindications include high preoperative levels of anxiety, because surgery with local anesthesia may increase anxiety. A patient who requests general anesthesia rarely does well under local anesthesia. For some surgical procedures, local anesthesia is impractical because of the number of injections and the amount of anesthetic that would be required (breast reconstruction, for example).

The skin is prepared as for any surgical procedure, and a small-gauge needle is used to inject a modest amount of the anesthetic into the skin layers. This produces blanching or a wheal. Additional anesthetic is then injected in the skin until an area the length of the proposed incision is anesthetized. A larger, longer needle then is used to infiltrate deeper tissues with the anesthetic.

The action of the agent is almost immediate, so surgery may begin as soon as the injection is complete. Anesthesia lasts 45 minutes to 3 hours, depending on the anesthetic and the use of epinephrine.

## Potential Intraoperative Complications

The surgical patient is subject to several risks. Potential intraoperative complications include nausea and vomiting, anaphylaxis, hypoxia, hypothermia, malignant hyperthermia, and disseminated intravascular coagulopathy.

## NAUSEA AND VOMITING

Nausea and vomiting, or regurgitation, may affect patients during the intraoperative period. If gagging occurs, the patient is turned to the side, the head of the table is lowered, and a basin is provided to collect the vomitus. Suction is used to remove saliva and vomited gastric contents. There is no single way to prevent

**Table 19-4 • Regional Anesthetic Agents**

AGENT	ADVANTAGES OF SPINAL ANESTHESIA (INCLUDES ALL AGENTS)	DISADVANTAGES OF SPINAL ANESTHESIA (INCLUDES ALL AGENTS)
procaine (Novocaine) tetracaine (Pontocaine) lidocaine (Xylocaine) bupivacaine (Marcaine)	Easily administered by a physician Inexpensive Minimum of equipment required Rapid onset Excellent muscular relaxation	Blood pressure may fall rapidly unless monitored carefully and treated with medications such as ephedrine. If the spinal anesthesia ascends to the chest, there may be respiratory distress. Occasionally, postoperative complications occur, such as headache or, rarely, meningitis or paralysis.

Table 19-5 • Local Anesthetic Agents

AGENT	ADMINISTRATION	ADVANTAGES	DISADVANTAGES	IMPLICATIONS/ CONSIDERATIONS
lidocaine (Xylocaine) and mepivacaine (Carbocaine)	Topical or injection	Rapid Longer duration of action (compared with procaine) Free from local irritative effect	Occasional idiosyncrasy	Useful topically for cystoscopy Injected for use in dental work and surgery Observe for untoward reactions—drowsiness, depressed respiration.
bupivacaine (Marcaine)	Infiltration Peripheral nerve block Epidural	Duration is 2–3 times longer than lidocaine or mepivacaine	Use cautiously in patients with known drug allergies or sensitivities.	A period of analgesia per- sists after return of sensa- tion; therefore, need for strong analgesics is reduced.
etidocaine (Duranest)	Infiltration Block			Greater potency and longer action than lidocaine
procaine (Novocaine)	Subcutaneously, intra- muscularly, intra- venously, or spinal	Low toxicity Inexpensive	Some idiosyncrasies Skin rash Poor stability	Observe for reaction: hy- potension, bradycardia, weak pulse. Usually administered with epinephrine, causing vasoconstriction, thereby slowing absorption and prolonging nerve- deadening effect
tetracaine (Pontocaine)	Topical Infiltration Nerve block	Same as procaine	Same as procaine	More than 10 times as potent as procaine Usually administered with epinephrine

nausea and vomiting; an interdisciplinary approach involving the surgeon, anesthesiologist or anesthetist, and nurse is best (Meeker & Rothrock, 1999).

In some cases, the anesthesiologist administers antiemetics preoperatively or intraoperatively to counteract possible aspiration. If the patient aspirates vomitus, an asthma-like attack with severe bronchial spasms and wheezing is triggered. Pneumonitis and pulmonary edema can subsequently develop, leading to extreme hypoxia. Increasing medical attention is being paid to silent regurgitation of gastric contents, which occurs more frequently than previously realized. The importance of pH in the etiology of acid aspiration is being studied, as is the value of perioperative administration of a histamine-2 receptor antagonist, such as cimetidine (Tagamet), and similar medications (Meeker & Rothrock, 1999).

## ANAPHYLAXIS

Any time a substance foreign to the patient is introduced, there is the potential for an anaphylactic reaction. Because medications are the most common cause of anaphylaxis, intraoperative nurses must be aware of the type and method of anesthesia used as well as the specific agents. An anaphylactic reaction can occur in response to many medications, latex, or other substances. The reaction may be immediate or delayed. Anaphylaxis is a life-threatening acute allergic reaction that causes vasodilation, hypotension, and bronchial constriction (Fortunato, 2000). See Chapters 15 and 53 for more details about the signs, symptoms, and treatment of anaphylaxis.

Fibrin sealants are used in a variety of surgical procedures, and cyanoacrylate tissue adhesives are used to close wounds without the use of sutures (Kassam et al., 2002; Vargas & Reger, 2000). These sealants have been implicated in allergic reactions and anaphylaxis. Although these reactions are rare, the nurse should be alert to the possibility and observe the patient for changes in vital signs and symptoms of anaphylaxis when these products are used.

## HYPOXIA AND OTHER RESPIRATORY COMPLICATIONS

Inadequate ventilation, occlusion of the airway, inadvertent intubation of the esophagus, and hypoxia are significant potential problems of general anesthesia. Many factors can contribute to inadequate ventilation. Respiratory depression caused by anesthetic agents, aspiration of respiratory tract secretions or vomitus, and the patient's position on the operating table can compromise the exchange of gases. Anatomic variation can make the trachea difficult to visualize and result in the artificial airway being inserted into the esophagus rather than the trachea. In addition to these dangers, asphyxia caused by foreign bodies in the mouth, spasm of the vocal cords, relaxation of the tongue, or aspiration of vomitus, saliva, or blood can occur. Since brain damage from hypoxia occurs within minutes, vigilant assessment of the patient's oxygenation status is a primary function of the anesthesiologist or anesthetist and the circulating nurse. Peripheral perfusion is checked frequently, and pulse oximetry values are monitored continuously.

## HYPOTHERMIA

During anesthesia, the patient's temperature may fall. Glucose metabolism is reduced, and as a result metabolic acidosis may develop. This condition is called hypothermia and is indicated by a core body temperature below normal (36.6°C [98.0°F] or lower). Inadvertent hypothermia may occur as a result of a low temperature in the OR, infusion of cold fluids, inhalation of cold gases, open body wounds or cavities, decreased muscle activity, advanced age, or the pharmaceutical agents used (eg, vasodilators, phenothiazines, general anesthetics). Hypothermia may also be intentionally induced in selected surgical procedures (such as cardiac surgeries requiring cardiopulmonary bypass) to reduce the patient's metabolic rate (Finkelmeier, 2000).

Preventing unintentional hypothermia is a major objective. If hypothermia occurs, the goal of intervention is to minimize or reverse the physiologic process. If hypothermia is intentional, the goal is safe return to normal body temperature. Environmental temperature in the OR can temporarily be set at 25° to 26.6°C (78° to 80°F). Intravenous and irrigating fluids are warmed to 37°C (98.6°F). Wet gowns and drapes are removed promptly and replaced with dry materials because wet linens promote heat loss. Whatever methods are used to rewarm the patient, warming must be accomplished gradually, not rapidly. Conscientious monitoring of core temperature, urinary output, ECG, blood pressure, arterial blood gas levels, and serum electrolyte levels is required.

## MALIGNANT HYPERTHERMIA

Malignant hyperthermia is an inherited muscle disorder chemically induced by anesthetic agents (Fortunato-Phillips, 2000; Vermette, 1998). With the mortality rate exceeding 50%, identifying patients at risk for malignant hyperthermia is imperative. Susceptible people include those with strong and bulky muscles, a history of muscle cramps or muscle weakness and unexplained temperature elevation, and an unexplained death of a family member during surgery that was accompanied by a febrile response.

### Pathophysiology

During anesthesia, potent agents such as inhalation anesthetics (halothane, enflurane) and muscle relaxants (succinylcholine), may trigger the symptoms of malignant hyperthermia (Fortunato-Phillips, 2000). Stress and some medications, such as sympathomimetics (epinephrine), theophylline, aminophylline, anticholinergics (atropine), and cardiac glycosides (digitalis), can induce or intensify such a reaction as well.

The pathophysiology is related to muscle cell activity. Muscle cells are composed of inner fluid (sarcoplasm) and an outer surrounding membrane. Calcium, an essential factor in muscle contraction, is normally stored in sacs in the sarcoplasm (Fortunato-Phillips, 2000). When nerve impulses stimulate the muscle, calcium is released, allowing contraction to occur. A pumping mechanism returns calcium to the sacs so that the muscle can relax. In malignant hyperthermia, this mechanism is disrupted. Calcium ions are not returned and they accumulate, causing clinical symptoms of hypermetabolism, which in turn increases muscle contraction (rigidity), hyperthermia, and damage to the central nervous system.

### Clinical Manifestations

The initial symptoms of malignant hyperthermia are related to cardiovascular and musculoskeletal activity. Tachycardia (heart rate above 150 beats/min) is often the earliest sign. In addition to

the tachycardia, sympathetic nervous stimulation leads to ventricular dysrhythmia, hypotension, decreased cardiac output, oliguria, and, later, cardiac arrest. With the abnormal transport of calcium, rigidity or tetanus-like movements occur, often in the jaw. The rise in temperature is actually a late sign that develops rapidly; body temperature can increase 1° to 2°C (2° to 4°F) every 5 minutes (Meeker & Rothrock, 1999). The temperature can reach or exceed 40°C (104°F) in a very short time (Fortunato-Phillips, 2000).

### Medical Management

Recognizing symptoms early and discontinuing anesthesia promptly are imperative. Goals of treatment are to decrease metabolism, reverse metabolic and respiratory acidosis, correct dysrhythmias, decrease body temperature, provide oxygen and nutrition to tissues, and correct electrolyte imbalance. The Malignant Hyperthermia Association of North America (MHAUS) publishes a treatment protocol that should be posted in the OR or be readily available on a malignant hyperthermia cart.

Although malignant hyperthermia usually presents about 10 to 20 minutes after induction of anesthesia, it can also occur in the first 24 hours after surgery. As soon as the diagnosis is made, anesthesia and surgery are halted and the patient is hyperventilated with 100% oxygen. Dantrolene sodium, a skeletal muscle relaxant, and sodium bicarbonate are administered immediately (Fortunato-Phillips, 2000; Vermette, 1998). Continued monitoring of all parameters is necessary to evaluate the patient's status.

### Nursing Management

Although malignant hyperthermia is uncommon, the nurse must identify patients at risk, recognize the signs and symptoms, have the appropriate medication and equipment available, and be knowledgeable about the protocol to follow (Fortunato-Phillips, 2000). This information may be lifesaving.

## DISSEMINATED INTRAVASCULAR COAGULOPATHY

Disseminated intravascular coagulopathy is a life-threatening condition characterized by thrombus formation and depletion of select coagulation proteins (Dice, 2000). The exact cause is unknown, but predisposing factors include many conditions that may occur with emergency surgery, such as massive trauma, head injury, massive transfusion, liver or kidney involvement, embolic events, or shock. The signs and symptoms, nursing assessment, and treatment are discussed in Chapter 33.

## NURSING PROCESS: THE PATIENT DURING SURGERY

The Perioperative Nursing Data Set (PNDS) is a helpful model used by nurses in the intraoperative phase of care (see Chap. 18, Fig. 18-1). Phenomena of concern to intraoperative nurses are nursing diagnoses, interventions, and outcomes that surgical patients and their families experience. Additional areas of concern include collaborative problems and expected goals.

### Assessment

Nursing assessment of the intraoperative patient involves obtaining data from the patient and the patient's record to identify variables that can affect care and serve as guidelines for developing an

individualized plan of patient care. The intraoperative nurse uses the focused preoperative nursing assessment documented on the patient record. This includes assessment of physiologic status (eg, health–illness level, level of consciousness), psychosocial status (eg, anxiety level, verbal communication problems, coping mechanisms), physical status (eg, surgical site, skin condition and effectiveness of preparation; immobile joints), and ethical concerns (Chart 19-3).

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, some major nursing diagnoses may include the following:

- Anxiety related to expressed concerns due to surgery or OR environment
- Risk for perioperative positioning injury related to environmental conditions in the OR
- Risk for injury related to anesthesia and surgery
- Disturbed sensory perception (global) related to general anesthesia or sedation

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications may include the following:

- Nausea and vomiting
- Anaphylaxis
- Hypoxia
- Unintentional hypothermia
- Malignant hyperthermia
- Disseminated intravascular coagulopathy
- Infection

### Chart 19-3 • Ethics and Related Issues

#### To Resuscitate or Not?

##### Situation

Your hospital has developed a policy, authorized through the medical staff, that allows for patients to have a do-not-resuscitate order (DNR) in place during a surgical procedure. This policy follows the American Society of Anesthesiologists guidelines for DNR in the operating room. You are getting a patient ready for surgery and the anesthesiologist who will be administering the anesthetic writes an order for the DNR to be rescinded during surgery. The physician is refusing to talk to the patient concerning the DNR.

##### Problem

The patient believes his/her wishes will be followed with regard to resuscitation in the event of a cardiac arrest and the physician does not believe he can administer anesthesia if the DNR is in place.

##### Discussion

- What are the rights of the patient with regard to advance directives?
- What can you do to advocate for the patient?
- Should you contact the ethics committee of the hospital?
- How do you contact the ethics committee?

## Planning and Goals

Goals for care of the patient during surgery include reducing anxiety, preventing positioning injuries, maintaining safety, maintaining the patient's dignity, and avoiding complications.

## Nursing Interventions

### REDUCING ANXIETY

The OR environment can seem cold, stark, and frightening to the patient, who may be feeling isolated and apprehensive. Introducing yourself, addressing the patient by name warmly and frequently, verifying details, providing explanations, and encouraging and answering questions provide a sense of professionalism and friendliness that can help the patient feel secure. When discussing what the patient can expect in surgery, the nurse uses common, basic communication skills, such as touch and eye contact, to reduce anxiety. Attention to physical comfort (warm blankets, position changes) helps the patient feel more comfortable. Telling the patient who else will be present in the OR, how long the procedure is expected to take, and other details helps the patient prepare for the experience and gain a sense of control.

### PREVENTING INTRAOPERATIVE POSITIONING INJURY

The patient's position on the operating table depends on the surgical procedure to be performed as well as on his or her physical condition (Fig. 19-3). The potential for transient discomfort or even permanent injury is clear because many positions are awkward. Hyperextending joints, compressing arteries, or pressing on nerves and bony prominences usually results in discomfort simply because the position must be sustained for a long period (Meeker & Rothrock, 1999). Factors to consider include the following:

- The patient should be in as comfortable a position as possible, whether asleep or awake.
- The operative field must be adequately exposed.
- An awkward position, undue pressure on a body part, or use of stirrups or traction should not obstruct the vascular supply.
- Respiration should not be impeded by pressure of arms on the chest or by a gown that constricts the neck or chest.
- Nerves must be protected from undue pressure. Improper positioning of the arms, hands, legs, or feet may cause serious injury or paralysis. Shoulder braces must be well padded to prevent irreparable nerve injury, especially when the Trendelenburg position is necessary.
- Precautions for patient safety must be observed, particularly with thin, elderly, or obese patients, or those with a physical deformity (Curet, 2000).
- The patient needs gentle restraint before induction in case of excitement.

The usual position for surgery, called the dorsal recumbent position, is flat on the back. One arm is positioned at the side of the table, with the hand placed palm down; the other is carefully positioned on an armboard to facilitate intravenous infusion of fluids, blood, or medications. This position is used for most abdominal surgeries except for surgery of the gallbladder and pelvis (see Fig. 19-3A).

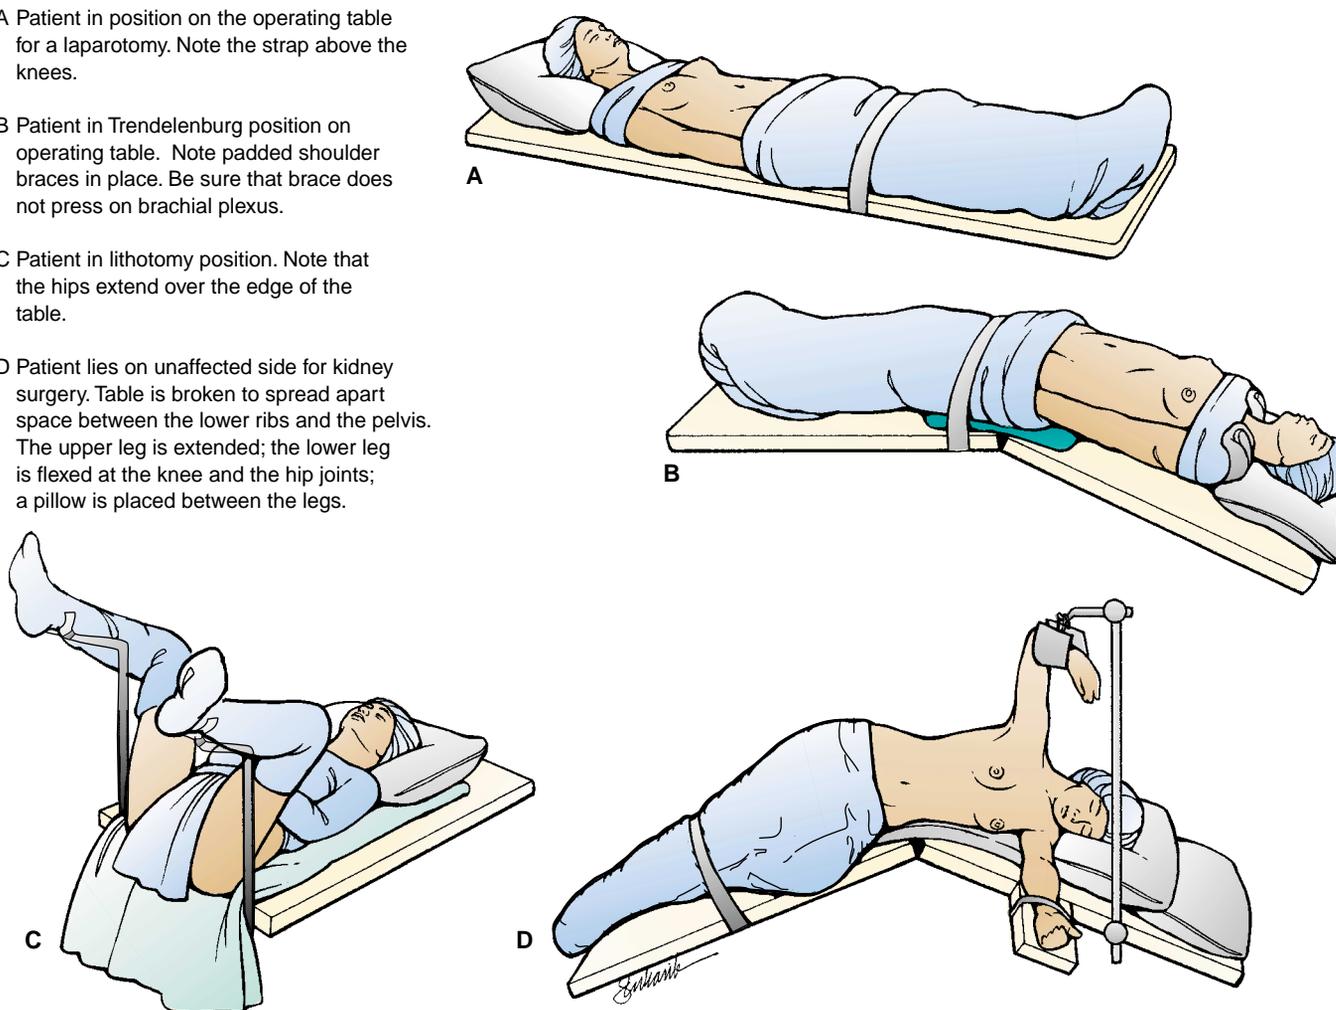

The Trendelenburg position usually is used for surgery on the lower abdomen and pelvis to obtain good exposure by displacing the intestines into the upper abdomen. In this position, the head and body are lowered. The patient is held in position by padded shoulder braces (see Fig. 19-3B).

A Patient in position on the operating table for a laparotomy. Note the strap above the knees.

B Patient in Trendelenburg position on operating table. Note padded shoulder braces in place. Be sure that brace does not press on brachial plexus.

C Patient in lithotomy position. Note that the hips extend over the edge of the table.

D Patient lies on unaffected side for kidney surgery. Table is broken to spread apart space between the lower ribs and the pelvis. The upper leg is extended; the lower leg is flexed at the knee and the hip joints; a pillow is placed between the legs.

**FIGURE 19-3** Positions on the operating table. Captions call attention to safety and comfort features. All surgical patients wear caps to cover the hair completely.

The lithotomy position is used for nearly all perineal, rectal, and vaginal surgical procedures (see Fig. 19-3C). The patient is positioned on the back with the legs and thighs flexed. The position is maintained by placing the feet in stirrups.

The Sims or lateral position is used for renal surgery. The patient is placed on the nonoperative side with an air pillow 12.5 to 15 cm (5 to 6 inches) thick under the loin, or on a table with a kidney or back lift (see Fig. 19-3D).

Other procedures, such as neurosurgery or abdominothoracic surgery, may require unique positioning and supplemental apparatus, depending on the operative approach.

### PROTECTING THE PATIENT FROM INJURY

One way the nurse protects the patient from injury is by providing a safe environment. A variety of activities are used to address the diverse patient safety issues that arise in the OR. Verifying information, checking the chart for completeness, and maintaining surgical asepsis and an optimal environment are critical nursing responsibilities. Verifying that all required documentation is completed is one of the first functions of the intraoperative nurse. The patient is identified, and the planned surgical procedure and type of anesthesia are verified. It is important to review the patient's record for the following:

- Correct informed surgical consent, with patient's signature
- Completed records for health history and physical examination
- Results of diagnostic studies
- Allergies (including latex)

In addition to checking that all necessary patient data are complete, the perioperative nurse obtains the necessary equipment specific to the procedure. The need for nonroutine medications, blood components, instruments, and other equipment and supplies is assessed, and the readiness of the room, completeness of physical setup, and completeness of instrument, suture, and dressing setups are determined. Any aspects of the OR environment that may negatively affect the patient are identified. These include physical features, such as room temperature and humidity; electrical hazards; potential contaminants (dust, blood, and discharge on floor or surfaces, uncovered hair, faulty attire of personnel, jewelry worn by personnel); and unnecessary traffic. The circulating nurse also sets up and maintains suction equipment in working order, sets up invasive monitoring equipment, assists with insertion of vascular access and monitoring devices (arterial, Swan-Ganz, central venous pressure, intravenous lines), and initiates appropriate physical comfort measures for the patient.

Preventing physical injury includes using safety straps and bed rails and not leaving the sedated patient unattended. Transferring the patient from the stretcher to the OR table requires safe transferring practices. Other safety measures include properly positioning the grounding pad under the patient to prevent electrical burns and shock, removing excess povidone-iodine (Betadine) or other surgical germicide from the patient's skin, and promptly and completely draping exposed areas after the sterile field has been created to decrease the risk for hypothermia.

Nursing measures to prevent injury from excessive blood loss include blood conservation using equipment such as a cell-saver (a device for recirculating the patient's own blood cells) or the administration of blood products (Finkelmeier, 2000). Few patients undergoing an elective procedure require blood transfusion, but those undergoing higher-risk procedures (such as orthopedic or cardiac surgeries) may require an intraoperative transfusion. The circulating nurse should anticipate this need, check that blood has been cross-matched and held in reserve, and be prepared to administer blood (Meeker & Rothrock, 1999).

### SERVING AS PATIENT ADVOCATE

Because the patient undergoing general anesthesia or moderate sedation experiences temporary sensory/perceptual alteration or loss, he or she has an increased need for protection and advocacy. Patient advocacy in the OR entails maintaining the patient's physical and emotional comfort, privacy, rights, and dignity. Patients, whether conscious or not, should not be subjected to excess noise, inappropriate conversation, or, most of all, derogatory comments. As surprising as this sounds, banter in the OR occasionally includes jokes about the patient's physical appearance, job, personal history, and so forth. Cases have been reported in which seemingly deeply anesthetized patients recalled the entire surgical experience, including disparaging personal remarks made by OR personnel. As an advocate, the nurse never engages in this conversation and discourages others from doing so. Other advocacy activities include correcting for the clinical, dehumanizing aspects of being a surgical patient by making sure the patient is treated as a person, respecting cultural and spiritual values, providing physical privacy, and maintaining confidentiality.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

It is the responsibility of the surgeon and the anesthesiologist or anesthesiologist to monitor and manage complications. However, intraoperative nurses also play an important role. Being alert to and reporting changes in vital signs and symptoms of nausea and vomiting, anaphylaxis, hypoxia, hypothermia, malignant hyperthermia, or disseminated vascular coagulation and assisting with their management are important nursing functions (Dice, 2000; Fortunato-Phillips, 2000). Each of these complications was discussed earlier. Maintaining asepsis and preventing infection is the responsibility of all members of the surgical team.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Exhibits low level of anxiety
2. Remains free of perioperative positioning injury
3. Experiences no unexpected threats to safety
4. Has dignity preserved throughout OR experience

### Critical Thinking Exercises

1. A patient in the holding area awaiting surgery indicates that he had not received instructions not to take his usual medications (antihypertensive agent, diuretic, digoxin, potassium chloride, and insulin injection); as a result, he took them a few hours ago. What implications does this have for the patient's care and well-being while awaiting surgery, during surgery, and in the immediate postoperative period?
  2. What are the differences in responsibility of the operating room nurse for care of patients who receive general anesthesia, conscious sedation, spinal anesthesia, and regional anesthesia?
  3. While she is being transferred from the stretcher to the operating table, a female patient says she is very anxious about her surgery because of previous negative experiences. What assessment and interventions are indicated at this time?
5. Is free of complications or experiences successful management of adverse effects of surgery and anesthesia

# ● Postoperative Nursing Management

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Describe the responsibilities of the postanesthesia care unit nurse in the prevention of immediate postoperative complications.
2. Compare postoperative care of the ambulatory surgery patient and the hospitalized surgery patient.
3. Identify common postoperative problems and their management.
4. Describe the gerontologic considerations related to postoperative management of patients.
5. Describe variables that affect wound healing.
6. Demonstrate postoperative dressing techniques.
7. Identify assessment parameters appropriate for the early detection of postoperative complications.

The postoperative period extends from the time the patient leaves the operating room until the last follow-up visit with the surgeon. This period may be as short as 1 week or as long as several months. During the postoperative period, nursing care focuses on reestablishing the patient's physiologic equilibrium, alleviating pain, preventing complications, and teaching the patient self-care. Careful assessment and immediate intervention assist the patient in returning to optimal function quickly, safely, and as comfortably as possible. Ongoing care in the community through home care, clinic visits, office visits, or telephone follow-up facilitates an uncomplicated recovery.

## The Postanesthesia Care Unit

The **postanesthesia care unit (PACU)**, also called the postanesthesia recovery room, is located adjacent to the operating rooms. Patients still under anesthesia or recovering from anesthesia are placed in this unit for easy access to experienced, highly skilled nurses, anesthesiologists or anesthetists, surgeons, advanced hemodynamic and pulmonary monitoring and support, special equipment, and medications (Litwack, 1999; Meeker & Rothrock, 1999).

The PACU is kept quiet, clean, and free of unnecessary equipment. This area is painted in soft, pleasing colors and has indirect lighting, a soundproof ceiling, equipment that controls or eliminates noise (eg, plastic emesis basins, rubber bumpers on beds and tables), and isolated but visible quarters for disruptive patients. The PACU should also be well ventilated. These features benefit the patient by helping to decrease anxiety and promote comfort. The PACU bed provides easy access to the patient, is safe and easily movable, can be readily placed in position to facilitate use of measures to counteract shock, and has features that facilitate care, such as intravenous (IV) poles, side rails, wheel brakes, and a chart storage rack.

## PHASES OF POSTANESTHESIA CARE

Postanesthesia care in some hospitals and ambulatory surgical centers is divided into two phases (Litwack, 1999; Meeker & Rothrock, 1999). In the **phase I PACU**, used during the immediate recovery phase, intensive nursing care is provided. The **phase II PACU** is reserved for patients who require less frequent observation and less nursing care. In the phase II unit, the patient is prepared for discharge. Recliners rather than stretchers or beds are standard in many phase II units, which may also be referred to as step-down, sit-up, or progressive care units. Patients may remain in a phase II PACU unit for as long as 4 to 6 hours, de-

pending on the type of surgery and any preexisting conditions of the patient. In facilities without separate phase I and phase II units, the patient remains in the PACU and may be discharged home directly from this unit.

Both phase I and phase II PACU nurses have special skills. The phase I PACU nurse provides frequent (every 15 minutes) monitoring of the patient's pulse, electrocardiogram, respiratory rate, blood pressure, and pulse oximeter value (blood oxygen level). In some cases, end-tidal carbon dioxide (ETCO<sub>2</sub>) levels are monitored as well. The patient's airway may become obstructed because of the latent effects of recent anesthesia, and the PACU nurse must be prepared to assist in reintubation and in handling other emergencies that may occur. The nurse in the phase II PACU must possess strong clinical assessment and patient teaching skills.

## ADMITTING THE PATIENT TO THE PACU

Transferring the postoperative patient from the operating room to the PACU is the responsibility of the anesthesiologist or anesthetist. During transport from the operating room to the PACU, the anesthesia provider remains at the head of the stretcher (to maintain the airway), and a surgical team member remains at the opposite end. Transporting the patient involves special consideration of the incision site, potential vascular changes, and exposure. The surgical incision is considered every time the postoperative patient is moved; many wounds are closed under considerable tension, and every effort is made to prevent further strain on the incision. The patient is positioned so that he or she is not lying on and obstructing drains or drainage tubes. Serious orthostatic hypotension may occur when a patient is moved from one position to another (eg, from a lithotomy position to a horizontal position or from a lateral to a supine position), so the patient must be moved slowly and carefully. As soon as the patient is placed on the stretcher or bed, the soiled gown is removed and replaced with a dry gown. The patient is covered with lightweight blankets and warmed. The side rails are raised to guard against falls.

The nurse who admits the patient to the PACU reviews the following information with the anesthesiologist or anesthetist:

- Medical diagnosis and type of surgery performed
- Pertinent past medical history and allergies
- Patient's age and general condition, airway patency, vital signs
- Anesthetics and other medications used during the procedure (eg, opioids and other analgesic agents, muscle relaxants, antibiotic agents)

## Glossary

**dehiscence:** partial or complete separation of wound edges

**visceration:** protrusion of abdominal organs through the surgical incision

**first-intention healing:** method of healing in which wound edges are surgically approximated and integumentary continuity is restored without granulation

**Phase I PACU:** area designated for care of surgical patients immediately after surgery

and patients whose condition warrants close monitoring

**Phase II PACU:** area designated for care of surgical patients who have been transferred from a phase I PACU because their condition no longer requires the close monitoring provided in a phase I PACU

**postanesthesia care unit (PACU):** area where postoperative patients are monitored as they recover from anesthesia; for-

merly referred to as the recovery room or postanesthesia recovery room

**second-intention healing:** method of healing in which wound edges are not surgically approximated and integumentary continuity is restored by the process known as granulation

**third-intention healing:** method of healing in which surgical approximation of wound edges is delayed and integumentary continuity is restored by apposing areas of granulation

- Any problems that occurred in the operating room that might influence postoperative care (eg, extensive hemorrhage, shock, cardiac arrest)
- Pathology encountered (if malignancy is an issue during surgery, the nurse needs to know whether the patient and/or family have been informed)
- Fluid administered, estimated blood loss and replacement fluids
- Any tubing, drains, catheters, or other supportive aids
- Specific information about which the surgeon, anesthesiologist, or anesthetist wishes to be notified (eg, blood pressure or heart rate below or above a specified level)

## NURSING MANAGEMENT IN THE PACU

The nursing management objectives for the patient in the PACU are to provide care until the patient has recovered from the effects of anesthesia (eg, until resumption of motor and sensory functions), is oriented, has stable vital signs, and shows no evidence of hemorrhage or other complications.

### Assessing the Patient

Frequent, skilled assessments of the blood oxygen saturation level, pulse rate and regularity, depth and nature of respirations, skin color, level of consciousness, and ability to respond to commands are the cornerstones of nursing care in the PACU. The nurse performs a baseline assessment, then checks the surgical site for drainage or hemorrhage and makes sure that all drainage tubes and monitoring lines are connected and functioning.

After the initial assessment, vital signs are monitored and the patient's general physical status is assessed at least every 15 minutes. Patency of the airway and respiratory function are always evaluated first, followed by assessment of cardiovascular function, the condition of the surgical site, and function of the central nervous system. The nurse needs to be aware of any pertinent information from the patient's history that may be significant (eg, patient is hard of hearing, has a history of seizures, has diabetes, or is allergic to certain medications or to latex).

### Maintaining a Patent Airway

The primary objective in the immediate postoperative period is to maintain pulmonary ventilation and thus prevent hypoxemia (reduced oxygen in the blood) and hypercapnia (excess carbon dioxide in the blood). Both can occur if the airway is obstructed and ventilation is reduced (hypoventilation). Besides checking the physician's orders for and administering supplemental oxygen, the nurse assesses respiratory rate and depth, ease of respirations, oxygen saturation, and breath sounds (Litwack, 1999; Meeker & Rothrock, 1999).

Patients who have experienced prolonged anesthesia usually are unconscious, with all muscles relaxed. This relaxation extends to the muscles of the pharynx. When the patient lies on his or her back, the lower jaw and the tongue fall backward and the air passages become obstructed (Fig. 20-1A). This is called hypopharyngeal obstruction. Signs of occlusion include choking, noisy and irregular respirations, decreased oxygen saturation scores, and within minutes a blue, dusky color (cyanosis) of the skin. Because movement of the thorax and the diaphragm does not necessarily indicate that the patient is breathing, the nurse needs to place the palm of the hand at the patient's nose and mouth to feel the exhaled breath.

**NURSING ALERT** The treatment of hypopharyngeal obstruction involves tilting the head back and pushing forward on the angle of the lower jaw, as if to push the lower teeth in front of the upper teeth (Figs. 20-1B, C). This maneuver pulls the tongue forward and opens the air passages.

The anesthesiologist or anesthetist may leave a hard rubber or plastic airway in the patient's mouth (Fig. 20-2) to maintain a patent airway. Such a device should not be removed until signs such as gagging indicate that reflex action is returning. Alternatively, the patient may enter the PACU with an endotracheal tube still in place and may require continued mechanical ventilation. The nurse assists in initiating the use of the ventilator and in the weaning and extubation processes. Some patients, particularly those who have had extensive or lengthy surgical procedures, may be transferred from the operating room directly to the intensive care unit or may be transferred from the PACU to the intensive care unit while still intubated and on mechanical ventilation.

Respiratory difficulty can also result from excessive secretion of mucus or aspiration of vomitus. Turning the patient to one side allows the collected fluid to escape from the side of the mouth. If the teeth are clenched, the mouth may be opened manually but cautiously with a padded tongue depressor. The head of the bed is elevated 15 to 30 degrees unless contraindicated, and the patient is closely observed to maintain the airway as well as to minimize the risk of aspiration. If vomiting occurs, the patient is turned to the side to prevent aspiration and the vomitus is collected in the emesis basin. Mucus or vomitus obstructing the pharynx or the trachea is suctioned with a pharyngeal suction tip or a nasal catheter introduced into the nasopharynx or oropharynx. The catheter can be passed into the nasopharynx or oropharynx safely to a distance of 15 to 20 cm (6 to 8 inches). Caution is necessary in suctioning the throat of a patient who has had a tonsillectomy or other oral or laryngeal surgery because of risk for bleeding and discomfort.

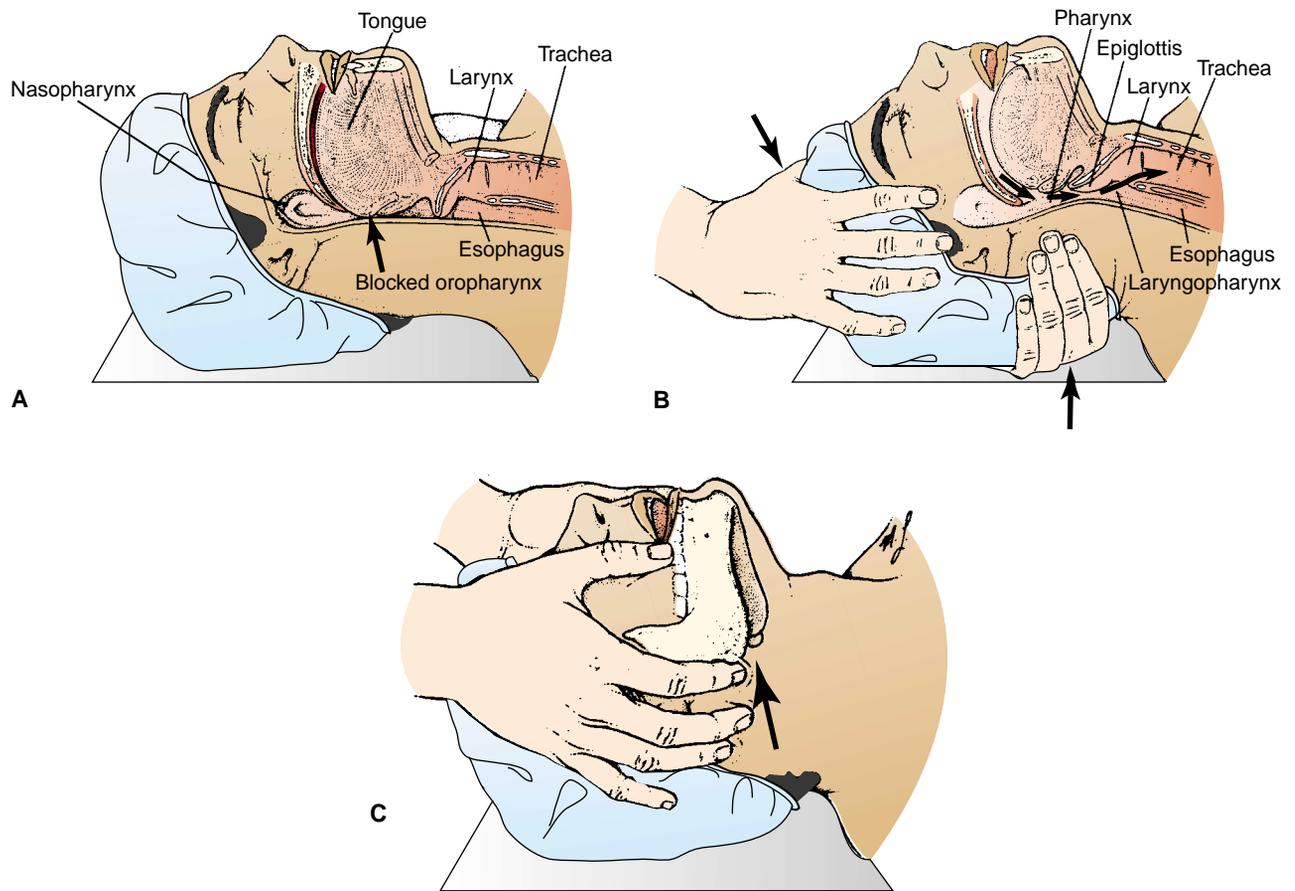

### Maintaining Cardiovascular Stability

To monitor cardiovascular stability, the nurse assesses the patient's mental status; vital signs; cardiac rhythm; skin temperature, color, and moisture; and urine output. Central venous pressure, pulmonary artery pressure, and arterial lines are monitored if the patient's condition requires such assessment. The nurse also assesses the patency of all IV lines. The primary cardiovascular complications seen in the PACU include hypotension and shock, hemorrhage, hypertension, and dysrhythmias.

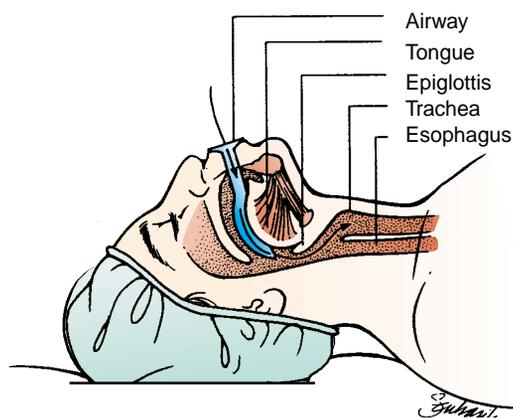

#### HYPOTENSION AND SHOCK

Hypotension can result from blood loss, hypoventilation, position changes, pooling of blood in the extremities, or side effects of medications and anesthetics; the most common cause is loss of circulating volume through blood and plasma loss. If the amount of blood loss exceeds 500 mL (especially if the loss is rapid), replacement is usually indicated.

Shock, one of the most serious postoperative complications, can result from hypovolemia. Shock may be described as inadequate cellular oxygenation accompanied by the inability to excrete waste products of metabolism. Hypovolemic shock is characterized by a fall in venous pressure, a rise in peripheral resistance, and tachycardia. Neurogenic shock, a less common cause of shock in the surgical patient, occurs as a result of decreased arterial resistance caused by spinal anesthesia. It is characterized by a fall in blood

**FIGURE 20-1** (A) A hypopharyngeal obstruction occurs when neck flexion permits the chin to drop toward the chest; obstruction almost always occurs when the head is in the midposition. (B) Tilting the head back to stretch the anterior neck structure lifts the base of the tongue off the posterior pharyngeal wall. The direction of the arrows indicates the pressure of the hands. (C) Opening the mouth is necessary to correct valvelike obstruction of the nasal passage during expiration, which occurs in about 30% of unconscious patients. Open the patient's mouth (separate lips and teeth) and move the lower jaw forward so that the lower teeth are in front of the upper teeth. To regain backward tilt of the neck, lift with both hands at the ascending rami of the mandible.

**FIGURE 20-2** Use of an airway to prevent respiratory difficulty after anesthesia. The airway passes over the base of the tongue and permits air to pass into the pharynx in the region of the epiglottis. Patients often leave the operating room with an airway in place. The airway should remain in place until the patient recovers sufficiently to breathe normally. As the patient regains consciousness, the airway usually causes irritation and should be removed.

pressure due to pooling of blood in dilated capacitance vessels (those with the ability to change volume capacity). Cardiogenic shock is unlikely in the surgical patient except if the patient has severe preexisting cardiac disease or experienced a myocardial infarction during surgery. See Chapter 15 for a detailed discussion of shock.

The classic signs of shock are:

- Pallor
- Cool, moist skin
- Rapid breathing
- Cyanosis of the lips, gums, and tongue
- Rapid, weak, thready pulse
- Decreasing pulse pressure
- Low blood pressure and concentrated urine

Hypovolemic shock can be avoided largely by the timely administration of IV fluids, blood, blood products, and medications that elevate blood pressure. Other factors may contribute to hemodynamic instability, and the PACU nurse implements multiple measures to manage these factors. Pain is controlled by making the patient as comfortable as possible and by using opioids

judiciously. Exposure is avoided, and normothermia is maintained to prevent vasodilation.

Volume replacement is the primary intervention for shock. An infusion of lactated Ringer's solution or blood component therapy is initiated. Oxygen is administered by nasal cannula, face-mask, or mechanical ventilation. Cardiotonic, vasodilator, and corticosteroid medications may be prescribed to improve cardiac function and reduce peripheral vascular resistance. The patient is kept warm while avoiding overheating to prevent cutaneous vessels from dilating and depriving vital organs of blood. The patient is placed flat in bed with the legs elevated. Respiratory and pulse rate, blood pressure, blood oxygen concentration, urinary output, level of consciousness, central venous pressure, pulmonary artery pressure, pulmonary capillary wedge pressure, and cardiac output are monitored to provide information on the patient's respiratory and cardiovascular status. Vital signs are monitored continuously until the patient's condition has stabilized.

## HEMORRHAGE

Hemorrhage is an uncommon yet serious complication of surgery that can result in death (Finkelmeier, 2000). It can present insidiously or emergently at any time in the immediate postoperative period or up to several days after surgery (Table 20-1). When blood loss is extreme, the patient is apprehensive, restless, and thirsty; the skin is cold, moist, and pale. The pulse rate increases, the temperature falls, and respirations are rapid and deep, often of the gasping type spoken of as "air hunger." If hemorrhage progresses untreated, cardiac output decreases, arterial and venous blood pressure and hemoglobin level fall rapidly, the lips and the conjunctivae become pallid, spots appear before the eyes, a ringing is heard in the ears, and the patient grows weaker but remains conscious until near death.

Transfusing blood or blood products and determining the cause of hemorrhage are the initial therapeutic measures. The surgical site and incision should always be inspected for bleeding. If bleeding is evident, a sterile gauze pad and a pressure dressing are

applied, and the site of the bleeding is elevated to heart level if possible. The patient is placed in the shock position (flat on back; legs elevated at a 20-degree angle; knees kept straight). If the source of bleeding is concealed, the patient may be taken back to the operating room for emergency exploration of the surgical site.

**NURSING ALERT** When IV fluids are given in cases of hemorrhage, it is important to remember that unless the hemorrhage has been well controlled, giving too large a quantity or administering the IV fluid too rapidly may raise the blood pressure enough to start the bleeding again.

Special considerations must be given to patients who decline blood transfusions, such as Jehovah's Witnesses and those who identify specific requests on their advance directives or living will.

## HYPERTENSION AND DYSRHYTHMIAS

Hypertension is common in the immediate postoperative period secondary to sympathetic nervous system stimulation from pain, hypoxia, or bladder distention. Dysrhythmias are associated with electrolyte imbalance, altered respiratory function, pain, hypothermia, stress, and anesthetic medications. Both conditions are managed by treating the underlying causes.

## Relieving Pain and Anxiety

Opioid analgesics are administered judiciously and often intravenously in the PACU (Meeker & Rothrock, 1999). Intravenous opioids provide immediate relief and are short-acting, thus minimizing the potential for drug interactions or prolonged respiratory depression while anesthetics are still active in the patient's system. In addition to monitoring the patient's physiologic status and managing pain, the PACU nurse provides psychological support in an effort to relieve the patient's fears and concerns. The nurse checks the medical record for special needs and concerns of the patient. When the patient's condition permits, a close member of the family may visit in the PACU for a few moments. This often decreases the family's anxiety and makes the patient feel more secure.

## Controlling Nausea and Vomiting

Nausea and vomiting are common problems in the PACU. The nurse should intervene at the patient's first report of nausea to control the problem rather than wait for it to progress to vomiting.

Many medications are available to control nausea and vomiting without oversedating the patient; they are commonly administered during surgery as well as in the PACU (Meeker & Rothrock, 1999). Intravenous or intramuscular administration of droperidol (Inapsine) is common, especially in the ambulatory setting. Other medications such as metoclopramide (Reglan), prochlorperazine (Compazine), and promethazine (Phenergan) are commonly prescribed (Karch, 2002; Meeker & Rothrock, 1999). Although it is costly, ondansetron (Zofran) is a frequently used, effective antiemetic with few side effects.

**NURSING ALERT** At the slightest indication of nausea, the patient is turned completely to one side to promote mouth drainage and prevent aspiration of vomitus, which can cause asphyxiation and death.

**Table 20-1 • Classifications of Hemorrhage**

CLASSIFICATION	DEFINING CHARACTERISTIC
<b>Time Frame</b>	
Primary	Hemorrhage occurs at the time of surgery.
Intermediary	Hemorrhage occurs during the first few hours after surgery when the rise of blood pressure to its normal level dislodges insecure clots from untied vessels.
Secondary	Hemorrhage may occur some time after surgery if a ligature slips because a blood vessel was insecurely tied, became infected, or was eroded by a drainage tube.
<b>Type of Vessel</b>	
Capillary	Hemorrhage is characterized by a slow, general ooze.
Venous	Darkly colored blood bubbles out quickly.
Arterial	Blood is bright red and appears in spurts with each heartbeat.
<b>Visibility</b>	
Evident	Hemorrhage is on the surface and can be seen.
Concealed	Hemorrhage is in a body cavity and cannot be seen.

### Gerontologic Considerations

The elderly patient, like all other patients, is transferred from the operating room table to the bed or stretcher slowly and gently. The effects of this action on blood pressure and ventilation are monitored. Special attention is given to keeping the patient warm because the elderly are more susceptible to hypothermia. The patient's position is changed frequently to stimulate respirations and to promote circulation and comfort.

Immediate postoperative care for the elderly patient is the same as that for any surgical patient, but additional support is given if there is impaired cardiovascular, pulmonary, or renal function. With invasive monitoring, it is possible to detect cardiopulmonary deficits before signs and symptoms are apparent. The elderly patient has less physiologic reserve, and physiologic responses to stress are diminished or slowed. These changes reinforce the need for close monitoring and prompt treatment of hypotension, shock, and hemorrhage. Because of monitoring and improved individualized preoperative preparation, many older adults tolerate surgery well and have an uneventful recovery.

Postoperative confusion is common in older patients. The confusion is aggravated by social isolation, restraints, anesthetics and analgesics, and sensory deprivation. Reorienting the patient to the environment and using smaller amounts of sedatives, anesthetics, and analgesics may help prevent confusion. However, unrelieved pain, particularly pain at rest, may increase the risk for delirium and must be addressed (Lynch, Lazor, Gellis et al., 1998). Hypoxia can present as confusion and restlessness, as can blood loss and electrolyte imbalance. Excluding all other causes of confusion must precede the assumption that confusion is related to age, circumstances, and medications.

### Determining Readiness for Discharge From the PACU

A patient remains in the PACU until he or she has fully recovered from the anesthetic agent (Meeker & Rothrock, 1999). Indicators of recovery include stable blood pressure, adequate respiratory function, adequate oxygen saturation level compared with baseline, and spontaneous movement or movement on command. Usually the following measures are used to determine the patient's readiness for discharge from the PACU:

- Stable vital signs
- Orientation to person, place, events, and time
- Uncompromised pulmonary function
- Pulse oximetry readings indicating adequate blood oxygen saturation
- Urine output at least 30 mL/h
- Nausea and vomiting absent or under control
- Minimal pain

Many hospitals use a scoring system (eg, Aldrete score) to determine the patient's general condition and readiness for transfer from the PACU (Quinn, 1999). Throughout the recovery period, the patient's physical signs are observed and evaluated by means of a scoring system based on a set of objective criteria. This evaluation guide, a modification of the Apgar scoring system used for evaluating newborns, allows a more objective assessment of the patient's condition in the PACU (Fig. 20-3). The patient is assessed at regular intervals (eg, every 15 or 30 minutes), and the score is totaled on the assessment record. Patients with a score lower than 7 must remain in the PACU until their condition im-

proves or they are transferred to an intensive care area, depending on their preoperative baseline scores.

The patient is discharged from the phase I PACU by the anesthesiologist or anesthesiologist to the critical care unit, the medical-surgical unit, the phase II PACU, or home with a responsible family member (Quinn, 1999). Patients being discharged directly to home require verbal and written instructions and information about follow-up care.

### Promoting Home and Community-Based Care

To ensure patient safety and recovery, expert patient teaching and discharge planning are necessary when a patient undergoes same-day or ambulatory surgery. Because anesthetics cloud memory for concurrent events, instructions should be given to both the patient and the adult who will be accompanying the patient home (Quinn, 1999).

### TEACHING PATIENTS SELF-CARE

The patient and caregiver (eg, family member or friend) are informed about expected outcomes and immediate postoperative changes anticipated in the patient's capacity for self-care (Fox, 1998; Quinn, 1999). Written instructions about wound care, activity and dietary recommendations, medication, and follow-up visits to the same-day surgery unit or the surgeon are provided. Written instructions (designed to be copied and given to patients) about the postoperative care following many types of surgery are usually provided (Economou & Economou, 1999). The patient's caregiver at home is provided with verbal and written instructions about what to observe the patient for and about the actions to take if complications occur. Prescriptions are given to the patient. The nurse or surgeon's telephone number is provided, and the patient and caregiver are encouraged to call with questions and to schedule follow-up appointments (Chart 20-1).

Although recovery time varies depending on the type and extent of surgery and the patient's overall condition, instructions usually advise limited activity for 24 to 48 hours. During this time, the patient should not drive a vehicle, drink alcoholic beverages, or perform tasks that require energy or skill. Fluids may be consumed as desired, and smaller-than-normal amounts are eaten at mealtime. The patient is cautioned not to make important decisions at this time because the medications, anesthesia, and surgery may affect his or her decision-making ability.

### CONTINUING CARE

Although most patients who undergo ambulatory surgery recover quickly and without complications, some patients require referral for home care. These may be elderly or frail patients, those who live alone, and patients with other health care problems that may interfere with self-care or resumption of usual activities. The home care nurse assesses the patient's physical status (eg, respiratory and cardiovascular status, adequacy of pain management, the surgical incision) and the patient's and family's ability to adhere to the recommendations given at the time of discharge. Previous teaching is reinforced as needed. The home care nurse may change surgical dressings, monitor the patency of a drainage system, or administer medications. The patient is assessed for any surgical complications. The patient and family are reminded about the importance of keeping follow-up appointments with the surgeon. Follow-up phone calls from the nurse or surgeon may also be used to assess the patient's progress and to answer any questions (Fox, 1998; Marley & Swanson, 2001).

## The Hospitalized Postoperative Patient

The patient admitted to the clinical unit for postoperative care has multiple needs. Seriously ill patients or those who have undergone major cardiovascular, pulmonary, or neurologic surgery

are admitted to specialized intensive care units for close monitoring and advanced interventions and support. The care required by these patients in the immediate postoperative period is discussed in specific chapters. Postoperative care for the surgical patient returning to the general medical-surgical unit is discussed below.

Chart 20-1

## Home Care Checklist • Discharge From Surgery

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Name the procedure that was performed and identify any permanent changes in anatomic structure or function.	✓	✓
• Describe ongoing postoperative therapeutic regimen, including medications, diet, activities to perform (such as walking and breathing exercises) and to avoid (such as driving a car or contact sports), adjuvant therapies, dressing changes and wound care, and any other treatments.	✓	✓
• Describe signs and symptoms of complications.	✓	✓
• State time and date of follow-up appointments.	✓	✓
• Identify interventions and strategies to use in adapting to any permanent changes in structure or function.	✓	✓
• Relate how to reach health care provider with questions or complications.	✓	✓
• State understanding of community resources and referrals (if any).	✓	✓
• Describe pertinent health promotion activities (eg, weight reduction, smoking cessation, stress management).	✓	✓

## RECEIVING THE PATIENT IN THE CLINICAL UNIT

The patient's room is readied by assembling the necessary equipment and supplies: IV pole, drainage receptacle holder, emesis basin, tissues, disposable pads (Chux), blankets, and postoperative charting forms. When the call comes to the unit about the patient's transfer from the PACU, the need for any additional items that may be needed is communicated. The PACU nurse reports the baseline data about the patient's condition to the receiving nurse. The report includes demographic data, medical diagnosis, procedure performed, comorbid conditions, allergies, unexpected intraoperative events, estimated blood loss, the type and amount of fluids received, medications administered for pain, whether the patient has voided, and information that the patient and family have received about the patient's condition. Usually the surgeon speaks to the family after surgery and relates the general condition of the patient. The receiving nurse reviews the postoperative orders, admits the patient to the unit, performs an initial assessment, and attends to the patient's immediate needs (Chart 20-2).

## NURSING MANAGEMENT AFTER SURGERY

During the first 24 hours after surgery, nursing care of the hospitalized patient on the general medical-surgical unit involves continuing to help the patient recover from the effects of anes-

thesia, frequently assessing the patient's physiologic status, monitoring for complications, managing pain, and implementing measures designed to achieve the long-range goals of independence with self-care, successful management of the therapeutic regimen, discharge to home, and full recovery. In the initial hours after admission to the clinical unit, adequate ventilation, hemodynamic stability, incisional pain, surgical site integrity, nausea and vomiting, neurologic status, and spontaneous voiding are primary concerns. The pulse rate, blood pressure, and respiration rate are recorded at least every 15 minutes for the first hour and every 30 minutes for the next 2 hours. Thereafter, they are measured less frequently if they remain stable. The temperature is monitored every 4 hours for the first 24 hours.

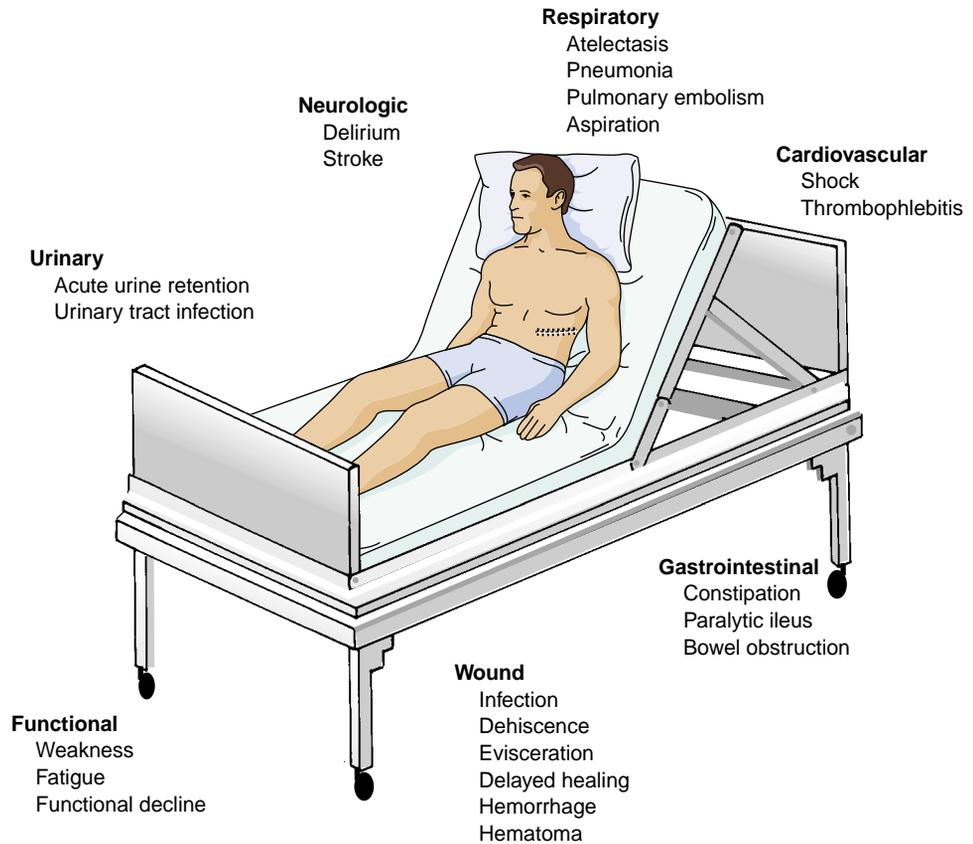

Patients usually begin to feel better several hours after surgery or after waking up the next morning. Although pain may still be intense, many patients feel more alert, less nauseous, and less anxious. They have begun their breathing and leg exercises, and many will have dangled their legs over the edge of the bed, stood, and ambulated a few feet or been assisted out of bed to the chair at least once. Many will have tolerated a light meal and had IV fluids discontinued. The focus of care shifts from intense physiologic management and symptomatic relief of the adverse effects of anesthesia to regaining independence with self-care and preparing for discharge. Despite these gains, the postoperative patient is still at risk for complications. Atelectasis, pneumonia, deep vein thrombosis, pulmonary embolism, constipation, paralytic ileus, and wound infection are ongoing threats for the postoperative patient (Fig. 20-4).

Chart 20-2

## Standard Postoperative Nursing Interventions

Once the patient leaves the PACU and is admitted to the unit, immediate nursing interventions include the following:

- Assess breathing and administer supplemental oxygen, if prescribed.
- Monitor vital signs and note skin warmth, moisture, and color.
- Assess the surgical site and wound drainage systems.
- Assess level of consciousness, orientation, and ability to move extremities.
- Connect all drainage tubes to gravity or suction as indicated and monitor closed drainage systems.
- Assess pain level, pain characteristics (location, quality) and timing, type, and route of administration of last pain medication.
- Administer analgesics as prescribed and assess their effectiveness in relieving pain.
- Position patient to enhance comfort, safety, and lung expansion.
- Assess IV sites for patency and infusions for correct rate and solution.
- Assess urine output in closed drainage system or the patient's urge to void and bladder distention.
- Reinforce need to begin deep-breathing and leg exercises.
- Place call light, emesis basin, ice chips (if allowed), and bedpan or urinal within reach.
- Provide information to patient and family.

**FIGURE 20-4** The postoperative patient is subject to a number of potential complications.

## NURSING PROCESS: THE HOSPITALIZED PATIENT RECOVERING FROM SURGERY

The Perioperative Nursing Data Set (PNDS) is a helpful model used by nurses in the postoperative phase of care (see Chap. 18, Fig. 18-1). Phenomena of concern to nurses on the clinical unit in the postoperative phase of care include nursing diagnoses, interventions, and outcomes for patients and their families. Additional areas of concern include collaborative problems and expected goals.

### Assessment

Assessment of the hospitalized postoperative patient includes monitoring vital signs and completing a review of the systems upon arrival of the patient to the clinical unit and thereafter (see Chart 20-2).

Respiratory status is important because pulmonary complications are among the most frequent and serious problems encountered by the surgical patient. The nurse observes for airway patency and the quality of respirations, including depth, rate, and sound. Chest auscultation verifies that breath sounds are normal (or not normal) bilaterally, and the findings are documented as a baseline for later comparisons. Often, because of the effects of pain medications, respirations are slow. Shallow and rapid respirations may be due to pain, constricting dressings, gastric dilation, or obesity. Noisy breathing may be due to obstruction by secretions or the tongue.

The nurse assesses the patient's pain level using a verbal or visual analog scale and assesses the characteristics of the pain. The

patient's appearance, pulse, respirations, blood pressure, skin color (adequate or cyanotic), and skin temperature (cold and clammy, warm and moist, or warm and dry) are clues to cardiovascular function. When the patient arrives in the clinical unit, the surgical site is observed for bleeding, type and integrity of dressing, and drains.

Also assessed when the patient arrives on the clinical unit are the patient's mental status and level of consciousness, speech, and orientation in comparison with preoperative baseline measures. Although a change in mental status or postoperative restlessness may be related to anxiety, pain, or medications, it may also be a symptom of oxygen deficit or hemorrhage. These serious causes must be investigated and excluded before other causes are pursued.

General discomfort resulting from lying in one position on the operating table, the surgeon's handling of tissues, the body's reaction to anesthesia, and anxiety are also common causes of restlessness. These discomforts may be relieved by administering the prescribed analgesics, changing the patient's position frequently, and assessing and alleviating the cause of anxiety. If tight, drainage-soaked bandages are causing discomfort, reinforcing or changing the dressing completely makes the patient more comfortable. The bladder is palpated for distention because urinary retention can also cause restlessness.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses may include the following:

- Risk for ineffective airway clearance related to depressed respiratory function, pain, and bed rest

- Acute pain related to surgical incision
- Decreased cardiac output related to shock or hemorrhage
- Activity intolerance related to generalized weakness secondary to surgery
- Impaired skin integrity related to surgical incision and drains
- Risk for imbalanced body temperature related to surgical environment and anesthetic agents
- Risk for imbalanced nutrition, less than body requirements related to decreased intake and increased need for nutrients secondary to surgery
- Risk for constipation related to effects of medications, surgery, dietary change, and immobility
- Risk for urinary retention related to anesthetic agents
- Risk for injury related to surgical procedure or anesthetic agents
- Anxiety related to surgical procedure
- Risk for ineffective management of therapeutic regimen related to insufficient knowledge about wound care, dietary restrictions, activity recommendations, medications, follow-up care, or signs and symptoms of complications

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications may include the following:

- Deep vein thrombosis
- Hematoma
- Infection
- Wound dehiscence or evisceration

### Planning and Goals

The major goals for the patient include optimal respiratory function, relief of pain, optimal cardiovascular function, increased activity tolerance, unimpaired wound healing, maintenance of body temperature, and maintenance of nutritional balance. Further goals include resumption of usual pattern of bowel and bladder elimination, identification of any perioperative positioning injury, acquisition of sufficient knowledge to manage self-care after discharge, and absence of complications.

### Nursing Interventions

#### PREVENTING RESPIRATORY COMPLICATIONS

Respiratory depressive effects of opioid medications, decreased lung expansion secondary to pain, and decreased mobility combine to put the patient at risk for common respiratory complications, particularly atelectasis (incomplete expansion of the lung), pneumonia, and hypoxemia (Finkelmeier, 2000; Meeker & Rothrock, 1999). Atelectasis remains a risk for the patient who is not moving well or ambulating or who is not performing deep-breathing and coughing exercises or using an incentive spirometer. Signs and symptoms include decreased breath sounds over the affected area, crackles, and cough. Pneumonia is characterized by chills and fever, tachycardia, and tachypnea. Cough may or may not be present and may or may not be productive. Hypostatic pulmonary congestion, caused by a weakened cardiovascular system that permits stagnation of secretions at lung bases, may develop; it occurs most frequently in elderly patients who are not mobilized effectively. The symptoms are often vague, with perhaps a slight elevation of temperature, pulse, and respiratory rate

and a cough. Physical examination reveals dullness and crackles at the base of the lungs. If the condition progresses, the outcome may be fatal.

The types of hypoxemia that can affect postoperative patients are subacute and episodic. Subacute hypoxemia is a constant low level of oxygen saturation, although breathing appears normal. Episodic hypoxemia develops suddenly, and the patient may be at risk for cerebral dysfunction, myocardial ischemia, and cardiac arrest. Patients at risk for hypoxemia include those who have undergone major surgery (particularly abdominal), are obese, or have preexisting pulmonary problems. Hypoxemia can be detected by pulse oximetry, which measures blood oxygen saturation. Factors that may affect the accuracy of pulse oximetry readings include cold extremities, tremors, atrial fibrillation, acrylic nails, and black or blue nail polish (these colors interfere with the functioning of the pulse oximeter; other colors do not).

Preventive measures and timely recognition of signs and symptoms help avert pulmonary complications. Strategies to prevent respiratory complications include use of an incentive spirometer and deep-breathing and coughing exercises. Crackles indicate static pulmonary secretions that need to be mobilized by coughing and deep-breathing exercises. When a mucus plug obstructs one of the bronchi entirely, the pulmonary tissue beyond the plug collapses, and a massive atelectasis results.

To clear secretions and prevent pneumonia, the nurse encourages the patient to turn frequently and take deep breaths at least every 2 hours. Coughing is also encouraged to dislodge mucus plugs. These pulmonary exercises should begin as soon as the patient arrives on the clinical unit and continue until the patient is discharged. Even if he or she is not fully awake from anesthesia, the patient can be asked to take several deep breaths. This helps to expel residual anesthetic agents, mobilize secretions, and prevent alveolar collapse (atelectasis). Careful splinting of abdominal or thoracic incision sites helps the patient overcome the fear that the exertion of coughing might open the incision. Analgesic agents are administered to permit more effective coughing, and oxygen is administered as prescribed to prevent or relieve hypoxia. To encourage lung expansion, the patient is encouraged to yawn or take sustained maximal inspirations to create a negative intrathoracic pressure of  $-40$  mm Hg and expand lung volume to total capacity. Chest physical therapy may be prescribed if indicated.

Coughing is contraindicated in patients who have head injuries or who have undergone intracranial surgery (because of the risk for increasing intracranial pressure), as well as in patients who have undergone eye surgery (risk for increasing intraocular pressure) or plastic surgery (risk for increasing tension on delicate tissues). In patients with an abdominal or thoracic incision, the nurse teaches the patient how to splint the incision while coughing.

Most postoperative patients, especially the elderly and those with an abdominal or thoracic incision, are given an incentive spirometer to use. In incentive spirometry, the patient performs sustained maximal inspirations and can see the results of these efforts as they register on the spirometer. Such feedback encourages the patient to continue to take deep breaths to maximize voluntary lung expansion. A target is established for each patient. The patient first exhales, then places the lips around the mouthpiece and slowly inhales, trying to drive the piston on the device to a marked goal. Using a spirometer has several advantages: it encourages the patient to participate actively in treatment; it ensures that the maneuver is physiologically appropriate and is repeated; and it is a cost-effective way of preventing complications. A common recommendation for use of the incentive spirometer is 10 deep

breaths every hour while awake. Refer to Chapter 25 for additional discussion of incentive spirometry.

Early ambulation increases metabolism and pulmonary aeration and, in general, improves all body functions. The patient is encouraged to be out of bed as soon as possible (ie, on the day of surgery, or no later than the first postoperative day). This practice is especially valuable in preventing pulmonary complications in older patients.

### RELIEVING PAIN

Most patients experience some pain after a surgical procedure (Meeker & Rothrock, 1999). Many factors (motivational, affective, cognitive, and emotional) influence the pain experience. Research findings have led to a better understanding of how perception, learning, personality, ethnic and cultural factors, and environment can affect anxiety, depression, and pain response (Schafheutle, Cantrill & Noyce, 2001; Watt-Watson, Stevens, Garfinkel et al., 2001). The degree and severity of postoperative pain and the patient's tolerance for pain depend on the incision site, the nature of the surgical procedure, the extent of surgical trauma, the type of anesthetic agent, and how the agent was administered. The preoperative preparation received by the patient (including information about what to expect as well as reassurance and psychological support) is a significant factor in decreasing anxiety, apprehension, and even the amount of postoperative pain.

The reasons for controlling pain are compelling. There is a well-known correlation between frequency of complications and localization of pain (Moline, 2001). Intense pain stimulates the stress response, which adversely affects the cardiac and immune systems. When pain impulses are transmitted, muscle tension increases, as does local vasoconstriction. The ischemia in the affected area causes further stimulation of pain receptors. When these noxious impulses travel centrally, sympathetic activity is compounded, which increases myocardial demand and oxygen consumption. Research has shown that cardiovascular insufficiency occurs three times more frequently, and the incidence of infection is five times greater, in people with poor postoperative pain control (Moline, 2001; Schafheutle et al., 2001; Watt-Watson et al., 2001). The hypothalamic stress response is also responsible for an increase in blood viscosity and platelet aggregation. This can lead to phlebothrombosis and pulmonary embolism.

Often the physician has prescribed different medications or dosages to cover various levels of pain. The nurse should discuss these options with the patient to determine the best medication. Then the nurse should assess the effectiveness of the medication periodically, beginning 30 minutes after administration or sooner if the medication is being delivered by patient-controlled analgesia.

### Opioid Analgesics

About one third of patients report severe pain, one third moderate pain, and one third little or no pain. These statistics do not mean that the patients in the last group have no pain; rather, they appear to activate psychodynamic mechanisms that impair the registering of pain ("gate closing" theory and nociceptive transmission). See Chapter 13 for a more detailed discussion of pain and the factors influencing the pain experience.

Opioid analgesics are commonly prescribed for pain and immediate postoperative restlessness. A preventive approach rather than an "as needed" (PRN) approach, is more effective in relieving pain. With a preventive approach, the medication is administered at prescribed intervals rather than when the pain becomes severe or unbearable. Many patients (and some health

### NURSING RESEARCH PROFILE 20-1

#### Inadequate Pain Relief Following Cardiac Surgery

Watt-Watson, J., Stevens, B., Garfinkel, P., Streiner, D., & Gallup, R. (2001). Relationships between nurses' pain knowledge and pain management outcomes for their postoperative cardiac patients. *Journal of Advanced Nursing*, 36(4), 535–545.

#### Purpose

Although studies have examined nurses' knowledge and perceived barriers to pain management, few studies have examined the relationship of nurses' knowledge and their actual implementation of pain management strategies. This Canadian study investigated the relationship between nursing pain knowledge and pain management outcomes for postoperative coronary artery bypass graft (CABG) patients.

#### Study Sample and Design

This was a descriptive, correlational, mixed between-within subjects design. A convenience sample of 94 nurses from four cardiovascular units in three university-affiliated hospitals were interviewed, along with 225 of their assigned patients. The nurses included 86 women and 8 men. The patients included 52 women and 173 men. Instruments used with the patients included the McGill Pain Questionnaire-Short Form (MPQ-SF), the present pain intensity (PPI) scale, and a visual analog scale (VAS); analgesic prescription and administration data were obtained by chart review. The Toronto Pain Management Inventory (TPMI) was used to measure pain knowledge in the nurses. The social desirability scale (SDS) was also used with the nurses.

#### Findings

The majority of patients reported moderate to severe pain during the previous 24 hours (86%) and at the time of interview while moving around (68%). The mean total score on the MPQ-SF, which has a range of possible scores from 0 to 45, was  $11.8 \pm 7$ . Chart review data indicated undermedication of patients for pain, with patients receiving only 47% of their prescribed analgesia. The nurses' scores on the TPMI indicated moderate pain knowledge, with the majority of nurses (53%) scoring 69% or less and only 15% scoring 75% or greater on the inventory. While hospital policy required documentation of pain as a fifth vital sign, charting of pain was minimal and high pain ratings did not result in an increase in analgesics administered.

#### Nursing Implications

Nurses caring for postoperative CABG patients need further education about pain management. Nurses also need to be aware that patients are undermedicated following CABG surgery and need to be more aware of patients' needs for medication, administer prescribed doses, and advocate for patients when pain medication is not prescribed.

care providers) are overly concerned with the risk of drug addiction in the postoperative patient. This risk, however, is negligible with the use of opioid medications for short-term pain control.

### Patient-Controlled Analgesia

Given the negative impact of pain on recovery, nurses need to think "pain prevention" rather than sporadic pain control and should encourage the use of patient-controlled analgesia (PCA). Patients recover more quickly when adequate pain measures are used, and PCA permits patients to administer their own pain

medication when needed (Quinn, 1999). The amount of medication delivered by the IV or epidural route and the time span during which the opioid medication is released are controlled by the PCA device. Self-administration promotes patient participation in care, eliminates delayed administration of pain medications, and maintains a therapeutic drug level.

Most patients are candidates for PCA. The two requirements for PCA are an understanding of the need to self-dose and the physical ability to self-dose. Upon sensing pain, the patient activates the medication-delivering pump with a hand-held button. PCA enables the patient to move, turn, cough, and take deep breaths with less pain, thus reducing postoperative pulmonary problems.

### Epidural Infusions and Intrapleural Anesthesia

For thoracic, orthopedic, obstetric, and major abdominal surgery, certain opioid analgesics may be administered by epidural or intrathecal infusion. Epidural infusions produce a more profound analgesia. Epidural infusions are used with caution in chest procedures because the effect of the analgesic may ascend along the spinal cord and affect respiration. Intrapleural anesthesia involves the administration of local anesthetic by a catheter between the parietal and visceral pleura. It provides sensory anesthesia without affecting motor function to the intercostal muscles. This anesthesia allows more effective coughing and deep breathing in conditions such as cholecystectomy, renal surgery, and rib fractures in which pain in the thoracic region would interfere with these functions.

A local opioid or a combination anesthetic (opioid plus local anesthetic agent) is used in the epidural infusion. Other local anesthetic methods may be used to provide analgesia and anesthesia. Intrapleural anesthesia has fewer adverse effects than systemic or spinal opioids and a lower incidence of urinary retention, vomiting, and pruritus when compared with thoracic epidural opioids (Moline, 2001; Quinn, 1999).

### Other Pain Relief Measures

For pain that is difficult to control, a subcutaneous pain management system may be used. This is a silicone catheter that is inserted at the affected area. The catheter is attached to a pump that delivers a continuous amount of local anesthetic at a specific amount determined and prescribed by the physician (Fig. 20-5).

Complete absence of pain in the area of the surgical incision may not occur for a few weeks, depending on the site and nature of surgery, but the intensity of postoperative pain gradually subsides on subsequent days. However, pain control continues to be an important concern for the patient and the nurse. Effective pain management allows the patient to participate in care, perform deep-breathing and leg exercises, and tolerate activity. As stated previously, poor pain control contributes to postoperative complications and increased length of stay. The nurse continues to assess the pain level, the effectiveness of pain medication, and factors that influence pain tolerance (eg, energy level, stress level, cultural background, meaning of pain to the patient). The nurse explains that taking pain medication before the pain becomes intense is more effective and offers pain medication at intervals rather than waiting for the patient to request medication. Non-pharmacologic pain relief measures, such as imagery, relaxation, massage, application of heat or cold (if prescribed), and distraction, can be used to supplement medications (Seers & Carroll, 1998). Changing the patient's position, using distraction, applying cool washcloths to the face, and rubbing the back with a soothing lotion may be useful in relieving general discomfort

**FIGURE 20-5** Subcutaneous pain management system comprises a pump, filter, and catheter that delivers a specific amount of prescribed local anesthetic at a rate determined by the physician. With permission from I-Flow Corporation, Lake Forest, CA.

temporarily and rendering medication more effective when it is administered.

### PROMOTING CARDIAC OUTPUT

If signs and symptoms of shock or hemorrhage occur, treatment and nursing care are implemented as described in the discussion of care in the PACU.

**NURSING ALERT** A systolic blood pressure of less than 90 mm Hg is usually considered reportable at once. However, the patient's preoperative or baseline blood pressure is used to make informed postoperative comparisons. A previously stable blood pressure that shows a downward trend of 5 mm Hg at each 15-minute reading should also be reported.

Although most patients do not hemorrhage or go into shock, changes in circulating volume, the stress of surgery, and the effects of medications and preoperative preparations all affect cardiovascular function. Intravenous fluid replacement is standard for up to 24 hours after surgery or until the patient is stable and tolerating oral fluids. Close monitoring is indicated to detect and correct conditions such as fluid volume deficit, altered tissue perfusion, and decreased cardiac output, all of which can increase the patient's discomfort, place him or her at risk for complications, and prolong the hospital stay. Some patients are at risk for fluid

volume excess secondary to existing cardiovascular or renal disease, advanced age, or the release of adrenocorticotrophic hormone and antidiuretic hormone as a result of the stress of surgery. Consequently, fluid replacement must be carefully managed, and intake and output records must be accurate.

Nursing management includes assessing the patency of the IV lines and ensuring that the appropriate fluids are administered at the prescribed rate. Intake and output, including emesis and output from wound drainage systems, are recorded separately and totaled to determine fluid balance. If the patient has an indwelling urinary catheter, hourly outputs are monitored and rates of less than 30 mL/h are reported; if the patient is voiding, an output of less than 240 mL per 8-hour shift is reported. Electrolyte levels and hemoglobin and hematocrit levels are monitored. Decreased hemoglobin and hematocrit levels can indicate blood loss or dilution of circulating volume by IV fluids. If dilution is contributing to the decreased levels, the hemoglobin and hematocrit rise as the stress response abates and fluids are mobilized and excreted.

Venous stasis from dehydration, immobility, and pressure on leg veins during surgery put the patient at risk for deep vein thrombosis. Leg exercises and frequent position changes are initiated early in the postoperative period to stimulate circulation. Patients should avoid positions that compromise venous return, such as raising the bed's knee gatch or placing a pillow under the knees, sitting for long periods, and dangling the legs with pressure at the back of the knees. Venous return is promoted by elastic compression stockings and early ambulation. Early ambulation has a significant effect on recovery and the prevention of complications and can begin, in many instances, the evening of surgery. Postoperative activity orders are checked before getting the patient out of bed. Sitting up at the edge of the bed for a few minutes may be all the patient can tolerate at first.

### ENCOURAGING ACTIVITY

Most surgical patients are encouraged to be out of bed as soon as possible. Early ambulation reduces the incidence of postoperative complications, such as atelectasis, hypostatic pneumonia, gastrointestinal discomfort, and circulatory problems (Meeker & Rothrock, 1999). Ambulation increases ventilation and reduces the stasis of bronchial secretions in the lung. It also reduces postoperative abdominal distention by increasing gastrointestinal tract and abdominal wall tone and stimulating peristalsis. Thrombophlebitis or phlebothrombosis occurs less frequently because early ambulation prevents stasis of blood by increasing the rate of circulation in the extremities. Pain is often decreased when early ambulation is possible, and the hospital stay is shorter and less costly, a further advantage to the patient and the hospital.

Despite the advantages of early ambulation, patients may be reluctant to get up the evening of surgery. Reminding them of the importance of early mobility in preventing complications may help them overcome their fears. One concern when the patient is to get out of bed for the first time is orthostatic hypotension, also called postural hypotension. Orthostatic hypotension is an abnormal drop in blood pressure that occurs as the patient changes from a supine to a standing position. It is common after surgery because of changes in circulating volume and bed rest. Signs and symptoms include a 20-mm Hg decrease in systolic blood pressure or a 10-mm Hg decrease in diastolic blood pressure, weakness, dizziness, and fainting. Older adults are at increased risk for

orthostatic hypotension secondary to age-related changes in vascular tone. To detect orthostatic hypotension, the nurse assesses the patient's feelings of dizziness and his or her blood pressure first in the supine position, after the patient sits up, again after the patient stands, and 2 to 3 minutes later. Gradual position change gives the circulatory system time to adjust. If the patient becomes dizzy, he or she should be returned to the supine position, and getting out of bed should be delayed for several hours.

To assist the postoperative patient in getting out of bed for the first time after surgery, the nurse performs the following actions:

1. Help the patient to move gradually from the lying position to the sitting position until dizziness passes. This can be achieved by raising the head of the bed.
2. Position the patient completely upright (sitting) and turned so that both legs are hanging over the edge of the bed.
3. Assist the patient to stand beside the bed.

When accustomed to the upright position, the patient may start to walk. The nurse should be at the patient's side to give physical support and encouragement. Care must be taken not to tire the patient; the extent of the first few periods of ambulation varies with the type of surgical procedure and the patient's physical condition and age.

Whether or not the patient can ambulate early in the postoperative period, bed exercises are encouraged to improve circulation. Bed exercises consist of the following:

- Arm exercises (full range of motion, with specific attention to abduction and external rotation of the shoulder)
- Hand and finger exercises
- Foot exercises to prevent deep vein thrombosis, foot drop, and toe deformities and to aid in maintaining good circulation
- Leg flexion and leg-lifting exercises to prepare the patient for ambulation
- Abdominal and gluteal contraction exercises

Hampered by pain, dressings, IV lines, or drains, many patients cannot engage in activity without assistance. Prolonged inactivity may lead to pressure ulcers, deep vein thrombosis, atelectasis, or hypostatic pneumonia. Helping the patient increase his or her activity level on the first postoperative day is an important nursing function. One way to increase the patient's activity is to have the patient perform as much routine hygiene care as possible. Setting up the patient to bathe with a bedside wash basin or, if possible, assisting the patient to the bathroom to sit in a chair at the sink not only gets the patient moving but helps restore a sense of self-control and prepares the patient for discharge.

To be safely discharged to home, patients need to be able to ambulate a functional distance (length of the house or apartment), get in and out of bed unassisted, and be independent with toileting. Patients can be asked to perform as much as they can and then to call for assistance. The patient and the nurse can collaborate on a schedule for progressive activity that includes ambulating in the room and hallway and sitting out of bed in the chair. Assessing the patient's vital signs before, during, and after a scheduled activity helps the nurse and patient determine the rate of progression. By providing physical support, the nurse maintains the patient's safety; by communicating a positive attitude about the patient's ability to perform the activity, the nurse pro-

motes the patient's confidence. The nurse should make sure the patient continues to perform bed exercises, wears pneumatic compression or thigh-high elastic compression stockings when in bed, and rests as needed.

### PROMOTING WOUND HEALING

Ongoing assessment of the surgical site involves inspection for approximation of wound edges, integrity of sutures or staples, redness, discoloration, warmth, swelling, unusual tenderness, or drainage. The area around the wound should also be inspected for reactions to tape or trauma from tight bandages.

Nursing interventions to promote wound healing also include management of surgical drains and dressings. Wound drains are tubes exiting the peri-incisional area into either a portable wound suction device (closed) or into the dressings (open). The principle involved is to allow the escape of blood and serous fluids that can otherwise serve as a culture medium for bacteria. In portable wound suction, the use of gentle, constant suction enhances drainage of these fluids and collapses the skin flaps against the underlying tissue, thus removing "dead space." Types of wound drains include the Penrose, Hemovac, and Jackson-Pratt drains (Fig. 20-6). Output from wound drainage systems and all new drainage is recorded. The amount of bloody drainage on the surgical dressing is assessed frequently. Spots of drainage on the dressings are outlined with a pen, and the date and time of the outline are recorded on the dressing so that increased drainage can be easily seen. A certain amount of bloody drainage in a wound drainage system or on the dressing is expected, but excessive amounts should be reported to the surgeon. Increasing amounts of fresh blood on the dressing should be reported immediately. Some wounds are irrigated heavily before closure in the operating room, and open drains exiting the wound may be embedded in the dressings. These wounds may drain large amounts of blood-tinged fluid that saturate the dressing. The dressing can be reinforced with sterile gauze bandages; the time that they were reinforced should be documented. If drainage continues, the surgeon should be notified so that the dressing can be changed. Multiple similar drains are numbered or otherwise labeled (eg, left lower quadrant, left upper quadrant) so that output measurements can be reliably and consistently recorded.

Surgical wound healing occurs in three phases: the inflammatory, proliferative, and maturation phases (Table 20-2). Wounds also heal by different mechanisms, depending on the condition

of the wound. These mechanisms include first-, second-, or third-intention wound healing (Meeker & Rothrock, 1999).

### First-Intention Healing

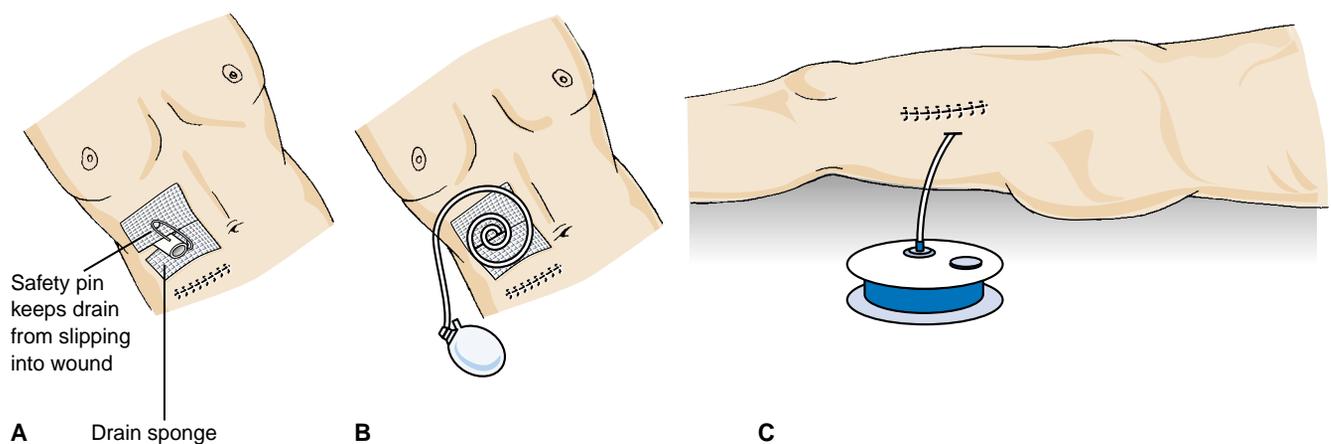

Wounds made aseptically, with a minimum of tissue destruction, and properly closed heal with little tissue reaction by first intention (primary union) (Fig. 20-7). When wounds heal by **first-intention healing**, granulation tissue is not visible and scar formation is minimal. Postoperatively, many of these wounds are covered with a dry sterile dressing. If a cyanoacrylate tissue adhesive was used to close the incision without the use of sutures, a dressing is contraindicated (Vargas & Reiger, 2000).

### Second-Intention Healing

**Second-intention healing** (granulation) occurs in infected wounds (abscess) or in wounds in which the edges have not been approximated. When an abscess is incised, it collapses partly, but the dead and the dying cells forming its walls are still being released into the cavity. For this reason, drainage tubes or gauze packing are inserted into the abscess pocket to allow drainage to escape easily. Gradually, the necrotic material disintegrates and escapes, and the abscess cavity fills with a red, soft, sensitive tissue that bleeds easily. This tissue is composed of minute, thin-walled capillaries and buds that later form connective tissue. These buds, called granulations, enlarge until they fill the area left by the destroyed tissue (see Fig. 20-7). The cells surrounding the capillaries change their round shape to become long, thin, and intertwined to form a scar (cicatrix). Healing is complete when skin cells (epithelium) grow over these granulations. This method of repair is called healing by granulation, and it takes place whenever pus is formed or when loss of tissue has occurred for any reason. When the postoperative wound is allowed to heal by secondary intention, it is usually packed with saline-moistened sterile dressings and covered with a dry sterile dressing.

### Third-Intention Healing

**Third-intention healing** (secondary suture) is used for deep wounds that have either not been sutured early or that break down and are resutured later, thus bringing together two apposing granulation surfaces. This results in a deeper and wider scar. These wounds are also packed postoperatively with moist gauze and covered with a dry sterile dressing.

**FIGURE 20-6** Types of surgical drains: (A) Penrose, (B) Jackson-Pratt, (C) Hemovac.

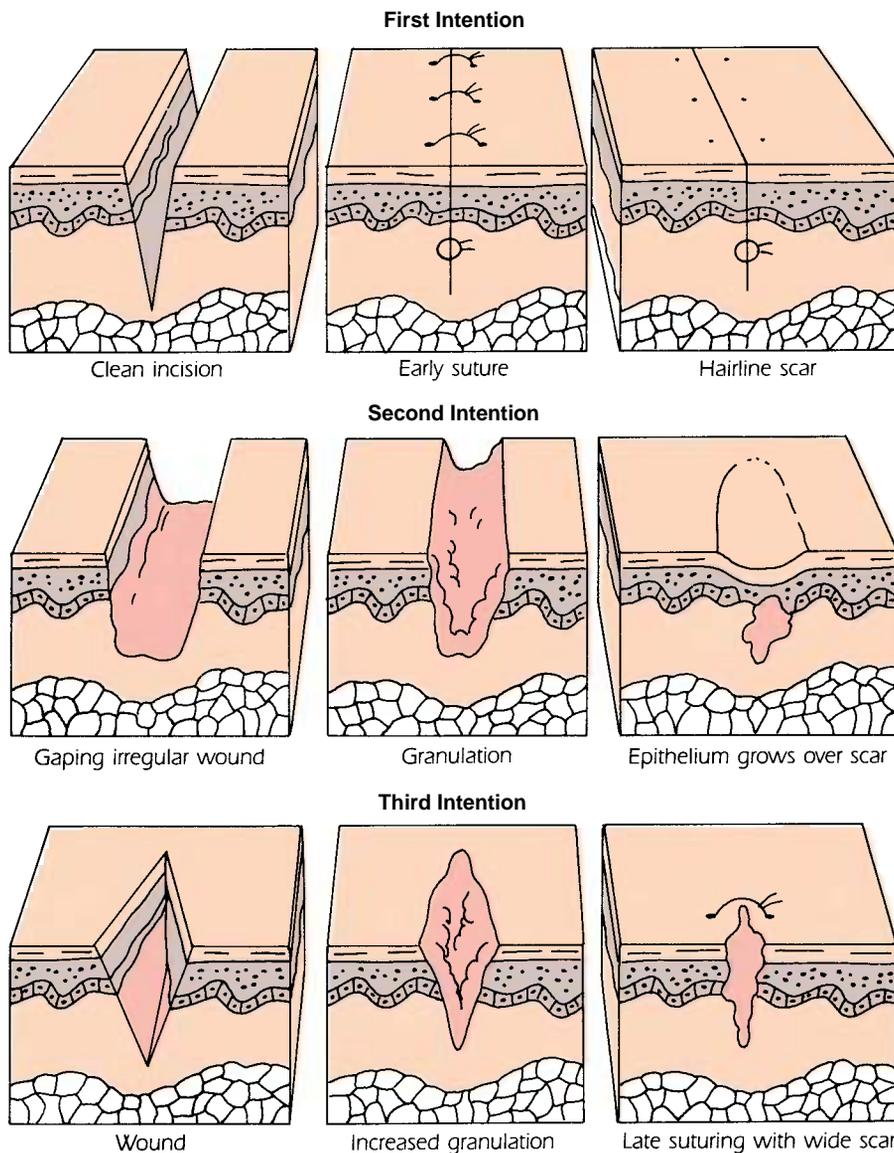

Table 20-2 • Phases of Wound Healing

PHASE	DURATION	EVENTS
Inflammatory (also called lag or exudative phase)	1–4 days	Blood clot forms Wound becomes edematous Debris of damaged tissue and blood clot are phagocytosed
Proliferative (also called fibroblastic or connective tissue phase)	5–20 days	Collagen produced Granulation tissue forms Wound tensile strength increases
Maturation (also called differentiation, resorptive, remodeling, or plateau phase)	21 days to months or even years	Fibroblasts leave wound Tensile strength increases Collagen fibers reorganize and tighten to reduce scar size

As a wound heals, many factors, such as adequate nutrition, cleanliness, rest, and position, determine how quickly healing occurs. These factors are influenced by nursing interventions. Specific nursing assessments and interventions that address these factors and help to promote wound healing are presented in Table 20-3. Other nursing interventions include assessment and care of the wound.

### CHANGING THE DRESSING

While the first postoperative dressing is usually changed by a member of the surgical team, subsequent dressing changes in the immediate postoperative period are usually performed by the nurse. A dressing is applied to a wound for one or more of the following reasons: (1) to provide a proper environment for wound

**FIGURE 20-7** Types of wound healing: first intention healing, second intention healing, and third intention healing.

**Table 20-3 • Factors Affecting Wound Healing**

FACTORS	RATIONALE	NURSING INTERVENTIONS
Age of patient Handling of tissues Hemorrhage	The older the patient, the less resilient the tissues. Rough handling causes injury and delayed healing. Accumulation of blood creates dead spaces as well as dead cells that must be removed. The area becomes a growth medium for organisms.	Handle all tissues gently. Handle tissues carefully and evenly. Monitor vital signs. Observe incision site for evidence of bleeding and infection.
Hypovolemia	Insufficient blood volume leads to vasoconstriction and reduced oxygen and nutrients available for wound healing.	Monitor for volume deficit (circulatory impairment). Correct by fluid replacement as prescribed.
Local factors Edema	Reduces blood supply by exerting increased interstitial pressure on vessels	Elevate part; apply cool compresses.
Inadequate dressing technique Too small Too tight	Permits bacterial invasion and contamination Reduces blood supply carrying nutrients and oxygen	Follow guidelines for proper dressing technique.
Nutritional deficits	Protein-calorie depletion may occur. Insulin secretion may be inhibited, causing blood glucose to rise.	Correct deficits; this may require parenteral nutritional therapy. Monitor blood glucose levels. Administer vitamin supplements as prescribed.
Foreign bodies	Foreign bodies retard healing.	Keep wounds free of dressing threads, talcum, and powder from gloves.
Oxygen deficit (tissue oxygenation insufficient)	Insufficient oxygen may be due to inadequate lung and cardiovascular function as well as localized vasoconstriction.	Encourage deep breathing, turning, controlled coughing.
Drainage accumulation	Accumulated secretions hamper healing process.	Monitor closed drainage systems for proper functioning. Institute measures to remove accumulated secretions.
Medications Corticosteroids	May mask presence of infection by impairing normal inflammatory response	Be aware of action and effect of medications patient is receiving.
Anticoagulants Broad-spectrum and specific antibiotics	May cause hemorrhage Effective if administered immediately before surgery for specific pathology or bacterial contamination. If administered after wound is closed, ineffective because of intravascular coagulation.	
Patient overactivity	Prevents approximation of wound edges. Resting favors healing.	Use measures to keep wound edges approximated: taping, bandaging, splints. Encourage rest.
Systemic disorders Hemorrhagic shock Acidosis Hypoxia Renal failure Hepatic disease Sepsis	These depress cell functions that directly affect wound healing.	Be familiar with the nature of the specific disorder. Administer prescribed treatment. Cultures may be indicated to determine appropriate antibiotic.
Immunosuppressed state	Patient is more vulnerable to bacterial and viral invasion; defense mechanisms are impaired.	Provide maximum protection to prevent infection. Restrict visitors with colds; institute mandatory hand hygiene by all staff.
Wound stressors Vomiting Valsalva maneuver Heavy coughing Straining	Produce tension on wounds, particularly of the torso.	Encourage frequent turning and ambulation and administer antiemetic medications as prescribed. Assist patient in splinting incision.

healing; (2) to absorb drainage; (3) to splint or immobilize the wound; (4) to protect the wound and new epithelial tissue from mechanical injury; (5) to protect the wound from bacterial contamination and from soiling by feces, vomitus, and urine; (6) to promote hemostasis, as in a pressure dressing; and (7) to provide mental and physical comfort for the patient.

The patient is told that the dressing is to be changed and that changing the dressing is a simple procedure associated with little discomfort. The dressing change is performed at a suitable time (eg, not at mealtimes or when visitors are present). Privacy is provided, and the patient is not unduly exposed. The nurse should avoid referring to the incision as a scar since the term may have negative connotations for the patient. Assurance is given that the incision will shrink as it heals and the redness will fade.

The nurse carries out hand hygiene before and after the dressing change and wears disposable gloves for the dressing change itself. The tape or adhesive portion of the dressing is removed by pulling it parallel with the skin surface and in the direction of hair growth, rather than at right angles. Alcohol wipes or nonirritating solvents aid in removing adhesive painlessly and quickly. The old dressing is removed and then deposited in a container designated for biomedical waste disposal. In accordance with standard precautions, dressings are never touched by ungloved hands because of the danger of transmitting pathogenic organisms.

If the patient is sensitive to adhesive tape, the dressing may be held in place with hypoallergenic tape. Many tapes are porous to permit ventilation and prevent skin maceration. The correct way to apply tape is to place the tape at the center of the dressing and then press the tape down on both sides, applying tension evenly away from the midline. The wrong method of applying tape—fixing one end of the tape to the skin and pulling it tight over the

dressing—often wrinkles and pulls the skin in the process. The resulting continuous and forceful traction produces a shearing effect, causing the epidermal layer to slip sideways and become separated from the deeper dermal layers. Some wounds become edematous after having been dressed, causing considerable tension on the tape. If the tape is not flexible, the stretching bandage will also cause a shear injury to the skin. This can result in denuded areas or large blisters. An elastic adhesive bandage (Elastoplast, Microfoam-3M) may be used to hold dressings in place over mobile areas, such as the neck or the extremities, or where pressure is required.

While changing the dressing, the nurse has an opportunity to teach the patient how to care for the incision and change the dressings at home. The nurse observes for indicators of the patient's readiness to learn, such as looking at the incision, expressing interest, or assisting in the dressing change. Information on self-care activities and possible signs of infection are summarized in Chart 20-3.

### MAINTAINING NORMAL BODY TEMPERATURE

The patient is still at risk for malignant hyperthermia and hypothermia in the postoperative period (Fortunato-Phillips, 2000). Efforts are made to identify malignant hyperthermia and to treat it early and promptly (Redmond, 2001). (See the discussion of malignant hyperthermia in Chap. 19.)

Patients who have been anesthetized are susceptible to chills and drafts. Attention to hypothermia management, begun in the intraoperative period, extends into the postoperative period to prevent significant nitrogen loss and catabolism. Signs of hypothermia are reported to the physician. The room is maintained at a comfortable temperature, and blankets are provided to prevent chilling. Treatment includes oxygen administration, adequate

### Chart 20-3 • PATIENT EDUCATION Wound Care Instructions

#### Until Sutures Are Removed

- Keep the wound dry and clean.
  - If there is no dressing, ask your nurse or physician if you can bathe or shower.
  - If a dressing or splint is in place, do not remove it unless it is wet or soiled.
  - If wet or soiled, change dressing yourself if you have been taught to do so; otherwise, call your nurse or physician for guidance.
  - If you have been taught, instruction might be as follows:
    - Cleanse area *gently* with sterile normal saline once or twice daily.
    - Cover with a sterile Telfa pad or gauze square large enough to cover wound.
    - Apply hypoallergenic tape (Dermacel or paper). Adhesive is not recommended because it is difficult to remove without possible injury to the incisional site.
- Immediately report any of these signs of infection:
  - Redness, marked swelling exceeding  $\frac{1}{2}$  inch (2.5 cm) from incision site; tenderness; or increased warmth around wound
  - Red streaks in skin near wound
  - Pus or discharge, foul odor
  - Chills or temperature higher than  $37.7^{\circ}\text{C}$  ( $100^{\circ}\text{F}$ )
- If soreness or pain causes discomfort, apply a dry cool pack (containing ice or cold water) or take prescribed

acetaminophen tablets (2) every 4–6 hours. Avoid using aspirin without direction or instruction because bleeding can occur with its use.

- Swelling after surgery is common. To help reduce swelling, elevate the affected part to the level of the heart.
  - Hand or arm
    - Sleep—elevate arm on pillow at side
    - Sitting—place arm on pillow on adjacent table
    - Standing—rest affected hand on opposite shoulder; support elbow with unaffected hand
  - Leg or foot
    - Sitting—place a pillow on a facing chair; provide support underneath the knee
    - Lying—place a pillow under affected leg

#### After Sutures Are Removed

Although the wound appears to be healed when sutures are removed, it is still tender and will continue to heal and strengthen for several weeks.

- Follow recommendations of physician or nurse regarding extent of activity.
- Keep suture line clean; do not rub vigorously; pat dry. Wound edges may look red and may be slightly raised. This is normal.
- If the site continues to be red, thick, and painful to pressure after 8 weeks, consult the health care provider. (This may be due to excessive collagen formation and should be checked.)

hydration, and proper nutrition. The patient is also monitored for cardiac dysrhythmias. The risk for hypothermia is greater in the elderly and in patients who were in the cool operating room environment for a prolonged period.

### MANAGING GASTROINTESTINAL FUNCTION AND RESUMING NUTRITION

Gastrointestinal discomfort (nausea, vomiting, hiccups) and resumption of oral intake are issues for both the patient and the nurse. Nausea and vomiting are common after anesthesia (Litwack, 1999; Meeker & Rothrock, 1999). They are more common in women, obese people (fat cells act as reservoirs for the anesthetic), patients prone to motion sickness, and patients who have undergone lengthy surgical procedures. Other causes of postoperative vomiting include an accumulation of fluid in the stomach, inflation of the stomach, and the ingestion of food and fluid before peristalsis resumes.

When vomiting is likely because of the nature of surgery, a nasogastric tube is inserted preoperatively and remains in place throughout the surgery and the immediate postoperative period. In addition, a nasogastric tube may be inserted when a patient who has food in the stomach requires emergency surgery.

Hiccups, produced by intermittent spasms of the diaphragm secondary to irritation of the phrenic nerve, can occur after surgery. The irritation may be direct, such as from stimulation of the nerve by a distended stomach, subdiaphragmatic abscess, or abdominal distention; indirect, such as from toxemia or uremia that stimulates the center; or reflexive, such as irritation from a drainage tube or obstruction of the intestines. Usually these occurrences are mild, transitory attacks that cease spontaneously. When hiccups persist, they may produce considerable distress and serious effects such as vomiting, exhaustion, and wound dehiscence. The physician may prescribe phenothiazine medications for severe, persistent hiccups.

Once nausea and vomiting have subsided and the patient is fully awake and alert, the sooner he or she can tolerate a usual diet, the more quickly normal gastrointestinal function will resume. Taking food by mouth stimulates digestive juices and promotes gastric function and intestinal peristalsis. The return to normal dietary intake should proceed at the pace set by the patient. Of course, the nature of surgery and the type of anesthesia directly affect the rate at which normal gastric activity resumes. Liquids are typically the first substances desired and tolerated by the patient after surgery. Water, fruit juices, and tea may be given in increasing amounts. Cool fluids are tolerated more easily than those that are ice cold or hot. Soft foods (gelatin, custard, milk, and creamed soups) are added gradually after clear fluids have been tolerated. As soon as the patient tolerates soft foods well, solid food may be given.

Assessment and management of gastrointestinal function are important after surgery because the gastrointestinal tract is subject to uncomfortable or potentially life-threatening complications. Any postoperative patient may suffer from distention. Postoperative distention of the abdomen results from the accumulation of gas in the intestinal tract. Manipulation of the abdominal organs during surgery may produce a loss of normal peristalsis for 24 to 48 hours, depending on the type and extent of surgery. Even though nothing is given by mouth, swallowed air and gastrointestinal secretions enter the stomach and the intestines; if not propelled by peristalsis, they collect in the intestines, producing distention and causing the patient to complain of fullness or pain in the abdomen. Most often, the gas collects in the colon.

Abdominal distention is further increased by immobility, anesthetic agents, and the use of opioid medications.

After major abdominal surgery, distention may be avoided by having the patient turn frequently, exercise, and ambulate as early as possible. This also alleviates distention produced by swallowing air, which is common in anxious patients. When postoperative distention is anticipated, a nasogastric tube may be inserted before surgery. The tube may remain in place until full peristaltic activity (indicated by the passage of flatus) has resumed. The nurse can determine when peristaltic bowel sounds return by listening to the abdomen with a stethoscope. Bowel sounds are documented so that diet progression can occur.

Paralytic ileus and intestinal obstruction are potential postoperative complications that occur more frequently in patients undergoing intestinal or abdominal surgery. Refer to Chapter 37 for discussion of treatment.

### PROMOTING BOWEL FUNCTION

Constipation is common after surgery and can range from a minor irritation to a serious complication (Fox, 1998). Decreased mobility, decreased oral intake, and opioid analgesics contribute to difficulty having a bowel movement. In addition, irritation and trauma to the bowel during surgery may inhibit intestinal movement for several days. The combined effect of early ambulation, improved dietary intake, and a stool softener (if prescribed) promotes bowel elimination. Until the patient reports return of normal bowel function, the nurse should assess the abdomen for distention and the presence and frequency of bowel sounds. If the abdomen is not distended and bowel sounds are normal, and if the patient does not have a bowel movement by the second or third postoperative day, the physician should be notified so that a laxative can be given that evening.

### MANAGING VOIDING

Urinary retention after surgery can occur for various reasons. Anesthetics, anticholinergic agents, and opioids interfere with the perception of bladder fullness and the urge to void and inhibit the ability to initiate voiding and completely empty the bladder. Abdominal, pelvic, and hip surgery may increase the likelihood of retention secondary to pain. Additionally, some patients find it difficult to use the bedpan or urinal in the recumbent position.

Bladder distention and the urge to void should be assessed on the patient's arrival on the unit and frequently thereafter. The patient is expected to void within 8 hours of surgery (this includes time spent in the PACU). If the patient has an urge to void and cannot, or if the bladder is distended and no urge is felt or the patient cannot void, catheterization is not delayed solely on the basis of the 8-hour time frame. All methods to encourage the patient to void should be tried (eg, letting water run, applying heat to the perineum). The bedpan should be warm; a cold bedpan causes discomfort and automatic tightening of muscles (including the urethral sphincter). When the patient cannot void on a bedpan, it may be permissible to use a commode rather than resorting to catheterization. Male patients are often permitted to sit up or stand beside the bed to use the urinal, but safeguards should be taken to prevent the patient from falling or fainting due to loss of coordination from medications or orthostatic hypotension. If the patient cannot void in the specified time frame, the patient is catheterized and the catheter removed after the bladder has emptied. Straight intermittent catheterization is preferred over indwelling catheterization because the risk for infection is increased with an indwelling catheter.

Even if the patient voids, the bladder may not necessarily be empty. The nurse notes the amount of urine voided and palpates the suprapubic area for distention or tenderness. A portable ultrasound device may also be used to assess residual volume. Intermittent catheterization continues every 4 to 6 hours until the patient can void spontaneously and the postvoid residual is less than 100 mL.

### MAINTAINING A SAFE ENVIRONMENT

During the immediate postoperative period, the patient recovering from anesthesia should have all side rails up, and the bed should be in the low position. The nurse assesses the patient's level of consciousness and orientation and determines if the patient needs his or her eyeglasses or hearing aid, because impaired vision, inability to hear postoperative instructions, or inability to communicate verbally place the patient at risk for injury. All objects the patient may need should be within reach, especially the call bell. Any immediate postoperative orders concerning special positioning, equipment, or interventions should be implemented as soon as possible. The patient is instructed to ask for assistance with any activity. Although they are occasionally necessary for the disoriented patient, restraints should not be used if at all possible.

Any surgical procedure has the potential for injury due to disrupted neurovascular integrity resulting from prolonged awkward positioning in the operating room, manipulation of tissues, inadvertent severing of nerves, or tight bandages. Any orthopedic surgery or surgery involving the extremities carries a risk for peripheral nerve damage. Vascular surgeries, such as replacing sections of diseased peripheral arteries or inserting an arteriovenous graft, put the patient at risk for thrombus formation at the surgical site and subsequent ischemia of tissues distal to the thrombus. Assessment includes having the patient move the hand or foot distal to the surgical site through a full range of motion, assessing that all surfaces have intact sensation, and assessing peripheral pulses.

### PROVIDING EMOTIONAL SUPPORT TO THE PATIENT AND FAMILY

Although patients and families are undoubtedly relieved that surgery is over, anxiety levels may remain high in the immediate postoperative period. Many factors contribute to this anxiety: pain, being in an unfamiliar environment, feeling unable to control one's circumstances, fear of the long-term effects of surgery, fear of complications, loss of ability to care for self, fatigue, spiritual distress, altered role responsibilities, ineffective coping, and altered body image are all potential reactions to the surgical experience. The nurse helps the patient and family work through their anxieties by providing reassurance and information and by spending time listening to and addressing their concerns. The nurse describes hospital routines and what to expect in the ensuing hours and days until discharge and explains the purpose of nursing assessments and interventions. Informing patients when they will be able to drink fluids or eat, when they will be getting out of bed, and when tubes and drains will be removed helps them gain a sense of control and participation in recovery and engages them in the plan of care. Acknowledging family members' concerns and accepting and encouraging their participation in the patient's care assists them in feeling they are helping their loved one. The nurse can manipulate the environment to enhance rest and relaxation by providing privacy, reducing noise, adjusting the lighting, providing enough seating for family members, and performing any other measures that will produce a supportive atmosphere.

## MANAGING POTENTIAL COMPLICATIONS

### Deep Vein Thrombosis

Deep vein thrombosis and other complications, such as pulmonary embolism, are serious potential complications of surgery (Chart 20-4). The stress response that is initiated as a result of surgery inhibits the fibrinolytic system, resulting in blood hypercoagulability. Dehydration, low cardiac output, blood pooling in the extremities, and bed rest add to the risk of thrombosis formation. Although all postoperative patients are at some risk, certain surgeries and patient populations carry a greater risk. The first symptom of deep vein thrombosis may be a pain or cramp in the calf. Although not present in all cases, calf pain elicited on ankle dorsiflexion (Homans' sign) suggests thrombosis (Fig. 20-8). Initial pain and tenderness may be followed by a painful swelling of the entire leg, often accompanied by a fever, chills, and diaphoresis.

Prophylactic treatment for postoperative patients at risk is common practice. Low-dose heparin may be prescribed and administered subcutaneously until the patient is ambulatory. Low-molecular-weight heparin and low-dose warfarin are other anticoagulants that may be used. External pneumatic compression and thigh-high elastic compression stockings can be used alone or in combination with low-dose heparin.

Chart 20-4

### Risk Factors for Postoperative Complications

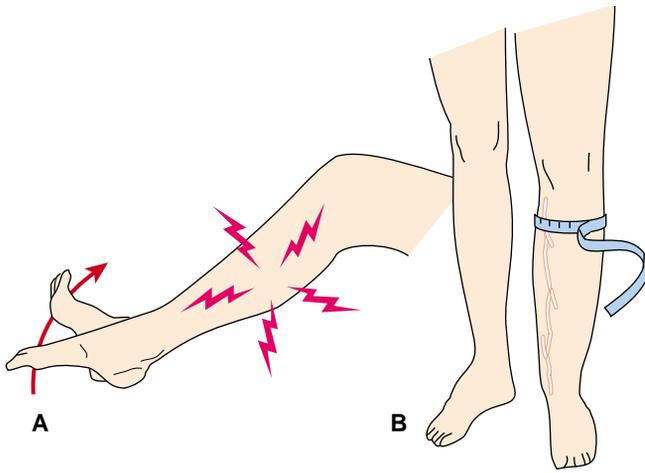

Patients at increased risk for postoperative complications (eg, deep vein thrombosis) and pulmonary problems include the following:

#### Deep Vein Thrombosis

- Orthopedic patients having hip surgery, knee reconstruction, and other lower extremity surgery
- Urologic patients having transurethral prostatectomy, and older patients having urologic surgery
- General surgical patients over 40 years of age, those who are obese, those with a malignancy, those who have had prior deep vein thrombosis or pulmonary embolism, or those undergoing extensive, complicated surgical procedures
- Gynecology (and obstetric) patients over 40 years of age with added risk factors (varicose veins, previous venous thrombosis, infection, malignancy, obesity)
- Neurosurgical patients, similar to other surgical high-risk groups (in patients with stroke, for instance, the risk of deep vein thrombosis in the paralyzed leg is as high as 75%)

#### Pulmonary Complications

- Type of surgery—greater incidence after all forms of abdominal surgery when compared with peripheral surgery
- Location of incision—the closer the incision to the diaphragm, the higher the incidence of pulmonary complications
- Preoperative respiratory problems
- Age—greater risk after age 40 than before age 40
- Sepsis
- Obesity—weight greater than 110% of ideal body weight
- Prolonged bed rest
- Duration of surgical procedure—more than 3 hours
- Aspiration
- Dehydration
- Malnutrition
- Hypotension and shock
- Immunosuppression

**FIGURE 20-8** Assessment of signs and symptoms of deep vein thrombosis. (A) With the knee flexed, the patient may complain of pain in the calf on dorsiflexion of the foot (Homans' sign). This is a sign of early and subclinical thrombosis, which may or may not be present. Gentle compression reveals tenderness of the calf muscles (note arrow). (B) The affected leg may swell; veins are more prominent and may be palpated easily.

The benefits of early ambulation and hourly leg exercises in preventing deep vein thrombosis cannot be overemphasized, and these activities are recommended for all patients, regardless of their risk. It is important to avoid the use of blanket rolls, pillow rolls, or any form of elevation that can constrict vessels under the knees. Even prolonged “dangling” (having the patient sit on the edge of the bed with legs hanging over the side) can be dangerous and is not recommended in susceptible patients because pressure under the knees can impede circulation. Adequate hydration is also encouraged; the patient can be offered juices and water

throughout the day to avoid dehydration. Refer to Chapter 30 for a complete discussion of deep vein thrombosis and to Chapter 23 for discussion of pulmonary embolus.

### Hematoma

At times, concealed bleeding occurs beneath the skin at the surgical site. This hemorrhage usually stops spontaneously but results in clot (hematoma) formation within the wound. If the clot is small, it will be absorbed and need not be treated. When the clot is large, the wound usually bulges somewhat, and healing will be delayed unless the clot is removed. After several sutures are removed by the physician, the clot is evacuated and the wound is packed lightly with gauze. Healing occurs usually by granulation, or a secondary closure may be performed.

### Infection (Wound Sepsis)

The creation of a surgical wound disrupts the integrity of the skin and its protective function. Exposure of deep body tissues to pathogens in the environment places the patient at risk for infection of the surgical site, a potentially life-threatening complication. Surgical site infection increases hospital length of stay, costs of care, and risk for further complications. In postoperative patients, surgical site infection is the most common nosocomial infection, with 67% of these infections occurring within the incision and 33% occurring in an organ or space around the surgical site (CDC, 1999). Recent research suggests that the administration of supplemental oxygen during colorectal resection and for 2 hours postoperatively reduces the incidence of postoperative infection (Greif, Ozan, Horn et al., 2000).

Multiple factors place the patient at risk for wound infection. One risk factor is the wound classification. Surgical wounds are classified according to the degree of contamination. Table 20-4 defines the terms used to describe surgical wounds and gives the expected rate of wound infection per category. Other risk factors

**Table 20-4 • Wound Classification and Associated Surgical Site Infection Risk**

SURGICAL CATEGORY	DETERMINANTS OF CATEGORY	EXPECTED RISK OF POSTSURGICAL INFECTION (%)
Clean	Nontraumatic site Uninfected site No inflammation No break in aseptic technique No entry into respiratory, alimentary, genitourinary, or oropharyngeal tracts	1–3
Clean-contaminated	Entry into respiratory, alimentary, genitourinary or oropharyngeal tracts without unusual contamination Appendectomy Minor break in aseptic technique Mechanical drainage	3–7
Contaminated	Open, newly experienced traumatic wounds Gross spillage from gastrointestinal tract Major break in aseptic technique Entry into genitourinary or biliary tract when urine or bile is infected	7–16
Dirty	Traumatic wound with delayed repair, devitalized tissue, foreign bodies, or fecal contamination Acute inflammation and purulent drainage encountered during procedure	16–29

include both patient-related factors and those associated with the surgical procedure. Patient-related factors include age, nutritional status, diabetes, smoking, obesity, remote infections, endogenous mucosal microorganisms, altered immune response, length of preoperative stay, and severity of illness (Bryant, 2000). Factors related to the surgical procedure include the method of preoperative skin preparation, surgical attire of the team, method of sterile draping, duration of surgery, antimicrobial prophylaxis, aseptic technique, factors related to surgical technique, drains or foreign material, operating room ventilation, and exogenous microorganisms. Efforts to prevent wound infection are directed at reducing these risks. Preoperative and intraoperative risks and interventions are discussed in Chapters 18 and 19. Although the conditions for surgical site infection and serious contamination of the wound occur in the preoperative and intraoperative time frames, postoperative care of the wound centers on assessing the wound, preventing contamination and infection before wound edges have sealed, and enhancing healing.

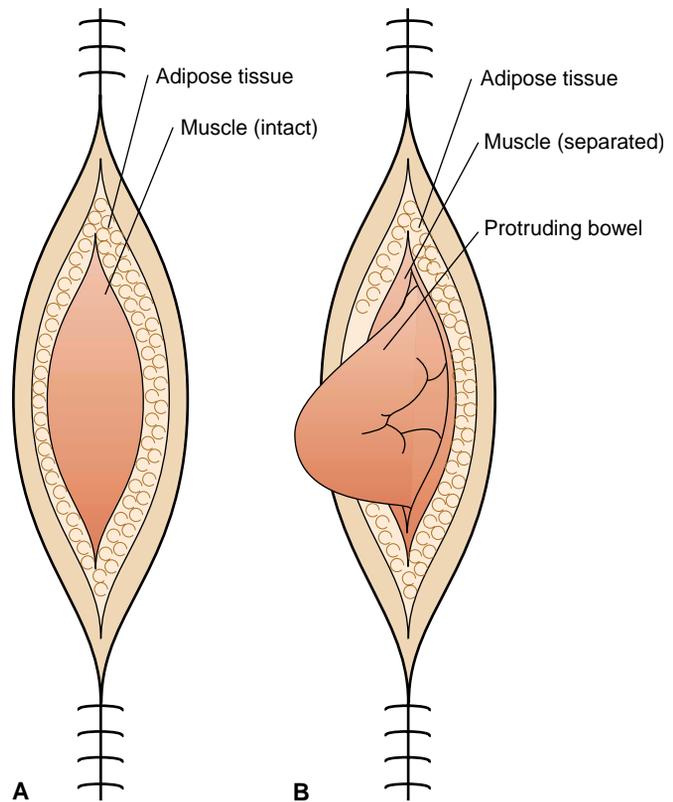

Wound infection may not present until at least postoperative day 5. Most patients are discharged before that time, and more than half of wound infections are diagnosed after discharge, highlighting the importance of patient education regarding wound care. Risk factors for wound sepsis include wound contamination, foreign body, faulty suturing technique, devitalized tissue, hematoma, debilitation, dehydration, malnutrition, anemia, advanced age, extreme obesity, shock, length of preoperative hospitalization, duration of surgical procedure, and associated disorders (eg, diabetes mellitus, immunosuppression). Signs and symptoms of wound infection include pulse rate and temperature elevation; an elevated white blood cell count; wound swelling, warmth, tenderness, or discharge; and incisional pain. Local signs may be absent if the infection is deep. *Staphylococcus aureus* accounts for many postoperative wound infections. Other infections may result from *Escherichia coli*, *Proteus vulgaris*, *Aerobacter aerogenes*, *Pseudomonas aeruginosa*, and other organisms. Although rare, beta-hemolytic streptococcal or clostridial infections can be rapid and deadly. If wound infection due to beta-hemolytic streptococcus or clostridium occurs, extreme care is needed to prevent spread of infection to others. Intensive medical and nursing care is essential if the patient is to survive.

When a wound infection is diagnosed in a surgical incision, the surgeon may remove one or more sutures or staples and, using aseptic precautions, separate the wound edges with a pair of blunt scissors or a hemostat. Once the incision is opened, a drain is inserted. If the infection is deep, an incision and drainage procedure may be necessary. Antimicrobial therapy and a wound care regimen are also initiated (Bryant, 2000).

### Wound Dehiscence and Evisceration

Wound **dehiscence** (disruption of surgical incision or wound) and **evisceration** (protrusion of wound contents) are serious surgical complications (Fig. 20-9). Dehiscence and evisceration are especially serious when they involve abdominal incisions or wounds. These complications result from sutures giving way, from infection, and, more frequently, after marked distention or strenuous cough. They may also occur because of increasing age, poor nutritional status, and pulmonary or cardiovascular disease in patients undergoing abdominal surgery.

When the wound edges separate slowly, the intestines may protrude gradually or not at all, and the earliest sign may be a gush of bloody (serosanguineous) peritoneal fluid from the wound. When a wound ruptures suddenly, coils of intestine may push out of the abdomen. The patient may report that “some-

**FIGURE 20-9** (A) Wound dehiscence; (B) wound evisceration.

thing gave way.” The evisceration causes pain and can be associated with vomiting.

**NURSING ALERT** When disruption of a wound occurs, the patient is placed in low Fowler’s position and instructed to lie quietly. These actions minimize protrusion of body tissues. The protruding coils of intestine are covered with sterile dressings moistened with sterile saline solution, and the surgeon is notified at once.

An abdominal binder, properly applied, is an excellent prophylactic measure against an evisceration and often is used along with the primary dressing, especially in patients with weak or pendulous abdominal walls or when rupture of a wound has occurred.

### Gerontologic Considerations

Older adults recover more slowly, have a longer hospital stay, and are at greater risk for developing postoperative complications (Polanczyk et al., 2001). Delirium, pneumonia, decline in functional ability, exacerbation of comorbid conditions, pressure ulcers, decreased oral intake, gastrointestinal disturbance, and falls are all threats to recovery in the older adult. Expert nursing care can help the older adult avoid these complications or minimize their effects.

Postoperative delirium, characterized by confusion, perceptual and cognitive deficits, altered attention levels, disturbed sleep patterns, and impaired psychomotor skills, is a significant problem for older adults. Causes of delirium are multifactorial (Chart 20-5).

Chart  
20-5

## Causes of Postoperative Delirium

- Fluid and electrolyte imbalance
- Dehydration
- Hypoxia
- Hypercarbia
- Acid–base disturbance
- Infection (urinary tract, wound, respiratory)
- Medications (anticholinergics, benzodiazepines, central nervous system depressants)
- Unrelieved pain
- Blood loss
- Decreased cardiac output
- Cerebral hypoxia
- Heart failure
- Acute myocardial infarction
- Hypothermia or hyperthermia
- Unfamiliar surroundings and sensory deprivation
- Emergent surgery
- Alcohol withdrawal
- Urinary retention
- Fecal impaction

Skilled and frequent assessment of mental status and of all physiologic factors influencing mental status helps the nurse plan care, because in the elderly patient delirium may be the initial or only early indicator of infection, fluid and electrolyte imbalance, or deterioration of respiratory or hemodynamic status. Factors that determine if the patient is at risk for delirium include age, history of alcohol abuse, preoperative cognitive function, physical function, serum chemistries, and type of surgery.

Recognizing postoperative delirium and identifying and treating its underlying cause are the goals of care. Postoperative delirium is sometimes mistaken for preexisting dementia or is attributed to age. In addition to monitoring and managing identifiable causes, nurses can implement supportive interventions. Keeping the patient in a well-lit room and close to the nurses' station can help with sensory deprivation. At the same time, distracting and unfamiliar noises should be minimized. Because pain can contribute to postoperative delirium, the nurse collaborates with the physician or geriatric nurse specialist and the patient to achieve pain relief without oversedation (Lynch, Lazor, Gellis et al., 1998). The patient is reoriented as often as necessary, and staff should introduce themselves each time they come in contact with the patient. Engaging the patient in conversation and care activities and placing a clock and calendar nearby may improve cognitive function. Physical activity should not be neglected while the patient is confused, because physical deterioration can worsen delirium and place the patient at increased risk for other complications. Restraints should be avoided because they can also worsen confusion. If possible, a family member or staff member is asked to sit with the patient instead. Haloperidol (Haldol) or lorazepam (Ativan) may be given during episodes of acute confusion, but these medications should be discontinued as soon as possible to avoid side effects.

Other problems confronting the older postoperative patient, such as pneumonia, altered bowel function, deep vein thrombosis, weakness, and functional decline, often can be prevented by early and progressive ambulation. Ambulation means walking,

not just getting out of bed and sitting in a chair. Prolonged sitting positions that promote venous stasis in the lower extremities should be avoided. Assistance with ambulation may be required to keep the patient from bumping into objects and falling. A physical therapy referral may be indicated to promote safe, regular exercise for the older adult.

Urinary incontinence can be prevented by providing easy access to the call bell and the commode and by prompting voiding. Early ambulation and familiarity with the room help the patient to become self-sufficient sooner.

Optimal nutritional status is important for wound healing, return of normal bowel function, and fluid and electrolyte balance. The nurse and patient can consult with the dietitian to plan appealing, high-protein meals that provide sufficient fiber, calories, and vitamins. Nutritional supplements, such as Ensure or Sustacal, may be recommended. Multivitamins, iron, and vitamin C supplements aid in tissue healing, formation of new red blood cells, and overall nutritional status and are commonly prescribed postoperatively.

In addition to monitoring and managing the older adult's physiologic recovery, the nurse identifies and addresses psychosocial needs. The older adult may require more encouragement and support to resume activities, and the pace may be slower. Sensory deficits may require frequent repetition of instructions, and decreased physiologic reserve may necessitate frequent rest periods. The older adult may require extensive discharge planning to coordinate both professional and family care providers, and the nurse, social worker, or nurse case manager may institute the plan for continuing care.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

Patients have always required detailed discharge instructions to become proficient in special self-care needs after surgery; however, dramatically reduced hospital lengths of stay during the past decade have greatly increased the amount of information that should be provided while reducing the amount of time in which to provide it (Fox, 1998; Quinn, 1999). Although needs are specific to individual patients and the procedures they have undergone, general patient education needs for postoperative care have been identified (see Chart 20-1).

### Continuing Care

Continuing care provided by community-based services is frequently necessary after surgery. Older patients, patients who live alone, patients without family support, and patients with preexisting disabilities are often in greatest need. Planning for discharge involves arranging for necessary services early in the acute care hospitalization. Wound care, drain management, catheter care, infusion therapy, and physical or occupational therapy are some of the needs addressed by community health care providers. The home care nurse coordinates these activities and services.

During home care visits, the nurse assesses the patient for postoperative complications; the nurse also assesses the surgical incision, respiratory and cardiovascular status, adequacy of pain management, fluid and nutritional status, and the patient's progress in returning to preoperative status. The nurse assesses the patient's and family's ability to manage dressing changes and drainage systems and other devices and to administer prescribed medications. The nurse may change dressings or catheters if needed. The nurse determines if any additional services are

needed and assists the patient and family to arrange for them. Previous teaching is reinforced, and the patient is reminded to keep follow-up appointments. The patient and family are instructed about signs and symptoms to be reported to the surgeon. In addition, the nurse may provide information about how to obtain needed supplies and may suggest resources or support groups the patient may want to contact. In many settings, post-operative telephone calls are made to answer questions, assess recovery, and reassure patients and families.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Maintains optimal respiratory function
  - a. Performs deep-breathing exercises
  - b. Displays clear breath sounds
  - c. Uses incentive spirometer as prescribed
  - d. Splints incisional site when coughing to reduce pain
2. Indicates that pain is decreased in intensity
3. Exercises and ambulates as prescribed
  - a. Alternates periods of rest and activity
  - b. Progressively increases ambulation
  - c. Resumes normal activities within prescribed time frame
  - d. Performs activities related to self-care
4. Wound heals without complication
5. Maintains body temperature within normal limits
6. Resumes oral intake
  - a. Reports absence of nausea and vomiting
  - b. Takes at least 75% of usual diet
  - c. Is free of abdominal distress and gas pains
  - d. Exhibits normal bowel sounds
7. Reports resumption of usual bowel elimination pattern
8. Resumes usual voiding pattern
9. Is free of injury
10. Exhibits decreased anxiety
11. Acquires knowledge and skills necessary to manage therapeutic regimen
12. Experiences no complications

## Critical Thinking Exercises

**1.** Your patient has a history of esophageal cancer and is HIV positive. After undergoing ambulatory surgery to insert a gastric feeding tube, he is to be discharged to home. Indicate which assessment findings would indicate his readiness for discharge. Describe a teaching plan for the patient and his family. How would you modify the plan if the patient lives alone?

**2.** A patient who has undergone abdominal surgery reports severe pain and as a result is unable to cough and deep breathe. When you listen to the patient's lungs you hear crackles in the bases. Analyze these findings and indicate the interventions you would implement in this situation. How would your care differ if the patient has a musculo-skeletal disorder that makes turning and ambulation difficult?

**3.** You are visiting a 72-year-old woman who had emergency surgery for a broken hip 3 weeks ago and has returned to her home, where she is living alone. How would you direct your assessment to identify the factors that might affect her recovery? How would you modify your assessment and nursing care plan because of her age?

# ● Assessment of Respiratory Function

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Describe the structures and functions of the upper and lower respiratory tracts.
2. Describe ventilation, perfusion, diffusion, shunting, and the relationship of pulmonary circulation to these processes.
3. Discriminate between normal and abnormal breath sounds.
4. Use assessment parameters appropriate for determining the characteristics and severity of the major symptoms of respiratory dysfunction.
5. Identify the nursing implications of the various procedures used for diagnostic evaluation of respiratory function.

**D**isorders of the respiratory system are common and are encountered by nurses in every setting from the community to the intensive care unit. To assess the respiratory system, the nurse must be skilled at differentiating normal assessment findings from abnormal ones. Good assessment skills must be developed and used when caring for patients with acute and chronic respiratory problems. In addition, an understanding of respiratory function and the significance of abnormal diagnostic test results is essential.

## Anatomic and Physiologic Overview

The respiratory system is composed of the upper and lower respiratory tracts. Together, the two tracts are responsible for **ventilation** (movement of air in and out of the airways). The upper tract, known as the upper airway, warms and filters inspired air so that the lower respiratory tract (the lungs) can accomplish gas exchange. Gas exchange involves delivering oxygen to the tissues through the bloodstream and expelling waste gases, such as carbon dioxide, during expiration.

### ANATOMY OF THE UPPER RESPIRATORY TRACT

Upper airway structures consist of the nose, sinuses and nasal passages, pharynx, tonsils and adenoids, larynx, and trachea.

#### Nose

The nose is composed of an external and an internal portion. The external portion protrudes from the face and is supported by the nasal bones and cartilage. The anterior nares (nostrils) are the external openings of the nasal cavities.

The internal portion of the nose is a hollow cavity separated into the right and left nasal cavities by a narrow vertical divider, the septum. Each nasal cavity is divided into three passageways by the projection of the turbinates (also called conchae) from the lateral walls. The nasal cavities are lined with highly vascular ciliated mucous membranes called the nasal mucosa. Mucus, secreted continuously by goblet cells, covers the surface of the nasal mucosa and is moved back to the nasopharynx by the action of the **cilia** (fine hairs).

The nose serves as a passageway for air to pass to and from the lungs. It filters impurities and humidifies and warms the air as it is inhaled. It is responsible for olfaction (smell) because the olfactory receptors are located in the nasal mucosa. This function diminishes with age.

### Paranasal Sinuses

The paranasal sinuses include four pairs of bony cavities that are lined with nasal mucosa and ciliated pseudostratified columnar epithelium. These air spaces are connected by a series of ducts that drain into the nasal cavity. The sinuses are named by their location: frontal, ethmoidal, sphenoidal, and maxillary (Fig. 21-1). A prominent function of the sinuses is to serve as a resonating chamber in speech. The sinuses are a common site of infection.

### Turbinate Bones (Conchae)

The turbinate bones are also called conchae (the name suggested by their shell-like appearance). Because of their curves, these bones increase the mucous membrane surface of the nasal passages and slightly obstruct the air flowing through them (Fig. 21-2).

Air entering the nostrils is deflected upward to the roof of the nose, and it follows a circuitous route before it reaches the nasopharynx. It comes into contact with a large surface of moist, warm mucous membrane that catches practically all the dust and organisms in the inhaled air. The air is moistened, warmed to body temperature, and brought into contact with sensitive nerves. Some of these nerves detect odors; others provoke sneezing to expel irritating dust.

### Pharynx, Tonsils, and Adenoids

The pharynx, or throat, is a tubelike structure that connects the nasal and oral cavities to the larynx. It is divided into three regions: nasal, oral, and laryngeal. The nasopharynx is located posterior to the nose and above the soft palate. The oropharynx houses the faucial, or palatine, tonsils. The laryngopharynx extends from the hyoid bone to the cricoid cartilage. The epiglottis forms the entrance of the larynx.

The adenoids, or pharyngeal tonsils, are located in the roof of the nasopharynx. The tonsils, the adenoids, and other lymphoid tissue encircle the throat. These structures are important links in the chain of lymph nodes guarding the body from invasion by organisms entering the nose and the throat. The pharynx functions as a passageway for the respiratory and digestive tracts.

### Larynx

The larynx, or voice organ, is a cartilaginous epithelium-lined structure that connects the pharynx and the trachea. The major function of the larynx is vocalization. It also protects the lower

## Glossary

**bronchoscopy:** direct examination of larynx, trachea, and bronchi using an endoscope

**cilia:** short hairs that provide a constant whipping motion that serves to propel mucus and foreign substances away from the lung toward the larynx

**crackles:** soft, high-pitched, discontinuous popping sounds during inspiration caused by delayed reopening of the airways

**diffusion:** exchange of gas molecules from areas of high concentration to areas of low concentration

**dyspnea:** labored breathing or shortness of breath

**hemoptysis:** expectoration of blood from the respiratory tract

**hypoxemia:** decrease in arterial oxygen tension in the blood

**hypoxia:** decrease in oxygen supply to the tissues and cells

**orthopnea:** inability to breathe easily except in an upright position

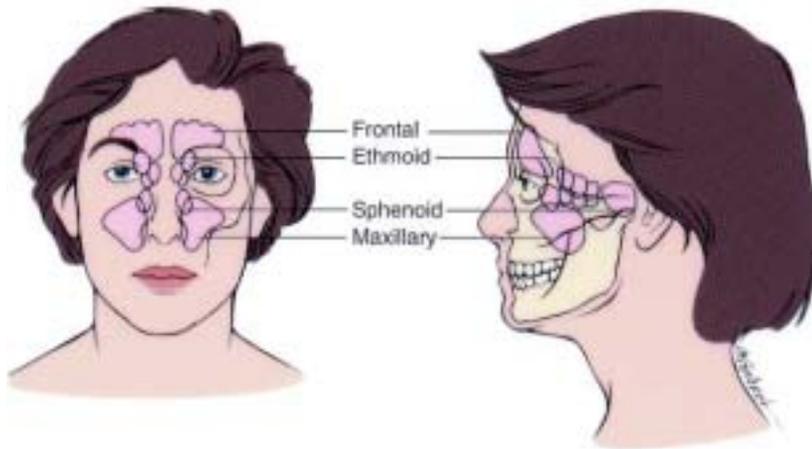

**physiologic dead space:** portion of the tracheobronchial tree that does not participate in gas exchange

**pulmonary perfusion:** blood flow through the pulmonary vasculature

**respiration:** gas exchange between atmospheric air and the blood and between the blood and cells of the body

**ventilation:** movement of air in and out of airways

**wheezes:** continuous musical sounds associated with airway narrowing or partial obstruction

**FIGURE 21-1** The paranasal sinuses.

airway from foreign substances and facilitates coughing. It is frequently referred to as the voice box and consists of the following:

- Epiglottis—a valve flap of cartilage that covers the opening to the larynx during swallowing
- Glottis—the opening between the vocal cords in the larynx
- Thyroid cartilage—the largest of the cartilage structures; part of it forms the Adam's apple
- Cricoid cartilage—the only complete cartilaginous ring in the larynx (located below the thyroid cartilage)
- Arytenoid cartilages—used in vocal cord movement with the thyroid cartilage

- Vocal cords—ligaments controlled by muscular movements that produce sounds; located in the lumen of the larynx

## Trachea

The trachea, or windpipe, is composed of smooth muscle with C-shaped rings of cartilage at regular intervals. The cartilaginous rings are incomplete on the posterior surface and give firmness to the wall of the trachea, preventing it from collapsing. The trachea serves as the passage between the larynx and the bronchi.

## ANATOMY OF THE LOWER RESPIRATORY TRACT: LUNGS

The lower respiratory tract consists of the lungs, which contain the bronchial and alveolar structures needed for gas exchange.

### Lungs

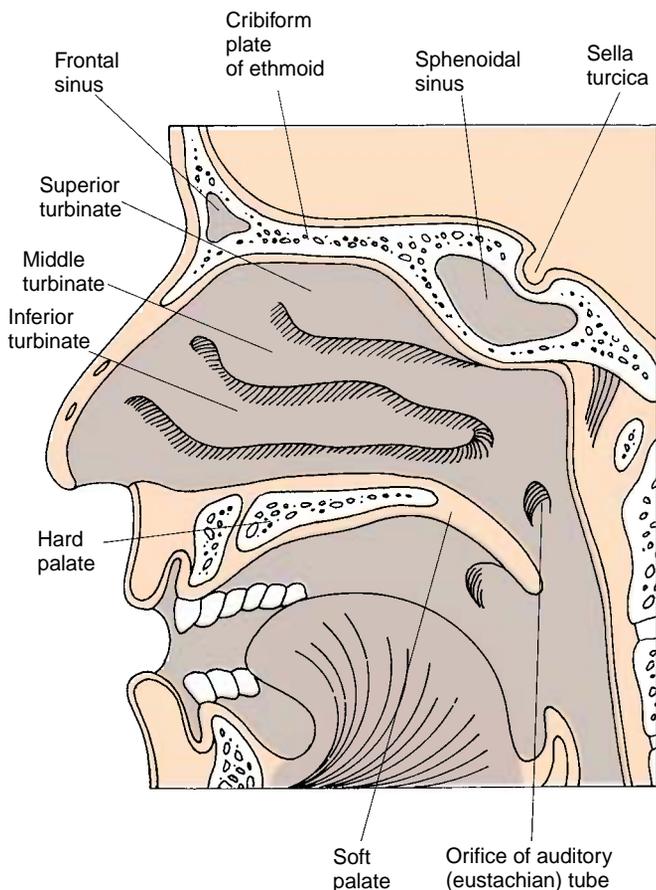

The lungs are paired elastic structures enclosed in the thoracic cage, which is an airtight chamber with distensible walls (Fig. 21-3). Ventilation requires movement of the walls of the thoracic cage and of its floor, the diaphragm. The effect of these movements is alternately to increase and decrease the capacity of the chest. When the capacity of the chest is increased, air enters through the trachea (inspiration) because of the lowered pressure within and inflates the lungs. When the chest wall and diaphragm return to their previous positions (expiration), the lungs recoil and force the air out through the bronchi and trachea. The inspiratory phase of respiration normally requires energy; the expiratory phase is normally passive. Inspiration occurs during the first third of the respiratory cycle, expiration during the latter two thirds.

### PLEURA

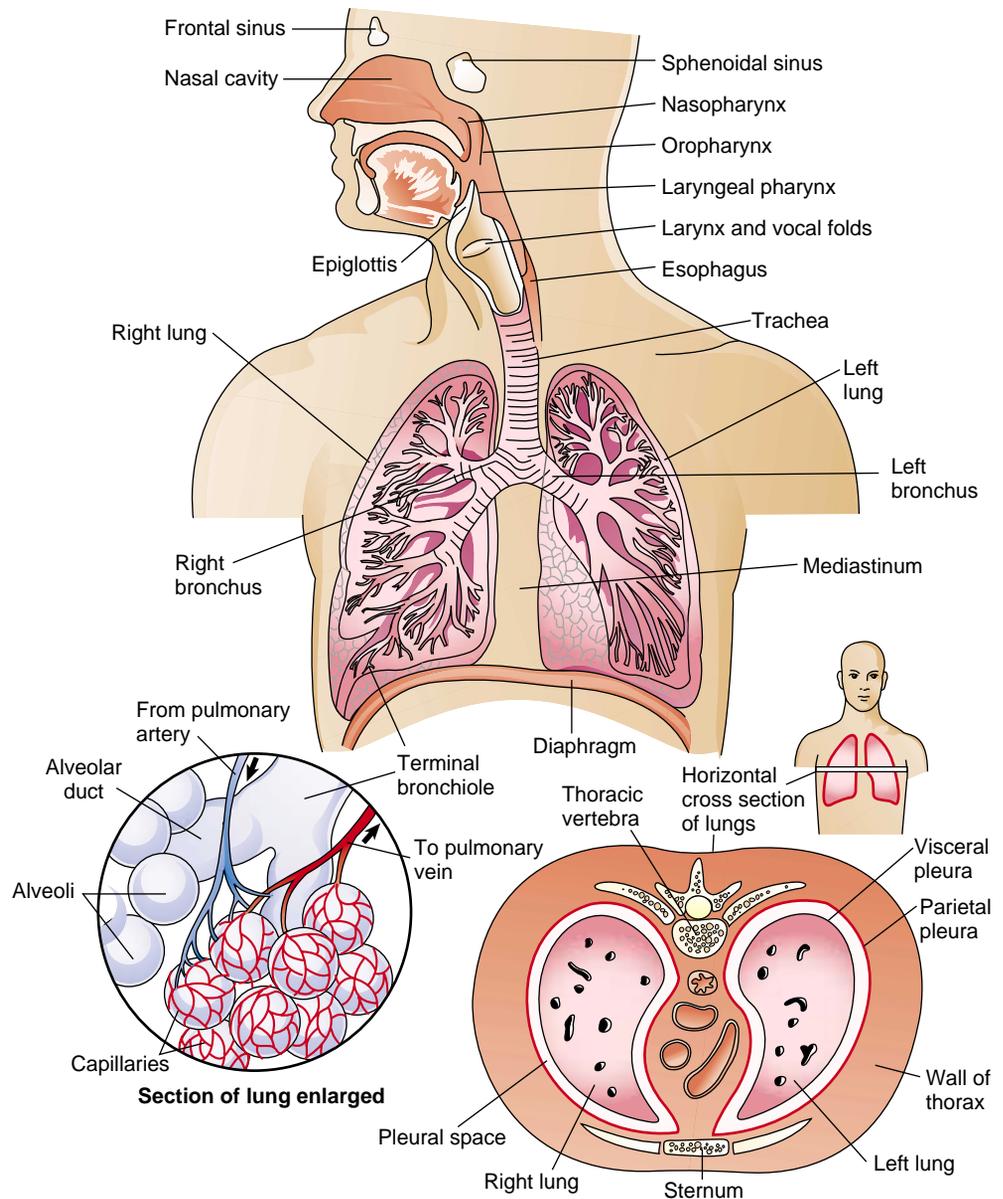

The lungs and wall of the thorax are lined with a serous membrane called the pleura. The visceral pleura covers the lungs; the parietal pleura lines the thorax. The visceral and parietal pleura and the small amount of pleural fluid between these two membranes serve to lubricate the thorax and lungs and permit smooth motion of the lungs within the thoracic cavity with each breath.

### MEDIASTINUM

The mediastinum is in the middle of the thorax, between the pleural sacs that contain the two lungs. It extends from the sternum to the vertebral column and contains all the thoracic tissue outside the lungs.

**FIGURE 21-2** Cross-section of nasal cavity.

**FIGURE 21-3** The respiratory system; upper respiratory structures and the structures of the thorax (*top*); alveoli and a horizontal cross section of the lungs (*bottom*).

## LOBES

Each lung is divided into lobes. The left lung consists of an upper and lower lobe, whereas the right lung has an upper, middle, and lower lobe (Fig. 21-4). Each lobe is further subdivided into two to five segments separated by fissures, which are extensions of the pleura.

## BRONCHI AND BRONCHIOLES

There are several divisions of the bronchi within each lobe of the lung. First are the lobar bronchi (three in the right lung and two in the left lung). Lobar bronchi divide into segmental bronchi (10 on the right and 8 on the left), which are the structures identified when choosing the most effective postural drainage position for a given patient. Segmental bronchi then divide into subsegmental bronchi. These bronchi are surrounded by connective tissue that contains arteries, lymphatics, and nerves.

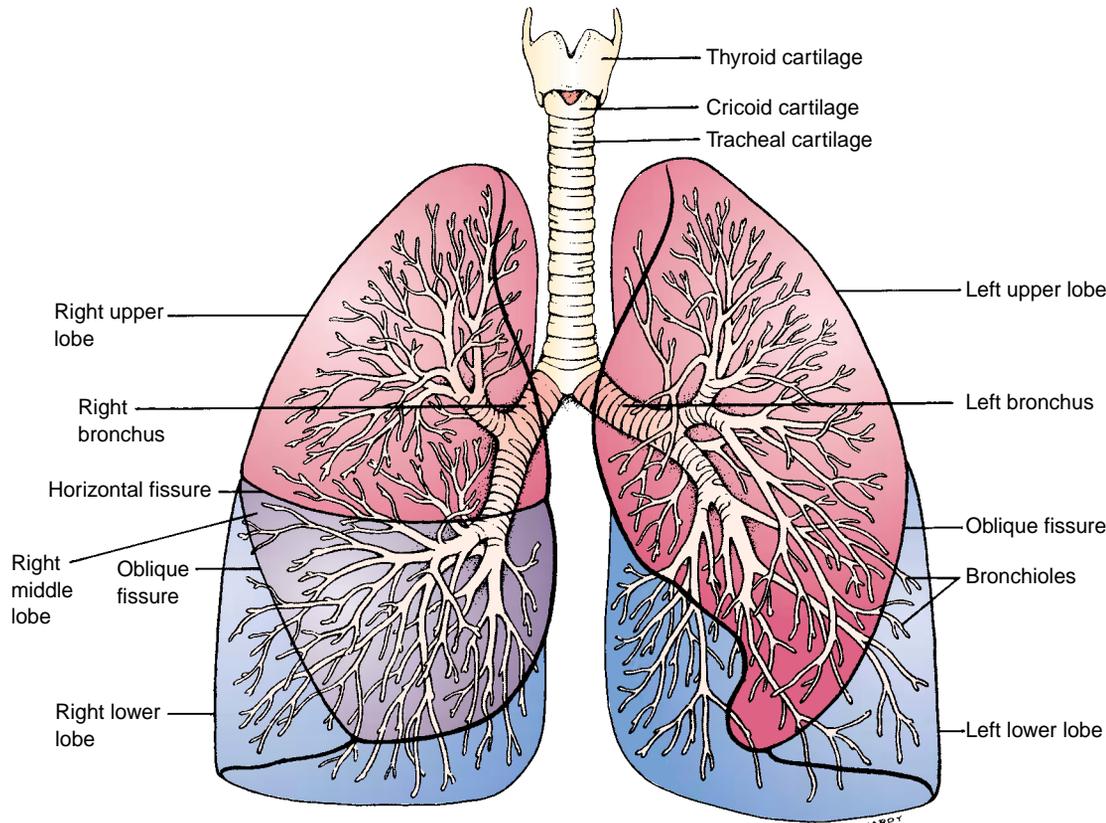

The subsegmental bronchi then branch into bronchioles, which have no cartilage in their walls. Their patency depends entirely on the elastic recoil of the surrounding smooth muscle and

on the alveolar pressure. The bronchioles contain submucosal glands, which produce mucus that covers the inside lining of the airways. The bronchi and bronchioles are lined also with cells that have surfaces covered with cilia. These cilia create a constant whipping motion that propels mucus and foreign substances away from the lung toward the larynx.

The bronchioles then branch into terminal bronchioles, which do not have mucous glands or cilia. Terminal bronchioles then become respiratory bronchioles, which are considered to be the transitional passageways between the conducting airways and the gas exchange airways. Up to this point, the conducting airways contain about 150 mL of air in the tracheobronchial tree that does not participate in gas exchange. This is known as **physiologic dead space**. The respiratory bronchioles then lead into alveolar ducts and alveolar sacs and then alveoli. Oxygen and carbon dioxide exchange takes place in the alveoli.

## ALVEOLI

The lung is made up of about 300 million alveoli, which are arranged in clusters of 15 to 20. These alveoli are so numerous

**FIGURE 21-4** The lungs consist of five lobes. The right lung has three lobes (upper, middle, lower); the left has two (upper and lower). The lobes are further subdivided by fissures. The bronchial tree, another lung structure, inflates with air to fill the lobes.

that if their surfaces were united to form one sheet, it would cover 70 square meters—the size of a tennis court.

There are three types of alveolar cells. Type I alveolar cells are epithelial cells that form the alveolar walls. Type II alveolar cells are metabolically active. These cells secrete surfactant, a phospholipid that lines the inner surface and prevents alveolar collapse. Type III alveolar cell macrophages are large phagocytic cells that ingest foreign matter (eg, mucus, bacteria) and act as an important defense mechanism.

## FUNCTION OF THE RESPIRATORY SYSTEM

The cells of the body derive the energy they need from the oxidation of carbohydrates, fats, and proteins. As with any type of combustion, this process requires oxygen. Certain vital tissues, such as those of the brain and the heart, cannot survive for long without a continuing supply of oxygen. However, as a result of oxidation in the body tissues, carbon dioxide is produced and must be removed from the cells to prevent the buildup of acid waste products. The respiratory system performs this function by facilitating life-sustaining processes such as oxygen transport, respiration and ventilation, and gas exchange.

### Oxygen Transport

Oxygen is supplied to, and carbon dioxide is removed from, cells by way of the circulating blood. Cells are in close contact with capillaries, whose thin walls permit easy passage or exchange of oxygen and carbon dioxide. Oxygen diffuses from the capillary

through the capillary wall to the interstitial fluid. At this point, it diffuses through the membrane of tissue cells, where it is used by mitochondria for cellular respiration. The movement of carbon dioxide occurs by diffusion in the opposite direction—from cell to blood.

### Respiration

After these tissue capillary exchanges, blood enters the systemic veins (where it is called venous blood) and travels to the pulmonary circulation. The oxygen concentration in blood within the capillaries of the lungs is lower than in the lungs' air sacs (alveoli). Because of this concentration gradient, oxygen diffuses from the alveoli to the blood. Carbon dioxide, which has a higher concentration in the blood than in the alveoli, diffuses from the blood into the alveoli. Movement of air in and out of the airways (ventilation) continually replenishes the oxygen and removes the carbon dioxide from the airways in the lung. This whole process of gas exchange between the atmospheric air and the blood and between the blood and cells of the body is called **respiration**.

### Ventilation

During inspiration, air flows from the environment into the trachea, bronchi, bronchioles, and alveoli. During expiration, alveolar gas travels the same route in reverse.

Physical factors that govern air flow in and out of the lungs are collectively referred to as the mechanics of ventilation and include air pressure variances, resistance to air flow, and lung compliance.

## AIR PRESSURE VARIANCES

Air flows from a region of higher pressure to a region of lower pressure. During inspiration, movement of the diaphragm and other muscles of respiration enlarges the thoracic cavity and thereby lowers the pressure inside the thorax to a level below that of atmospheric pressure. As a result, air is drawn through the trachea and bronchi into the alveoli.

During normal expiration, the diaphragm relaxes and the lungs recoil, resulting in a decrease in the size of the thoracic cavity. The alveolar pressure then exceeds atmospheric pressure, and air flows from the lungs into the atmosphere.

## AIRWAY RESISTANCE

Resistance is determined chiefly by the radius or size of the airway through which the air is flowing. Any process that changes the bronchial diameter or width affects airway resistance and alters the rate of air flow for a given pressure gradient during respiration (Chart 21-1). With increased resistance, greater-than-normal respiratory effort is required by the patient to achieve normal levels of ventilation.

## COMPLIANCE

The pressure gradient between the thoracic cavity and the atmosphere causes air to flow in and out of the lungs. When pressure changes are applied in the normal lung, there is a proportional change in the lung volume. A measure of the elasticity, expandability, and distensibility of the lungs and thoracic structures is called compliance. Factors that determine lung compliance are the surface tension of the alveoli (normally low with the presence of surfactant) and the connective tissue (ie, collagen and elastin) of the lungs.

Compliance is determined by examining the volume–pressure relationship in the lungs and the thorax. In normal compliance (1.0 L/cm H<sub>2</sub>O), the lungs and thorax easily stretch and distend when pressure is applied. High or increased compliance occurs when the lungs have lost their elasticity and the thorax is overdistended (ie, in emphysema). When the lungs and thorax are “stiff,” there is low or decreased compliance. Conditions associated with this include pneumothorax, hemothorax, pleural effusion, pulmonary edema, atelectasis, pulmonary fibrosis, and acute respiratory distress syndrome (ARDS), all of which are discussed in later chapters in this unit. Measurement of compliance is one method used to assess the progression and improvement in ARDS. Lungs with decreased compliance require greater-than-normal energy expenditure to achieve normal levels of ventilation. Compliance is usually measured under static conditions.

Chart  
21-1

### Causes of Increased Airway Resistance

Common phenomena that may alter bronchial diameter, which affects airway resistance, include:

- Contraction of bronchial smooth muscle—as in asthma
- Thickening of bronchial mucosa—as in chronic bronchitis
- Obstruction of the airway—by mucus, a tumor, or a foreign body
- Loss of lung elasticity—as in emphysema, which is characterized by connective tissue encircling the airways, thereby keeping them open during both inspiration and expiration

## Lung Volumes and Capacities

Lung function, which reflects the mechanics of ventilation, is viewed in terms of lung volumes and lung capacities. Lung volumes are categorized as tidal volume, inspiratory reserve volume, expiratory reserve volume, and residual volume. Lung capacity is evaluated in terms of vital capacity, inspiratory capacity, functional residual capacity, and total lung capacity. These terms are described in Table 21-1.

## Diffusion and Perfusion

**Diffusion** is the process by which oxygen and carbon dioxide are exchanged at the air–blood interface. The alveolar–capillary membrane is ideal for diffusion because of its large surface area and thin membrane. In the normal healthy adult, oxygen and carbon dioxide travel across the alveolar–capillary membrane without difficulty as a result of differences in gas concentrations in the alveoli and capillaries.

**Pulmonary perfusion** is the actual blood flow through the pulmonary circulation. The blood is pumped into the lungs by the right ventricle through the pulmonary artery. The pulmonary artery divides into the right and left branches to supply both lungs. These two branches divide further to supply all parts of each lung. Normally about 2% of the blood pumped by the right ventricle does not perfuse the alveolar capillaries. This shunted blood drains into the left side of the heart without participating in alveolar gas exchange.

The pulmonary circulation is considered a low-pressure system because the systolic blood pressure in the pulmonary artery is 20 to 30 mm Hg and the diastolic pressure is 5 to 15 mm Hg. Because of these low pressures, the pulmonary vasculature normally can vary its capacity to accommodate the blood flow it receives. When a person is in an upright position, however, the pulmonary artery pressure is not great enough to supply blood to the apex of the lung against the force of gravity. Thus, when a person is upright, the lung may be considered to be divided into three sections: an upper part with poor blood supply, a lower part with maximal blood supply, and a section in between the two with an intermediate supply of blood. When a person lying down turns to one side, more blood passes to the dependent lung.

Perfusion also is influenced by alveolar pressure. The pulmonary capillaries are sandwiched between adjacent alveoli. If the alveolar pressure is sufficiently high, the capillaries will be squeezed. Depending on the pressure, some capillaries completely collapse, whereas others narrow.

Pulmonary artery pressure, gravity, and alveolar pressure determine the patterns of perfusion. In lung disease these factors vary, and the perfusion of the lung may become very abnormal.

## Ventilation and Perfusion Balance and Imbalance

Ventilation is the flow of gas in and out of the lungs, and perfusion is the filling of the pulmonary capillaries with blood. Adequate gas exchange depends on an adequate ventilation–perfusion ratio. In different areas of the lung, the ratio varies.

Alterations in perfusion may occur with a change in the pulmonary artery pressure, alveolar pressure, and gravity. Airway blockages, local changes in compliance, and gravity may alter ventilation.

A ventilation–perfusion  $\dot{V}/\dot{Q}$  imbalance occurs from inadequate ventilation, inadequate perfusion, or both. There are four possible  $\dot{V}/\dot{Q}$  states in the lung: normal  $\dot{V}/\dot{Q}$  ratio, low  $\dot{V}/\dot{Q}$  ratio

Table 21-1 • Lung Volumes and Lung Capacities

TERM	SYMBOL	DESCRIPTION	NORMAL VALUE*	SIGNIFICANCE
<b>Lung Volumes</b>				
Tidal volume	$V_T$ or TV	The volume of air inhaled and exhaled with each breath	500 mL or 5–10 mL/kg	The tidal volume may not vary, even with severe disease.
Inspiratory reserve volume	IRV	The maximum volume of air that can be inhaled after a normal inhalation	3,000 mL	
Expiratory reserve volume	ERV	The maximum volume of air that can be exhaled forcibly after a normal exhalation	1,100 mL	Expiratory reserve volume is decreased with restrictive conditions, such as obesity, ascites, pregnancy.
Residual volume	RV	The volume of air remaining in the lungs after a maximum exhalation	1,200 mL	Residual volume may be increased with obstructive disease.
<b>Lung Capacities</b>				
Vital capacity	VC	The maximum volume of air exhaled from the point of maximum inspiration $VC = TV + IRV + ERV$	4,600 mL	A decrease in vital capacity may be found in neuromuscular disease, generalized fatigue, atelectasis, pulmonary edema, and COPD.
Inspiratory capacity	IC	The maximum volume of air inhaled after normal expiration $IC = TV + IRV$	3,500 mL	A decrease in inspiratory capacity may indicate restrictive disease.
Functional residual capacity	FRC	The volume of air remaining in the lungs after a normal expiration $FRV = ERV + RV$	2,300 mL	Functional residual capacity may be increased with COPD and decreased in ARDS.
Total lung capacity	TLC	The volume of air in the lungs after a maximum inspiration $TLC = TV + IRV + ERV + RV$	5,800 mL	Total lung capacity may be decreased with restrictive disease (atelectasis, pneumonia) and increased in COPD.

\*Values for healthy men; women are 20%–25% less.

(shunt), high  $\dot{V}/\dot{Q}$  ratio (dead space), and absence of ventilation and perfusion (silent unit) (Chart 21-2).

Ventilation and perfusion imbalance causes shunting of blood, resulting in **hypoxia** (low cellular oxygen level). Shunting appears to be the main cause of hypoxia after thoracic or abdominal surgery and most types of respiratory failure. Severe hypoxia results when the amount of shunting exceeds 20%. Supplemental oxygen may eliminate hypoxia, depending on the type of  $\dot{V}/\dot{Q}$  imbalance.

## Gas Exchange

The air we breathe is a gaseous mixture consisting mainly of nitrogen (78.62%) and oxygen (20.84%), with traces of carbon dioxide (0.04%), water vapor (0.05%), helium, and argon. The atmospheric pressure at sea level is about 760 mm Hg. Partial pressure is the pressure exerted by each type of gas in a mixture of gases. The partial pressure of a gas is proportional to the concentration of that gas in the mixture. The total pressure exerted by the gaseous mixture is equal to the sum of the partial pressures.

### PARTIAL PRESSURE OF GASES

Based on these facts, the partial pressures of nitrogen and oxygen can be calculated. The partial pressure of nitrogen is 79% of 760 ( $0.79 \times 760$ ), or 600 mm Hg; that of oxygen is 21% of 760 ( $0.21 \times 760$ ), or 160 mm Hg. Chart 21-3 spells out terms and abbreviations related to partial pressure of gases.

Once the air enters the trachea, it becomes fully saturated with water vapor, which displaces some of the gases so that the air pressure within the lung remains equal to the air pressure outside (760 mm Hg). Water vapor exerts a pressure of 47 mm Hg when

it fully saturates a mixture of gases at the body temperature of 37°C (98.6°F). Nitrogen and oxygen are responsible for the remaining 713 mm Hg (760 – 47) pressure. Once this mixture enters the alveoli, it is further diluted by carbon dioxide. In the alveoli, the water vapor continues to exert a pressure of 47 mm Hg. The remaining 713 mm Hg pressure is now exerted as follows: nitrogen, 569 mm Hg (74.9%); oxygen, 104 mm Hg (13.6%); and carbon dioxide, 40 mm Hg (5.3%).

### PARTIAL PRESSURE IN GAS EXCHANGE

When a gas is exposed to a liquid, the gas dissolves in the liquid until an equilibrium is reached. The dissolved gas also exerts a partial pressure. At equilibrium, the partial pressure of the gas in the liquid is the same as the partial pressure of the gas in the gaseous mixture. Oxygenation of venous blood in the lung illustrates this point. In the lung, venous blood and alveolar oxygen are separated by a very thin alveolar membrane. Oxygen diffuses across this membrane to dissolve in the blood until the partial pressure of oxygen in the blood is the same as that in the alveoli (104 mm Hg). However, because carbon dioxide is a byproduct of oxidation in the cells, venous blood contains carbon dioxide at a higher partial pressure than that in the alveolar gas. In the lung, carbon dioxide diffuses out of venous blood into the alveolar gas. At equilibrium, the partial pressure of carbon dioxide in the blood and in alveolar gas is the same (40 mm Hg). The changes in partial pressure are shown in Figure 21-5.

### EFFECTS OF PRESSURE ON OXYGEN TRANSPORT

Oxygen and carbon dioxide are transported simultaneously dissolved in blood or combined with some of the elements of blood. Oxygen is carried in the blood in two forms: first as physically dis-

Chart  
21-2

## Ventilation-Perfusion Ratios

**Normal Ratio (A)**

In the healthy lung, a given amount of blood passes an alveolus and is matched with an equal amount of gas (A). The ratio is 1:1 (ventilation matches perfusion).

**Low Ventilation-Perfusion Ratio: Shunts (B)**

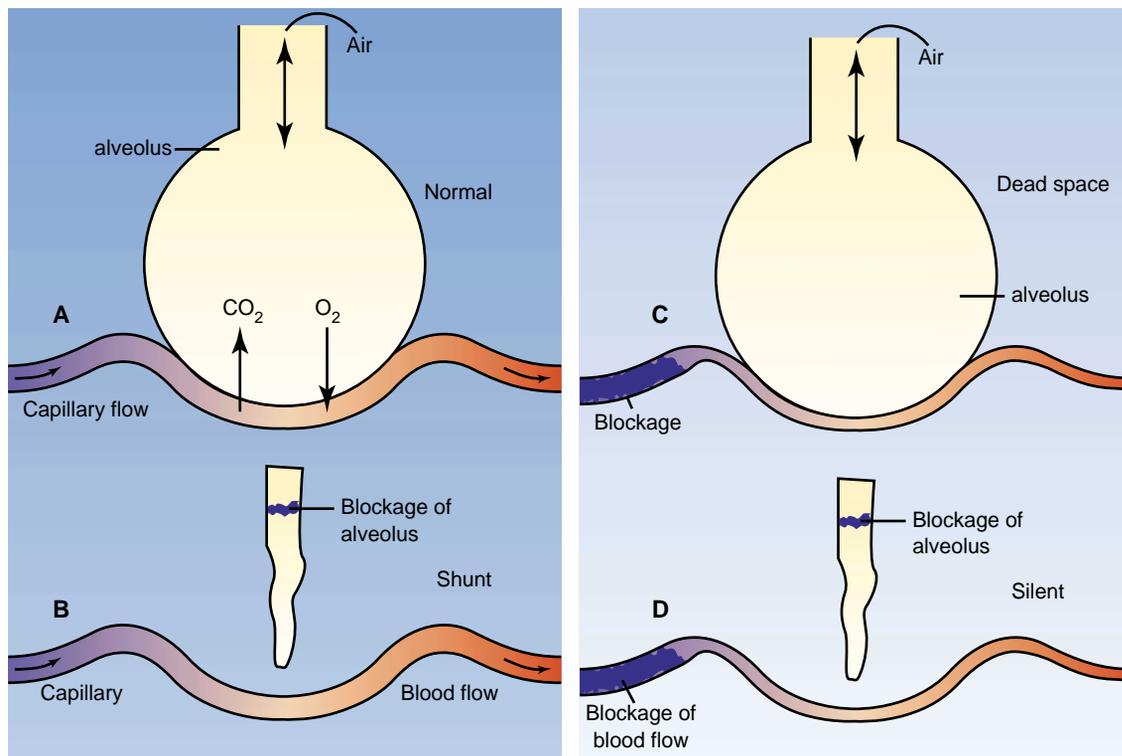

Low ventilation-perfusion states may be called shunt-producing disorders. When perfusion exceeds ventilation, a shunt exists (B). Blood bypasses the alveoli without gas exchange occurring. This is seen with obstruction of the distal airways, such as with pneumonia, atelectasis, tumor, or a mucus plug.

**High Ventilation-Perfusion Ratio: Dead Space (C)**

When ventilation exceeds perfusion, dead space results (C). The alveoli do not have an adequate blood supply for gas exchange to occur. This is characteristic of a variety of disorders, including pulmonary emboli, pulmonary infarction, and cardiogenic shock.

**Silent Unit (D)**

In the absence of ventilation and perfusion or with limited ventilation and perfusion, a condition known as a silent unit occurs (D). This is seen with pneumothorax and severe acute respiratory distress syndrome.

solved oxygen in the plasma, and second in combination with the hemoglobin of the red blood cells. Each 100 mL of normal arterial blood carries 0.3 mL of oxygen physically dissolved in the plasma and 20 mL of oxygen in combination with hemoglobin. Large amounts of oxygen can be transported in the blood because it combines easily with hemoglobin to form oxyhemoglobin:

The volume of oxygen physically dissolved in the plasma varies directly with the partial pressure of oxygen in the arteries (PaO<sub>2</sub>). The higher the PaO<sub>2</sub>, the greater the amount of oxygen dissolved. For example, at a PaO<sub>2</sub> of 10 mm Hg, 0.03 mL of oxygen is dissolved in 100 mL of plasma. At 20 mm Hg, twice this amount is dissolved in plasma, and at 100 mm Hg, 10 times this amount is dissolved. Therefore, the amount of dissolved oxygen is directly proportional to the partial pressure, regardless of how high the oxygen pressure rises.

The amount of oxygen that combines with hemoglobin also depends on PaO<sub>2</sub>, but only up to a PaO<sub>2</sub> of about 150 mm Hg. When the PaO<sub>2</sub> is 150 mm Hg, hemoglobin is 100% saturated and will not combine with any additional oxygen. When hemoglobin is 100% saturated, 1 g of hemoglobin will combine with 1.34 mL of oxygen. Therefore, in a person with 14 g/dL of hemoglobin, each 100 mL of blood will contain about 19 mL of oxygen associated with hemoglobin. If the PaO<sub>2</sub> is less than 150 mm Hg, the percentage of hemoglobin saturated with oxygen is lower. For example, at a PaO<sub>2</sub> of 100 mm Hg (normal value), saturation is 97%; at a PaO<sub>2</sub> of 40 mm Hg, saturation is 70%.

Chart  
21-3

## Partial Pressure Abbreviations

P	= pressure
PO <sub>2</sub>	= partial pressure of oxygen
PCO <sub>2</sub>	= partial pressure of carbon dioxide
PAO <sub>2</sub>	= partial pressure of alveolar oxygen
PACO <sub>2</sub>	= partial pressure of alveolar carbon dioxide
PaO <sub>2</sub>	= partial pressure of arterial oxygen
PaCO <sub>2</sub>	= partial pressure of arterial carbon dioxide
PvO <sub>2</sub>	= partial pressure of venous oxygen
PvCO <sub>2</sub>	= partial pressure of venous carbon dioxide
P <sub>50</sub>	= partial pressure of oxygen when the hemoglobin is 50% saturated

### OXYHEMOGLOBIN DISSOCIATION CURVE

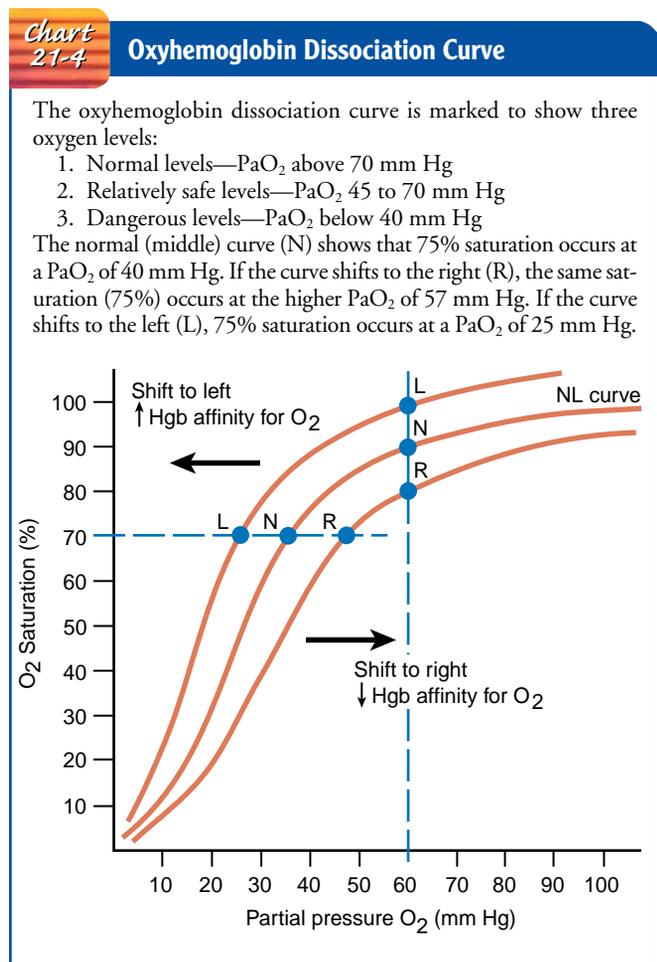

The oxyhemoglobin dissociation curve (Chart 21-4) shows the relationship between the partial pressure of oxygen ( $\text{PaO}_2$ ) and the percentage of saturation of oxygen ( $\text{SaO}_2$ ). The percentage of saturation can be affected by the following factors: carbon dioxide, hydrogen ion concentration, temperature, and 2,3-diphosphoglycerate. A rise in these factors shifts the curve to the right so that more oxygen is then released to the tissues at the same  $\text{PaO}_2$ . A reduction in these factors causes the curve to shift to the left, making the bond between oxygen and hemoglobin stronger, so that less oxygen is given up to the tissues at the same  $\text{PaO}_2$ . The unusual shape of the oxyhemoglobin dissociation curve is a distinct advantage to the patient for two reasons:

1. If the arterial  $\text{PO}_2$  decreases from 100 to 80 mm Hg as a result of lung disease or heart disease, the hemoglobin of the arterial blood remains almost maximally saturated (94%) and the tissues will not suffer from hypoxia.
2. When the arterial blood passes into tissue capillaries and is exposed to the tissue tension of oxygen (about 40 mm Hg), hemoglobin gives up large quantities of oxygen for use by the tissues.

**Clinical Significance.** The normal value of  $\text{PaO}_2$  is 80 to 100 mm Hg (95% to 98% saturation). With this level of oxygenation, there is a 15% margin of excess oxygen available to the tissues. With a normal hemoglobin level of 15 mg/dL and a  $\text{PaO}_2$  level of 40 mm Hg (oxygen saturation 75%), there is adequate oxygen available for the tissues but no reserve for physiologic stresses that increase tissue oxygen demand. When a serious incident occurs (eg, bronchospasm, aspiration, hypotension, or cardiac dysrhythmias) that reduces the intake of oxygen from the lungs, tissue hypoxia will result.

An important consideration in the transport of oxygen is cardiac output, which determines the amount of oxygen delivered to the body and which affects lung and tissue perfusion. If the cardiac output is normal (5 L/min), the amount of oxygen delivered to the

**FIGURE 21-5** Changes occur in the partial pressure of gases during respiration. These values vary as a result of the exchange of oxygen and carbon dioxide and the changes that occur in their partial pressures as venous blood flows through the lungs. Adapted from Willis, M. C. (1996). *Medical terminology: The language of healthcare*. Baltimore: Williams & Wilkins.

body per minute is normal. If cardiac output falls, the amount of oxygen delivered to the tissues also falls. Under normal conditions, most of the oxygen delivered to the body is not used. In fact, only 250 mL of oxygen is used per minute. Under normal conditions, this is approximately 25% of available oxygen. The rest of the oxygen returns to the right side of the heart, and the PaO<sub>2</sub> of venous blood drops from 80 to 100 mm Hg to about 40 mm Hg.

## Carbon Dioxide Transport

At the same time that oxygen diffuses from the blood into the tissues, carbon dioxide diffuses in the opposite direction (ie, from tissue cells to blood) and is transported to the lungs for excretion. The amount of carbon dioxide in transit is one of the major determinants of the acid–base balance of the body. Normally, only 6% of the venous carbon dioxide is removed, and enough remains in the arterial blood to exert a pressure of 40 mm Hg. Most of the carbon dioxide (90%) enters the red blood cells; the small portion (5%) that remains dissolved in the plasma (PCO<sub>2</sub>) is the critical factor that determines carbon dioxide movement in or out of the blood.

In summary, the many processes involved in respiratory gas transport do not occur in intermittent stages; rather, they are rapid, simultaneous, and continuous.

## Neurologic Control of Ventilation

Resting respiration is the result of cyclical excitation of the respiratory muscles by the phrenic nerve. The rhythm of breathing is controlled by respiratory centers in the brain. The inspiratory and expiratory centers in the medulla oblongata and pons control the rate and depth of ventilation to meet the body's metabolic demands.

The apneustic center in the lower pons stimulates the inspiratory medullary center to promote deep, prolonged inspirations. The pneumotaxic center in the upper pons is thought to control the pattern of respirations.

Several groups of receptor sites assist in the brain's control of respiratory function. The central chemoreceptors are located in the medulla and respond to chemical changes in the cerebrospinal fluid, which result from chemical changes in the blood. These receptors respond to an increase or decrease in the pH and convey a message to the lungs to change the depth and then the rate of ventilation to correct the imbalance. The peripheral chemoreceptors are located in the aortic arch and the carotid arteries and respond first to changes in PaO<sub>2</sub>, then to PaCO<sub>2</sub> and pH. The Hering–Breuer reflex is activated by stretch receptors in the alveoli. When the lungs are distended, inspiration is inhibited; as a result, the lungs do not become overdistended. In addition, proprioceptors in the muscles and joints respond to body movements, such as exercise, causing an increase in ventilation. Thus, range-of-motion exercises in an immobile patient stimulate breathing. Baroreceptors, also located in the aortic and carotid bodies, respond to an increase or decrease in arterial blood pressure and cause reflex hypoventilation or hyperventilation.

### Gerontologic Considerations

A gradual decline in respiratory function begins in early to middle adulthood and affects the structure and function of the respiratory system. The vital capacity of the lungs and respiratory muscle strength peak between ages 20 and 25 and decrease thereafter. With aging (40 years and older), changes occur in the alveoli that reduce the surface area available for the exchange of oxygen and

carbon dioxide. At approximately age 50, the alveoli begin to lose elasticity. A decrease in vital capacity occurs with loss of chest wall mobility, thus restricting the tidal flow of air. The amount of respiratory dead space increases with age. These changes result in a decreased diffusion capacity for oxygen with age, producing lower oxygen levels in the arterial circulation. Elderly people have a decreased ability to move air rapidly in and out of the lungs. Gerontologic changes in the respiratory system are summarized in Table 21-2. Despite these changes, in the absence of chronic pulmonary disease, elderly people are able to carry out activities of daily living, but they may have decreased tolerance for and require additional rest after prolonged or vigorous activity.

## Assessment

### HEALTH HISTORY

The health history focuses on the physical and functional problems of the patient and the effect of these problems on his or her life. The reason the patient is seeking health care often is related to one of the following: **dyspnea** (shortness of breath), pain, accumulation of mucus, wheezing, **hemoptysis** (blood spit up from the respiratory tract), edema of the ankles and feet, cough, and general fatigue and weakness.

In addition to identifying the chief reason why the patient is seeking health care, the nurse tries to determine when the health problem or symptom started, how long it lasted, if it was relieved at any time, and how relief was obtained. The nurse collects information about precipitating factors, duration, severity, and associated factors or symptoms and also assesses for risk factors and genetic factors that may contribute to the patient's lung condition (Chart 21-5).

The nurse assesses the impact of signs and symptoms on the patient's ability to perform activities of daily living and to participate in usual work and family activities. In addition, psychosocial factors that may affect the patient are explored (Chart 21-6). These factors include anxiety, role changes, family relationships, financial problems, employment status, and the strategies the patient uses to cope with them.

Many respiratory diseases are chronic and progressively debilitating. Therefore, ongoing assessment of the patient's physical abilities, psychosocial supports, and quality of life is needed to plan appropriate interventions. It is important for the patient with a respiratory disorder to understand the condition and to be familiar with necessary self-care interventions. The nurse evaluates these factors over time and provides education as needed.

### Signs and Symptoms

The major signs and symptoms of respiratory disease are dyspnea, cough, sputum production, chest pain, wheezing, clubbing of the fingers, hemoptysis, and cyanosis. These clinical manifestations are related to the duration and severity of the disease.

#### DYSPNEA

Dyspnea (difficult or labored breathing, shortness of breath) is a symptom common to many pulmonary and cardiac disorders, particularly when there is decreased lung compliance or increased airway resistance. The right ventricle of the heart will be affected ultimately by lung disease because it must pump blood through the lungs against greater resistance. It may also be associated with neurologic or neuromuscular disorders such as myasthenia gravis, Guillain-Barré syndrome, or muscular dystrophy.

**Clinical Significance.** In general, acute diseases of the lungs produce a more severe grade of dyspnea than do chronic diseases. Sudden dyspnea in a healthy person may indicate pneumothorax (air in the pleural cavity), acute respiratory obstruction, or ARDS. In immobilized patients, sudden dyspnea may denote pulmonary embolism. **Orthopnea** (inability to breathe easily except in an upright position) may be found in patients with heart disease and occasionally in patients with chronic obstructive pulmonary disease (COPD); dyspnea with an expiratory wheeze occurs with COPD. Noisy breathing may result from a narrowing of the airway or localized obstruction of a major bronchus by a tumor or foreign body. The presence of both inspiratory and expiratory wheezing usually signifies asthma if the patient does not have heart failure.

The circumstance that produces the dyspnea must be determined. Therefore, it is important to ask the patient the following questions:

- How much exertion triggers shortness of breath?
- Is there an associated cough?
- Is dyspnea related to other symptoms?
- Was the onset of shortness of breath sudden or gradual?

- At what time of day or night does the dyspnea occur?
- Is the shortness of breath worse when the patient is flat in bed?
- Does the shortness of breath occur at rest? With exercise? Running? Climbing stairs?
- Is the shortness of breath worse while walking? If so, when walking how far? How fast?

**Relief Measures.** The management of dyspnea is aimed at identifying and correcting its cause. Relief of the symptom sometimes is achieved by placing the patient at rest with the head elevated (high Fowler's position) and, in severe cases, by administering oxygen.

### COUGH

Cough results from irritation of the mucous membranes anywhere in the respiratory tract. The stimulus producing a cough may arise from an infectious process or from an airborne irritant, such as smoke, smog, dust, or a gas. The cough is the patient's chief protection against the accumulation of secretions in the bronchi and bronchioles.

**Clinical Significance.** Cough may indicate serious pulmonary disease. The nurse needs to evaluate the character of the cough—is it dry, hacking, brassy, wheezing, loose, or severe? A dry, irritative cough is characteristic of an upper respiratory tract infection of viral origin or may be a side effect of angiotensin-converting enzyme (ACE) inhibitor therapy. Laryngotracheitis causes an irritative, high-pitched cough. Tracheal lesions produce a brassy cough. A severe or changing cough may indicate bronchogenic carcinoma. Pleuritic chest pain accompanying coughing may indicate pleural or chest wall (musculoskeletal) involvement.

### NURSING RESEARCH PROFILE 21-1

#### Dyspnea Self-Management

Nield, M. (2000). Dyspnea self-management in African Americans with chronic lung disease. *Heart & Lung*, 29(1), 50–55.

#### Purpose

The purpose of this qualitative analysis, part of a larger study of the relationship between dyspnea and respiratory muscle function in patients with chronic lung disease, was to explore dyspnea self-management in African Americans with COPD or chronic restrictive pulmonary disease resulting from sarcoidosis.

#### Study Sample and Design

A qualitative study approach was used with a convenience sample of 29 patients recruited from the pulmonary clinic at a large medical center in the midwestern United States. Fifteen of the subjects had COPD and 14 had sarcoidosis. All routinely experienced dyspnea. A semistructured interview guide was used to obtain data. The taped interviews were transcribed and content analysis was performed using open coding methods.

#### Findings

The investigators identified the following self-management themes from the data:

- Traditional medical care (formal health care and prescription medications)
- Self-care wisdom (learned insight regarding the impact of dyspnea on quality of life)
- Self-care action (specific strategies for dyspnea relief included exercise, environmental control, cognitive strategies, and controlled breathing, which refers to patient-initiated position and breathing to manage dyspnea). Patients with sarcoidosis used inhalation-focused breathing only, while patients with COPD used both inhalation- and exhalation-focused breathing.
- Self-care resources (internal or external assets that could be used for sustenance of the self-care actions such as spiritual and social support)

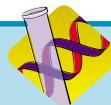

#### Nursing Implications

These findings mirror previous research; however, this study extends previous knowledge as it focused on African Americans exclusively. When working with patients with chronic respiratory disorders, nurses should assess all four aspects of dyspnea self-management, which reflect a holistic approach to care. Self-care actions should be encouraged and taught, and self-care resources facilitated. The breathing techniques used by patients with COPD and those with sarcoidosis should be considered during patient and family education. Further research is warranted to determine if the differences in the breathing techniques used by these two populations of patients are also found in a research study with a larger sample size.

The time of coughing is also noted. Coughing at night may herald the onset of left-sided heart failure or bronchial asthma. A cough in the morning with sputum production may indicate bronchitis. A cough that worsens when the patient is supine suggests postnasal drip (sinusitis). Coughing after food intake may indicate aspiration of material into the tracheobronchial tree. A cough of recent onset is usually from an acute infection.

#### SPUTUM PRODUCTION

A patient who coughs long enough almost invariably produces sputum. Violent coughing causes bronchial spasm, obstruction, and further irritation of the bronchi and may result in syncope (fainting). A severe, repeated, or uncontrolled cough that is non-productive is exhausting and potentially harmful. Sputum pro-

### GENETICS IN NURSING PRACTICE— Genetic Influences

Various conditions that affect gas exchange and respiratory function are influenced by genetic factors, including:

- Asthma
- Chronic obstructive pulmonary disease
- Cystic fibrosis
- Alpha-1 antitrypsin deficiency

#### NURSING ASSESSMENTS

##### FAMILY HISTORY ASSESSMENT

- Assess family history for other family members with histories of respiratory impairment.
- Assess family history for individuals with early-onset chronic pulmonary disease, family history of hepatic disease in infants (clinical symptoms of alpha-1 antitrypsin deficiency).
- Inquire about family history of genetic cystic fibrosis.

##### MANAGEMENT ISSUES SPECIFIC TO GENETICS

- Inquire whether DNA mutation or other genetic testing has been performed on affected family members.
- Refer for further genetic counseling and evaluation so that family members can discuss inheritance, risk to other family members, availability of genetic testing and gene-based interventions.
- Offer appropriate genetics information and resources.
- Assess patient's understanding of genetics information.
- Provide support to families with newly diagnosed genetic-related respiratory disorders.
- Participate in management and coordination of care of patients with genetic conditions, individuals predisposed to develop or pass on a genetic condition.

duction is the reaction of the lungs to any constantly recurring irritant. It also may be associated with a nasal discharge.

**Clinical Significance.** A profuse amount of purulent sputum (thick and yellow, green, or rust-colored) or a change in color of the sputum probably indicates a bacterial infection. Thin, mucoid sputum frequently results from viral bronchitis. A gradual increase of sputum over time may indicate the presence of chronic bronchitis or bronchiectasis. Pink-tinged mucoid sputum suggests

### Chart 21-6 • ASSESSMENT

#### Psychosocial Factors

Questions to consider when assessing psychosocial factors related to pulmonary disease and respiratory function include:

- What strategies does the patient use to cope with the signs and symptoms and challenges associated with pulmonary disease?
- Does the patient exhibit anxiety, anger, hostility, dependency, withdrawal, isolation, avoidance, noncompliance, acceptance, or denial?
- What support systems does the patient use to cope with the illness?
- Are resources (relatives, friends, or community groups) available? Do the patient and family use them effectively?

a lung tumor. Profuse, frothy, pink material, often welling up into the throat, may indicate pulmonary edema. Foul-smelling sputum and bad breath point to the presence of a lung abscess, bronchiectasis, or an infection caused by fusospirochetal or other anaerobic organisms.

**Relief Measures.** If the sputum is too thick for the patient to expectorate, it is necessary to decrease its viscosity by increasing its water content through adequate hydration (drinking water) and inhalation of aerosolized solutions, which may be delivered by any type of nebulizer. Strategies to assist the patient to cough productively are discussed later in this chapter.

Smoking is contraindicated with excessive sputum production because it interferes with ciliary action, increases bronchial secretions, causes inflammation and hyperplasia of the mucous membranes, and reduces production of surfactant. Thus, smoking impairs bronchial drainage. When the person stops smoking, sputum volume decreases and resistance to bronchial infections increases.

The patient's appetite may decrease because of the odor of the sputum or the taste it leaves in the mouth. The nurse encourages adequate oral hygiene and wise selection of food, measures that will stimulate appetite. In addition, the nurse encourages the patient and family to remove sputum cups, emesis basins, and soiled tissues before mealtime. Encouraging the patient to drink citrus juices at the beginning of the meal may increase the palatability of the rest of the meal because these juices cleanse the palate of the sputum taste.

#### CHEST PAIN

Chest pain or discomfort may be associated with pulmonary or cardiac disease. Chest pain associated with pulmonary conditions may be sharp, stabbing, and intermittent, or it may be dull, aching, and persistent. The pain usually is felt on the side where the pathologic process is located, but it may be referred elsewhere—for example, to the neck, back, or abdomen.

**Clinical Significance.** Chest pain may occur with pneumonia, pulmonary embolism with lung infarction, and pleurisy. It also may be a late symptom of bronchogenic carcinoma. In carcinoma the pain may be dull and persistent because the cancer has invaded the chest wall, mediastinum, or spine.

Lung disease does not always produce thoracic pain because the lungs and the visceral pleura lack sensory nerves and are insensitive to pain stimuli. However, the parietal pleura has a rich

supply of sensory nerves that are stimulated by inflammation and stretching of the membrane. Pleuritic pain from irritation of the parietal pleura is sharp and seems to “catch” on inspiration; patients often describe it as “like the stabbing of a knife.” Patients are more comfortable when they lie on the affected side as this splints the chest wall, limits expansion and contraction of the lung, and reduces the friction between the injured or diseased pleurae on that side. Pain associated with cough may be reduced manually by splinting the rib cage.

The nurse assesses the quality, intensity, and radiation of pain and identifies and explores precipitating factors, along with their relationship to the patient's position. Also, it is important to assess the relationship of pain to the inspiratory and expiratory phases of respiration.

**Relief Measures.** Analgesic medications may be effective in relieving chest pain, but care must be taken not to depress the respiratory center or a productive cough, if present. Nonsteroidal anti-inflammatory drugs (NSAIDs) achieve this goal and thus are used for pleuritic pain. A regional anesthetic block may be performed to relieve extreme pain.

#### WHEEZING

Wheezing is often the major finding in a patient with bronchoconstriction or airway narrowing. It is heard with or without a stethoscope, depending on its location. Wheezing is a high-pitched, musical sound heard mainly on expiration.

**Relief Measures.** Oral or inhalant bronchodilator medications reverse wheezing in most instances.

#### CLUBBING OF THE FINGERS

Clubbing of the fingers is a sign of lung disease found in patients with chronic hypoxic conditions, chronic lung infections, and malignancies of the lung. This finding may be manifested initially as sponginess of the nailbed and loss of the nailbed angle (Fig. 21-6).

#### HEMOPTYSIS

Hemoptysis (expectoration of blood from the respiratory tract) is a symptom of both pulmonary and cardiac disorders. The onset of hemoptysis is usually sudden, and it may be intermittent or continuous. Signs, which vary from blood-stained sputum to a

**FIGURE 21-6** Clubbed finger. In clubbing, the distal phalanx of each finger is rounded and bulbous. The nail plate is more convex, and the angle between the plate and the proximal nail fold increases to 180 degrees or more. The proximal nail fold, when palpated, feels spongy or floating. Among the many causes are chronic hypoxia and lung cancer.

large, sudden hemorrhage, always merit investigation. The most common causes are:

- Pulmonary infection
- Carcinoma of the lung
- Abnormalities of the heart or blood vessels
- Pulmonary artery or vein abnormalities
- Pulmonary emboli and infarction

Diagnostic evaluation to determine the cause includes several studies: chest x-ray, chest angiography, and bronchoscopy. A careful history and physical examination are necessary to diagnose the underlying disease, irrespective of whether the bleeding involved a very small amount of blood in the sputum or a massive hemorrhage. The amount of blood produced is not always proportional to the seriousness of the cause.

First, it is important to determine the source of the bleeding—the gums, nasopharynx, lungs, or stomach. The nurse may be the only witness to the episode. When documenting the bleeding episode, the nurse considers the following points:

- Bloody sputum from the nose or the nasopharynx is usually preceded by considerable sniffing, with blood possibly appearing in the nose.
- Blood from the lung is usually bright red, frothy, and mixed with sputum. Initial symptoms include a tickling sensation in the throat, a salty taste, a burning or bubbling sensation in the chest, and perhaps chest pain, in which case the patient tends to splint the bleeding side. The term “hemoptysis” is reserved for the coughing up of blood arising from a pulmonary hemorrhage. This blood has an alkaline pH (greater than 7.0).
- If the hemorrhage is in the stomach, the blood is vomited (hematemesis) rather than coughed up. Blood that has been in contact with gastric juice is sometimes so dark that it is referred to as “coffee grounds.” This blood has an acid pH (less than 7.0).

## CYANOSIS

Cyanosis, a bluish coloring of the skin, is a very late indicator of hypoxia. The presence or absence of cyanosis is determined by the amount of unoxygenated hemoglobin in the blood. Cyanosis appears when there is 5 g/dL of unoxygenated hemoglobin. A patient with a hemoglobin level of 15 g/dL will not demonstrate cyanosis until 5 g/dL of that hemoglobin becomes unoxygenated, reducing the effective circulating hemoglobin to two thirds of the normal level. An anemic patient rarely manifests cyanosis, and a polycythemic patient may appear cyanotic even if adequately oxygenated. Therefore, cyanosis is *not* a reliable sign of hypoxia.

Assessment of cyanosis is affected by room lighting, the patient’s skin color, and the distance of the blood vessels from the surface of the skin. In the presence of a pulmonary condition, central cyanosis is assessed by observing the color of the tongue and lips. This indicates a decrease in oxygen tension in the blood. Peripheral cyanosis results from decreased blood flow to a certain area of the body, as in vasoconstriction of the nailbeds or earlobes from exposure to cold, and does not necessarily indicate a central systemic problem.

## PHYSICAL ASSESSMENT OF THE UPPER RESPIRATORY STRUCTURES

For a routine examination of the upper airway, only a simple light source, such as a penlight, is necessary. A more thorough examination requires the use of a nasal speculum.

## Nose and Sinuses

The nurse inspects the external nose for lesions, asymmetry, or inflammation and then asks the patient to tilt the head backward. Gently pushing the tip of the nose upward, the nurse examines the internal structures of the nose, inspecting the mucosa for color, swelling, exudate, or bleeding. The nasal mucosa is normally redder than the oral mucosa, but it may appear swollen and hyperemic if the patient has a common cold. In allergic rhinitis, however, the mucosa appears pale and swollen.

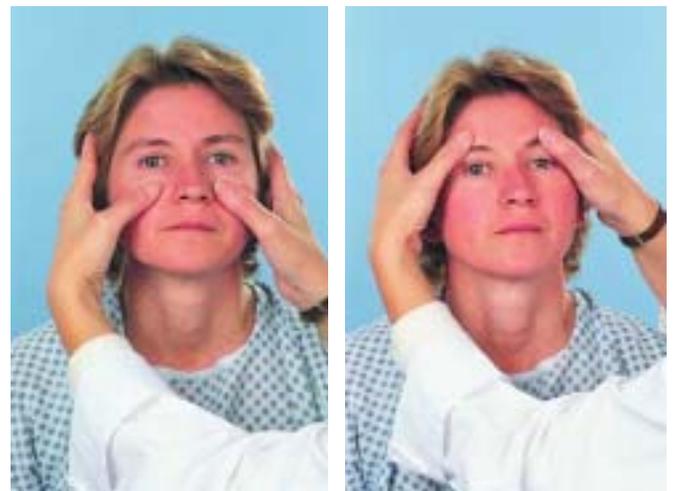

Next the nurse inspects the septum for deviation, perforation, or bleeding. Most people have a slight degree of septal deviation, but actual displacement of the cartilage into either the right or left side of the nose may produce nasal obstruction. Such deviation usually causes no symptoms.

While the head is still tilted back, the nurse inspects the inferior and middle turbinates. In chronic rhinitis, nasal polyps may develop between the inferior and middle turbinates; they are distinguished by their gray appearance. Unlike the turbinates, they are gelatinous and freely movable.

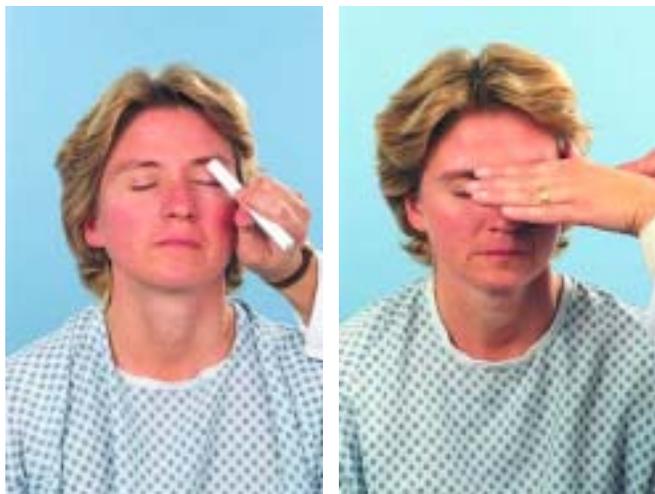

Next the nurse may palpate the frontal and maxillary sinuses for tenderness (Fig. 21-7). Using the thumbs, the nurse applies gentle pressure in an upward fashion at the supraorbital ridges (frontal sinuses) and in the cheek area adjacent to the nose (maxillary sinuses). Tenderness in either area suggests inflammation. The frontal and maxillary sinuses can be inspected by transillumination (passing a strong light through a bony area, such as the sinuses, to inspect the cavity; Fig. 21-8). If the light fails to penetrate, the cavity is likely to contain fluid or pus.

## Pharynx and Mouth

After the nasal inspection, the nurse may assess the mouth and pharynx, instructing the patient to open the mouth wide and take a deep breath. Usually this will flatten the posterior tongue and briefly allow a full view of the anterior and posterior pillars, tonsils, uvula, and posterior pharynx (Fig. 21-9). The nurse inspects these structures for color, symmetry, and evidence of exudate, ulceration, or enlargement. If a tongue blade is needed to depress the tongue to visualize the pharynx, it is pressed firmly beyond the midpoint of the tongue to avoid a gagging response.

**FIGURE 21-7** Technique for palpating the frontal sinuses at left and the maxillary sinuses at right. From Weber, J. & Kelley, J. (2003). *Health assessment in nursing* (2nd ed.). Philadelphia: Lippincott Williams & Wilkins.

**FIGURE 21-8** At left, the nurse positions the light source for transillumination of the frontal sinus. At right, the nurse shields the patient's brow and shines the light. In normal conditions (a darkened room), the light should shine through the tissues and appear as a reddish glow (above the nurse's hand) over the sinus. From Weber, J. & Kelley, J. (2003). *Health assessment in nursing* (2nd ed.). Philadelphia: Lippincott Williams & Wilkins.

## Trachea

Next the position and mobility of the trachea are usually noted by direct palpation. This is performed by placing the thumb and index finger of one hand on either side of the trachea just above the sternal notch. The trachea is highly sensitive, and palpating too firmly may trigger a coughing or gagging response. The trachea is normally in the midline as it enters the thoracic inlet behind the sternum, but it may be deviated by masses in the neck or mediastinum. Pleural or pulmonary disorders, such as a pneumothorax, may also displace the trachea.

## PHYSICAL ASSESSMENT OF THE LOWER RESPIRATORY STRUCTURES AND BREATHING

### Thorax

Inspection of the thorax provides information about the musculoskeletal structure, the patient's nutritional status, and the respiratory system. The nurse observes the skin over the thorax for

color and turgor and for evidence of loss of subcutaneous tissue. It is important to note asymmetry, if present. When findings are recorded or reported, anatomic landmarks are used as points of reference (Chart 21-7).

### CHEST CONFIGURATION

Normally, the ratio of the anteroposterior diameter to the lateral diameter is 1 : 2. However, there are four main deformities of the chest associated with respiratory disease that alter this relationship: barrel chest, funnel chest (pectus excavatum), pigeon chest (pectus carinatum), and kyphoscoliosis.

**Barrel Chest.** Barrel chest occurs as a result of overinflation of the lungs. There is an increase in the anteroposterior diameter of the thorax. In a patient with emphysema, the ribs are more widely spaced and the intercostal spaces tend to bulge on expiration. The appearance of the patient with advanced emphysema is thus quite characteristic and often allows the observer to detect its presence easily, even from a distance.

**Funnel Chest (Pectus Excavatum).** Funnel chest occurs when there is a depression in the lower portion of the sternum. This may compress the heart and great vessels, resulting in murmurs. Funnel chest may occur with rickets or Marfan's syndrome.

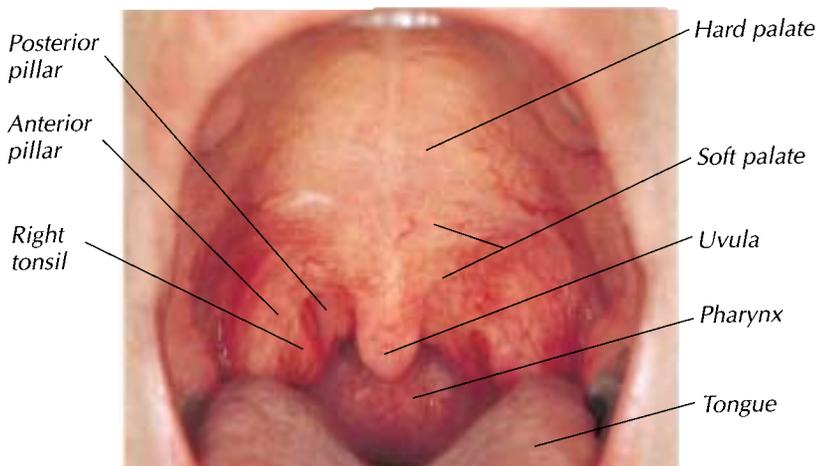

**Pigeon Chest (Pectus Carinatum).** A pigeon chest occurs as a result of displacement of the sternum. There is an increase in the anteroposterior diameter. This may occur with rickets, Marfan's syndrome, or severe kyphoscoliosis.

**Kyphoscoliosis.** A kyphoscoliosis is characterized by elevation of the scapula and a corresponding S-shaped spine. This deformity limits lung expansion within the thorax. It may occur with osteoporosis and other skeletal disorders that affect the thorax.

### BREATHING PATTERNS AND RESPIRATORY RATES

Observing the rate and depth of respiration is a simple but important aspect of assessment. The normal adult who is resting comfortably takes 12 to 18 breaths per minute. Except for occasional sighs, respirations are regular in depth and rhythm. This normal pattern is described as eupnea.

Bradypnea, also called slow breathing, is associated with increased intracranial pressure, brain injury, and drug overdose. Tachypnea, or rapid breathing, is commonly seen in patients with pneumonia, pulmonary edema, metabolic acidosis, septicemia,

**FIGURE 21-9** The pharynx and other oral structures—pillars, tonsils, uvula, hard and soft palates, posterior pharynx, and tongue—are easily seen when the mouth is open.

Chart  
21-7

## Locating Thoracic Landmarks

With respect to the thorax, location is defined both horizontally and vertically. With respect to the lungs, location is defined by lobe.

**Horizontal Reference Points**

Horizontally, thoracic locations are identified according to their proximity to the rib or the intercostal space under the examiner's fingers. On the anterior surface, identification of a specific rib is facilitated by first locating the angle of Louis. This is where the manubrium joins the body of the sternum in the midline. The second rib joins the sternum at this prominent landmark.

Other ribs may be identified by counting down from the second rib. The intercostal spaces are referred to in terms of the rib immediately above the intercostal space; for example, the fifth intercostal space is directly below the fifth rib.

Locating ribs on the posterior surface of the thorax is more difficult. The first step is to identify the spinous process. This is accomplished by finding the seventh cervical vertebra (*vertebra prominens*), which is the most prominent spinous process. When the neck is slightly flexed, the seventh cervical spinous process stands out. Other vertebrae are then identified by counting downward.

**Vertical Reference Points**

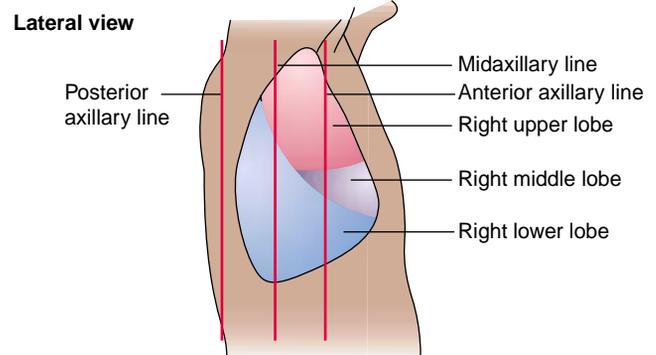

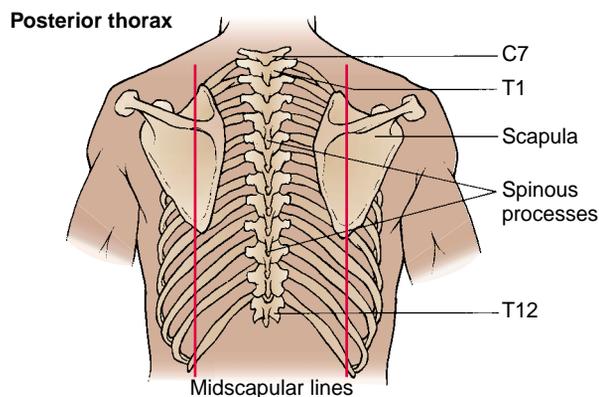

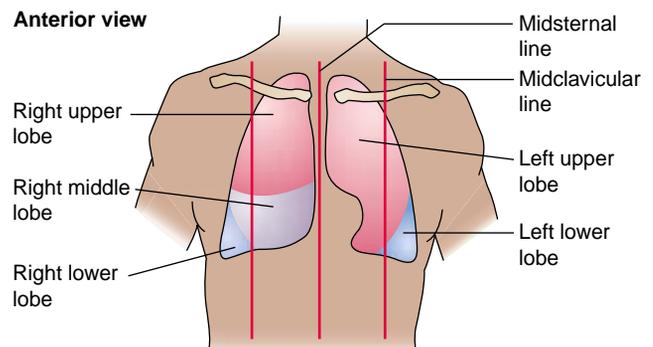

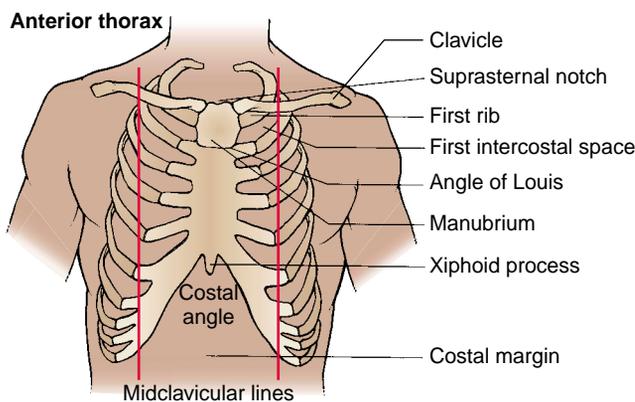

Several imaginary lines are used as vertical referents or landmarks to identify the location of thoracic findings. The *midsternal line* passes through the center of the sternum. The *midclavicular line* is an imagi-

nary line that descends from the middle of the clavicle. The *point of maximal impulse* of the heart normally lies along this line on the left thorax.

When the arm is abducted from the body at 90°, imaginary vertical lines may be drawn from the anterior axillary fold, from the middle of the axilla, and from the posterior axillary fold. These lines are called, respectively, the *anterior axillary line*, the *midaxillary line*, and the *posterior axillary line*. A line drawn vertically through the superior and inferior poles of the scapula is called the *scapular line*, and a line drawn down the center of the vertebral column is called the *vertebral line*. Using these landmarks, for example, the examiner communicates findings by referring to an area of dullness extending from the vertebral to the scapular line between the seventh and tenth ribs on the right.

**Lobes of the Lungs**

The lobes of the lung may be mapped on the surface of the chest wall in the following manner. The line between the upper and lower lobes on the left begins at the fourth thoracic spinous process posteriorly, proceeds around to cross the fifth rib in the midaxillary line, and meets the sixth rib at the sternum. This line on the right divides the right middle lobe from the right lower lobe. The line dividing the right upper lobe from the middle lobe is an incomplete one that begins at the fifth rib in the midaxillary line, where it intersects the line between the upper and lower lobes and traverses horizontally to the sternum. Thus, the upper lobes are dominant on the anterior surface of the thorax and the lower lobes are dominant on the posterior surface. There is no presentation of the middle lobe on the posterior surface of the chest.

severe pain, and rib fracture. Shallow, irregular breathing is referred to as hypoventilation.

An increase in depth of respirations is called hyperpnea. An increase in both rate and depth that results in a lowered arterial PCO<sub>2</sub> level is referred to as hyperventilation. With rapid breathing, inspiration and expiration are nearly equal in duration. Hyperventilation that is marked by an increase in rate and depth,

associated with severe acidosis of diabetic or renal origin, is called Kussmaul's respiration.

Apnea describes varying periods of cessation of breathing. If sustained, apnea is life-threatening.

Cheyne-Stokes respiration is characterized by alternating episodes of apnea (cessation of breathing) and periods of deep breathing. Deep respirations become increasingly shallow, followed by

apnea that may last approximately 20 seconds. The cycle repeats after each apneic period. The duration of the period of apnea may vary and may progressively lengthen; therefore, it is timed and reported. Cheyne-Stokes respiration is usually associated with heart failure and damage to the respiratory center (drug-induced, tumor, trauma).

Biot's respirations, or cluster breathing, are cycles of breaths that vary in depth and have varying periods of apnea. Biot's respirations are seen with some central nervous system disorders.

Certain patterns of respiration are characteristic of specific disease states. Respiratory rhythms and their deviation from normal are important observations that the nurse reports and documents. The rate and depth of different patterns of respiration are presented in Figure 21-10.

In thin people, it is quite normal to note a slight retraction of the intercostal spaces during quiet breathing. Bulging during expiration implies obstruction of expiratory airflow, as in emphysema. Marked retraction on inspiration, particularly if asymmetric, implies blockage of a branch of the respiratory tree. Asymmetric bulging of the intercostal spaces, on one side or the other, is created by an increase in pressure within the hemithorax. This may be a result of air trapped under pressure within the pleural cavity where it does not normally appear (pneumothorax) or the pressure of fluid within the pleural space (pleural effusion).

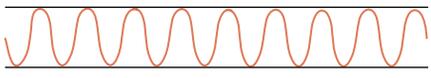

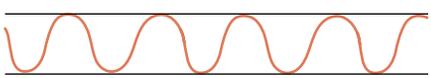

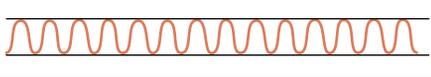

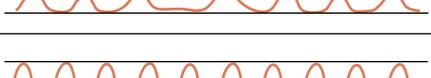

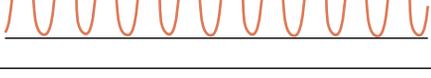

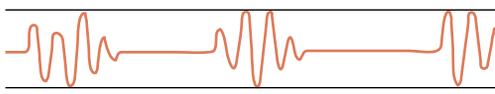

## Thoracic Palpation

The nurse palpates the thorax for tenderness, masses, lesions, respiratory excursion, and vocal fremitus. If the patient has reported an area of pain or if lesions are apparent, the nurse performs direct palpation with the fingertips (for skin lesions and subcutaneous masses) or with the ball of the hand (for deeper masses or generalized flank or rib discomfort).

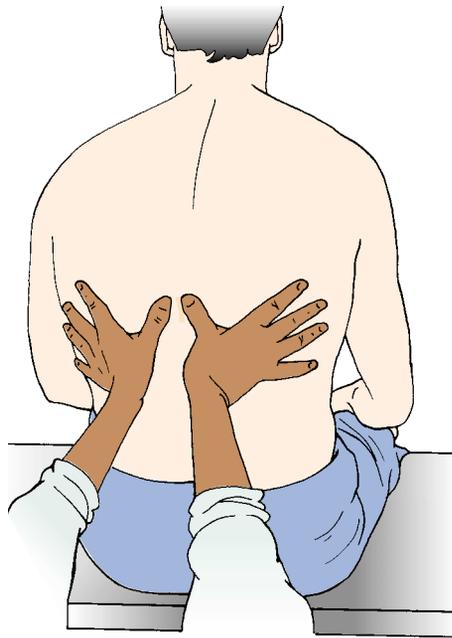

## RESPIRATORY EXCURSION

Respiratory excursion is an estimation of thoracic expansion and may disclose significant information about thoracic movement during breathing. The nurse assesses the patient for range and symmetry of excursion. The patient is instructed to inhale deeply while the movement of the nurse's thumbs (placed along the costal margin on the anterior chest wall) during inspiration and expiration is observed. This movement is normally symmetric.

Posterior assessment is performed by placing the thumbs adjacent to the spinal column at the level of the tenth rib (Fig. 21-11). The hands lightly grasp the lateral rib cage. Sliding the thumbs medially about 2.5 cm (1 inch) raises a small skinfold between the thumbs. The patient is instructed to take a full inspiration and to exhale fully. The nurse observes for normal flattening of the skinfold and feels the symmetric movement of the thorax.

	Definition	Graphic Representation
<b>Eupnea</b>	Normal, breathing at 12-18 breaths/minute	
<b>Bradypnea</b>	Slower than normal rate (< 10 breaths/minute), with normal depth and regular rhythm	
<b>Tachypnea</b>	Rapid, shallow breathing > 24 breaths/minute	
<b>Hypoventilation</b>	Shallow, irregular breathing	
<b>Hyperventilation</b>	Increased rate and depth of breathing (called Kussmaul's respiration if caused by diabetic ketoacidosis)	
<b>Apnea</b>	Period of cessation of breathing. Time duration varies; apnea may occur briefly during other breathing disorders, such as with sleep apnea. Life threatening if sustained.	
<b>Cheyne-Stokes</b>	Regular cycle where the rate and depth of breathing increase, then decrease until apnea (usually about 20 seconds) occurs.	
<b>Biot's respiration</b>	Periods of normal breathing (3-4 breaths) followed by a varying period of apnea (usually 10 seconds to 1 minute).	

**FIGURE 21-10** Graphic representation of different rates and depths of respiration.

**FIGURE 21-11** Method for assessing posterior respiratory excursion. Place both hands posteriorly at the level of T9 or T10. Slide hands medially to pinch a small amount of skin between your thumbs. Observe for symmetry.

Decreased chest excursion may be due to chronic fibrotic disease. Asymmetric excursion may be due to splinting secondary to pleurisy, fractured ribs, trauma, or unilateral bronchial obstruction.

### TACTILE FREMITUS

Sound generated by the larynx travels distally along the bronchial tree to set the chest wall in resonant motion. This is especially

true of consonant sounds. The detection of the resulting vibration on the chest wall by touch is called tactile fremitus.

Normal fremitus is widely varied. It is influenced by the thickness of the chest wall, especially if that thickness is muscular. However, the increase in subcutaneous tissue associated with obesity may also affect fremitus. Lower-pitched sounds travel better through the normal lung and produce greater vibration of the chest wall. Thus, fremitus is more pronounced in men than in women because of the deeper male voice. Normally, fremitus is most pronounced where the large bronchi are closest to the chest wall and least palpable over the distant lung fields. Therefore, it is most palpable in the upper thorax, anteriorly and posteriorly.

The patient is asked to repeat “ninety-nine” or “one, two, three,” or “eee, eee, eee” as the nurse’s hands move down the patient’s thorax. The vibrations are detected with the palmar surfaces of the fingers and hands, or the ulnar aspect of the extended hands, on the thorax. The hand or hands are moved in sequence down the thorax. Corresponding areas of the thorax are compared (Fig. 21-12). Bony areas are not tested.

Air does not conduct sound well but a solid substance such as tissue does, provided that it has elasticity and is not compressed. Thus, an increase in solid tissue per unit volume of lung will enhance fremitus; an increase in air per unit volume of lung will impede sound. Patients with emphysema, which results in the rupture of alveoli and trapping of air, exhibit almost no tactile fremitus. A patient with consolidation of a lobe of the lung from pneumonia will have increased tactile fremitus over that lobe. Air in the pleural space will not conduct sound.

### Thoracic Percussion

Percussion sets the chest wall and underlying structures in motion, producing audible and tactile vibrations. The nurse uses percussion to determine whether underlying tissues are filled with air, fluid, or solid material. Percussion also is used to estimate the size and location of certain structures within the thorax (eg, diaphragm, heart, liver).

**FIGURE 21-12** When palpating for tactile fremitus (*left*), the nurse places the ball or ulnar surface of the hands on the chest area being assessed. The palpation sequence is at right. From Bickley L. S. (2003). *Bates’ guide to physical examination and history taking* (8th ed.). Philadelphia: Lippincott Williams & Wilkins.

Percussion usually begins with the posterior thorax. Ideally, the patient is in a sitting position with the head flexed forward and the arms crossed on the lap. This position separates the scapulae widely and exposes more lung area for assessment. The nurse percusses across each shoulder top, locating the 5-cm width of resonance overlying the lung apices (Fig. 21-13). Then the nurse proceeds down the posterior thorax, percussing symmetric areas at 5- to 6-cm (2- to 2.5-inch) intervals. The middle finger is positioned parallel to the ribs in the intercostal space; the finger is placed firmly against the chest wall before striking it with the middle finger of the opposite hand. Bony structures (scapulae or ribs) are not percussed.

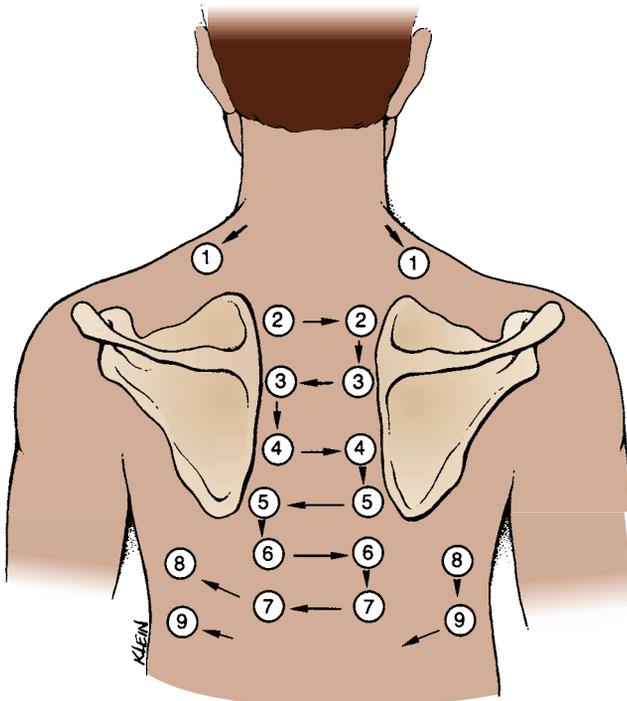

Percussion over the anterior chest is performed with the patient in an upright position with shoulders arched backward and arms at the side. The nurse begins in the supraclavicular area and proceeds downward, from one intercostal space to the next. In the female patient, it may be necessary to displace the breasts for an adequate examination. Dullness noted to the left of the sternum between the third and fifth intercostal spaces is a normal finding because it is the location of the heart. Similarly, there is a normal span of liver dullness in the right thorax from the fifth intercostal space to the right costal margin at the midclavicular line.

The anterior and lateral thorax is examined with the patient in a supine position. If the patient cannot sit up, percussion of the posterior thorax is performed with the patient positioned on the side.

Dullness over the lung occurs when air-filled lung tissue is replaced by fluid or solid tissue. Table 21-3 reviews percussion sounds and their characteristics.

### DIAPHRAGMATIC EXCURSION

The normal resonance of the lung stops at the diaphragm. The position of the diaphragm is different during inspiration than during expiration.

**FIGURE 21-13** Percussion of the posterior thorax. With the patient in a sitting position, symmetric areas of the lungs are percussed at 5-cm intervals. This progression starts at the apex of each lung and concludes with percussion of each lateral chest wall.

To assess the position and motion of the diaphragm, the nurse instructs the patient to take a deep breath and hold it while the maximal descent of the diaphragm is percussed. The point at which the percussion note at the midscapular line changes from resonance to dullness is marked with a pen. The patient is then instructed to exhale fully and hold it while the nurse again percusses downward to the dullness of the diaphragm. This point is also marked. The distance between the two markings indicates the range of motion of the diaphragm.

Maximal excursion of the diaphragm may be as much as 8 to 10 cm (3 to 4 inches) in healthy, tall young men, but for most people it is usually 5 to 7 cm (2 to 2.75 inches). Normally, the diaphragm is about 2 cm (0.75 inches) higher on the right because of the position of the heart and the liver above and below the left and right segments of the diaphragm, respectively. Decreased diaphragmatic excursion may occur with pleural effusion and emphysema. An increase in intra-abdominal pressure, as in pregnancy or ascites, may account for a diaphragm that is positioned high in the thorax.

### Thoracic Auscultation

Auscultation is useful in assessing the flow of air through the bronchial tree and in evaluating the presence of fluid or solid obstruction in the lung structures. The nurse auscultates for normal breath sounds, adventitious sounds, and voice sounds.

Examination includes auscultation of the anterior, posterior, and lateral thorax and is performed as follows. The nurse places the diaphragm of the stethoscope firmly against the chest wall as the patient breathes slowly and deeply through the mouth. Corresponding areas of the chest are auscultated in a systematic fashion from the apices to the bases and along midaxillary lines. The sequence of auscultation and the positioning of the patient are similar to those used for percussion. It often is necessary to listen to two full inspirations and expirations at each anatomic location for valid interpretation of the sound heard. Repeated deep breaths may result in symptoms of hyperventilation (eg, light-headedness); this is avoided by having the patient rest and breathe normally periodically during the examination.

### BREATH SOUNDS

Normal breath sounds are distinguished by their location over a specific area of the lung and are identified as vesicular, bronchovesicular, and bronchial (tubular) breath sounds (Table 21-4).

The location, quality, and intensity of breath sounds are determined during auscultation. When airflow is decreased by bronchial obstruction (atelectasis) or when fluid (pleural effusion) or tissue (obesity) separates the air passages from the stethoscope, breath sounds are diminished or absent. For example, the breath sounds of the patient with emphysema are faint or often completely inaudible. When heard, the expiratory phase is prolonged. Bronchial and bronchovesicular sounds that are audible anywhere except over the main bronchus in the lungs signify pathology, usually indicating consolidation in the lung (eg, pneumonia, heart failure). This finding requires further evaluation.

### ADVENTITIOUS SOUNDS

An abnormal condition that affects the bronchial tree and alveoli may produce adventitious (additional) sounds. Adventitious sounds are divided into two categories: discrete, noncontinuous sounds (crackles) and continuous musical sounds (wheezes). The duration of the sound is the important distinction to make in identifying the sound as noncontinuous or continuous. Pleural friction rubs are specific examples of crackles (Table 21-5).

**Table 21-3 • Characteristics of Percussion Sounds**

SOUND	RELATIVE INTENSITY	RELATIVE PITCH	RELATIVE DURATION	LOCATION EXAMPLE	EXAMPLES
Flatness	Soft	High	Short	Thigh	Large pleural effusion
Dullness	Medium	Medium	Medium	Liver	Lobar pneumonia
Resonance	Loud	Low	Long	Normal lung	Simple chronic bronchitis
Hyperresonance	Very loud	Lower	Longer	None normally	Emphysema, pneumothorax
Tympany	Loud	High*	*	Gastric air bubble or puffed-out cheek	Large pneumothorax

\*Distinguished mainly by its musical timbre

**Crackles** (formerly referred to as rales) are discrete, noncontinuous sounds that result from delayed reopening of deflated airways. Crackles may or may not be cleared by coughing. Crackles reflect underlying inflammation or congestion and are often present in such conditions as pneumonia, bronchitis, heart failure, bronchiectasis, and pulmonary fibrosis.

Friction rubs result from inflammation of the pleural surfaces that induces a crackling, grating sound usually heard in inspiration and expiration. The sound can be enhanced by applying pressure to the chest wall with the diaphragm of the stethoscope. The sound is imitated by rubbing the thumb and index finger together near the ear. A friction rub is best heard over the lower lateral anterior surface of the thorax.

**Wheezes** are associated with bronchial wall oscillation and changes in airway diameter. Wheezes are commonly heard in patients with asthma, chronic bronchitis, and bronchiectasis.

### VOICE SOUNDS

The sound heard through the stethoscope as the patient speaks is known as vocal resonance. The vibrations produced in the larynx are transmitted to the chest wall as they pass through the bronchi and alveolar tissue. During the process, the sounds are dimin-

ished in intensity and altered so that syllables are not distinguishable. Voice sounds are usually assessed by having the patient repeat “ninety-nine” or “eee” while the nurse listens with the stethoscope in corresponding areas of the chest from the apices to the bases.

Bronchophony describes vocal resonance that is more intense and clearer than normal. Egophony describes voice sounds that are distorted. It is best appreciated by having the patient repeat the letter E. The distortion produced by consolidation transforms the sound into a clearly heard A rather than E. Bronchophony and egophony have precisely the same significance as bronchial breathing with an increase in tactile fremitus. When an abnormality is detected, it should be evident using more than one assessment method. A change in tactile fremitus is more subtle and can be missed, but bronchial breathing and bronchophony can be noted loudly and clearly.

Whispered pectoriloquy is a very subtle finding, heard only in the presence of rather dense consolidation of the lungs. Transmission of high-frequency components of sound is so enhanced by the consolidated tissue that even whispered words are heard, a circumstance not noted in normal physiology. The significance is the same as that of bronchophony.

**Table 21-4 • Breath Sounds**

	DURATION OF SOUNDS	INTENSITY OF EXPIRATORY SOUND	PITCH OF EXPIRATORY SOUND	LOCATIONS WHERE HEARD NORMALLY
Vesicular* 	Inspiratory sounds last longer than expiratory ones.	Soft	Relatively low	Entire lung field except over the upper sternum and between the scapulae
Broncho-vesicular 	Inspiratory and expiratory sounds are about equal.	Intermediate	Intermediate	Often in the 1st and 2nd interspaces anteriorly and between the scapulae (over the main bronchus)
Bronchial 	Expiratory sounds last longer than inspiratory ones.	Loud	Relatively high	Over the manubrium, if heard at all
Tracheal 	Inspiratory and expiratory sounds are about equal.	Very loud	Relatively high	Over the trachea in the neck

\*The thickness of the bars indicates intensity of breath sounds; the steeper their incline, the higher the pitch of the sounds.

**Table 21-5 • Abnormal (Adventitious) Breath Sounds**

BREATH SOUND	DESCRIPTION	ETIOLOGY
<b>Crackles</b>		
Crackles in general	Soft, high-pitched, discontinuous popping sounds that occur during inspiration	Secondary to fluid in the airways or alveoli or to opening of collapsed alveoli
Coarse crackles	Discontinuous popping sounds heard in early inspiration; harsh, moist sound originating in the large bronchi	Associated with obstructive pulmonary disease
Fine crackles	Discontinuous popping sounds heard in late inspiration; sounds like hair rubbing together; originates in the alveoli	Associated with interstitial pneumonia, restrictive pulmonary disease (eg, fibrosis). Fine crackles in early inspiration are associated with bronchitis or pneumonia.
<b>Wheezes</b>		
Sonorous wheezes (rhonchi)	Deep, low-pitched rumbling sounds heard primarily during expiration; caused by air moving through narrowed tracheobronchial passages	Secretions or tumor
Sibilant wheezes	Continuous, musical, high-pitched, whistle-like sounds heard during inspiration and expiration caused by air passing through narrowed or partially obstructed airways; may clear with coughing	Bronchospasm, asthma, and buildup of secretions
<b>Friction rubs</b>		
Pleural friction rub	Harsh, crackling sound, like two pieces of leather being rubbed together. Heard during inspiration alone or during both inspiration and expiration. May subside when patient holds breath. Coughing will not clear sound.	Secondary to inflammation and loss of lubricating pleural fluid

The physical findings for the most common respiratory diseases are summarized in Table 21-6.

## PHYSICAL ASSESSMENT OF BREATHING ABILITY IN THE ACUTELY ILL PATIENT

Tests of the patient's breathing ability are easily performed at the bedside by measuring the respiratory rate (see the previous section "Breathing Patterns and Respiratory Rates"), tidal volume, minute ventilation, vital capacity, inspiratory force, and compliance. These tests are particularly important for patients at risk for developing pulmonary complications, including those who have undergone chest or abdominal surgery, have had prolonged anesthesia, have preexisting pulmonary disease, or are elderly. These tests are also used routinely for mechanically ventilated patients.

Patients whose chest expansion is limited by external restrictions such as obesity or abdominal distention and who cannot breathe deeply because of postoperative pain or sedation will inhale and exhale a low volume of air (referred to as low tidal volumes). Prolonged hypoventilation at low tidal volumes can produce alveolar collapse or atelectasis. The amount of air remaining in the lungs after a normal expiration (functional residual capacity) falls, the ability of the lungs to expand (compliance) is reduced, and the patient must breathe faster to maintain the same degree of tissue oxygenation. These events can be exaggerated in patients who have preexisting pulmonary diseases and in elderly patients whose airways are less compliant, because the small airways may collapse during expiration.

**NURSING ALERT** One should not rely only on visual inspection of the rate and depth of a patient's respiratory excursions to determine the adequacy of ventilation. Respiratory excursions may appear normal or exaggerated due to an increased work of breathing, but the patient may actually be moving only enough air to ventilate the dead space. If there is any question regarding adequacy of ventilation, auscultation and/or pulse oximetry should be used for additional assessment of respiratory status.

### Tidal Volume

The volume of each breath is referred to as the tidal volume (see Table 21-1 to review lung capacities and volumes). A spirometer is an instrument that can be used at the bedside to measure volumes. If the patient is breathing through an endotracheal tube or tracheostomy, the spirometer is directly attached to it and the exhaled volume is obtained from the reading on the gauge. In other patients, the spirometer is attached to a facemask or a mouthpiece positioned so that it is airtight, and the exhaled volume is measured.

The tidal volume may vary from breath to breath. To make the measurement reliable, it is important to measure the volumes of several breaths and to note the range of tidal volumes, together with the average tidal volume.

### Minute Ventilation

Respiratory rates and tidal volume alone are unreliable indicators of adequate ventilation because both can vary widely from breath to breath. Together, however, the tidal volume and respiratory

Table 21-6 • Assessment Findings in Common Respiratory Problems

PROBLEM	TACTILE FREMITUS	PERCUSSION	AUSCULTATION
Consolidation (eg, pneumonia)	Increased	Dull	Bronchial breath sounds, crackles, bronchophony, egophony, whispered pectoriloquy
Bronchitis	Normal	Resonant	Normal to decreased breath sounds, wheezes
Emphysema	Decreased	Hyperresonant	Decreased intensity of breath sounds, usually with prolonged expiration
Asthma (severe attack)	Normal to decreased	Resonant to hyperresonant	Wheezes
Pulmonary edema	Normal	Resonant	Crackles at lung bases, possibly wheezes
Pleural effusion	Absent	Dull to flat	Decreased to absent breath sounds, bronchial breath sounds and bronchophony, egophony, and whispered pectoriloquy above the effusion over the area of compressed lung
Pneumothorax	Decreased	Hyperresonant	Absent breath sounds
Atelectasis	Absent	Flat	Decreased to absent breath sounds

rate are important because the minute ventilation, which is useful in detecting respiratory failure, can be determined from them. Minute ventilation is the volume of air expired per minute. It is equal to the product of the tidal volume and the respiratory rate or frequency. In practice, the minute ventilation is not calculated but is measured directly using a spirometer.

Minute ventilation may be decreased by a variety of conditions that result in hypoventilation. When the minute ventilation falls, alveolar ventilation in the lungs also decreases, and the PaCO<sub>2</sub> increases. Risk factors for hypoventilation are listed in Chart 21-8.

## Vital Capacity

Vital capacity is measured by having the patient take in a maximal breath and exhale fully through a spirometer. The normal value depends on the patient's age, gender, body build, and weight.

**NURSING ALERT** Most patients can generate a vital capacity twice the volume they normally breathe in and out (tidal volume). If the vital capacity is less than 10 mL/kg, the patient will be unable to sustain spontaneous ventilation and will require respiratory assistance.

When the vital capacity is exhaled at a maximal flow rate, the forced vital capacity is measured. Most patients can exhale at least 80% of their vital capacity in 1 second (forced expiratory volume in 1 second, or FEV<sub>1</sub>) and almost all of it in 3 seconds (FEV<sub>3</sub>). A reduction in FEV<sub>1</sub> suggests abnormal pulmonary air flow. If the patient's FEV<sub>1</sub> and forced vital capacity are proportionately reduced, maximal lung expansion is restricted in some way. If the reduction in FEV<sub>1</sub> greatly exceeds the reduction in forced vital capacity, the patient may have some degree of airway obstruction.

## Inspiratory Force

Inspiratory force evaluates the effort the patient is making during inspiration. It does not require patient cooperation and thus is

useful in the unconscious patient. The equipment needed for this measurement includes a manometer that measures negative pressure and adapters that are connected to an anesthesia mask or a cuffed endotracheal tube. The manometer is attached and the airway is completely occluded for 10 to 20 seconds while the inspiratory efforts of the patient are registered on the manometer. The normal inspiratory pressure is about 100 cm H<sub>2</sub>O. If the negative pressure registered after 15 seconds of occluding the airway is less than about 25 cm H<sub>2</sub>O, mechanical ventilation is usually required because the patient lacks sufficient muscle strength for deep breathing or effective coughing.

## Diagnostic Evaluation

A wide range of diagnostic studies, described on the following pages, may be performed in patients with respiratory conditions.

## PULMONARY FUNCTION TESTS

Pulmonary function tests (PFTs) are routinely used in patients with chronic respiratory disorders. They are performed to assess respiratory function and to determine the extent of dysfunction. Such tests include measurements of lung volumes, ventilatory

Chart 21-8  
Risk Factors for Hypoventilation

- Limited neurologic impulses transmitted from the brain to the respiratory muscles, as in spinal cord trauma, cerebrovascular accidents, tumors, myasthenia gravis, Guillain-Barré syndrome, polio, and drug overdose
- Depressed respiratory centers in the medulla, as with anesthesia and drug overdose
- Limited thoracic movement (kyphoscoliosis), limited lung movement (pleural effusion, pneumothorax), or reduced functional lung tissue (chronic pulmonary diseases, severe pulmonary edema)

function, and the mechanics of breathing, diffusion, and gas exchange (Table 21-7).

PFTs are useful in following the course of a patient with an established respiratory disease and assessing the response to therapy. They are useful as screening tests in potentially hazardous industries, such as coal mining and those that involve exposure to asbestos and other noxious fumes, dusts, or gases. They are useful for screening patients scheduled for thoracic and upper abdominal surgery, and symptomatic patients with a history suggesting high risk.

PFTs generally are performed by a technician using a spirometer that has a volume-collecting device attached to a recorder that demonstrates volume and time simultaneously. A number of tests are carried out because no single measurement provides a complete picture of pulmonary function. The most frequently used PFTs are described in Table 21-7. Technology is available that allows for more complex assessment of pulmonary function. Methods include exercise tidal flow-volume loops, negative expiratory pressure, nitric oxide, and forced oscillation. These assessment methods allow for detailed evaluation of expiratory flow limitations and airway inflammation (Johnson, Beck, Zeballos & Weisman, 1999).

PFT results are interpreted on the basis of the degree of deviation from normal, taking into consideration the patient's height, weight, age, and gender. Because there is a wide range of normal values, PFTs may not detect early localized changes. The patient with respiratory symptoms (dyspnea, wheezing, cough, sputum production) usually undergoes a complete diagnostic evaluation, even though the results of PFTs are "normal." Trends of results provide information about disease progression as well as the patient's response to therapy.

Patients with respiratory disorders may be taught how to measure their peak flow rate (reflects maximal expiratory flow) at home using a spirometer. This allows them to monitor the progress of therapy, to alter medications and other interventions as needed based on caregiver guidelines, or to notify the health care provider if there is inadequate response to their own interventions. Home care teaching instructions are described in Chapter 24, which discusses asthma.

## ARTERIAL BLOOD GAS STUDIES

Measurements of blood pH and of arterial oxygen and carbon dioxide tensions are obtained when managing patients with respiratory problems and in adjusting oxygen therapy as needed. The arterial oxygen tension ( $\text{PaO}_2$ ) indicates the degree of oxygenation of the blood, and the arterial carbon dioxide tension ( $\text{PaCO}_2$ ) indicates the adequacy of alveolar ventilation. Arterial blood gas studies aid in assessing the ability of the lungs to provide adequate oxygen and remove carbon dioxide and the ability of the kidneys to reabsorb or excrete bicarbonate ions to maintain normal body pH. Serial blood gas analysis also is a sensitive indicator of whether the lung has been damaged after chest trauma. Arterial blood gas levels are obtained through an arterial puncture at the radial, brachial, or femoral artery or through an indwelling arterial catheter. Arterial blood gas levels are discussed in detail in Chapter 14.

## PULSE OXIMETRY

Pulse oximetry is a noninvasive method of continuously monitoring the oxygen saturation of hemoglobin ( $\text{SpO}_2$  or  $\text{SaO}_2$ ). Although pulse oximetry does not replace arterial blood gas measurement, it is an effective tool to monitor for subtle or sudden changes in oxygen saturation. It is used in all settings where oxygen saturation monitoring is needed, such as the home, clinics, ambulatory surgical settings, and hospitals.

A probe or sensor is attached to the fingertip (Fig. 21-14), forehead, earlobe, or bridge of the nose. The sensor detects changes in oxygen saturation levels by monitoring light signals generated by the oximeter and reflected by blood pulsing through the tissue at the probe. Normal  $\text{SpO}_2$  values are 95% to 100%. Values less than 85% indicate that the tissues are not receiving enough oxygen, and the patient needs further evaluation.  $\text{SpO}_2$  values obtained by pulse oximetry are unreliable in cardiac arrest and shock, when dyes (ie, methylene blue) or vasoconstrictor medications have been used, or when the patient has severe anemia or a high carbon monoxide level.

**Table 21-7 • Pulmonary Function Tests**

TERM USED	SYMBOL	DESCRIPTION	REMARKS
Forced vital capacity	FVC	Vital capacity performed with a maximally forced expiratory effort	Forced vital capacity is often reduced in COPD because of air trapping.
Forced expiratory volume (qualified by subscript indicating the time intervals in seconds)	$\text{FEV}_t$ , usually $\text{FEV}_1$	Volume of air exhaled in the specified time during the performance of forced vital capacity; $\text{FEV}_1$ is volume exhaled in 1 second	A valuable clue to the severity of the expiratory airway obstruction
Ratio of timed forced expiratory volume to forced vital capacity	$\text{FEV}_t/\text{FVC}\%$ , usually $\text{FEV}_1/\text{FVC}\%$	$\text{FEV}_t$ expressed as a percentage of the forced vital capacity	Another way of expressing the presence or absence of airway obstruction
Forced expiratory flow	$\text{FEF}_{200-1200}$	Mean forced expiratory flow between 200 and 1,200 mL of the FVC	An indicator of large airway obstruction
Forced midexpiratory flow	$\text{FEF}_{25\%-75\%}$	Mean forced expiratory flow during the middle half of the FVC	Slowed in small airway obstruction
Forced end expiratory flow	$\text{FEF}_{75\%-85\%}$	Mean forced expiratory flow during the terminal portion of the FVC	Slowed in obstruction of smallest airways
Maximal voluntary ventilation	MVV	Volume of air expired in a specified period (12 seconds) during repetitive maximal effort	An important factor in exercise tolerance

**FIGURE 21-14** Measuring blood oxygenation with pulse oximetry reduces the need for invasive procedures, such as drawing blood for analysis of oxygen levels. After the pulse oximeter sensor slips easily over a patient's finger, the oxygen saturation level appears on the monitor. The oximeter is portable and ideal for home use. Courtesy Novamatrix Medical Systems, Inc.

## CULTURES

Throat cultures may be performed to identify organisms responsible for pharyngitis. Throat culture may also assist in identifying organisms responsible for infection of the lower respiratory tract. Nasal swabs also may be performed for the same purpose.

## SPUTUM STUDIES

Sputum is obtained for analysis to identify pathogenic organisms and to determine whether malignant cells are present. It also may be used to assess for hypersensitivity states (in which there is an increase in eosinophils). Periodic sputum examinations may be necessary for patients receiving antibiotics, corticosteroids, and immunosuppressive medications for prolonged periods because these agents are associated with opportunistic infections. In general, sputum cultures are used in diagnosis, for drug sensitivity testing, and to guide treatment.

Expectoration is the usual method for collecting a sputum specimen. The patient is instructed to clear the nose and throat and rinse the mouth to decrease contamination of the sputum. After taking a few deep breaths, the patient coughs (rather than spits), using the diaphragm, and expectorates into a sterile container.

If the sputum cannot be raised spontaneously, the patient often can be induced to cough deeply by breathing an irritating aerosol of supersaturated saline, propylene glycol, or some other agent delivered with an ultrasonic nebulizer. Other methods of collecting sputum specimens include endotracheal aspiration, bronchoscopic removal, bronchial brushing, transtracheal aspiration, and gastric aspiration—usually for tuberculosis organisms (see Chap. 23). Generally, the deepest specimens (those from the base of the lungs) are obtained in the early morning after they have accumulated overnight.

The specimen is delivered to the laboratory within 2 hours by the patient or nurse. Allowing the specimen to stand for several hours in a warm room results in the overgrowth of contaminant organisms and may make it difficult to identify the organisms (especially *Mycobacterium tuberculosis*). The home care nurse may assist patients who need help obtaining the sample or who cannot deliver the specimen to the laboratory in a timely fashion.

## IMAGING STUDIES

Imaging studies, including x-rays, computed tomography (CT) scans, magnetic resonance imaging (MRI), contrast studies, and radioisotope diagnostic scans may be part of any diagnostic workup, ranging from a determination of the extent of infection in sinusitis to tumor growth in cancer.

### Chest X-Ray

Normal pulmonary tissue is radiolucent; therefore, densities produced by fluid, tumors, foreign bodies, and other pathologic conditions can be detected by x-ray examination. A chest x-ray may reveal an extensive pathologic process in the lungs in the absence of symptoms. The routine chest x-ray consists of two views—the posteroanterior projection and the lateral projection. Chest x-rays are usually taken after full inspiration (a deep breath) because the lungs are best visualized when they are well aerated. Also, the diaphragm is at its lowest level and the largest expanse of lung is visible. If taken on expiration, x-ray films may accentuate an otherwise unnoticed pneumothorax or obstruction of a major artery.

### Computed Tomography

CT is an imaging method in which the lungs are scanned in successive layers by a narrow-beam x-ray. The images produced provide a cross-sectional view of the chest. Whereas a chest x-ray shows major contrast between body densities, such as bones, soft tissues, and air, CT scans can distinguish fine tissue density. CT may be used to define pulmonary nodules and small tumors adjacent to pleural surfaces that are not visible on routine chest x-ray, and to demonstrate mediastinal abnormalities and hilar adenopathy, which are difficult to visualize with other techniques. Contrast agents are useful when evaluating the mediastinum and its contents.

### Magnetic Resonance Imaging

MRIs are similar to CT scans except that magnetic fields and radiofrequency signals are used instead of a narrow-beam x-ray. MRIs yield a much more detailed diagnostic image than CT scans. MRI is used to characterize pulmonary nodules, stage bronchogenic carcinoma (assessment of chest wall invasion), and evaluate inflammatory activity in interstitial lung disease, acute pulmonary embolism, and chronic thrombotic pulmonary hypertension (Kauczor & Kreitner, 2000).

### Fluoroscopic Studies

Fluoroscopy is used to assist with invasive procedures, such as a chest needle biopsy or transbronchial biopsy, performed to identify lesions. It also may be used to study the movement of the chest wall, mediastinum, heart, and diaphragm, to detect diaphragm paralysis, and to locate lung masses.

### Pulmonary Angiography

Pulmonary angiography is most commonly used to investigate thromboembolic disease of the lungs, such as pulmonary emboli and congenital abnormalities of the pulmonary vascular tree. It involves the rapid injection of a radiopaque agent into the vasculature of the lungs for radiographic study of the pulmonary vessels.

It can be performed by injecting the radiopaque agent into a vein in one or both arms (simultaneously) or into the femoral vein, with a needle or catheter. The agent also can be injected into a catheter that has been inserted in the main pulmonary artery or its branches or into the great veins proximal to the pulmonary artery.

## Radioisotope Diagnostic Procedures (Lung Scans)

Several types of lung scans—ventilation-perfusion scan, gallium scan, and positron emission tomography—are used to detect normal lung functioning, pulmonary vascular supply, and gas exchange.

A ventilation-perfusion lung scan is first performed by injecting a radioactive agent into a peripheral vein and then obtaining a scan of the chest to detect radiation. The isotope particles pass through the right side of the heart and are distributed into the lungs in amounts proportional to the regional blood flow, making it possible to trace and measure blood perfusion through the lung. This procedure is used clinically to measure the integrity of the pulmonary vessels relative to blood flow and to evaluate blood flow abnormalities, as seen in pulmonary emboli. The imaging time is 20 to 40 minutes, during which the patient will lie under the camera with a mask fitted over the nose and mouth. This is followed by the ventilation component of the scan. The patient takes a deep breath of a mixture of oxygen and radioactive gas, which diffuses throughout the lungs. A scan is performed to detect ventilation abnormalities in patients who have regional differences in ventilation. It may be helpful in the diagnosis of bronchitis, asthma, inflammatory fibrosis, pneumonia, emphysema, and lung cancer. Ventilation without perfusion is seen with pulmonary emboli.

A gallium scan is a radioisotope lung scan used to detect inflammatory conditions, abscesses, adhesions, and the presence, location, and size of tumors. It is used to stage bronchogenic cancer and record tumor regression after chemotherapy or radiation. Gallium is injected intravenously, and scans are taken at 6, 24, and/or 48 hours to evaluate gallium uptake by the pulmonary tissues.

Positron emission tomography (PET) is a radioisotope study with advanced diagnostic capabilities. It is used to evaluate lung nodules for malignancy. PET scans can detect and display metabolic changes in tissue, distinguish normal tissue from tissues that are diseased (such as in cancer), differentiate viable from dead or dying tissue, show regional blood flow, and determine the distribution and fate of medications in the body (Shuster, 1998). PET scans are more accurate in detecting malignancies than CT scans (Coleman, 1999; Graeber, Gupta & Murray, 1999) and have equivalent accuracy in detecting malignant nodules when compared to invasive procedures such as thoracoscopy (Lowe, Fletcher, Gobar et al., 1998).

## ENDOSCOPIC PROCEDURES

### Bronchoscopy

**Bronchoscopy** is the direct inspection and examination of the larynx, trachea, and bronchi through either a flexible fiberoptic bronchoscope or a rigid bronchoscope. The fiberoptic scope is used more frequently in current practice.

The purposes of diagnostic bronchoscopy are: (1) to examine tissues or collect secretions, (2) to determine the location and extent of the pathologic process and to obtain a tissue sample for diagnosis (by biting or cutting forceps, curettage, or brush biopsy), (3) to determine if a tumor can be resected surgically, and (4) to diagnose bleeding sites (source of hemoptysis).

Therapeutic bronchoscopy is used to: (1) remove foreign bodies from the tracheobronchial tree, (2) remove secretions obstructing the tracheobronchial tree when the patient cannot clear them, (3) treat postoperative atelectasis, and (4) destroy and excise lesions.

The fiberoptic bronchoscope is a thin, flexible bronchoscope that can be directed into the segmental bronchi (Fig. 21-15). Because of its small size, its flexibility, and its excellent optical system, it allows increased visualization of the peripheral airways and is ideal for diagnosing pulmonary lesions. Fiberoptic bronchoscopy allows biopsy of previously inaccessible tumors and can be performed at the bedside. It also can be performed through endotracheal or tracheostomy tubes of patients on ventilators. Cytologic examinations can be performed without surgical intervention.

The rigid bronchoscope is a hollow metal tube with a light at its end. It is used mainly for removing foreign substances, investigating the source of massive hemoptysis, or performing endobronchial surgical procedures. Rigid bronchoscopy is performed in the operating room, not at the bedside.

Possible complications of bronchoscopy include a reaction to the local anesthetic, infection, aspiration, bronchospasm, **hypoxemia** (low blood oxygen level), pneumothorax, bleeding, and perforation.

### NURSING INTERVENTIONS

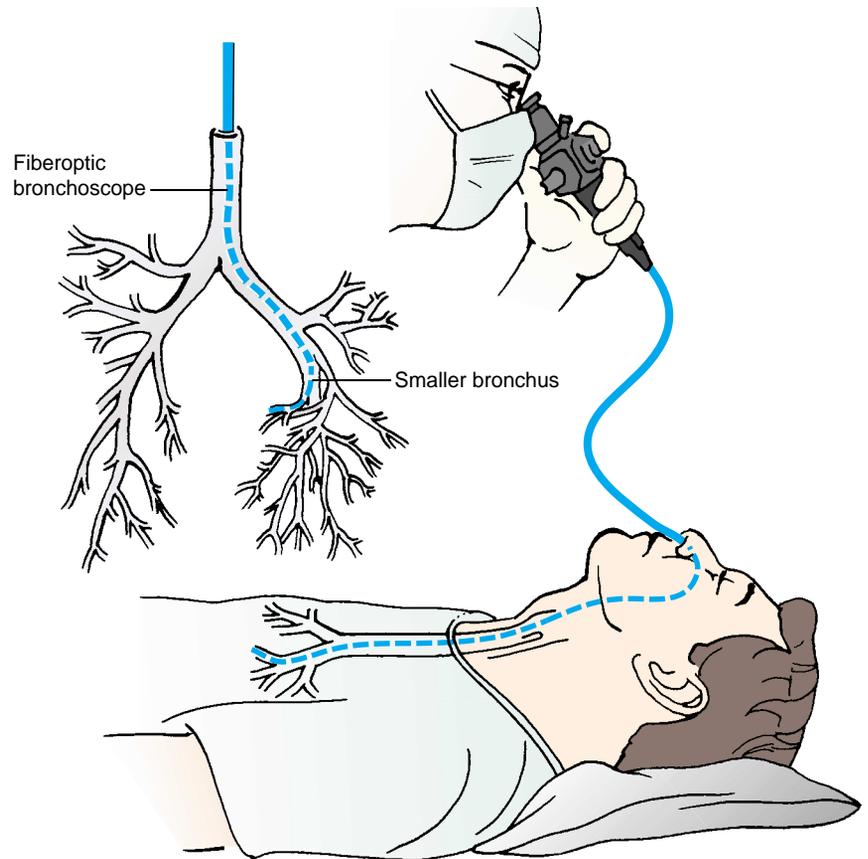

Before the procedure, a signed consent form is obtained from the patient, and food and fluids are withheld for 6 hours before the test to reduce the risk of aspiration when the cough reflex is blocked by anesthesia. The nurse explains the procedure to the patient to reduce fear and decrease anxiety and administers preoperative medications (usually atropine and a sedative or opioid) as prescribed to inhibit vagal stimulation (thereby guarding against bradycardia, dysrhythmias, and hypotension), suppress the cough reflex, sedate the patient, and relieve anxiety.

**NURSING ALERT** Sedation given to patients with respiratory insufficiency may precipitate respiratory arrest.

The patient must remove dentures and other oral prostheses. The examination is usually performed under local anesthesia, but general anesthesia may be needed for rigid bronchoscopy. A topical anesthetic such as lidocaine (Xylocaine) may be sprayed on the pharynx or dropped on the epiglottis and vocal cords and into the trachea to suppress the cough reflex and minimize discomfort. Sedatives or opioids are administered intravenously as prescribed to provide moderate sedation.

After the procedure, it is important that the patient takes nothing by mouth until the cough reflex returns, because the preoperative sedation and local anesthesia impair the protective laryngeal reflex and swallowing for several hours. Once the patient demonstrates a cough reflex, the nurse may offer ice chips and eventually fluids. The nurse assesses for confusion and lethargy in the elderly, which may be due to the large doses of lidocaine given during the procedure. The nurse also monitors the patient's res-

**FIGURE 21-15** Endoscopic bronchoscopy permits visualization of bronchial structures. The bronchoscope is advanced into bronchial structures orally. Bronchoscopy permits the clinician not only to diagnose but also to treat various lung problems.

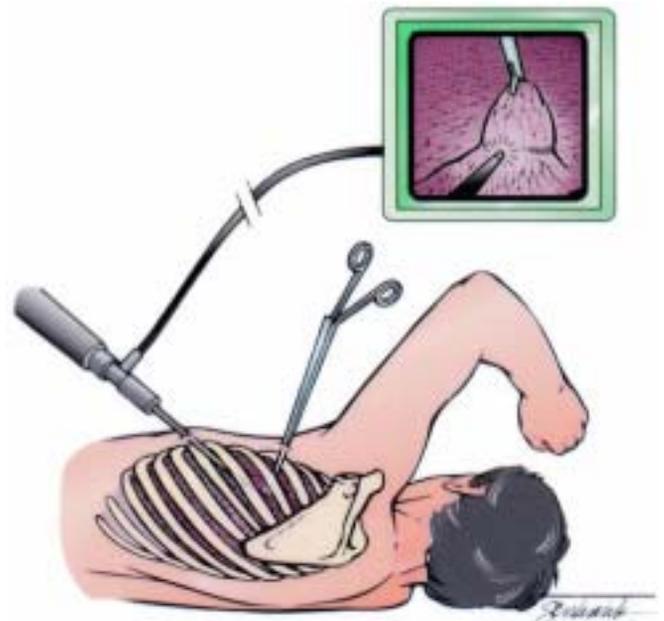

piratory status and observes for hypoxia, hypotension, tachycardia, dysrhythmias, hemoptysis, and dyspnea. Any abnormality is reported promptly. The patient is not discharged from the recovery area until adequate cough reflex and respiratory status are present. The nurse instructs the patient and family caregivers to report any shortness of breath or bleeding immediately.

## Thoracoscopy

Thoracoscopy is a diagnostic procedure in which the pleural cavity is examined with an endoscope (Fig. 21-16). Small incisions are made into the pleural cavity in an intercostal space; the location of the incision depends on the clinical and diagnostic findings. After any fluid present in the pleural cavity is aspirated, the fiberoptic mediastinoscope is inserted into the pleural cavity, and its surface is inspected through the instrument. After the procedure, a chest tube may be inserted, and the pleural cavity is drained by negative-pressure water-seal drainage.

Thoracoscopy is primarily indicated in the diagnostic evaluation of pleural effusions, pleural disease, and tumor staging. Biopsies of the lesions can be performed under visualization for diagnosis.

Thorascopic procedures have expanded with the availability of video monitoring, which permits improved visualization of the lung. Such procedures also have been used with the carbon dioxide laser in the removal of pulmonary blebs and bullae and in the treatment of spontaneous pneumothorax. Lasers have also

**FIGURE 21-16** Endoscopic thoracoscopy. Like bronchoscopy, thoracoscopy uses fiberoptic instruments and video cameras for visualizing thoracic structures. Unlike bronchoscopy, thoracoscopy usually requires the surgeon to make a small incision before inserting the endoscope. A combined diagnostic–treatment procedure, thoracoscopy includes excising tissue for biopsy.

been used in the excision of peripheral pulmonary nodules. Although the laser does not replace the need for thoracotomy in the treatment of some lung cancers, its use continues to expand because it is less invasive.

### NURSING INTERVENTIONS

Follow-up care in the health care facility and at home involves monitoring the patient for shortness of breath (which might indicate a pneumothorax), and minor activity restrictions, which vary depending on the intensity of the procedure. If a chest tube is in place, monitoring the chest drainage system and chest tube insertion site is essential (see Chap. 25).

## THORACENTESIS

A thin layer of pleural fluid normally remains in the pleural space. An accumulation of pleural fluid may occur with some disorders. A sample of this fluid can be obtained by thoracentesis (aspiration of pleural fluid for diagnostic or therapeutic purposes). It is important to position the patient as shown in Chart 21-9.

A needle biopsy of the pleura may be performed at the same time. Studies of pleural fluid include Gram's stain culture and sensitivity, acid-fast staining and culture, differential cell count, cytology, pH, specific gravity, total protein, and lactic dehydrogenase.

## BIOPSY

Biopsy, the excision of a small amount of tissue, may be performed to permit examination of cells from the pharynx, larynx, and nasal passages. Local, topical, or general anesthesia may be administered, depending on the site and the procedure (see also "Lung Biopsy Procedures" below).

### Pleural Biopsy

Pleural biopsy is accomplished by needle biopsy of the pleura or by pleuroscopy, a visual exploration through a fiberoptic bronchoscope inserted into the pleural space. Pleural biopsy is performed when there is pleural exudate of undetermined origin and when there is a need to culture or stain the tissue to identify tuberculosis or fungi.

### Lung Biopsy Procedures

When the chest x-ray findings are inconclusive or show pulmonary density (indicating an infiltrate or lesion), biopsy may be performed to obtain lung tissue for examination to identify the nature of the lesion. There are several nonsurgical lung biopsy techniques that are used because they yield accurate information with low morbidity: (1) transcatheter bronchial brushing, (2) transbronchial lung biopsy, or (3) percutaneous (through-the-skin) needle biopsy.

In transcatheter bronchial brushing, a fiberoptic bronchoscope is introduced into the bronchus under fluoroscopy. A small brush attached to the end of a flexible wire is inserted through the bronchoscope. Under direct visualization, the area under suspicion is brushed back and forth, causing cells to slough off and adhere to the brush. The catheter port of the bronchoscope may be used to irrigate the lung tissue with saline solution to secure material for additional studies. The brush is removed from the bronchoscope and a microscopic slide is made. The brush may be cut off and sent to the pathology laboratory for analysis.

This procedure is useful for cytologic evaluations of lung lesions and for the identification of pathogenic organisms (*Nocardia*, *Aspergillus*, *Pneumocystis carinii*, and other pathogens). It is especially useful in the immunologically compromised patient.

A transbronchial lung biopsy uses biting or cutting forceps introduced by a fiberoptic bronchoscope. A biopsy is indicated when a lung lesion is suspected and the results of routine sputum samples and bronchoscopic washings are negative.

Another method of bronchial brushing involves the introduction of the catheter through the transcrithyroid membrane by needle puncture. After this procedure, the patient is instructed to hold a finger or thumb over the puncture site while coughing to prevent air from leaking into the surrounding tissues.

Percutaneous needle biopsy may be accomplished with a cutting needle or by aspiration with a spinal-type needle that provides a tissue specimen for histologic study. Analgesia may be administered before the procedure. The skin over the biopsy site is cleansed and anesthetized and a small incision is made. The biopsy needle is inserted through the incision into the pleura with the patient holding the breath in mid-expiration. Using fluoroscopic monitoring, the surgeon guides the needle into the periphery of the lesion and obtains a tissue sample from the mass. Possible complications include pneumothorax, pulmonary hemorrhage, and empyema.

### NURSING INTERVENTIONS

After the procedure, recovery and home care are similar to those for bronchoscopy and thoracoscopy. Nursing care involves monitoring the patient for shortness of breath, bleeding, and infection. In preparation for discharge, the patient and/or family is instructed to report pain, shortness of breath, visible bleeding, or redness of the biopsy site or pus to the health care provider immediately. Patients who have undergone biopsy are often anxious because of the need for the biopsy and the potential findings; the nurse must consider this in providing postbiopsy care and teaching.

### Lymph Node Biopsy

The scalene lymph nodes are enmeshed in the deep cervical pad of fat overlying the scalenus anterior muscle. They drain the lungs and mediastinum and may show histologic changes from intrathoracic disease. When these nodes are palpable on physical examination, a scalene node biopsy may be performed. A biopsy of these nodes may be performed to detect lymph node spread of pulmonary disease and to establish a diagnosis or prognosis in such diseases as Hodgkin's disease, sarcoidosis, fungal disease, tuberculosis, and carcinoma.

Mediastinoscopy is the endoscopic examination of the mediastinum for exploration and biopsy of mediastinal lymph nodes that drain the lungs; this examination does not require a thoracotomy. Biopsy is usually performed through a suprasternal incision. Mediastinoscopy is carried out to detect mediastinal involvement of pulmonary malignancy and to obtain tissue for diagnostic studies of other conditions (eg, sarcoidosis).

An anterior mediastinotomy is thought to provide better exposure and diagnostic possibilities than a mediastinoscopy. An incision is made in the area of the second or third costal cartilage. The mediastinum is explored and biopsies are performed on any lymph nodes found. Chest tube drainage is required after the procedure. Mediastinotomy is particularly valuable to determine whether a pulmonary lesion is resectable.

Chart 21-9

## GUIDELINES FOR Assisting the Patient Undergoing Thoracentesis

A thoracentesis (aspiration of fluid or air from the pleural space) is performed on patients with various clinical problems. A diagnostic or therapeutic procedure, thoracentesis may be used for:

- Removal of fluid and air from the pleural cavity
- Aspiration of pleural fluid for analysis
- Pleural biopsy
- Instillation of medication into the pleural space

The responsibilities of the nurse and rationale for the nursing actions are summarized below.

### NURSING ACTIVITIES

1. Ascertain in advance that a chest x-ray has been ordered and completed and the consent form has been signed.
2. Assess the patient for allergy to the local anesthetic to be used. Administer sedation if prescribed.
3. Inform the patient about the nature of the procedure and:
  - a. The importance of remaining immobile
  - b. Pressure sensations to be experienced
  - c. That minimal discomfort is anticipated after the procedure
4. Position the patient comfortably with adequate supports. If possible, place the patient upright or in one of the following positions:
  - a. Sitting on the edge of the bed with the feet supported and arms and head on a padded over-the-bed table

Patient positioned for thoracentesis.

### RATIONALE

1. Posteroanterior and lateral chest x-ray films are used to localize fluid and air in the pleural cavity and to aid in determining the puncture site. When fluid is loculated (isolated in a pocket of pleural fluid), ultrasound scans are performed to help select the best site for needle aspiration.
  2. If the patient is allergic to the initially prescribed anesthetic, assessment findings provide an opportunity to use a safer anesthetic.
  3. An explanation helps to orient the patient to the procedure, assists the patient to mobilize resources, and provides an opportunity to ask questions and verbalize anxiety.
  4. The upright position facilitates the removal of fluid that usually localizes at the base of the chest. A position of comfort helps the patient to relax.
- b. Straddling a chair with arms and head resting on the back of the chair
  - c. Lying on the unaffected side with the bed elevated 30 degrees to 45 degrees if unable to assume a sitting position
5. Sudden and unexpected movement, such as coughing, by the patient can traumatize the visceral pleura and lung.
    - a. Prepare the patient for the cold sensation of skin germicide solution and for a pressure sensation from infiltration of local anesthetic agent.
    - b. Encourage the patient to refrain from coughing.

(continued)

Chart 21-9

## GUIDELINES FOR Assisting the Patient Undergoing Thoracentesis (Continued)

### NURSING ACTIVITIES

6. Expose the entire chest. The site for aspiration is visualized by chest x-ray film and percussion. If fluid is in the pleural cavity, the thoracentesis site is determined by the chest x-ray, ultrasound scanning, and physical findings, with attention to the site of maximal dullness on percussion.
7. The procedure is performed under aseptic conditions. After the skin is cleansed, the physician uses a small-caliber needle to inject a local anesthetic slowly into the intercostal space.
8. The physician advances the thoracentesis needle with the syringe attached. When the pleural space is reached, suction may be applied with the syringe.
  - a. A 20-mL syringe with a three-way stopcock is attached to the needle (one end of the adapter is attached to the needle and the other to the tubing leading to a receptacle that receives the fluid being aspirated).
  - b. If a considerable quantity of fluid is removed, the needle is held in place on the chest wall with a small hemostat.
9. After the needle is withdrawn, pressure is applied over the puncture site and a small, sterile dressing is fixed in place.
10. Advise the patient that he or she will be on bed rest and a chest x-ray will be obtained after thoracentesis.
11. Record the total amount of fluid withdrawn from the procedure and document the nature of the fluid, its color, and its viscosity. If indicated, prepare samples of fluid for laboratory evaluation. A specimen container with formalin may be needed for a pleural biopsy.
12. Monitor the patient at intervals for increasing respiratory rate; asymmetry in respiratory movement; faintness; vertigo; tightness in chest; uncontrollable cough; blood-tinged, frothy mucus; a rapid pulse; and signs of hypoxemia.

### RATIONALE

6. If air is in the pleural cavity, the thoracentesis site is usually in the second or third intercostal space in the midclavicular line because air rises in the thorax.
7. An intradermal wheal is raised slowly; rapid injection causes pain. The parietal pleura is very sensitive and should be well infiltrated with anesthetic before the physician passes the thoracentesis needle through it.
  - a. When a large quantity of fluid is withdrawn, a three-way stopcock serves to keep air from entering the pleural cavity.
  - b. The hemostat steadies the needle on the chest wall. Sudden pleuritic chest pain or shoulder pain may indicate that the needle point is irritating the visceral or the diaphragmatic pleura.
9. Pressure helps to stop bleeding and the dressing protects the site.
10. A chest x-ray verifies that there is no pneumothorax.
11. The fluid may be clear, serous, bloody, purulent, etc.
12. Pneumothorax, tension pneumothorax, subcutaneous emphysema, or pyrogenic infection are complications of a thoracentesis. Pulmonary edema or cardiac distress can occur after a sudden shift in mediastinal contents when large amounts of fluid are aspirated.

### NURSING INTERVENTIONS

Postprocedure care focuses on providing adequate oxygenation, monitoring for bleeding, and providing pain relief. The patient may be discharged a few hours after the chest drainage system is removed. The nurse should instruct the patient and family about monitoring for changes in respiratory status, taking into consideration the impact of anxiety about the potential findings of the biopsy on their ability to remember those instructions.

### Critical Thinking Exercises

1. After a transbronchial lung biopsy, your patient reports shortness of breath and appears anxious. He is coughing up blood-tinged sputum. Based on your knowledge of the risks associated with lung biopsy, how would you focus your assessment? What physical and psychological nursing interventions would be appropriate for the patient at this time?
2. Your patient is scheduled for a video-assisted thoracoscopy. Describe the postprocedure nursing care and teaching for a patient undergoing this procedure. Identify the specific assessment parameters that are indicated.

3. Your patient has had a thoracentesis to remove pleural fluid for laboratory analysis and to relieve shortness of breath. What assessment should be carried out following the procedure? What teaching is warranted for the patient and family if she is to be discharged an hour after the procedure? How would you modify your instructions to the patient if she lives alone?

4. Your frail, elderly patient has a diagnosis of long-standing cardiac disease and is scheduled for PFTs prior to surgery to repair her cardiac valves. What specific explanations about the tests would you provide to the patient? What problems would you monitor for following the PFT?

# ● Management of Patients With Upper Respiratory Tract Disorders

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Describe nursing management of patients with upper airway disorders.
2. Compare and contrast the upper respiratory tract infections with regard to cause, incidence, clinical manifestations, management, and the significance of preventive health care.
3. Use the nursing process as a framework for care of patients with upper airway infection.
4. Describe nursing management of the patient with epistaxis.
5. Use the nursing process as a framework for care of patients undergoing laryngectomy.

Many upper airway disorders are relatively minor, and their effects are limited to mild and temporary discomfort and inconvenience for the patient. However, other upper airway disorders are acute, severe, and life-threatening and may require permanent alterations in breathing and speaking. Thus, the nurse must have good assessment skills, an understanding of the wide variety of disorders that may affect the upper airway, and an awareness of the impact of these alterations on patients.

Because many of the disorders are treated outside the hospital or at home by patients themselves, patient teaching is an important aspect of nursing care. When caring for patients with acute, life-threatening disorders, the nurse needs highly developed assessment and clinical management skills, along with a focus on rehabilitation needs.

## Upper Airway Infections

Upper airway infections are common conditions that affect most people on occasion. Some infections are acute, with symptoms that last several days; others are chronic, with symptoms that last a long time or recur. Patients with these conditions seldom require hospitalization. However, nurses working in community settings or long-term care facilities may encounter patients who have these infections. Thus, it is important for the nurse to recognize the signs and symptoms and to provide appropriate care.

### RHINITIS

**Rhinitis** is a group of disorders characterized by inflammation and irritation of the mucous membranes of the nose. It may be classified as nonallergic or allergic. It is estimated that 10% to 15% of the population of the United States has allergic rhinitis (Middleton et al., 1998). Rhinitis may be an acute or chronic condition.

### Pathophysiology

Nonallergic rhinitis may be caused by a variety of factors, including environmental factors such as changes in temperature or humidity, odors, or foods; infection; age; systemic disease; drugs (cocaine) or prescribed medications; or the presence of a foreign body. Drug-induced rhinitis is associated with use of antihypertensive agents and oral contraceptives and chronic use of nasal decongestants. Rhinitis also may be a manifestation of an allergy (see Chap. 53), in which case it is referred to as allergic rhinitis. Figure 22-1 shows the pathological processes involved in rhinitis and sinusitis.

### Clinical Manifestations

The signs and symptoms of rhinitis include **rhinorrhea** (excessive nasal drainage, runny nose), nasal congestion, nasal discharge (purulent with bacterial rhinitis), nasal itchiness, and sneezing. Headache may occur, particularly if sinusitis is also present.

### Medical Management

The management of rhinitis depends on the cause, which may be identified in the history and physical examination. The examiner asks the patient about recent symptoms as well as possible exposure to allergens in the home, environment, or workplace. If viral rhinitis is the cause, medications are given to relieve the symptoms. In allergic rhinitis, tests may be performed to identify possible allergens. Depending on the severity of the allergy, desensitizing immunizations and corticosteroids may be required (see Chap. 53 for more details). If symptoms suggest a bacterial infection, an antimicrobial agent will be used (see “Medical Management of Sinusitis”).

### PHARMACOLOGIC THERAPY

Medication therapy for allergic and nonallergic rhinitis focuses on symptom relief. Antihistamines are administered for sneezing, itching, and rhinorrhea. Oral decongestant agents are used for nasal obstruction. In addition, intranasal corticosteroids may be used for severe congestion, and ophthalmic agents are used to relieve irritation, itching, and redness of the eyes.

### Nursing Management

#### TEACHING PATIENTS SELF-CARE

The nurse instructs the patient with allergic rhinitis to avoid or reduce exposure to allergens and irritants, such as dusts, molds, animals, fumes, odors, powders, sprays, and tobacco smoke. The patient is instructed about the importance of controlling the environment at home and work. Saline nasal or aerosol sprays may be helpful in soothing mucous membranes, softening crusted secretions, and removing irritants. The nurse instructs the patient in the proper use of and technique for administering nasal medications. To achieve maximal relief, the patient is instructed to blow the nose before applying any medication into the nasal cavity. In the case of infectious rhinitis, the nurse reviews with the patient hand hygiene technique as a measure to prevent transmission of organisms. The nurse teaches methods to treat symptoms of the viral rhinitis. In the elderly and other high-risk populations, the nurse reviews the value of receiving a vaccination

## Glossary

**alaryngeal communication:** alternative modes of speaking that do not involve the normal larynx; used by patients whose larynx has been surgically removed  
**aphonia:** impaired ability to use one's voice due to disease or injury to the larynx  
**apnea:** cessation of breathing  
**dysphagia:** difficulties in swallowing  
**epistaxis:** hemorrhage from the nose due to rupture of tiny, distended vessels in the mucous membrane of any area of the nose  
**herpes simplex:** cold sore (cutaneous viral infection with painful vesicles and

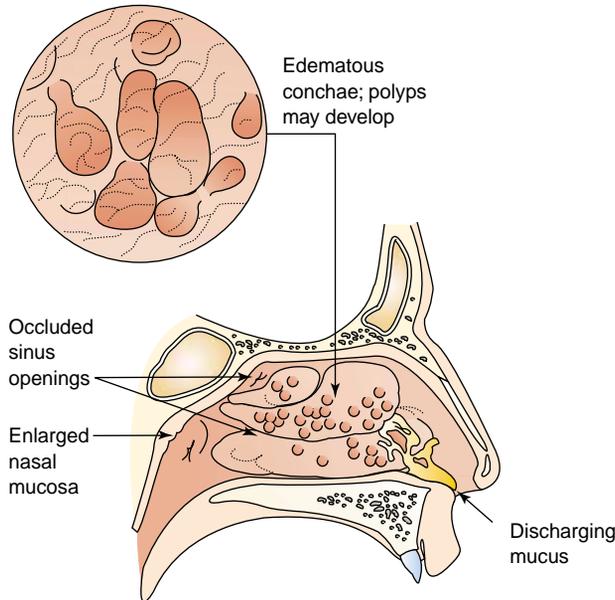

erosions on the tongue, palate, gingival, buccal membranes, or lips)  
**laryngitis:** inflammation of the larynx; may be due to voice abuse, exposure to irritants, or infectious organisms  
**laryngectomy:** removal of all or part of the larynx and surrounding structures  
**pharyngitis:** inflammation of the throat; usually viral or bacterial in origin  
**rhinitis:** inflammation of the mucous membranes of the nose; may be infectious, allergic, or inflammatory in origin

**rhinorrhea:** drainage of a large amount of fluid from the nose  
**sinusitis:** inflammation of the sinuses; may be acute or chronic; may be viral, bacterial, or fungal in origin  
**submucosal resection:** surgical procedure to correct nasal obstruction due to deviated septum; also called septoplasty  
**tonsillitis:** inflammation of the tonsils, usually due to an acute infection  
**xerostomia:** dryness of the mouth from a variety of causes

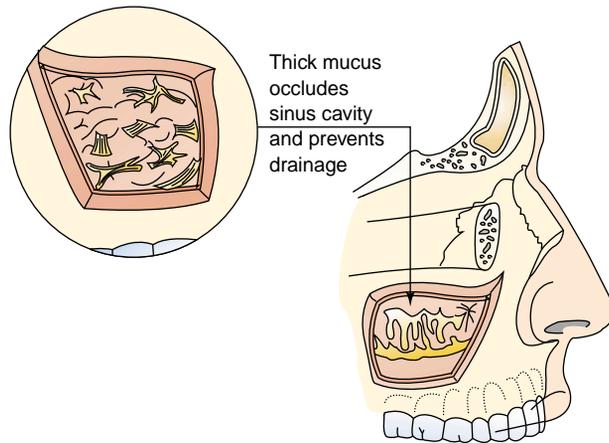

## Physiology/Pathophysiology

### A. Rhinitis

### B. Sinusitis

**FIGURE 22-1** Pathophysiologic processes in rhinitis and sinusitis. Although pathophysiologic processes are similar in rhinitis and sinusitis, they affect different structures. In rhinitis (A), the mucous membranes lining the nasal passages become inflamed, congested, and edematous. The swollen nasal conchae block the sinus openings, and mucus is discharged from the nostrils. Sinusitis (B) is also marked by inflammation and congestion, with thickened mucous secretions filling the sinus cavities and occluding the openings.

of the mucous membranes of the nasal cavity. More broadly, the term refers to an acute upper respiratory tract infection, whereas terms such as “rhinitis,” “pharyngitis,” and “laryngitis” distinguish the sites of the symptoms. It can also be used when the causative virus is influenza (“the flu”). Colds are highly contagious because virus is shed for about 2 days before the symptoms appear and during the first part of the symptomatic phase. It is estimated that adults in the United States average two to four colds each year. The common cold is the most common cause of absenteeism from work and school (Mandell, Bennett, & Dolin, 2000).

The six viruses known to produce the signs and symptoms of the viral rhinitis are rhinovirus, parainfluenza virus, coronavirus, respiratory syncytial virus (RSV), influenza virus, and adenovirus. Each virus may have multiple strains. For example, there are over 100 strains of rhinovirus, which accounts for 50% of all colds. The incidence of viral rhinitis follows a specific pattern during the year, depending on the causative agent (Fig. 22-2). Even though viral rhinitis can occur at any time of the year, three waves account for the epidemics in the United States:

- In September, just after the opening of school
- In late January
- Toward the end of April

Immunity after recovery is variable and depends on many factors, including a person’s natural host resistance and the specific virus that caused the cold.

## Clinical Manifestations

Signs and symptoms of viral rhinitis are nasal congestion, runny nose, sneezing, nasal discharge, nasal itchiness, tearing watery eyes, “scratchy” or sore throat, general malaise, low-grade fever, chills,

in the fall in order to achieve immunity prior to the beginning of the “flu season.”

## VIRAL RHINITIS (COMMON COLD)

The term “common cold” often is used when referring to an upper respiratory tract infection that is self-limited and caused by a virus (viral rhinitis). Nasal congestion, rhinorrhea, sneezing, sore throat, and general malaise characterize it. Specifically, the term “cold” refers to an afebrile, infectious, acute inflammation

**FIGURE 22-2** Schematic diagram incidence of viral rhinitis (common cold) in the United States and the frequency of the causative agents. Redrawn from Goldman, L. & Bennett, J. C. (eds.) (2000) *Cecil textbook of medicine* (21st ed., Vol. 2). Philadelphia: W. B. Saunders, p. 1791.

and often headache and muscle aches. As the illness progresses, cough usually appears. In some people, viral rhinitis exacerbates the **herpes simplex**, commonly called a cold sore (Chart 22-1).

The symptoms last from 1 to 2 weeks. If there is significant fever or more severe systemic respiratory symptoms, it is no longer viral rhinitis but one of the other acute upper respiratory tract infections. Allergic conditions can also affect the nose, mimicking the symptoms of a cold.

## Medical Management

There is no specific treatment for the common cold or influenza. Management consists of symptomatic therapy. Some measures include providing adequate fluid intake, encouraging rest, preventing chilling, increasing intake of vitamin C, and using expectorants as needed. Warm salt-water gargles soothe the sore throat and nonsteroidal anti-inflammatory agents (NSAIDs) such as aspirin or ibuprofen relieve the aches, pains, and fever in adults. Antihistamines are used to relieve sneezing, rhinorrhea, and nasal congestion. Topical (nasal) decongestant agents may re-

lieve nasal congestion; however, if they are overused they may create a rebound congestion that may be worse than the original symptoms. Some research suggests that zinc lozenges may reduce the duration of cold symptoms if taken within the first 24 hours of onset (Prasad, Fitzgerald, & Bao, 2000). Amantadine (Symmetrel) or rimantadine (Flumadine) may be prescribed prophylactically to decrease the signs and symptoms as well. Antimicrobial agents (antibiotics) should not be used because they do not affect the virus or reduce the incidence of bacterial complications.

## Nursing Management

### TEACHING PATIENTS SELF-CARE

Most viruses can be transmitted in several ways: direct contact with infected secretions; inhalation of large particles that land on a mucosal surface from coughing or sneezing; or inhalation of small particles (aerosol) that may be suspended in the air for up to an hour. It is important to teach the patient how to break the chain of infection. Hand washing remains the most effective measure to prevent transmission of organisms. The nurse teaches methods to treat symptoms of the common cold and preventive measures (Chart 22-2).

Chart  
22-1

### Colds and Cold Sores (Herpes Simplex Virus)

The herpes simplex virus (HSV-1) produces the familiar *herpes labialis*, commonly called a cold sore or fever blister. In the past, this painful blisterlike lip sore was thought to be caused by a cold or a fever. Even now that scientists recognize the origin of herpes labialis, the condition is still referred to as a cold sore. The herpes virus infection remains latent in cells of the lips or nose and is activated by stress, sunlight, and febrile illnesses from the common cold to streptococcal pneumonia, meningococcal meningitis, and even malaria.

The incubation period is 2 to 12 days. The virus is transmitted primarily by direct contact with infected secretions. The virus may also be transmitted from an asymptomatic person. Small vesicles, single or clustered, may erupt on the lips, inside the mouth, including the tongue, soft and hard palate, gums, buccal mucosa, and the pharynx. These soon rupture, forming sore shallow ulcers that increase in number. The gums may bleed and feel painful.

The herpes virus may subside spontaneously in 10 to 14 days. If it does not, acyclovir, an antiviral agent, may be administered orally or topically to minimize the symptoms and the duration or length of the flare-up. Analgesics, such as acetaminophen (Tylenol) with codeine or aspirin with codeine, are helpful in relieving pain and discomfort. Topical anesthetics, such as lidocaine (Xylocaine) or dyclonine (Dyclone), and over-the-counter preparations, such as Herpecin-L, may relieve oral pain. Applications of drying lotions or liquids may help to dry the lesions.

## ACUTE SINUSITIS

The sinuses, mucus-lined cavities filled with air that drain normally into the nose, are involved in a high proportion of upper respiratory tract infections. If their openings into the nasal passages are clear, the infections resolve promptly. However, if their drainage is obstructed by a deviated septum or by hypertrophied turbinates, spurs, or nasal polyps or tumors, sinus infection may persist as a smoldering secondary infection or progress to an acute suppurative process (causing purulent discharge). **Sinusitis** affects over 14% of the population and accounts for billions of dollars in direct health care costs (Tierney, McPhee, & Papadakis, 2001). Some individuals are more prone to sinusitis because of their occupations. For example, continuous exposure to environmental hazards such as paint, sawdust, and chemicals may result in chronic inflammation of the nasal passages.

## Pathophysiology

Acute sinusitis is an infection of the paranasal sinuses. It frequently develops as a result of an upper respiratory infection, such as an unresolved viral or bacterial infection, or an exacerbation of allergic rhinitis. Nasal congestion, caused by inflammation, edema, and transudation of fluid, leads to obstruction of the sinus cavities (see Fig. 22-1). This provides an excellent medium for bacterial growth. Bacterial organisms account for more than 60% of the cases of acute sinusitis, namely *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis* (Murray & Nadel, 2001). Dental infections also have been associated with acute sinusitis.

## Clinical Manifestations

Symptoms of acute sinusitis may include facial pain or pressure over the affected sinus area, nasal obstruction, fatigue, purulent nasal discharge, fever, headache, ear pain and fullness, dental pain, cough, a decreased sense of smell, sore throat, eyelid edema, or facial congestion or fullness. Acute sinusitis can be difficult to differentiate from an upper respiratory infection or allergic rhinitis.

Chart 22-2

### Home Care Checklist • Preventing and Managing Upper Respiratory Infections

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
<b>Prevention</b>		
• Identify strategies to prevent infection and, if infected, to prevent spread of infection to others	✓	✓
Perform hand hygiene often		
Use disposable tissues		
Avoid crowds during the flu season		
Avoid individuals with colds or respiratory infections		
Obtain influenza vaccination, if recommended (especially if elderly or diagnosed with a chronic illness)		
• Practice good health habits	✓	✓
Eat a nutritious diet		
Get plenty of rest and sleep		
Avoid or reduce stress when possible		
Exercise appropriately		
Avoid smoking or second-hand smoke and excessive intake of alcohol		
Increase humidity in house, especially during winter		
Practice adequate oral hygiene		
• Avoid allergens, if allergies are associated with upper respiratory infections	✓	
<b>Prevention and Management</b>		
• Identify strategies to control the environment	✓	✓
Adequately humidify (avoid overhumidifying) living quarters		
Place a dehumidifier in the basement, if appropriate		
Provide central ventilation fans, air conditioning with microstatic air filters		
Reduce irritants (dust, chemical, tobacco smoke) when possible		
Limit exposure to animals and house pets, particularly in the bedroom		
<b>Management</b>		
• Describe strategies to relieve symptoms of upper respiratory infection	✓	✓
Gargle with salt water		
Increase fluid intake, particularly of hot liquids		
Provide warm, moist air by shower or humidifier to relieve swollen mucous membranes		
Avoid irritants (dust, chemicals, tobacco smoke) when possible		
• Recognize signs and symptoms of infection and state when to contact a health care provider	✓	✓
Upper respiratory infection symptoms persisting longer than 7 to 10 days		
Extreme red throat or white patches on the back of the throat		
Discolored drainage or foul-smelling nasal discharge		
Prolonged fever of 100.5°F (38°C) >2 days		
Shortness of breath, wheezing		
Swollen lymph nodes		
Severe pain or tenderness around the eyes or persistent pain in sinus areas		
Severe headache		

## Assessment and Diagnostic Findings

A careful history and physical examination are performed. The head and neck, particularly the nose, ears, teeth, sinuses, pharynx, and chest, are examined. There may be tenderness to palpation over the infected sinus area. The sinuses are percussed using the index finger, tapping lightly to determine if the patient experiences pain. The affected area is also transilluminated; with sinusitis, there is a decrease in the transmission of light (see Chap. 21, Fig. 21-8). Sinus x-rays may be performed to detect sinus opacity, mucosal thickening, bone destruction, and air–fluid levels. Computed tomography scanning of the sinuses is the most effective diagnostic tool. It is also used to rule out other local or systemic disorders, such as tumor, fistula, and allergy.

## Complications

Acute sinusitis, if left untreated, may lead to severe and occasionally life-threatening complications such as meningitis, brain abscess, ischemic infarction, and osteomyelitis. Other complica-

tions of sinusitis, although uncommon, include severe orbital cellulitis, subperiosteal abscess, and cavernous sinus thrombosis.

## Medical Management

The goals of treatment of acute sinusitis are to treat the infection, shrink the nasal mucosa, and relieve pain. There is a growing concern over the inappropriate use of antibiotics for viral upper respiratory infections; such overuse has resulted in antibiotics being less effective (more resistant) in treating bacterial infections such as sinusitis. As a result, careful consideration is given to the potential pathogen before antimicrobial agents are prescribed.

The antimicrobial agents of choice for a bacterial infection vary in clinical practice. First-line antibiotics include amoxicillin (Amoxil), trimethoprim/sulfamethoxazole (Bactrim, Septra), and erythromycin. Second-line antibiotics include cephalosporins such as cefuroxime axetil (Ceftin), cefpodoxime (Vantin), and cefprozil (Cefzil) and amoxicillin clavulanate (Augmentin). Newer and more expensive antibiotics with a broader spectrum include

macrolides, azithromycin (Zithromax), and clarithromycin (Biaxin). Quinolones such as ciprofloxacin (Cipro), levofloxacin (Levaquin) (used with severe penicillin allergy), and sparfloxacin (Zagam) have also been used. The course of treatment is usually 10 to 14 days. A recent report found little difference in clinical outcomes between first-line and second-line antibiotics; however, costs were greater when newer second-line antibiotics were used (Piccirillo, Mager, Frisse et al., 2001).

Use of oral and topical decongestant agents may decrease mucosal swelling of nasal polyps, thereby improving drainage of the sinuses. Heated mist and saline irrigation also may be effective for opening blocked passages. Decongestant agents such as pseudoephedrine (Sudafed, Dimetapp) have proven effective because of their vasoconstrictive properties. Topical decongestant agents such as oxymetazoline (Afrin) may be used for up to 72 hours. It is important to administer them with the patient's head tilted back to promote maximal dispersion of the medication. Guaifenesin (Robitussin, Anti-Tuss), a mucolytic agent, may also be effective in reducing nasal congestion.

In 2000, the U.S. Food and Drug Administration issued a public health advisory concerning phenylpropanolamine, which previously had been commonly used in oral decongestants and diet pills. The voluntary recall of products containing this ingredient was based on a study linking its use with hemorrhagic stroke in women. Men may also be at risk (Kernan et al., 2000).

Antihistamines such as diphenhydramine (Benadryl), cetirizine (Zyrtec), and fexofenadine (Allegra) may be used if an allergic component is suspected. If the patient continues to have symptoms after 7 to 10 days, the sinuses may need to be irrigated and hospitalization may be required.

## Nursing Management

### TEACHING PATIENTS SELF-CARE

Patient teaching is an important aspect of nursing care for the patient with acute sinusitis. The nurse instructs the patient about methods to promote drainage such as inhaling steam (steam bath, hot shower, and facial sauna), increasing fluid intake, and applying local heat (hot wet packs). The nurse also informs the patient about the side effects of nasal sprays and about rebound congestion. In the case of rebound congestion, the body's receptors, which have become dependent on the decongestant sprays to keep the nasal passages open, close and congestion results after the spray is discontinued.

The nurse stresses the importance of following the recommended antibiotic regimen, because a consistent blood level of the medication is critical to treat the infection. The nurse teaches the patient the early signs of a sinus infection and recommends preventive measures such as following healthy practices and avoiding contact with people who have upper respiratory infections (see Chart 22-2).

The nurse should explain to the patient that fever, severe headache, and nuchal rigidity are signs of potential complications. If fever persists despite antibiotic therapy, the patient should seek additional care.

## CHRONIC SINUSITIS

Chronic sinusitis is an inflammation of the sinuses that persists for more than 3 weeks in an adult and 2 weeks in a child. It is estimated that 32 million people a year develop chronic sinusitis.

## Pathophysiology

A narrowing or obstruction in the ostia of the frontal, maxillary, and anterior ethmoid sinuses usually causes chronic sinusitis, preventing adequate drainage to the nasal passages. This combined area is known as the osteomeatal complex. Blockage that persists for greater than 3 weeks in an adult may occur because of infection, allergy, or structural abnormalities. This results in stagnant secretions, an ideal medium for infection. The organisms that cause chronic sinusitis are the same as those implicated in acute sinusitis. Immunocompromised patients, however, are at increased risk for developing fungal sinusitis. *Aspergillus fumigatus* is the most common organism associated with fungal sinusitis.

## Clinical Manifestations

Clinical manifestations of chronic sinusitis include impaired mucociliary clearance and ventilation, cough (because the thick discharge constantly drips backward into the nasopharynx), chronic hoarseness, chronic headaches in the periorbital area, and facial pain. These symptoms are generally most pronounced on awakening in the morning. Fatigue and nasal stuffiness are also common. In addition, some patients experience a decrease in smell and taste and a fullness in the ears.

## Assessment and Diagnostic Findings

A careful history and diagnostic assessment, including a computed tomography scan of the sinuses or magnetic resonance imaging (if fungal sinusitis is suspected), are performed to rule out other local or systemic disorders, such as tumor, fistula, and allergy. Nasal endoscopy may be indicated to rule out underlying diseases such as tumors and sinus mycetomas (fungus balls). The fungus ball is usually a brown or greenish-black material with the consistency of peanut butter or cottage cheese.

## Complications

Complications of chronic sinusitis, although uncommon, include severe orbital cellulitis, subperiosteal abscess, cavernous sinus thrombosis, meningitis, encephalitis, and ischemic infarction.

## Medical Management

Medical management of chronic sinusitis is almost the same as for acute sinusitis. The antimicrobial agents of choice include amoxicillin clavulanate (Augmentin) or ampicillin (Ampicin). Clarithromycin (Biaxin) and third-generation cephalosporins such as cefuroxime axetil (Ceftin), cefpodoxime (Vantin), and cefprozil (Cefzil) have also been effective. Levofloxacin (Levaquin), a quinolone, may also be used. The course of treatment may be 3 to 4 weeks. Decongestant agents, antihistamines, saline sprays, and heated mist may also provide some symptom relief.

## SURGICAL MANAGEMENT

When standard medical therapy fails, surgery, usually endoscopic, may be indicated to correct structural deformities that obstruct the ostia (openings) of the sinus. Excising and cauterizing nasal polyps, correcting a deviated septum, incising and draining the sinuses, aerating the sinuses, and removing tumors are some of the specific procedures performed. When sinusitis is caused by a fungal infection, surgery is required to excise the fungus ball and necrotic tissue and drain the sinuses. Oral and topical cortico-

steroids are usually prescribed. Antimicrobial agents are administered before and after surgery. Some patients with severe chronic sinusitis obtain relief only by moving to a dry climate.

## Nursing Management

Because the patient usually performs care measures for sinusitis at home, nursing management consists mainly of patient teaching.

### TEACHING PATIENTS SELF-CARE

The nurse teaches the patient how to promote sinus drainage by increasing the environmental humidity (steam bath, hot shower, and facial sauna), increasing fluid intake, and applying local heat (hot wet packs). The nurse also instructs the patient about the importance of following the medication regimen. Instructions on the early signs of a sinus infection are provided and preventive measures are reviewed.

## ACUTE PHARYNGITIS

Acute **pharyngitis** is an inflammation or infection in the throat, usually causing symptoms of a sore throat.

### Pathophysiology

Most cases of acute pharyngitis are caused by viral infection. When group A beta-hemolytic streptococcus, the most common bacterial organism, causes acute pharyngitis, the condition is known as strep throat (Bisno, 2001). The body responds by triggering an inflammatory response in the pharynx. This results in pain, fever, vasodilation, edema, and tissue damage, manifested by redness and swelling in the tonsillar pillars, uvula, and soft palate. A creamy exudate may be present in the tonsillar pillars (Fig. 22-3).

Uncomplicated viral infections usually subside promptly, within 3 to 10 days after the onset. However, pharyngitis caused by more virulent bacteria such as group A beta-hemolytic streptococci is a more severe illness. If left untreated, the complications can be severe and life-threatening. Complications include sinusitis, otitis media, peritonsillar abscess, mastoiditis, and cervical adenitis. In rare cases the infection may lead to bacteremia, pneumonia, meningitis, rheumatic fever, or nephritis.

### Clinical Manifestations

The signs and symptoms of acute pharyngitis include a fiery-red pharyngeal membrane and tonsils, lymphoid follicles that are swollen and flecked with white-purple exudate, and enlarged and tender cervical lymph nodes and no cough. Fever, malaise, and sore throat also may be present.

## Assessment and Diagnostic Findings

Rapid screening tests for streptococcal antigens such as the latex agglutination (LA) antigen test and solid-phase enzyme immunoassays (ELISA), optical immunoassay (OIA), streptolysin titers, and throat cultures are used to determine the causative organism, after which appropriate therapy is prescribed. Nasal swabs and blood cultures may also be necessary to identify the organism (Corneli, 2001).

### Medical Management

Viral pharyngitis is treated with supportive measures since antibiotics will have no effect on the organism. Bacterial pharyngitis is treated with a variety of antimicrobial agents.

### PHARMACOLOGIC THERAPY

If a bacterial cause is suggested or demonstrated, penicillin is usually the treatment of choice. For patients who are allergic to penicillin or have organisms that are resistant to erythromycin (one fifth of group A beta-hemolytic streptococci and most *S. aureus* organisms are resistant to penicillin and erythromycin), cephalosporins and macrolides (clarithromycin and azithromycin) may be used. Antibiotics are administered for at least 10 days to eradicate the infection from the oropharynx.

Severe sore throats can also be relieved by analgesic medications, as prescribed. For example, aspirin or acetaminophen (Tylenol) can be taken at 3- to 6-hour intervals; if required, acetaminophen with codeine can be taken three or four times daily. Antitussive medication, in the form of codeine, dextromethorphan (Robitussin DM), or hydrocodone bitartrate (Hycodan), may be required to control the persistent and painful cough that often accompanies acute pharyngitis.

### NUTRITIONAL THERAPY

A liquid or soft diet is provided during the acute stage of the disease, depending on the patient's appetite and the degree of discomfort that occurs with swallowing. Occasionally, the throat is so sore that liquids cannot be taken in adequate amounts by mouth. In severe situations, fluids are administered intravenously. Otherwise, the patient is encouraged to drink as much fluid as possible (at least 2 to 3 L per day).

### Nursing Management

The nurse instructs the patient to stay in bed during the febrile stage of illness and to rest frequently once up and about. Used tissues should be disposed of properly to prevent the spread of infection. It is important to examine the skin once or twice daily for

**FIGURE 22-3** Pharyngitis—inflammation without exudate. (A) Redness and vascularity of the pillars and uvula are mild to moderate. (B) Redness is diffuse and intense. Each patient would probably complain of a sore throat. From Bickley, L. S. (2003). *Bates' guide to physical examination and history taking* (8th ed.). Philadelphia: Lippincott Williams & Wilkins.

possible rash, because acute pharyngitis may precede some other communicable diseases (ie, rubella).

Warm saline gargles or irrigations are used depending on the severity of the lesion and the degree of pain. The benefits of this treatment depend on the degree of heat that is applied. The nurse teaches the patient about the recommended temperature of the solution: high enough to be effective and as warm as the patient can tolerate, usually 105°F to 110°F (40.6°C to 43.3°C). Irrigating the throat properly is an effective means of reducing spasm in the pharyngeal muscles and relieving soreness of the throat. Unless the purpose of the procedure and its technique are understood clearly by the patient and family, the results may be less than satisfactory.

An ice collar also can relieve severe sore throats. Mouth care may add greatly to the patient's comfort and prevent the development of fissures (cracking) of the lips and oral inflammation when bacterial infection is present. The nurse instructs the patient to resume activity gradually. A full course of antibiotic therapy is indicated in patients with group A beta-hemolytic streptococcal infection in view of the possible development of complications such as nephritis and rheumatic fever, which may have their onset 2 or 3 weeks after the pharyngitis has subsided. The nurse instructs the patient and family about the importance of taking the full course of therapy and informs them about the symptoms to watch for that may indicate complications.

## CHRONIC PHARYNGITIS

Chronic pharyngitis is a persistent inflammation of the pharynx. It is common in adults who work or live in dusty surroundings, use their voice to excess, suffer from chronic cough, and habitually use alcohol and tobacco.

Three types of chronic pharyngitis are recognized:

- Hypertrophic: characterized by general thickening and congestion of the pharyngeal mucous membrane
- Atrophic: probably a late stage of the first type (the membrane is thin, whitish, glistening, and at times wrinkled)
- Chronic granular ("clergyman's sore throat"): characterized by numerous swollen lymph follicles on the pharyngeal wall

### Clinical Manifestations

Patients with chronic pharyngitis complain of a constant sense of irritation or fullness in the throat, mucus that collects in the throat and can be expelled by coughing, and difficulty swallowing.

### Medical Management

Treatment of chronic pharyngitis is based on relieving symptoms, avoiding exposure to irritants, and correcting any upper respiratory, pulmonary, or cardiac condition that might be responsible for a chronic cough.

Nasal congestion may be relieved by short-term use of nasal sprays or medications containing ephedrine sulfate (Kondon's Nasal) or phenylephrine hydrochloride (Neo-Synephrine). If there is a history of allergy, one of the antihistamine decongestant medications, such as Drixoral or Dimetapp, is taken orally every 4 to 6 hours. Aspirin or acetaminophen is recommended for its anti-inflammatory and analgesic properties.

## Nursing Management

### TEACHING PATIENTS SELF-CARE

To prevent the infection from spreading, the nurse instructs the patient to avoid contact with others until the fever subsides. Alcohol, tobacco, second-hand smoke, and exposure to cold are avoided, as are environmental or occupational pollutants if possible. The patient may minimize exposure to pollutants by wearing a disposable facemask. The nurse encourages the patient to drink plenty of fluids. Gargling with warm saline solutions may relieve throat discomfort. Lozenges will keep the throat moistened.

## TONSILLITIS AND ADENOIDITIS

The tonsils are composed of lymphatic tissue and are situated on each side of the oropharynx. The faucial or palatine tonsils and lingual tonsils are located behind the pillars of fauces and tongue, respectively. They frequently serve as the site of acute infection (**tonsillitis**). Chronic tonsillitis is less common and may be mistaken for other disorders such as allergy, asthma, and sinusitis.

The adenoids or pharyngeal tonsils consist of lymphatic tissue near the center of the posterior wall of the nasopharynx. Infection of the adenoids frequently accompanies acute tonsillitis. Group A beta-streptococcus is the most common organism associated with tonsillitis and adenoiditis.

### Clinical Manifestations

The symptoms of tonsillitis include sore throat, fever, snoring, and difficulty swallowing. Enlarged adenoids may cause mouth-breathing, earache, draining ears, frequent head colds, bronchitis, foul-smelling breath, voice impairment, and noisy respiration. Unusually enlarged adenoids fill the space behind the posterior nares, making it difficult for the air to travel from the nose to the throat and resulting in a nasal obstruction. Infection can extend to the middle ears by way of the auditory (eustachian) tubes and may result in acute otitis media, which can lead to spontaneous rupture of the eardrums and further extension of the infection into the mastoid cells, causing acute mastoiditis. The infection also may reside in the middle ear as a chronic, low-grade, smoldering process that eventually may cause permanent deafness.

### Assessment and Diagnostic Findings

A thorough physical examination is performed and a careful history is obtained to rule out related or systemic conditions. The tonsillar site is cultured to determine the presence of bacterial infection. In adenoiditis, if recurrent episodes of suppurative otitis media result in hearing loss, the patient should be given a comprehensive audiometric examination (see Chap. 59).

### Medical Management

Tonsillectomy is usually performed for recurrent tonsillitis when medical treatment is unsuccessful and there is severe hypertrophy, asymmetry, or peritonsillar abscess that occludes the pharynx, making swallowing difficult and endangering the airway (particularly during sleep). Enlargement of the tonsils is rarely an indication for their removal; most children normally have large tonsils, which decrease in size with age. Despite the continuing debate over the effectiveness of many tonsillectomies, the operation is still a common surgical procedure in the United States.

Tonsillectomy or adenoidectomy is indicated only if the patient has had any of the following problems: repeated bouts of tonsillitis; hypertrophy of the tonsils and adenoids that could cause obstruction and obstructive sleep apnea; repeated attacks of purulent otitis media; suspected hearing loss due to serous otitis media that has occurred in association with enlarged tonsils and adenoids; and some other conditions, such as an exacerbation of asthma or rheumatic fever. Appropriate antibiotic therapy is initiated for patients undergoing tonsillectomy or adenoidectomy. The most common antimicrobial agent is oral penicillin, which is taken for 7 days. Amoxicillin and erythromycin are alternatives.

## Nursing Management

### PROVIDING POSTOPERATIVE CARE

Continuous nursing observation is required in the immediate postoperative and recovery period because of the significant risk of hemorrhage. In the immediate postoperative period, the most comfortable position is prone with the head turned to the side to allow drainage from the mouth and pharynx. The nurse must not remove the oral airway until the patient's gag and swallowing reflexes have returned. The nurse applies an ice collar to the neck, and a basin and tissues are provided for the expectoration of blood and mucus.

Bleeding may be bright red if the patient expectorates blood before swallowing it. Often, however, the patient swallows the blood, which immediately becomes brown because of the action of the acidic gastric juice.

Hemorrhage is a potential complication after a tonsillectomy and adenoidectomy. If the patient vomits large amounts of dark blood or bright-red blood at frequent intervals, or if the pulse rate and temperature rise and the patient is restless, the nurse notifies the surgeon immediately. The nurse should have the following items ready for examination of the surgical site for bleeding: a light, a mirror, gauze, curved hemostats, and a waste basin.

Occasionally, suture or ligation of the bleeding vessel is required. In such cases, the patient is taken to the operating room and given general anesthesia. After ligation, continuous nursing observation and postoperative care are required, as in the initial postoperative period.

If there is no bleeding, water and ice chips may be given to the patient as soon as desired. The patient is instructed to refrain from too much talking and coughing because these activities can produce throat pain.

### TEACHING PATIENTS SELF-CARE

Tonsillectomy and adenoidectomy usually do not require hospitalization and are performed as outpatient surgery with a short length of stay. Because the patient will be sent home soon after surgery, the patient and family must understand the signs and symptoms of hemorrhage. Hemorrhage usually occurs in the first 12 to 24 hours. The patient is instructed to report frank red bleeding to the physician.

Alkaline mouthwashes and warm saline solutions are useful in coping with the thick mucus and halitosis that may be present after surgery. It is important to explain to the patient that a sore throat, stiff neck, and vomiting may occur in the first 24 hours. A liquid or semiliquid diet is given for several days. Sherbet and gelatin are acceptable foods. The patient should avoid spicy, hot, acidic, or rough foods. Milk and milk products (ice cream and yogurt) may be restricted because they may make removal of mucus more difficult.

The nurse explains to the patient that halitosis and some minor ear pain may occur for the first few days. The nurse instructs the patient to avoid vigorous tooth brushing or gargling, since these actions could cause bleeding.

## PERITONSILLAR ABSCESS

A peritonsillar abscess is a collection of purulent exudate between the tonsillar capsule and the surrounding tissues, including the soft palate. It is believed to develop after an acute tonsillar infection, which progresses to a local cellulitis and abscess.

### Clinical Manifestations

The usual symptoms of an infection are present, together with such local symptoms as a raspy voice,odynophagia (a severe sensation of burning, squeezing pain while swallowing), **dysphagia** (difficulty swallowing), otalgia (pain in the ear), and drooling. An examination shows marked swelling of the soft palate, often occluding almost half of the opening from the mouth into the pharynx, unilateral tonsillar hypertrophy, and dehydration.

### Assessment and Diagnostic Findings

Aspiration of purulent material (pus) by needle aspiration is required to make the appropriate diagnosis. The aspirated material is sent for culture and Gram's stain. A CT scan is performed when it is not possible to aspirate the abscess.

### Medical Management

Antibiotics (usually penicillin) are extremely effective in controlling the infection in peritonsillar abscess. If antibiotics are prescribed early in the course of the disease, the abscess may resolve without needing to be incised.

### SURGICAL MANAGEMENT

If treatment is delayed, the abscess is evacuated as soon as possible. The mucous membrane over the swelling is first sprayed with a topical anesthetic and then injected with a local anesthetic. Single or repeated needle aspirations are performed to decompress the abscess. The abscess may also be incised and drained. These procedures are performed best with the patient in the sitting position to make it easier to expectorate the pus and blood that accumulate in the pharynx. Almost immediate relief is experienced. Approximately 30% of patients with peritonsillar abscess have indications for tonsillectomy (Tierney et al., 2001).

### Nursing Management

Considerable relief may be obtained by the use of topical anesthetic agents and throat irrigations or the frequent use of mouthwashes or gargles, using saline or alkaline solutions at a temperature of 105°F to 110°F (40.6°C to 43.3°C). The nurse instructs the patient to gargle at intervals of 1 or 2 hours for 24 to 36 hours. Liquids that are cool or at room temperature are usually well tolerated.

## LARYNGITIS

**Laryngitis**, an inflammation of the larynx, often occurs as a result of voice abuse or exposure to dust, chemicals, smoke, and other pollutants, or as part of an upper respiratory tract infection.

It also may be caused by isolated infection involving only the vocal cords.

The cause of infection is almost always a virus. Bacterial invasion may be secondary. Laryngitis is usually associated with allergic rhinitis or pharyngitis. The onset of infection may be associated with exposure to sudden temperature changes, dietary deficiencies, malnutrition, and an immunosuppressed state. Laryngitis is common in the winter and is easily transmitted.

## Clinical Manifestations

Signs of acute laryngitis include hoarseness or **aphonia** (complete loss of voice) and severe cough. Chronic laryngitis is marked by persistent hoarseness. Laryngitis may be a complication of upper respiratory infections.

## Medical Management

Management of acute laryngitis includes resting the voice, avoiding smoking, resting, and inhaling cool steam or an aerosol. If the laryngitis is part of a more extensive respiratory infection due to a bacterial organism or if it is severe, appropriate antibacterial therapy is instituted. The majority of patients recover with conservative treatment; however, laryngitis tends to be more severe in elderly patients and may be complicated by pneumonia.

For chronic laryngitis, the treatment includes resting the voice, eliminating any primary respiratory tract infection, eliminating smoking, and avoiding second-hand smoke. Topical corticosteroids, such as beclomethasone dipropionate (Vanceril) inhalation, may also be used. These preparations have no systemic or long-lasting effects and may reduce local inflammatory reactions.

## Nursing Management

The nurse instructs the patient to rest the voice and to maintain a well-humidified environment. If laryngeal secretions are present during acute episodes, expectorant agents are suggested, along with a daily fluid intake of 3 L to thin secretions.

## NURSING PROCESS: THE PATIENT WITH UPPER AIRWAY INFECTION

### Assessment

A health history may reveal signs and symptoms of headache, sore throat, pain around the eyes and on either side of the nose, difficulty in swallowing, cough, hoarseness, fever, stuffiness, and generalized discomfort and fatigue. Determining when the symptoms began, what precipitated them, what if anything relieves them, and what aggravates them is part of the assessment. It also is important to determine any history of allergy or the existence of a concomitant illness.

Inspection may reveal swelling, lesions, or asymmetry of the nose as well as bleeding or discharge. The nurse inspects the nasal mucosa for abnormal findings such as increased redness, swelling, or exudate, and nasal polyps, which may develop in chronic rhinitis.

The nurse palpates the frontal and maxillary sinuses for tenderness, which suggests inflammation, and then inspects the throat by having the patient open the mouth wide and take a deep breath. The tonsils and pharynx are inspected for abnormal find-

ings such as redness, asymmetry, or evidence of drainage, ulceration, or enlargement.

Next the nurse palpates the trachea to determine the midline position in the neck and to detect any masses or deformities. The neck lymph nodes also are palpated for associated enlargement and tenderness.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Ineffective airway clearance related to excessive mucus production secondary to retained secretions and inflammation
- Acute pain related to upper airway irritation secondary to an infection
- Impaired verbal communication related to physiologic changes and upper airway irritation secondary to infection or swelling
- Deficient fluid volume related to increased fluid loss secondary to diaphoresis associated with a fever
- Deficient knowledge regarding prevention of upper respiratory infections, treatment regimen, surgical procedure, or postoperative care

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on assessment data, potential complications may include:

- Sepsis
- Meningitis
- Peritonsillar abscess
- Otitis media
- Sinusitis

## Planning and Goals

The major goals for the patient may include maintenance of a patent airway, relief of pain, maintenance of effective means of communication, normal hydration, knowledge of how to prevent upper airway infections, and absence of complications.

## Nursing Interventions

### MAINTAINING A PATENT AIRWAY

An accumulation of secretions can block the airway in patients with an upper airway infection. As a result, changes in the respiratory pattern occur, and the work of breathing required to get beyond the blockage increases. The nurse can implement several measures to loosen thick secretions or to keep the secretions moist so that they can be easily expectorated. Increasing fluid intake helps thin the mucus. Use of room vaporizers or steam inhalation also loosens secretions and reduces inflammation of the mucous membranes. To enhance drainage from the sinuses, the nurse instructs the patient about the best position to assume; this depends on the location of the infection or inflammation. For example, drainage for sinusitis or rhinitis is achieved in the upright position. In some conditions, topical or systemic medications, when prescribed, help to relieve nasal or throat congestion.

### PROMOTING COMFORT

Upper respiratory tract infections usually produce localized discomfort. In sinusitis, pain may occur in the area of the sinuses or

may produce a general headache. In pharyngitis, laryngitis, or tonsillitis, a sore throat occurs. The nurse encourages the patient to take analgesics, such as acetaminophen with codeine, as prescribed, which will help relieve this discomfort. Other helpful measures include topical anesthetic agents for symptomatic relief of herpes simplex blisters (see Chart 22-1) and sore throats, hot packs to relieve the congestion of sinusitis and promote drainage, and warm water gargles or irrigations to relieve the pain of a sore throat. The nurse encourages rest to relieve the generalized discomfort and fever that accompany many upper airway conditions (especially rhinitis, pharyngitis, and laryngitis). The nurse instructs the patient in general hygiene techniques to prevent the spread of infection. For postoperative care following tonsillectomy and adenoidectomy, an ice collar may reduce swelling and decrease bleeding.

### PROMOTING COMMUNICATION

Upper airway infections may result in hoarseness or loss of speech. The nurse instructs the patient to refrain from speaking as much as possible and to communicate in writing instead, if possible. Additional strain on the vocal cords may delay full return of the voice.

### ENCOURAGING FLUID INTAKE

In upper airway infections, the work of breathing and the respiratory rate increase as inflammation and secretions develop. This, in turn, may increase insensible fluid loss. Fever further increases the metabolic rate, diaphoresis, and fluid loss.

Sore throat, malaise, and fever may interfere with a patient's willingness to eat. The nurse encourages the patient to drink 2 to 3 L of fluid per day during the acute stage of airway infection, unless contraindicated, to thin secretions and promote drainage. Liquids (hot or cold) may be soothing, depending on the illness.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

Prevention of most upper airway infections is difficult because of the many potential causes. However, most upper respiratory infections are transmitted by hand-to-hand contact. Therefore, it is important to teach the patient and family how to minimize the spread of infection to others. Other preventive strategies are identified in Chart 22-2. The nurse advises the patient to avoid exposure to others at risk for serious illness if respiratory infection is transmitted. Those at risk include elderly adults, immunosuppressed people, and those with chronic health problems.

The nurse teaches patients and their families strategies to relieve symptoms of upper respiratory infections. These include increasing the humidity level, encouraging adequate fluid intake, getting adequate rest, using warm water gargles or irrigations and topical anesthetic agents to relieve sore throat, and applying hot packs to relieve congestion. The nurse reinforces the need to complete the treatment regimen, particularly when antibiotics are prescribed.

#### Continuing Care

Referral for home care is rare. However, it may be indicated for the person whose health status was compromised before the onset of the respiratory infection and for those who cannot manage self-care without assistance. In such circumstances, the home care nurse assesses the patient's respiratory status and progress in recovery. The nurse may advise elderly patients and those who would be at increased risk from a respiratory infection to consider

an annual influenza vaccine. A follow-up appointment with the primary care provider may be indicated for patients with compromised health status to ensure that the respiratory infection has resolved.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

While major complications of upper respiratory infections are rare, the nurse must be aware of them and assess the patient for them. Because most patients with upper respiratory infections are managed at home, patients and their families must be instructed to monitor for signs and symptoms and to seek immediate medical care if the patient's condition does not improve or if the patient's physical status appears to be worsening.

Sepsis and meningitis may occur in patients with compromised immune status or in those with an overwhelming bacterial infection. The patient with an upper respiratory infection and family members are instructed to seek medical care if the patient's condition fails to improve within several days of the onset of symptoms, if unusual symptoms develop, or if the patient's condition deteriorates. They are instructed about signs and symptoms that require further attention: persistent or high fever, increasing shortness of breath, confusion, and increasing weakness and malaise. The patient with sepsis requires expert care to treat the infection, stabilize vital signs, and prevent or treat septicemia and shock. Deterioration of the patient's condition necessitates intensive care measures (eg, hemodynamic monitoring and administration of vasoactive medications, intravenous fluids, nutritional support, corticosteroids) to monitor the patient's status and to support the patient's vital signs. High doses of antibiotics may be administered to treat the causative organism. The nurse's role is to monitor the patient's vital signs, hemodynamic status, and laboratory values, administer needed treatment, alleviate the patient's physical discomfort, and provide explanations, teaching, and emotional support to the patient and family.

Peritonsillar abscess may develop following an acute infection of the tonsils. The patient requires treatment to drain the abscess and receives antibiotics for infection and topical anesthetic agents and throat irrigations to relieve pain and sore throat. Follow-up is necessary to ensure that the abscess resolves; tonsillectomy may be required. The nurse assists the patient in administering throat irrigations and instructs the patient and family about the importance of adhering to the prescribed treatment regimen and recommended follow-up appointments.

Otitis media and sinusitis may develop with upper respiratory infection. The patient and family are instructed about the signs and symptoms of otitis media and sinusitis and about the importance of follow-up with the primary health care practitioner to ensure adequate evaluation and treatment of these conditions.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Maintains a patent airway by managing secretions
  - a. Reports decreased congestion
  - b. Assumes best position to facilitate drainage of secretions
2. Reports feeling more comfortable
  - a. Uses comfort measures: analgesics, hot packs, gargles, rest
  - b. Demonstrates adequate oral hygiene
3. Demonstrates ability to communicate needs, wants, level of comfort

4. Maintains adequate fluid intake
5. Identifies strategies to prevent upper airway infections and allergic reactions
  - a. Demonstrates hand hygiene technique
  - b. Identifies the value of the influenza vaccine
6. Demonstrates an adequate level of knowledge and performs self-care adequately
7. Becomes free of signs and symptoms of infection
  - a. Exhibits normal vital signs (temperature, pulse, respiratory rate)
  - b. Absence of purulent drainage
  - c. Free of pain in ears, sinuses, and throat

## Obstruction and Trauma of the Upper Respiratory Airway

### OBSTRUCTION DURING SLEEP

A variety of respiratory disorders are associated with sleep, the most common being sleep apnea syndrome. Sleep apnea syndrome is defined as cessation of breathing (**apnea**) during sleep.

#### Pathophysiology

Sleep apnea is classified into three types:

- Obstructive—lack of air flow due to pharyngeal occlusion
- Central—simultaneous cessation of both air flow and respiratory movements
- Mixed—a combination of central and obstructive apnea within one apneic episode

The most common type of sleep apnea syndrome, obstructive sleep apnea, will be presented here.

#### Clinical Manifestations

It is estimated that 12 million Americans have sleep apnea (National Institute of Health, 2000). It is more prevalent in men, especially those who are older and overweight. Cigarette smoking is a risk factor. Obstructive sleep apnea is defined as frequent and loud snoring and breathing cessation for 10 seconds or more for five episodes per hour or more, followed by awakening abruptly with a loud snort as the blood oxygen level drops. Patients with sleep apnea may experience anywhere from five apneic episodes per hour to several hundred per night. Other symptoms include excessive daytime sleepiness, morning headache, sore throat, intellectual deterioration, personality changes, behavioral disorders, enuresis, impotence, obesity, and complaints by the partner that the patient snores loudly or is unusually restless during sleep (Chart 22-3).

The obstruction may be caused by mechanical factors such as a reduced diameter of the upper airway or dynamic changes in the upper airway during sleep. The activity of the tonic dilator muscles of the upper airway is reduced during sleep. These sleep-related changes may predispose the patient to increased upper airway collapse with the small amounts of negative pressure generated during inspiration. Obstructive sleep apnea may be associated with obesity and with other conditions that reduce pharyngeal muscle tone (eg, neuromuscular disease, sedative/hypnotic medications, acute ingestion of alcohol). The diagnosis of sleep apnea is made based on clinical features plus polysomnographic findings (sleep test), in which the cardiopulmonary status of the patient is monitored during an episode of sleep.

### Chart 22-3 • ASSESSMENT

#### Obstructive Sleep Apnea

Clinical features of obstructive sleep apnea include:

- Excessive daytime sleepiness
- Frequent nocturnal awakening
- Insomnia
- Loud snoring
- Morning headaches
- Intellectual deterioration
- Personality changes, irritability
- Impotence
- Systemic hypertension
- Dysrhythmias
- Pulmonary hypertension, cor pulmonale
- Polycythemia
- Enuresis

The effects of obstructive sleep apnea can seriously tax the heart and lungs. Repetitive apneic events result in hypoxia and hypercapnia, which triggers a sympathetic response. As a consequence, patients have a high prevalence of hypertension and an increased risk of myocardial infarction and stroke. In patients with underlying cardiovascular disease, the nocturnal hypoxemia may predispose to dysrhythmias.

#### Medical Management

Patients usually seek medical treatment because their partners express concern or because they experience excessive sleeplessness at inappropriate times or settings (eg, while driving a car). A variety of treatments are used. In mild cases, the patient is advised to avoid alcohol and medications that depress the upper airway and to lose weight. In more severe cases involving hypoxemia with severe CO<sub>2</sub> retention (hypercapnia), the treatment includes continuous positive airway pressure or bilevel positive airway pressure therapy with supplemental oxygen via nasal cannula. These treatment methods are described in Chapter 25.

Surgical procedures (eg, uvulopalatopharyngoplasty) may be performed to correct the obstruction. As a last resort, a tracheostomy is performed to bypass the obstruction if the potential for respiratory failure or life-threatening dysrhythmias exists. The tracheostomy is unplugged only during sleep. Although this is an effective treatment, it is used in a limited number of patients because of its associated physical disfigurement (Murray & Nadel, 2001).

#### PHARMACOLOGIC THERAPY

Treatment of central sleep apnea also includes medication. Protriptyline (Triptil) given at bedtime is thought to increase the respiratory drive and improve upper airway muscle tone. Medroxyprogesterone acetate (Provera) and acetazolamide (Diamox) have been recommended for sleep apnea associated with chronic alveolar hypoventilation, but their benefits have not been well established. Administration of low-flow nasal oxygen at night can help relieve hypoxemia in some patients but has little effect on the frequency or severity of apnea.

#### Nursing Management

The patient with obstructive sleep apnea may not recognize the potential consequences of the disorder. Therefore, the nurse explains the disorder in language that is understandable to the

patient and relates symptoms (daytime sleepiness) to the underlying disorder. The nurse also instructs the patient and family about treatments, including the correct and safe use of oxygen, if prescribed.

## EPISTAXIS (NOSEBLEED)

A hemorrhage from the nose, referred to as **epistaxis**, is caused by the rupture of tiny, distended vessels in the mucous membrane of any area of the nose. Rarely does epistaxis originate in the densely vascular tissue over the turbinates. Most commonly, the site is the anterior septum, where three major blood vessels enter the nasal cavity: (1) the anterior ethmoidal artery on the forward part of the roof (Kesselbach's plexus), (2) the sphenopalatine artery in the posterosuperior region, and (3) the internal maxillary branches (the plexus of veins located at the back of the lateral wall under the inferior turbinate).

There are a variety of causes associated with epistaxis, including trauma, infection, inhalation of illicit drugs, cardiovascular diseases, blood dyscrasias, nasal tumors, low humidity, a foreign body in the nose, and a deviated nasal septum. Additionally, vigorous nose blowing and nose picking have been associated with epistaxis.

## Medical Management

Management of epistaxis depends on the location of the bleeding site. A nasal speculum or headlight may be used to determine the site of bleeding in the nasal cavity. Most nosebleeds originate from the anterior portion of the nose. Initial treatment may include applying direct pressure. The patient sits upright with the head tilted forward to prevent swallowing and aspiration of blood and is directed to pinch the soft outer portion of the nose against the midline septum for 5 or 10 minutes continuously. If this measure is unsuccessful, additional treatment is indicated. In anterior nosebleeds, the area may be treated with a silver nitrate applicator and Gelfoam, or by electrocautery. Topical vasoconstrictors,

such as adrenaline (1 : 1,000), cocaine (0.5%), and phenylephrine may be prescribed.

If bleeding is occurring from the posterior regions, cotton pledgets soaked in a vasoconstricting solution may be inserted into the nose to reduce the blood flow and improve the examiner's view of the bleeding site. Alternatively, a cotton tampon may be used to try to stop the bleeding. Suction may be used to remove excess blood and clots from the field of inspection. The search for the bleeding site should shift from the anteroinferior quadrant to the anterosuperior, then to the posterosuperior, and finally to the posteroinferior area. The field is kept clear by using suction and by shifting the cotton tampon. Only about 60% of the total nasal cavity can actually be seen, however.

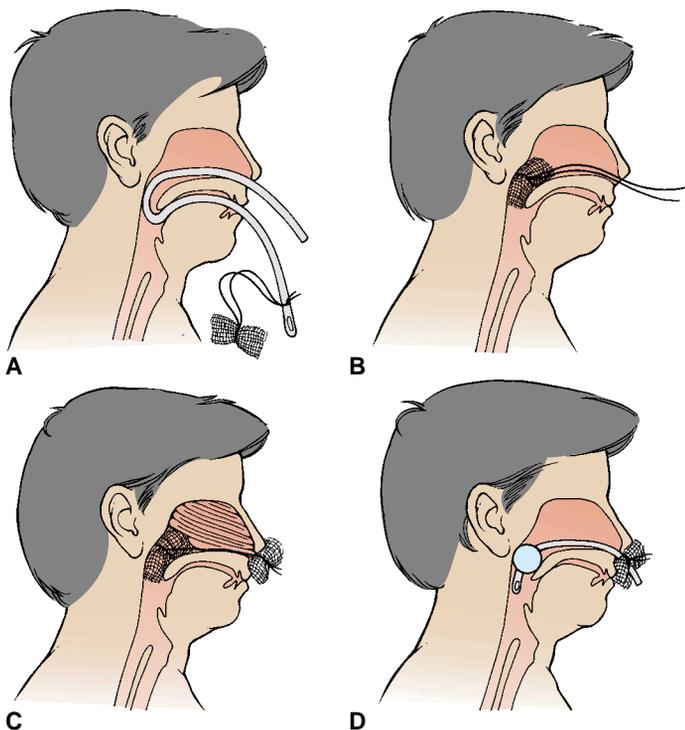

When the origin of the bleeding cannot be identified, the nose may be packed with gauze impregnated with petrolatum jelly or antibiotic ointment; a topical anesthetic spray and decongestant agent may be used prior to inserting the gauze packing, or a balloon-inflated catheter may be used (Fig. 22-4). The packing may remain in place for 48 hours or up to 5 or 6 days if necessary to control bleeding. Antibiotics may be prescribed because of the risk of iatrogenic sinusitis and toxic shock syndrome.

## Nursing Management

The nurse monitors the vital signs, assists in the control of bleeding, and provides tissues and an emesis basin to allow the patient to expectorate any excess blood. It is not uncommon for patients to be anxious in response to a nosebleed. Blood loss on clothing and handkerchiefs can be frightening, and the nasal examination and treatment are uncomfortable. Assuring the patient in a calm, efficient manner that bleeding can be controlled can help reduce anxiety.

## TEACHING PATIENTS SELF-CARE

Discharge teaching includes reviewing ways to prevent epistaxis: avoiding forceful nose blowing, straining, high altitudes, and

**FIGURE 22-4** Packing to control bleeding from the posterior nose. (A) Catheter is inserted and packing is attached. (B) Packing is drawn into position as the catheter is removed. (C) Strip is tied over a bolster to hold the packing in place with an anterior pack installed “accordion pleat” style. (D) Alternative method, using a balloon catheter instead of gauze packing.

nasal trauma (including nose picking). Adequate humidification may prevent drying of the nasal passages. The nurse instructs the patient how to apply direct pressure to the nose with the thumb and the index finger for 15 minutes in the case of a recurrent nosebleed. If recurrent bleeding cannot be stopped, the patient is instructed to seek additional medical attention.

## NASAL OBSTRUCTION

The passage of air through the nostrils is frequently obstructed by a deviation of the nasal septum, hypertrophy of the turbinate bones, or the pressure of nasal polyps, which are grapelike swellings that arise from the mucous membrane of the sinuses, especially the ethmoids. This obstruction also may lead to a condition of chronic infection of the nose and result in frequent episodes of nasopharyngitis. Frequently, the infection extends to the sinuses of the nose. When sinusitis develops and the drainage from these cavities is obstructed by deformity or swelling within the nose, pain is experienced in the region of the affected sinus.

### Medical Management

The treatment of nasal obstruction requires the removal of the obstruction, followed by measures to overcome whatever chronic infection exists. In many patients an underlying allergy requires treatment. At times endoscopic surgery is necessary to drain the nasal sinuses. The specific procedure performed depends on the type of nasal obstruction found. Usually, surgery is performed under local anesthesia.

If a deviation of the septum is the cause of the obstruction, the surgeon makes an incision into the mucous membrane and, after raising it from the bone, removes the deviated bone and cartilage with bone forceps. The mucosa then is allowed to fall back in place and is held there by tight packing. Generally, the packing is soaked in liquid petrolatum so that it can be removed easily in 24 to 36 hours. This operation is called a **submucous resection** or septoplasty.

Nasal polyps are removed by clipping them at their base with a wire snare. Hypertrophied turbinates may be treated by applying an astringent agent to shrink them.

### Nursing Management

Most of these procedures are performed on an outpatient basis. If the patient is hospitalized, the nurse elevates the head of the bed to promote drainage and to help alleviate discomfort from edema. Frequent oral hygiene is encouraged to overcome dryness caused by breathing through the mouth.

## FRACTURES OF THE NOSE

The location of the nose makes it susceptible to injury by a wide variety of causes. In fact, nasal fractures are more common than those of any other bone in the body. Fractures of the nose usually result from a direct assault. As a rule, no serious consequences result, but the deformity that may follow often gives rise to obstruction of the nasal air passages and to facial disfigurement.

### Clinical Manifestations

The signs and symptoms of a nasal fracture are bleeding from the nose externally and internally into the pharynx, swelling of the soft tissues adjacent to the nose, and deformity.

## Assessment and Diagnostic Findings

The nose is examined internally to rule out the possibility that the injury may be complicated by a fracture of the nasal septum and a submucosal septal hematoma. Because of the swelling and bleeding that occur with a nasal fracture, an accurate diagnosis can be made only after the swelling subsides.

Clear fluid draining from either nostril suggests a fracture of the cribriform plate with leakage of cerebrospinal fluid. Because cerebrospinal fluid contains glucose, it can readily be differentiated from nasal mucus by means of a dipstick (Dextrostix). Usually, careful inspection or palpation will disclose any deviations of the bone or disruptions of the nasal cartilages. An x-ray may reveal displacement of the fractured bones and may help rule out extension of the fracture into the skull.

### Medical Management

As a rule, bleeding is controlled with the use of cold compresses. The nose is assessed for symmetry either before swelling has occurred or after it has subsided. The patient is referred to a specialist, usually 3 to 5 days after the injury, to evaluate the need to realign the bones. Nasal fractures are surgically reduced 7 to 10 days after the injury.

### Nursing Management

The nurse instructs the patient to apply ice packs to the nose for 20 minutes four times each day to decrease swelling. The patient who experiences bleeding from the nose (epistaxis) because of injury or for unexplained reasons is usually frightened and anxious. The packing inserted to stop the bleeding may be uncomfortable and unpleasant, and obstruction of the nasal passages by the packing forces the patient to breathe through the mouth. This in turn causes the oral mucous membranes to become dry. Mouth rinses will help to moisten the mucous membranes and to reduce the odor and taste of dried blood in the oropharynx and nasopharynx.

## LARYNGEAL OBSTRUCTION

Edema of the larynx is a serious, often fatal, condition. The larynx is a stiff box that will not stretch. It contains a narrow space between the vocal cords (glottis) through which air must pass. Swelling of the laryngeal mucous membranes, therefore, may close off the opening tightly, leading to suffocation. Edema of the glottis occurs rarely in patients with acute laryngitis, occasionally in patients with urticaria, and more frequently in patients with severe inflammations of the throat, as in scarlet fever. It is an occasional cause of death in severe anaphylaxis (angioneurotic edema).

Foreign bodies frequently are aspirated into the pharynx, the larynx, or the trachea and cause a twofold problem. First, they obstruct the air passages and cause difficulty in breathing, which may lead to asphyxia; later, they may be drawn farther down, entering the bronchi or a bronchial branch and causing symptoms of irritation, such as a croupy cough, expectoration of blood or mucus, or labored breathing. The physical signs and x-ray findings confirm the diagnosis.

### Medical Management

When the obstruction is caused by edema resulting from an allergic reaction, treatment includes administering subcutaneous epinephrine or a corticosteroid (see Chap. 53) and applying an

ice pack to the neck. In emergencies caused by obstruction by a foreign body, when signs of asphyxia are apparent, immediate treatment is necessary. Frequently, if the foreign body has lodged in the pharynx and can be visualized, the finger can dislodge it.

If the obstruction is in the larynx or the trachea, the nurse or other rescuer tries the subdiaphragmatic abdominal thrust maneuver (Chart 22-4). If all efforts are unsuccessful, an immediate tracheotomy is necessary (see Chap. 25 for further discussion).

## Cancer of the Larynx

Cancer of the larynx is a malignant tumor in the larynx (voice box). It is potentially curable if detected early. It represents less than 1% of all cancers and occurs about four times more frequently in men than in women, and most commonly in persons 50 to 70 years of age. The incidence of laryngeal cancer continues to decline, but the incidence in women versus men continues to increase. Each year in the United States, approximately 9,000 new cases are discovered, and 3,700 persons with cancer of the larynx will die (American Cancer Society, 2002).

Carcinogens that have been associated with the development of laryngeal cancer include tobacco (smoke, smokeless) and alcohol and their combined effects, exposure to asbestos, mustard gas, wood dust, cement dust, tar products, leather, and metals. Other contributing factors include straining the voice, chronic laryngitis, nutritional deficiencies (riboflavin), and family predisposition (Chart 22-5).

A malignant growth may occur in three different areas of the larynx: the glottic area (vocal cords), supraglottic area (area above the glottis or vocal cords, including epiglottis and false cords), and subglottis (area below the glottis or vocal cords to the cricoid). Two thirds of laryngeal cancers are in the glottic area. Supraglottic cancers account for approximately one third of the cases, subglottic tumors for less than 1%. Glottic tumors seldom spread if found early because of the limited lymph vessels found in the vocal cords (Lenhard, Osteen, & Gansler, 2001).

### Chart 22-5 Risk Factors for Laryngeal Cancer

#### Carcinogens

- Tobacco (smoke, smokeless)
- Combined effects of alcohol and tobacco
- Asbestos
- Second-hand smoke
- Paint fumes
- Wood dust
- Cement dust
- Chemicals
- Tar products
- Mustard gas
- Leather and metals

#### Other Factors

- Straining the voice
- Chronic laryngitis
- Nutritional deficiencies (riboflavin)
- History of alcohol abuse
- Familial predisposition
- Age (higher incidence after 60 years of age)
- Gender (more common in men)
- Race (more prevalent in African Americans)
- Weakened immune system

## Clinical Manifestations

Hoarseness of more than 2 weeks' duration is noted early in the patient with cancer in the glottic area because the tumor impedes the action of the vocal cords during speech. The voice may sound harsh, raspy, and lower in pitch. Affected voice sounds are not early signs of subglottic or supraglottic cancer. The patient may complain of a cough or sore throat that does not go away and pain and burning in the throat, especially when consuming hot liquids or citrus juices. A lump may be felt in the neck. Later symptoms include dysphagia, dyspnea (difficulty breathing), unilateral nasal

### Chart 22-4

## Performing the Abdominal Thrust Maneuver

To assist a patient or other person who is choking on a foreign object, the nurse performs the abdominal thrust maneuver (sometimes called the Heimlich maneuver) according to guidelines set forth by the American Heart Association. (*Note:* Hands crossed at the neck is the universal sign for choking.)

1. Stand behind the person who is choking.
2. Place both arms around the person's waist.
3. Make a fist with one hand with the thumb outside the fist.
4. Place thumb side of fist against the person's abdomen above the navel and below the xiphoid process.
5. Grasp fist with other hand.
6. Quickly and forcefully exert pressure against the person's diaphragm, pressing upward with quick, firm thrusts.
7. Apply thrusts 6 to 10 times until the obstruction is cleared.
8. The pressure from the thrusts should lift the diaphragm, force air into the lungs, and create an artificial cough powerful enough to expel the aspirated object.

obstruction or discharge, persistent hoarseness, persistent ulceration, and foul breath. Cervical lymph adenopathy, unplanned weight loss, a general debilitated state, and pain radiating to the ear may occur with metastasis.

### Assessment and Diagnostic Findings

An initial assessment includes a complete history and physical examination of the head and neck. This will include assessment of risk factors, family history, and any underlying medical conditions. An indirect laryngoscopy, using a flexible endoscope, is initially performed in the otolaryngologist's office to visually evaluate the pharynx, larynx, and possible tumor. Mobility of the vocal cords is assessed; if normal movement is limited, the growth may affect muscle, other tissue, and even the airway. The lymph

nodes of the neck and the thyroid gland are palpated to determine spread of the malignancy (Haskell, 2001).

If a tumor of the larynx is suspected on an initial examination, a direct laryngoscopic examination is scheduled. This examination is done under local or general anesthesia and allows evaluation of all areas of the larynx. Samples of the suspicious tissue are obtained for histologic evaluation. The tumor may involve any of the three areas of the larynx and may vary in appearance.

Squamous cell carcinoma accounts for over 90% of the cases of laryngeal carcinoma (Haskell, 2001). The staging of the tumor serves as a framework for the therapeutic regimen. The TNM classification system, developed by the American Joint Committee on Cancer (AJCC) (Chart 22-6), is the accepted method used to classify head and neck tumors. The classification of the tumor determines the suggested treatment modalities. Because many of

these lesions are submucosal, biopsy may require that an incision be made using microlaryngeal techniques or using a CO<sub>2</sub> laser to transect the mucosa and reach the tumor.

Computed tomography and magnetic resonance imaging (MRI) are used to assess regional adenopathy and soft tissue and to help stage and determine the extent of a tumor. MRI is also helpful in post-treatment follow-up in order to detect a recurrence. Positron emission tomography (PET scan) may also be used to detect recurrence of a laryngeal tumor after treatment.

## Medical Management

Treatment of laryngeal cancer depends on the staging of the tumor, which includes the location, size, and histology of the tumor and the presence and extent of cervical lymph node involvement. Treatment options include surgery, radiation therapy, and chemotherapy. The prognosis depends on a variety of factors: tumor stage, the patient's gender and age, and pathologic features of the tumor, including the grade and depth of infiltration. The treatment plan also depends on whether this is an initial diagnosis or a recurrence. Small glottic tumors, stage I and II, with no infiltration to the lymph nodes are associated with a 75% to 95% survival rate. Patients with stage III and IV or advanced tumors have a 50% to 60% survival rate and have a 50% chance of recurrence and a 30% chance of metastasis. The highest risk of laryngeal cancer recurrence is in the first 2 to 3 years. Recurrence after 5 years is rare and is usually due to a new primary malignancy (Lenhard et al., 2001) (Chart 22-7).

Surgery and radiation therapy are both effective methods in the early stages of cancer of the larynx. Chemotherapy traditionally has been used for recurrence or metastatic disease. It has also been used more recently in conjunction with either radiation

therapy to avoid a total laryngectomy or preoperatively to shrink a tumor before surgery. A complete dental examination is performed to rule out any oral disease. Any dental problems are resolved, if possible, prior to surgery. If surgery is to be performed, a multidisciplinary team evaluates the needs of the patient and family to develop a successful plan of care (Forastiere et al., 2001).

## SURGICAL MANAGEMENT

Recent advances in surgical techniques for treating laryngeal cancer may minimize the ensuing cosmetic and functional deficits. Depending on the location and staging of the tumor, four different types of **laryngectomy** (surgical removal of part or all of the larynx and surrounding structures) are considered:

- Partial laryngectomy
- Supraglottic laryngectomy
- Hemilaryngectomy
- Total laryngectomy

Some microlaryngeal surgery can be performed endoscopically. The CO<sub>2</sub> laser can be used for the treatment of many laryngeal tumors, with the exception of large vascular tumors.

**Partial Laryngectomy.** A partial laryngectomy (laryngofissure-thyrotomy) is recommended in the early stages of cancer in the glottic area when only one vocal cord is involved. The surgery is associated with a very high cure rate. It may also be performed for a recurrence when high-dose radiation has failed. A portion of the larynx is removed, along with one vocal cord and the tumor; all other structures remain. The airway remains intact and the patient is expected to have no difficulty swallowing. The voice quality may change or the patient may be hoarse.

**Supraglottic Laryngectomy.** A supraglottic laryngectomy is indicated in the management of early (stage I) supraglottic and stage II lesions. The hyoid bone, glottis, and false cords are removed. The true vocal cords, cricoid cartilage, and trachea remain intact. During surgery, a radical neck dissection is performed on the involved side. A tracheostomy tube (see Chap. 25) is left in the trachea until the glottic airway is established. It is usually removed after a few days and the stoma is allowed to close. Nutrition is provided through a nasogastric tube until there is healing, followed by a semisolid diet. Postoperatively, the patient may experience some difficulty swallowing for the first 2 weeks. Aspiration is a potential complication since the patient must learn a new method of swallowing (supraglottic swallowing). The chief advantage of this surgical procedure is that it preserves the voice, even though the quality of the voice may change. Speech therapy is required before and after surgery. The major problem is the high risk for recurrence of the cancer; therefore, patients are selected carefully.

**Hemilaryngectomy.** A hemilaryngectomy is performed when the tumor extends beyond the vocal cord but is less than 1 cm in size and is limited to the subglottic area. It may be used in stage I glottic lesions. In this procedure, the thyroid cartilage of the larynx is split in the midline of the neck and the portion of the vocal cord (one true cord and one false cord) is removed with the tumor. The arytenoid cartilage and half of the thyroid are removed. The patient will have a tracheostomy tube and nasogastric tube in place for 10 to 14 days following surgery. The patient is at risk for aspiration postoperatively. Some change may occur in the voice quality. The voice may be rough, raspy, and hoarse and have limited projection. The airway and swallowing remain intact.

### Chart 22-7 • Ethics and Related Issues

#### Situation

A 68-year-old attorney was diagnosed with cancer of the larynx 8 years ago. He was treated successfully with radiation therapy, resulting in an altered voice quality. Recently, he has complained of shortness of breath and difficulty swallowing. In the past few months, he also has noticed a marked change in his voice and physical condition, which he attributed to “winter colds.”

After a complete physical exam and an extensive diagnostic workup and biopsy, it is determined that the cancer has recurred at a new primary site. His health care provider recommends surgery (a total laryngectomy) and chemotherapy as the best options. The patient states that he is not willing to “lose my voice and my livelihood” but instead will “take my chances.” He has also expressed concern about his quality of life after surgery. His family has approached you about trying to convince him to have surgery.

#### Dilemma

The patient's right to refuse treatment conflicts with the family's wishes and recommendation from his health care provider.

#### Discussion

1. Is the patient making a decision based upon all pertinent information concerning his health status, treatment, options, risk/benefits, and long-term prognosis?
2. What arguments can be made to support the patient's decision to forego treatment?
3. What arguments can be made to question the patient's decision to forego treatment?

**Total Laryngectomy.** A total laryngectomy is performed in the most advanced stage IV laryngeal cancer, when the tumor extends beyond the vocal cords, or for recurrent or persistent cancer following radiation therapy. In a total laryngectomy, the laryngeal structures are removed, including the hyoid bone, epiglottis, cricoid cartilage, and two or three rings of the trachea. The tongue, pharyngeal walls, and trachea are preserved. A total laryngectomy will result in permanent loss of the voice and a change in the airway.

Many surgeons recommend that a radical neck dissection be performed on the same side as the lesion even if no lymph nodes are palpable because metastasis to the cervical lymph nodes is common. Surgery is more difficult when the lesion involves the midline structures or both vocal cords. With or without neck dissection, a total laryngectomy requires a permanent tracheal stoma because the larynx that provides the protective sphincter is no longer present. The tracheal stoma prevents the aspiration of food and fluid into the lower respiratory tract. The patient will have no voice but will have normal swallowing. A total laryngectomy changes the manner in which airflow is used for breathing and speaking, as depicted in Figure 22-5. Complications that may occur include a salivary leak, wound infection from the development of a pharyngocutaneous fistula, stomal stenosis, and dysphagia secondary to pharyngeal and cervical esophageal stricture.

### RADIATION THERAPY

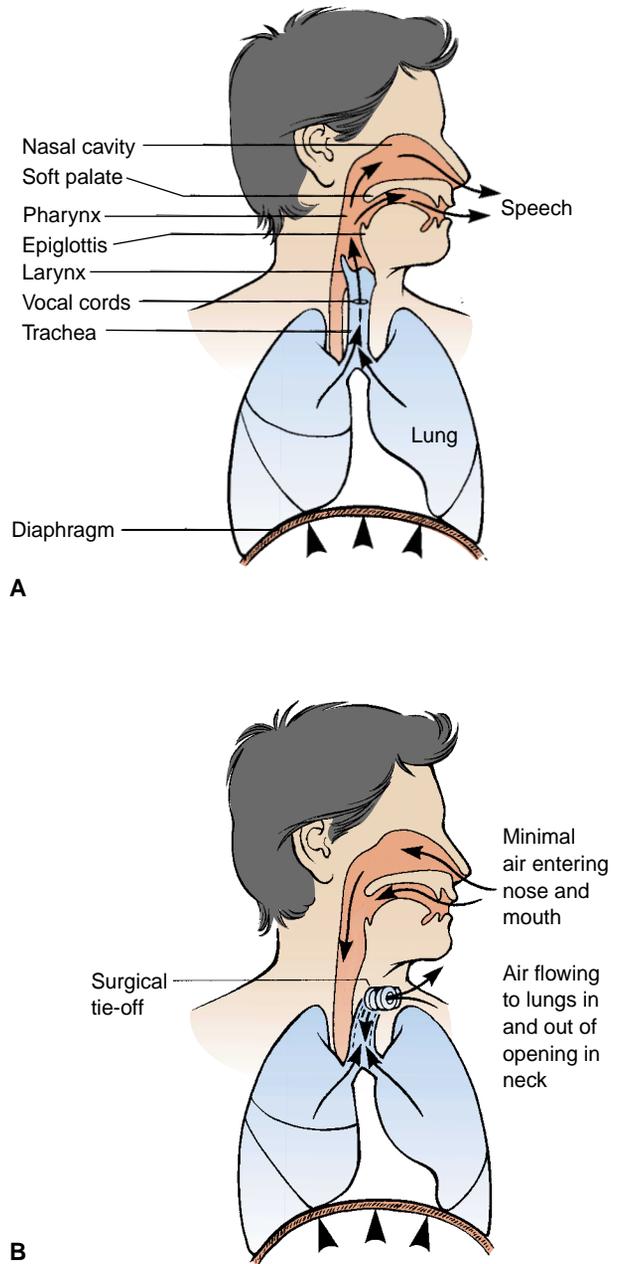

The goal of radiation therapy is to eradicate the cancer and preserve the function of the larynx. The decision to use radiation therapy is based on several factors, including the staging of the tumor (usually used for stage I and stage II tumors as a standard treatment option) and the patient's overall health status, lifestyle (including occupation), and personal preference. Excellent results have been achieved with radiation therapy in patients with early-stage (I and II) glottic tumors when only one vocal cord is involved and there is normal mobility (ie, moves with phonation) and in small supraglottic lesions. One of the benefits of radiation therapy is that patients retain a near-normal voice. A few may develop chondritis (inflammation of the cartilage) or stenosis; a small number may later require laryngectomy.

Radiation therapy may also be used preoperatively to reduce the tumor size. Radiation therapy is combined with surgery in advanced (stages III and IV) laryngeal cancer as adjunctive therapy to surgery or chemotherapy, and as a palliative measure. A variety of clinical trials have combined chemotherapy and radiation therapy in the treatment of advanced laryngeal tumors. Early studies suggest that combined modality therapy may improve the tumor's response to radiation therapy. Radiation therapy combined with chemotherapy may be an alternative to a total laryngectomy.

The complications from radiation therapy are a result of external radiation to the head and neck area, which may also include the parotid gland responsible for mucus production. The symptoms may include acute mucositis, ulceration of the mucous membranes, pain, **xerostomia** (dry mouth), loss of taste, dysphasia, fatigue, and skin reactions. Later complications may include laryngeal necrosis, edema, and fibrosis.

### SPEECH THERAPY

The loss or alteration of speech is discussed with the patient and family before surgery, and the speech therapist conducts a preoperative evaluation. During this time, the nurse should inform the patient and family about methods of communication that will be available in the immediate postoperative period. These include

**FIGURE 22-5** Total laryngectomy produces a change in airflow for breathing and speaking. (A) Normal airflow. (B) Airflow after total laryngectomy.

writing, lip speaking, and communication or word boards. A system of communication is established with the patient, family, nurse, and physician and implemented consistently after surgery.

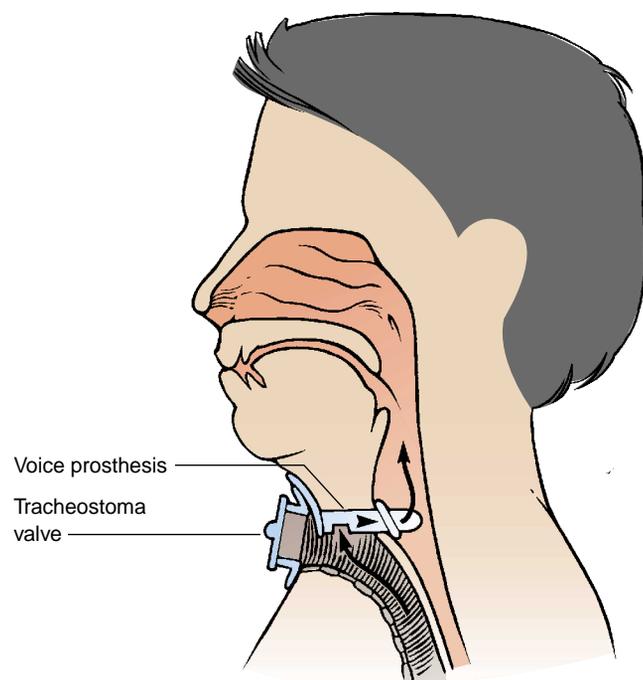

A postoperative communication plan is also developed. The three most common techniques of **alaryngeal communication** are esophageal speech, artificial larynx (electrolarynx), and tracheoesophageal puncture. Training in these techniques begins once medical clearance is obtained from the physician.

**Esophageal Speech.** Esophageal speech was the primary method of alaryngeal speech taught to patients until the 1980s. The patient needs the ability to compress air into the esophagus and expel it, setting off a vibration of the pharyngeal esophageal segment. The technique can be taught once the patient begins oral feedings, approximately 1 week after surgery. First, the patient

learns to belch and is reminded to do so an hour after eating. Then the technique is practiced repeatedly. Later, this conscious belching action is transformed into simple explosions of air from the esophagus for speech purposes. Thereafter, the speech therapist works with the patient in an attempt to make speech intelligible and as close to normal as possible. Because it takes a long time to become proficient, the success rate is low.

**Electric Larynx.** If esophageal speech is not successful, or until the patient masters the technique, an electric larynx may be used for communication. This battery-powered apparatus projects sound into the oral cavity. When the mouth forms words (articulated), the sounds from the electric larynx become audible words. The voice that is produced sounds mechanical, and some words may be difficult to distinguish. The advantage is that the patient is able to communicate with relative ease while working to become proficient at either esophageal or tracheoesophageal puncture speech.

**Tracheoesophageal Puncture.** The third technique of alaryngeal speech is tracheoesophageal puncture (Fig. 22-6). This technique is the most widely used because the speech associated with it most resembles normal speech (the sound produced is a combination of esophageal speech and voice), and it is easily learned. A valve is placed in the tracheal stoma to divert air into the esophagus and out of the mouth. Once the puncture is surgically created and has healed, a voice prosthesis (Blom–Singer) is fitted over the puncture site. To prevent airway obstruction, the prosthesis is removed and cleaned when mucus builds up. A speech therapist teaches the patient how to produce sounds. Moving the tongue and lips to form the sound into words produces speech as before. Tracheoesophageal speech is successful in 80% to 90% of patients (DeLisa & Gans, 1998).

**FIGURE 22-6** Schematic representation of tracheoesophageal puncture speech (TEP). Air travels from the lung through a puncture in the posterior wall of the trachea into the esophagus and out the mouth. A voice prosthesis is fitted over the puncture site.

## NURSING PROCESS: THE PATIENT UNDERGOING LARYNGECTOMY

### Assessment

The nurse assesses the patient for the following symptoms: hoarseness, sore throat, dyspnea, dysphagia, or pain and burning in the throat. The neck is palpated for swelling.

If treatment includes surgery, the nurse must know the nature of the surgery to plan appropriate care. If the patient is expected to have no voice, a preoperative evaluation by the speech therapist is indicated. The patient's ability to hear, see, read, and write is assessed. Visual impairment and functional illiteracy may create additional problems with communication and require creative approaches to ensure that the patient is able to communicate any needs.

In addition, the nurse determines the psychological readiness of the patient and family. The idea of cancer is terrifying to most people. Fear is compounded by the possibility of permanently losing one's voice and, in some cases, of having some degree of disfigurement. The nurse evaluates the patient's and family's coping methods to support them effectively both preoperatively and postoperatively.

### Diagnosis

#### NURSING DIAGNOSES

Based on all the assessment data, major nursing diagnoses may include the following:

- Deficient knowledge about the surgical procedure and postoperative course
- Anxiety and depression related to the diagnosis of cancer and impending surgery
- Ineffective airway clearance related to excess mucus production secondary to surgical alterations in the airway
- Impaired verbal communication related to anatomic deficit secondary to removal of the larynx and to edema
- Imbalanced nutrition: less than body requirements, related to inability to ingest food secondary to swallowing difficulties
- Disturbed body image and low self-esteem secondary to major neck surgery, change in the structure and function of the larynx
- Self-care deficit related to pain, weakness, fatigue, musculoskeletal impairment related to surgical procedure and postoperative course

#### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on assessment data, potential complications that may develop include:

- Respiratory distress (hypoxia, airway obstruction, tracheal edema)
- Hemorrhage
- Infection
- Wound breakdown

### Planning and Goals

The major goals for the patient may include attainment of an adequate level of knowledge, reduction in anxiety, maintenance of a patent airway (patient is able to handle own secretions), effec-

tive use of alternative means of communication, attainment of optimal levels of nutrition and hydration, improvement in body image and self-esteem, improved self-care management, and absence of complications.

## Nursing Interventions

### TEACHING THE PATIENT PREOPERATIVELY

The diagnosis of laryngeal cancer is associated with misconceptions and fears. Many people assume that loss of speech and disfigurement are inevitable with this condition. Once the physician explains the diagnosis to the patient, the nurse clarifies any misconceptions by identifying the location of the larynx, its function, the nature of the surgical procedure, and its effect on speech. Informational materials (written and audiovisual) about the surgery are given to the patient and family for review and reinforcement.

If a complete laryngectomy is planned, the patient should know that the natural voice will be lost, but that special training can provide a means for communicating. However, the ability to sing, laugh, or whistle will be lost. Until this training is initiated, the patient needs to know that communication will be possible by using the call light or special communication board and by writing. The nurse answers questions about the nature of the surgery and reinforces the physician's explanation that the patient will lose the ability to vocalize, but that a rehabilitation program is available. The multidisciplinary team conducts an initial assessment of the patient and family. The team might include the nurse, physician, respiratory therapist, speech therapist, clinical nurse specialist, social worker, dietitian, and home care nurse.

Next, the nurse reviews equipment and treatments for postoperative care with the patient and family, teaches important coughing and deep-breathing exercises, and assists the patient to perform a return demonstration. The nurse clarifies the patient's role in the postoperative and rehabilitation periods.

### REDUCING ANXIETY AND DEPRESSION

Because surgery of the larynx is performed most commonly for a malignant tumor, the patient may have many questions: Will the surgeon be able to remove all of the tumor? Is it cancer? Will I die? Will I choke? Will I suffocate? Will I ever speak again? What will I look like? The psychological preparation of the patient is as important as the physical preparation.

Any patient undergoing surgery may have many fears. In laryngeal surgery, these fears may relate to the diagnosis of cancer and may be compounded by the possibility of permanent loss of the voice and disfigurement. The nurse provides the patient and family with opportunities to ask questions, verbalize feelings, and discuss perceptions. It is important to address any questions and misconceptions the patient and family have. During the preoperative or postoperative period, a visit from someone who has had a laryngectomy may reassure the patient that people are available to help and that rehabilitation is possible.

### MAINTAINING A PATENT AIRWAY

The nurse promotes a patent airway by positioning the patient in the semi-Fowler's or Fowler's position after recovery from anesthesia. Observing the patient for restlessness, labored breathing, apprehension, and increased pulse rate helps the nurse identify possible respiratory or circulatory problems. Medications that depress respiration, particularly opioids, should be used cautiously. As with other surgical patients, the nurse encourages the laryngectomy patient to turn, cough, and take deep breaths. If necessary, suctioning may be performed to remove secretions. The

nurse also encourages and assists the patient with early ambulation to prevent atelectasis and pneumonia.

If a total laryngectomy was performed, a laryngectomy tube will most likely be in place. (In some instances a laryngectomy tube is not used; in others it is used temporarily, and in many it is used permanently.) The laryngectomy tube, which is shorter than a tracheostomy tube but has a larger diameter, is the patient's only airway. The care of this tube is the same as for a tracheostomy tube (see Chap. 25). The nurse cleans the stoma daily with saline solution or another prescribed solution. If a non-oil-based antibiotic ointment is prescribed, the nurse applies it around the stoma and suture line. If crusting appears around the stoma, the nurse removes the crusts with sterile tweezers and applies additional ointment.

Wound drains may be in place to assist in removal of fluid and air from the surgical site. Suction also may be used, but cautiously, to avoid trauma to the surgical site and incision. The nurse observes, measures, and records drainage. When drainage is less than 50 to 60 mL/day, the physician usually removes the drains.

Frequently, the patient coughs up large amounts of mucus through this opening. Because air passes directly into the trachea without being warmed and moistened by the upper respiratory mucosa, the tracheobronchial tree compensates by secreting excessive amounts of mucus. Therefore, the patient will have frequent coughing episodes and may develop a brassy-sounding, mucus-producing cough. The nurse should reassure the patient that these problems will diminish in time as the tracheobronchial mucosa adapts to the altered physiology.

After the patient coughs, the tracheostomy opening must be wiped clean and clear of mucus. A simple gauze dressing, washcloth, or even paper towel (because of its size and absorbency) worn below the tracheostomy may serve as a barrier to protect the clothing from the copious mucus that the patient may expel initially.

One of the most important factors in decreasing cough, mucus production, and crusting around the stoma is adequate humidification of the environment. Mechanical humidifiers and aerosol generators (nebulizers) increase the humidity and are important for the patient's comfort.

The laryngectomy tube may be removed when the stoma is well healed, within 3 to 6 weeks after surgery. The nurse can teach the patient how to clean and change the tube (see Chap. 25) and remove secretions.

### PROMOTING ALTERNATIVE COMMUNICATION METHODS

Understanding the patient's postoperative needs is critical. Alternative means of communication are established and used consistently by all personnel who come in contact with the patient—for example, a call bell or hand bell may be placed within easy reach of the patient. Because a Magic Slate often is used for communication, the nurse should document which hand the patient uses for writing so that the opposite arm can be used for intravenous infusions. (The nurse should discard any old notes used for communication to ensure the patient's privacy.) If the patient cannot write, a picture-word-phrase board or hand signals can be used. Preoperatively, the nurse reviews the system of communication to be used postoperatively with the patient.

Because it is very time-consuming to have to write everything or communicate through gestures, the inability to speak can be very frustrating. The patient may become impatient and angry when not understood. In such cases, other staff members need to be alert to the problem and also recognize that the patient will be unable to use the intercom system.

The return of communication is generally the ultimate goal in the rehabilitation of the laryngectomy patient. The nurse works with the patient, speech therapist, and family to encourage use of alternative communication methods.

### PROMOTING ADEQUATE NUTRITION

Postoperatively, the patient may not be permitted to eat or drink for 10 to 14 days. Alternative sources of nutrition and hydration include intravenous fluids, enteral feedings through a nasogastric tube, and parenteral nutrition.

Once the patient is ready to start oral feedings, the nurse explains that thick liquids will be used first because they are easy to swallow. The nurse instructs the patient to avoid sweet foods, which increase salivation and suppress the appetite. Solid foods are introduced as tolerated. The nurse instructs the patient to rinse the mouth with warm water or mouthwash and to brush the teeth frequently.

The patient can expect to have a diminished sense of taste and smell for a period of time after surgery. Inhaled air passes directly into the trachea, bypassing the nose and the olfactory end organs. Because taste and smell are so closely connected, taste sensations are altered. In time, however, the patient usually accommodates to this problem and olfactory sensation adapts, often with return of interest in eating. The nurse observes the patient for any difficulty swallowing, particularly when eating resumes, and reports its occurrence to the physician.

### PROMOTING POSITIVE BODY IMAGE AND SELF-ESTEEM

Disfiguring surgery and an altered communication pattern are a threat to a patient's body image and self-esteem. The reaction of family members and friends is a major concern for the patient. The nurse encourages the patient to express any feelings about the changes brought about by surgery, particularly those related to fear, anger, depression, and isolation.

A positive approach is important when caring for the patient. Promoting self-care activities is part of this approach. It is important for the patient and family to begin participating in self-care activities as soon as possible. The nurse needs to be a good listener and a support to the family, especially when explaining the tubes, dressings, and drains that are in place postoperatively. Referral to a support group, such as Lost Chord or New Voice clubs (through the International Association of Laryngectomees) and I Can Cope (through the American Cancer Society), may help the patient and family deal with the changes in their lives. Groups such as Lost Chord and New Voice promote and support the rehabilitation of people who have had a laryngectomy by providing an opportunity for exchanging ideas and sharing information.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

The immediate potential complications after laryngectomy include respiratory distress and hypoxia, hemorrhage, infection, and wound breakdown.

#### Respiratory Distress and Hypoxia

The nurse monitors the patient for signs and symptoms of respiratory distress and hypoxia, particularly restlessness, irritation, agitation, confusion, tachypnea, use of accessory muscles, and decreased oxygen saturation on pulse oximetry ( $SpO_2$ ). Any change in the respiratory status requires immediate intervention. Obstruction needs to be ruled out immediately by suctioning and having the patient cough and breathe deeply. Hypoxia and airway obstruction, if not immediately treated, are life-threatening.

The nurse contacts the physician immediately if nursing measures do not improve the patient's respiratory status.

#### Hemorrhage

Bleeding at the surgical site from the drains or with tracheal suctioning may signal the occurrence of hemorrhage. The nurse should notify the surgeon of any active bleeding immediately. Bleeding may occur at a variety of sites, including the surgical site, drains, or trachea. Rupture of the carotid artery is especially dangerous. Should this occur, the nurse should apply direct pressure over the artery, summon assistance, and provide emotional support to the patient until the vessel can be ligated. It is important to monitor vital signs for changes, particularly increased pulse rate, decreased blood pressure, and rapid deep respirations. Cold, clammy, pale skin may indicate active bleeding.

#### Infection

The nurse observes for postoperative infection. Early signs of infection include an increase in temperature and pulse, a change in the type of wound drainage, or increased areas of redness or tenderness at the surgical site. Other signs include purulent drainage, odor, and increased wound drainage. The nurse reports any significant change to the surgeon.

#### Wound Breakdown

Wound breakdown due to infection, poor wound healing, or development of a fistula or as a result of radiation therapy or tumor growth can create a life-threatening emergency. The carotid artery, which is close to the stoma, may rupture from erosion if the wound does not heal properly. The nurse observes the stoma area for wound breakdown, hematoma, and bleeding and reports any significant changes to the surgeon. If wound breakdown occurs, the patient must be monitored carefully and identified as being at high risk for carotid hemorrhage.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

The nurse has an important role in the recovery and rehabilitation of the laryngectomy patient. In an effort to facilitate the patient's ability to manage self-care, discharge instruction begins as soon as the patient is able to participate. Nursing care and patient teaching in the hospital, outpatient setting, and rehabilitation or long-term care facility must take into consideration the many emotions, physical changes, and lifestyle changes experienced by the patient. In preparing the patient to go home, the nurse assesses the patient's readiness to learn and the level of knowledge about self-care management. The nurse also reassures the patient and family that most self-care management strategies can be mastered. The patient will need to learn a variety of self-care behaviors, including tracheostomy and stoma care, wound care, and oral hygiene. In addition, the nurse instructs the patient about the need for safe hygiene and recreational activities.

**Tracheostomy and Stoma Care.** The nurse provides specific instructions to the patient and family about what to expect from the tracheostomy and its management. The nurse teaches the patient and family caregiver to perform suctioning and emergency measures and tracheostomy and stoma care. The nurse stresses the importance of humidification at home and instructs the family to set up a humidification system before the patient returns home. In addition, the nurse cautions the patient and family that air-conditioned air may be too cool or too dry, and thus too irritating, for the patient with a new laryngectomy. (See Chap. 25 for details about tracheostomy care.)

**Hygiene and Safety Measures.** The nurse instructs the patient and family about safety precautions needed because of the structural changes resulting from the surgery. Special precautions are needed in the shower to prevent water from entering the stoma. Wearing a loose-fitting plastic bib over the tracheostomy or simply holding the hand over the opening is effective. Swimming is not recommended, however, because people with a laryngectomy can drown without getting their face wet. Barbers and beauticians need to be alerted so that hair sprays, loose hair, and powder do not get near the stoma, because they can block or irritate the trachea and possibly cause infection. These self-care points are summarized in Chart 22-8.

Recreation and exercise are important, and all but very strenuous exercise can be enjoyed safely. Avoidance of strenuous exercise and fatigue is important because, when tired, the patient has more difficulty speaking, which can be discouraging. Additional safety points to address include the need for the patient to wear or carry medical identification, such as a bracelet or card, to alert medical personnel to the special requirements for resuscitation should this need arise. When resuscitation is needed, direct mouth-to-stoma ventilation should be performed. For home emergency situations, prerecorded emergency messages for police, the fire department, or other rescue services can be kept near the phone to be used quickly.

The nurse instructs and encourages the patient to perform oral care on a regular basis to prevent halitosis and infection. If the patient is receiving radiation therapy, there will be a decrease in saliva, and synthetic saliva may be required. The nurse instructs the patient to drink water or sugar-free liquids throughout the day and to use a humidifier at home. Brushing the teeth or dentures and rinsing the mouth several times a day will assist in maintaining proper oral hygiene.

### Continuing Care

Referral for home care is an important aspect of postoperative care for the patient who has had a laryngectomy and will assist the patient and family in the transition to the home. The home care nurse assesses the patient's general health status and the ability of the patient and family to care for the stoma and tracheostomy.

The nurse assesses the surgical incisions, nutritional and respiratory status, and adequacy of pain management. The nurse assesses not only for signs and symptoms of complications but also for the patient's and family's knowledge of which signs and symptoms to report to the physician. During the home visit, the nurse identifies and addresses other learning needs of the patient and family, such as adaptation to physical, lifestyle, and functional changes. It is important to assess the patient's psychological status as well. The home care nurse reinforces previous teaching and provides reassurance and support to the patient and family as needed.

The nurse encourages the person who has had a laryngectomy to have regular physical examinations and to seek advice concerning any problems related to recovery and rehabilitation. The patient is also reminded to participate in health promotion activities and health screening and about the importance of keeping scheduled appointments with the physician, speech therapist, and other health care providers.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Acquires an adequate level of knowledge, verbalizing an understanding of the surgical procedure and performing self-care adequately
2. Demonstrates less anxiety and depression
  - a. Expresses a sense of hope
  - b. Is aware of available community organizations and agencies such as the Lost Chord or New Voice groups
  - c. Participates in support group, such as I Can Cope
3. Maintains a clear airway and handles own secretions; also demonstrates practical, safe, and correct technique for cleaning and changing the laryngectomy tube
4. Acquires effective communication techniques
  - a. Uses assistive devices and strategies for communication (Magic Slate, call bell, picture board, sign language, lip reading, computer aids)
  - b. Follows the recommendations of the speech therapist

Chart 22-8

#### Home Care Checklist • The Patient With a Laryngectomy

*At the completion of the home care instruction, the patient or caregiver will be able to:*

	Patient	Caregiver
• Demonstrate methods to clear the airway and handle secretions	✓	✓
• Explain the rationale for maintaining adequate humidification with a humidifier or nebulizer	✓	✓
• Demonstrate how to clean the skin around the stoma and how to use ointments and tweezers to remove encrustations	✓	✓
• State the rationale for wearing a loose-fitting protective cloth at the stoma	✓	✓
• Discuss the need to avoid cold air from air conditioning and the environment to prevent irritation of the airway	✓	✓
• Demonstrate safe technique in changing the laryngectomy tube	✓	✓
• Identify the signs and symptoms of wound infection and state what to do about them	✓	✓
• Describe safety or emergency measures to implement in case of breathing difficulty or bleeding	✓	✓
• State the rationale for wearing or carrying special medical identification and ways to obtain help in an emergency	✓	✓
• Explain the importance of covering the stoma when showering or bathing	✓	✓
• Identify fluid and caloric needs	✓	✓
• Describe mouth care and discuss its importance	✓	✓
• Demonstrate alternative communication methods	✓	✓
• Identify support groups and agency resources	✓	✓
• State the need for regular check-ups and reporting of any problems immediately	✓	✓

5. Maintains balanced nutrition and adequate fluid intake
6. Exhibits improved body image, self-esteem, and self-concept
  - a. Expresses feelings and concerns
  - b. Participates in self-care and decision making
  - c. Accepts information about support group
7. Exhibits no complications
  - a. Vital signs (blood pressure, temperature, pulse, respiratory rate) normal
  - b. No redness, tenderness, or purulent drainage at surgical site
  - c. Demonstrates a patent airway and appropriate respirations
  - d. No bleeding from surgical site and minimal bleeding from drains
  - e. No wound breakdown
8. Adheres to rehabilitation and home care program
  - a. Practices recommended speech therapy
  - b. Demonstrates proper methods for caring for stoma and laryngectomy tube (if present)
  - c. Verbalizes understanding of symptoms that require medical attention
  - d. States safety measures to take in emergencies
  - e. Performs oral hygiene as prescribed

### Critical Thinking Exercises

1. A 36-year-old teacher is diagnosed with acute sinusitis. She has been self-medicating with over-the-counter medications for the past 2 weeks with no relief. What assessment and treatment should the nurse anticipate? What teaching and management strategies would you discuss with the patient? What is the rationale for your approach?
2. Your 68-year-old patient is scheduled for total laryngectomy for treatment of laryngeal cancer. What information would you provide to the patient about managing changes in breathing and speech that are expected in the immediate postoperative period and in the long term? What information would you provide to the patient's family?
3. You are making the first home visit to a patient who has just been discharged from the hospital following treatment for pneumonia and a 60-lb weight loss. He had a laryngectomy 8 months ago to treat laryngeal cancer. What will be the focus of your initial home visit? What aspects of assessment and nursing management are key at this point in caring for this patient? How would you assist this patient and his family to plan his care for the next month? Next 6 months?
4. Your patient, age 36, has been admitted to the emergency department with profuse epistaxis following a car crash. He tells you that he has hemophilia and is HIV-positive as a result of repeated use of clotting factors. What are the initial measures you would use to stop the bleeding? What other options are available if the bleeding does not stop within a reasonable period? How will his HIV status and the diagnosis of hemophilia affect your plan of care for him?

# ● Management of Patients With Chest and Lower Respiratory Tract Disorders

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Identify patients at risk for atelectasis and nursing interventions related to its prevention and management.
2. Compare the various pulmonary infections with regard to causes, clinical manifestations, nursing management, complications, and prevention.
3. Use the nursing process as a framework for care of the patient with pneumonia.
4. Relate pleurisy, pleural effusion, and empyema to pulmonary infection.
5. Describe smoking and air pollution as causes of pulmonary disease.
6. Relate the therapeutic management techniques of acute respiratory distress syndrome to the underlying pathophysiology of the syndrome.
7. Describe risk factors for and measures appropriate for prevention and management of pulmonary embolism.
8. Describe preventive measures appropriate for controlling and eliminating the problem of occupational lung disease.
9. Discuss the modes of therapy and related nursing management for patients with lung cancer.
10. Describe the complications of chest trauma and their clinical manifestations and nursing management.
11. Describe nursing measures to prevent aspiration.

Conditions affecting the lower respiratory tract range from acute problems to long-term chronic disorders. Many of these disorders are serious and often life-threatening. The patient with a lower respiratory tract disorder requires care from nurses with astute assessment and clinical management skills as well as an understanding of the impact of the disorder on the patient's quality of life and ability to carry out usual activities of daily living. Patient and family teaching is an important nursing intervention in the management of all lower respiratory tract disorders.

## Atelectasis

**Atelectasis** refers to closure or collapse of alveoli and often is described in relation to x-ray findings and clinical signs and symptoms. Atelectasis may be acute or chronic and may cover a broad range of pathophysiologic changes, from microatelectasis (which is not detectable on chest x-ray) to macroatelectasis with loss of segmental, lobar, or overall lung volume. The most commonly described atelectasis is acute atelectasis, which occurs frequently in the postoperative setting or in people who are immobilized and have a shallow, monotonous breathing pattern. Excess secretions or mucus plugs may also cause obstruction of airflow and result in atelectasis in an area of the lung. Atelectasis also is observed in patients with a chronic airway obstruction that impedes or blocks air flow to an area of the lung (eg, obstructive atelectasis in the patient with lung cancer that is invading or compressing the airways). This type of atelectasis is more insidious and slower in onset.

## Pathophysiology

Atelectasis may occur in the adult as a result of reduced alveolar ventilation or any type of blockage that impedes the passage of air to and from the alveoli that normally receive air through the

bronchi and network of airways. The trapped alveolar air becomes absorbed into the bloodstream, but outside air cannot replace the absorbed air because of the blockage. As a result, the isolated portion of the lung becomes airless and the alveoli collapse. This may occur with altered breathing patterns, retained secretions, pain, alterations in small airway function, prolonged supine positioning, increased abdominal pressure, reduced lung volumes due to musculoskeletal or neurologic disorders, restrictive defects, and specific surgical procedures (eg, upper abdominal, thoracic, or open heart surgery). Persistent low lung volumes, secretions or a mass obstructing or impeding airflow, and compression of lung tissue may all cause collapse or obstruction of the airways, which leads to atelectasis.

The postoperative patient is at high risk for atelectasis because of the numerous respiratory changes that may occur. A monotonous low tidal breathing pattern may cause airway closure and alveolar collapse. This results from the effects of anesthesia or analgesic agents, supine positioning, splinting of the chest wall because of pain, and abdominal distention. The postoperative patient may also have secretion retention, airway obstruction, and an impaired cough reflex or may be reluctant to cough because of pain. Figure 23-1 shows the pathogenic mechanisms and consequences of acute atelectasis in the postoperative patient.

Atelectasis resulting from bronchial obstruction by secretions may occur in patients with impaired cough mechanisms (eg, postoperative, musculoskeletal or neurologic disorders) or in debilitated, bedridden patients. Atelectasis may also result from excessive pressure on the lung tissue, which restricts normal lung expansion on inspiration. Such pressure may be produced by fluid accumulating within the pleural space (**pleural effusion**), air in the pleural space (**pneumothorax**), or blood in the pleural space (**hemothorax**). The **pleural space** is the area between the parietal and the visceral pleurae. Pressure may also be produced

## Glossary

### acute respiratory distress syndrome

(ARDS): nonspecific pulmonary response to a variety of pulmonary and non-pulmonary insults to the lung; characterized by interstitial infiltrates, alveolar hemorrhage, atelectasis, decreased compliance, and refractory hypoxemia

**asbestosis:** diffuse lung fibrosis resulting from exposure to asbestos fibers

**atelectasis:** collapse or airless condition of the alveoli caused by hypoventilation, obstruction to the airways, or compression

**central cyanosis:** bluish discoloration of the skin or mucous membranes due to hemoglobin carrying reduced amounts of oxygen

**consolidation:** lung tissue that has become more solid in nature due to collapse of alveoli or infectious process (pneumonia)

**cor pulmonale:** "heart of the lungs"; enlargement of the right ventricle from hypertrophy or dilation or as a secondary response to disorders that affect the lungs

**empyema:** accumulation of purulent material in the pleural space

**fine-needle aspiration:** insertion of a needle through the chest wall to obtain cells of a mass or tumor; usually performed under fluoroscopy or chest CT guidance

**hemoptysis:** the coughing up of blood from the lower respiratory tract

**hemothorax:** partial or complete collapse of the lung due to blood accumulating in the pleural space; may occur after surgery or trauma

**induration:** an abnormally hard lesion or reaction, as in a positive tuberculin skin test

**nosocomial:** pertaining to or originating from a hospitalization; not present at the time of hospital admission

**open lung biopsy:** biopsy of lung tissue performed through a limited thoracotomy incision

**orthopnea:** shortness of breath when reclining or in the supine position

**pleural effusion:** abnormal accumulation of fluid in the pleural space

**pleural friction rub:** localized grating or creaking sound caused by the rubbing together of inflamed parietal and visceral pleurae

**pleural space:** the area between the parietal and visceral pleurae; a potential space

**pneumothorax:** partial or complete collapse of the lung due to positive pressure in the pleural space

**pulmonary edema:** increase in the amount of extravascular fluid in the lung

**pulmonary embolism:** obstruction of the pulmonary vasculature with an embolus; embolus may be due to blood clot, air bubbles, or fat droplets

**purulent:** consisting of, containing, or discharging pus

**restrictive lung disease:** disease of the lung that causes a decrease in lung volumes

**tension pneumothorax:** pneumothorax characterized by increasing positive pressure in the pleural space with each breath; this is an emergency situation and the positive pressure needs to be decompressed or released immediately

**thoracentesis:** insertion of a needle into the pleural space to remove fluid that has accumulated and decrease pressure on the lung tissue; may also be used diagnostically to identify potential causes of a pleural effusion

**transbronchial:** through the bronchial wall, as in a transbronchial lung biopsy

**ventilation-perfusion ratio:** the ratio between ventilation and perfusion in the lung; matching of ventilation to perfusion optimizes gas exchange

## Physiology/Pathophysiology

**FIGURE 23-1** Relationship of risk factors, pathogenic mechanisms, and consequences of acute atelectasis in the post-operative patient. COPD, chronic obstructive pulmonary disease; BMI, body mass index; FRC, functional residual capacity; diaphragm fx, diaphragm function; ASA, American Society of Anesthesiology physical status;  $\dot{V}/\dot{Q}$ , ventilation-perfusion ratio. From the work of Jo Ann Brooks-Brunn, DNS, RN, FAAN, FCCP, Indiana University Medical Center, Indianapolis.

by a pericardium distended with fluid (pericardial effusion), tumor growth within the thorax, or an elevated diaphragm.

### Clinical Manifestations

The development of atelectasis usually is insidious. Signs and symptoms include cough, sputum production, and low-grade fever. Fever is universally cited as a clinical sign of atelectasis, but there are few data to support this. Most likely the fever that accompanies atelectasis is due to infection or inflammation distal to the obstructed airway.

In acute atelectasis involving a large amount of lung tissue (lobar atelectasis), marked respiratory distress may be observed. In addition to the above signs and symptoms, dyspnea, tachycar-

dia, tachypnea, pleural pain, and **central cyanosis** (a bluish skin hue that is a late sign of hypoxemia) may be anticipated. The patient characteristically has difficulty breathing in the supine position and is anxious. Signs and symptoms of chronic atelectasis are similar to those of acute atelectasis. Because the alveolar collapse is chronic, infection may occur distal to the obstruction. Thus, the signs and symptoms of a pulmonary infection also may be present.

### Assessment and Diagnostic Findings

Decreased breath sounds and crackles are heard over the affected area. In addition, chest x-ray findings may reveal patchy infiltrates or consolidated areas. In the patient who is confined to bed,

atelectasis is usually diagnosed by chest x-ray or identified by physical assessment in the dependent, posterior, basilar areas of the lungs. Depending on the degree of hypoxemia, pulse oximetry (SpO<sub>2</sub>) may demonstrate a low saturation of hemoglobin with oxygen (less than 90%) or a lower-than-normal partial pressure of arterial oxygen (PaO<sub>2</sub>).

## Prevention

Nursing measures to prevent atelectasis include frequent turning, early mobilization, and strategies to expand the lungs and to manage secretions. Deep-breathing maneuvers (at least every 2 hours) assist in preventing and treating atelectasis. The performance of these maneuvers requires a patient who is alert and cooperative. Patient education and reinforcement are key to the success of these interventions. The use of incentive spirometry or voluntary deep breathing enhances lung expansion, decreases the potential for airway closure, and may generate a cough. Secretion management techniques may include directed cough, suctioning, aerosol nebulizer treatments followed by chest physical therapy (postural drainage and chest percussion), or bronchoscopy. In some settings, a metered-dose inhaler (MDI) is used to dispense a bronchodilator rather than an aerosol nebulizer treatment. Chart 23-1 summarizes measures to prevent atelectasis.

## Management

The goal in treating the patient with atelectasis is to improve ventilation and remove secretions. The strategies to prevent atelectasis, which include frequent turning, early ambulation, lung volume expansion maneuvers (eg, deep-breathing exercises, incentive spirometry), and coughing also serve as the first-line measures to minimize or treat atelectasis by improving ventilation. In patients who do not respond to first-line measures or who cannot perform deep-breathing exercises, other treatments such as positive expiratory pressure or PEP therapy (a simple mask and one-way valve system that provides varying amounts of expiratory resistance [usually 5 to 15 cm H<sub>2</sub>O]), continuous or intermittent positive pressure-breathing (IPPB), or bronchoscopy may be used. Although IPPB may be used in some settings, few data support its use in the postoperative setting (Duffy & Farley, 1993). Before initiating more complex, costly, and labor-intensive therapies, the nurse should ask several questions:

- Has the patient been given an adequate trial of deep-breathing exercises?

- Has the patient received adequate education, supervision, and coaching to carry out the deep-breathing exercises?
- Have other factors been evaluated that may impair ventilation or prohibit a good patient effort (eg, lack of turning, mobilization; excessive pain; excessive sedation)?

If the cause of atelectasis is bronchial obstruction from secretions, the secretions must be removed by coughing or suctioning to permit air to re-enter that portion of the lung. Chest physical therapy (chest percussion and postural drainage) may also be used to mobilize secretions. Nebulizer treatments with a bronchodilator medication or sodium bicarbonate may be used to assist the patient in the expectoration of secretions. If respiratory care measures fail to remove the obstruction, a bronchoscopy is performed. Severe or massive atelectasis may lead to acute respiratory failure, especially in a patient with underlying lung disease. Endotracheal intubation and mechanical ventilation may be necessary. Prompt treatment reduces the risk for acute respiratory failure or pneumonia.

If atelectasis has resulted from compression of lung tissue, the goal is to decrease the compression. With a large pleural effusion that is compressing lung tissue and causing alveolar collapse, treatment may include **thoracentesis**, removal of the fluid by needle aspiration, or insertion of a chest tube. The measures to increase lung expansion described above also are used.

Management of chronic atelectasis focuses on removing the cause of the obstruction of the airways or the compression of the lung tissue. For example, bronchoscopy may be used to open an airway obstructed by lung cancer or a nonmalignant lesion, and the procedure may involve cryotherapy or laser therapy. The goal is to reopen the airways and provide ventilation to the collapsed area. In some cases, surgical management may be indicated.

## Respiratory Infections

### ACUTE TRACHEOBRONCHITIS

Acute tracheobronchitis, an acute inflammation of the mucous membranes of the trachea and the bronchial tree, often follows infection of the upper respiratory tract. A patient with a viral infection has decreased resistance and can readily develop a secondary bacterial infection. Thus, adequate treatment of upper respiratory tract infection is one of the major factors in the prevention of acute bronchitis. Aside from infection, inhalation of physical and chemical irritants, gases, and other air contaminants can also cause acute bronchial irritation.

### Pathophysiology

In acute tracheobronchitis, the inflamed mucosa of the bronchi produces mucopurulent sputum, often in response to *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Mycoplasma pneumoniae*. In addition, a fungal infection (eg, *Aspergillus* tracheobronchitis) may also cause tracheobronchitis. A sputum culture is essential to identify the specific causative organism.

### Clinical Manifestations

Initially, the patient has a dry, irritating cough and expectorates a scanty amount of mucoid sputum. The patient complains of sternal soreness from coughing and has fever or chills and night sweats, headache, and general malaise. As the infection progresses, the patient may be short of breath, have noisy inspiration and expiration (inspiratory stridor and expiratory wheeze), and

Chart  
23-1

### Preventing Atelectasis

- Change patient's position frequently, especially from supine to upright position, to promote ventilation and prevent secretions from accumulating.
- Encourage early mobilization from bed to chair followed by early ambulation.
- Encourage appropriate deep breathing and coughing to mobilize secretions and prevent them from accumulating.
- Teach/reinforce appropriate technique for incentive spirometry.
- Administer prescribed opioids and sedatives judiciously to prevent respiratory depression.
- Perform postural drainage and chest percussion, if indicated.
- Institute suctioning to remove tracheobronchial secretions, if indicated.

produce **purulent** (pus-filled) sputum. With severe tracheobronchitis, blood-streaked secretions may be expectorated as a result of the irritation of the mucosa of the airways.

## Medical Management

Antibiotic treatment may be indicated depending on the symptoms, sputum purulence, and results of the sputum culture. Antihistamines are usually not prescribed because they may cause excessive drying and make secretions more difficult to expectorate. Expectorants may be prescribed, although their efficacy is questionable. Fluid intake is increased to thin the viscous and tenacious secretions. Copious, purulent secretions that cannot be cleared by coughing place the patient at risk for increasing airway obstruction and the development of a more severe lower respiratory tract infection, such as pneumonia. Suctioning and bronchoscopy may be needed to remove secretions. Rarely, endotracheal intubation may be required in cases of acute tracheobronchitis leading to acute respiratory failure. This may be necessary for patients who are severely debilitated or who have coexisting diseases that also impair the respiratory system.

In most cases, treatment of tracheobronchitis is largely symptomatic. The patient is advised to rest. Increasing the vapor pressure (moisture content) in the air will reduce irritation. Cool vapor therapy or steam inhalations may help relieve laryngeal and tracheal irritation. Moist heat to the chest may relieve the soreness and pain. Mild analgesics or antipyretics may be indicated.

## Nursing Management

Acute tracheobronchitis is frequently treated in the home setting. A primary nursing function is to encourage bronchial hygiene, such as increasing fluid intake and directed coughing to remove secretions. The nurse should encourage and assist the patient to sit up frequently to cough effectively and to prevent retention of mucopurulent sputum. If the patient is treated with antibiotics for an underlying infection, it is important to emphasize the need to complete the full course of antibiotics prescribed. Fatigue is a consequence of tracheobronchitis; therefore, the nurse must caution the patient against overexertion, which can induce a relapse or exacerbation of the infection.

## PNEUMONIA

Pneumonia is an inflammation of the lung parenchyma that is caused by a microbial agent. “Pneumonitis” is a more general term that describes an inflammatory process in the lung tissue that may predispose a patient to or place a patient at risk for microbial invasion. Pneumonia is the most common cause of death from infectious diseases in the United States. It is the seventh leading cause of death in the United States for all ages and both genders, resulting in almost 70,000 deaths per year. In persons 65 years of age and older, it is the fifth leading cause of death (National Center for Health Statistics, 2000; Minino & Smith, 2001). It is treated extensively on both an inpatient and outpatient basis.

Bacteria commonly enter the lower airway but do not cause pneumonia in the presence of an intact host defense mechanism. When pneumonia does occur, it is caused by various microorganisms, including bacteria, mycobacteria, chlamydiae, mycoplasma, fungi, parasites, and viruses. Several systems are used to classify pneumonias. Classically, pneumonia has been categorized into one of four categories: bacterial or typical, atypical, anaerobic/cavitary, and opportunistic. However, there is overlap in the microorganisms thought to be responsible for typical and atypical pneu-

monias. A more widely used classification scheme categorizes the major pneumonias as community-acquired pneumonia, hospital-acquired pneumonia, pneumonia in the immunocompromised host, and aspiration pneumonia (Table 23-1). There is overlap in how specific pneumonias are classified because they may occur in differing settings.

Community-acquired pneumonia (CAP) occurs either in the community setting or within the first 48 hours of hospitalization or institutionalization. The need for hospitalization for CAP depends on the severity of the pneumonia. The agents that most frequently cause CAP requiring hospitalization are *S. pneumoniae*, *H. influenzae*, *Legionella*, *Pseudomonas aeruginosa*, and other gram-negative rods. The specific etiologic agent of CAP is identified in about 50% of the cases. The absence of a responsible caregiver in the home may be another indication for hospitalization. More than 5.5 million people develop CAP and as many as 1.1 million require hospitalization each year (Centers for Disease Control and Prevention [CDC], 1997; Marston, Plouffe, File et al., 1997).

Pneumonia caused by *S. pneumoniae* (pneumococcus) is the most common CAP in people younger than 60 without comorbidity and in those older than 60 with comorbidity. It is most prevalent during the winter and spring, when upper respiratory tract infections are most frequent. *S. pneumoniae* is a gram-positive, capsulated, nonmotile coccus that resides naturally in the upper respiratory tract. The organism colonizes the upper respiratory tract and can cause the following types of illnesses: disseminated invasive infections, pneumonia and other lower respiratory tract infections, and upper respiratory tract infections, including otitis media and sinusitis (CDC, 1998). It may occur as a lobar or bronchopneumonic form in patients of any age and may follow a recent respiratory illness.

Mycoplasma pneumonia, another type of CAP, occurs most often in older children and young adults and is spread by infected respiratory droplets through person-to-person contact. Patients can be tested for mycoplasma antibodies. The inflammatory infiltrate is primarily interstitial rather than alveolar. It spreads throughout the entire respiratory tract, including the bronchioles, and has the characteristics of a bronchopneumonia. Earache and bullous myringitis are common. Impaired ventilation and diffusion may occur.

*H. influenzae* is another cause of CAP. It frequently affects elderly people or those with comorbid illnesses (eg, chronic obstructive pulmonary disease [COPD], alcoholism, diabetes mellitus). The presentation of this pneumonia is indistinguishable from that of other forms of bacterial CAP. The presentation may be subacute, with cough or low-grade fever for weeks before diagnosis. Chest x-rays may reveal multilobar, patchy bronchopneumonia or areas of **consolidation** (tissue that solidifies as a result of collapsed alveoli or pneumonia).

Viruses are the most common cause of pneumonia in infants and children but are relatively uncommon causes of CAP in adults. The chief causes of viral pneumonia in the immunocompetent adult are influenza viruses types A and B, adenovirus, parainfluenza virus, coronavirus, and varicella-zoster virus. In immunocompromised adults, cytomegalovirus is the most common viral pathogen, followed by herpes simplex virus, adenovirus, and respiratory syncytial virus. The acute stage of a viral respiratory infection occurs within the ciliated cells of the airways. This is followed by infiltration of the tracheobronchial tree. With pneumonia, the inflammatory process extends into the alveolar area, resulting in edema and exudation. The clinical signs and symptoms of a viral pneumonia are often difficult to distinguish from those of a bacterial pneumonia.

(text continues on page 524)

Table 23-1 • Commonly Encountered Pneumonias

TYPE	ORGANISM RESPONSIBLE	EPIDEMIOLOGY	CLINICAL FEATURES	TREATMENT	COMMENTS
<b>Community-Acquired Pneumonia</b> Streptococcal pneumonia (pneumococcal)	<i>Streptococcus pneumoniae</i>	Highest occurrence in winter months. Incidence greatest in the elderly and in patients with COPD, heart failure, alcoholism, asplenia, following influenza. Leading infectious cause of illness worldwide among young children, persons with underlying chronic health conditions, and the elderly. Death occurs in 14% of hospitalized adults with invasive disease.	Abrupt onset, toxic appearance, pleuritic chest pain. Usually involves one or more lobes. Lobar infiltrate common on chest x-ray or bronchopneumonia pattern. Bacteremia in 15% to 25% of all patients.	Penicillins Alternate antibiotic therapy, such as cefotaxime or ceftriaxone; antipseudomonal fluoroquinolones (levofloxacin, gatifloxacin, moxifloxacin).	Complications include shock, pleural effusion, superinfections, pericarditis, and otitis media.
<i>Haemophilus influenzae</i>	<i>Haemophilus influenzae</i>	Incidence greatest in alcoholics, the elderly, patients in chronic care facilities and nursing homes, patients with diabetes or COPD, and children <5 years old. Accounts for 5% to 20% of community-acquired pneumonias. Mortality rate: 30%.	Frequently insidious onset associated with upper respiratory tract infection 2 to 6 weeks before onset of illness. Fever, chills, productive cough. Usually involves one or more lobes. Bacteremia is common. Infiltrate, occasional bronchopneumonia pattern on chest x-ray.	Ampicillin, 3rd-generation cephalosporin, macrolides (azithromycin, clarithromycin), fluoroquinolones	Complications include lung abscess, pleural effusion, meningitis, arthritis, pericarditis, epiglottitis.
Legionnaires' disease	<i>Legionella pneumophila</i>	Highest occurrence in summer and fall. May cause disease sporadically or as part of an epidemic. Incidence greatest in middle-aged and older men, smokers, and patients with chronic diseases, those receiving immunosuppressive therapy, or those in close proximity to excavation sites. Accounts for 15% of community-acquired pneumonias. Mortality rate: 15% to 50%.	Flulike symptoms. High fevers, mental confusion, headache, pleuritic pain, myalgias, dyspnea, productive cough, hemoptysis, leukocytosis. Bronchopneumonia, unilateral or bilateral disease, lobar consolidation.	Erythromycin +/- rifampin (in severely compromised patient) or clarithromycin, or a macrolide (azithromycin), or a fluoroquinolone (ofloxacin, levofloxacin, sparfloxacin).	Complications include hypotension, shock, and acute renal failure.

(continued)

Table 23-1 • Commonly Encountered Pneumonias (Continued)

TYPE	ORGANISM RESPONSIBLE	EPIDEMIOLOGY	CLINICAL FEATURES	TREATMENT	COMMENTS
<i>Mycoplasma pneumoniae</i>	<i>Mycoplasma pneumoniae</i>	Increase in fall and winter. Responsible for epidemics of respiratory illness. Most common type of atypical pneumonia. Accounts for 20% of community-acquired pneumonias. More common in children and young adults. Mortality rate: <0.1%.	Onset is usually insidious. Patients not usually as ill as in other pneumonias. Sore throat, nasal congestion, ear pain, headache, low-grade fever, pleuritic pain, myalgias, diarrhea, erythematous rash, pharyngitis. Interstitial infiltrates on chest x-ray.	Erythromycin; macrolide, fluoroquinolone or tetracycline.	Complications include aseptic meningitis, meningoencephalitis, transverse myelitis, cranial nerve palsies, pericarditis, myocarditis.
Viral pneumonia	Influenza viruses types A, B adenovirus, parainfluenza, cytomegalovirus, coronavirus	Incidence greatest in winter months. Epidemics occur every 2 to 3 years. Most common causative organisms in adults. Other organisms in children (eg, cytomegalovirus and respiratory syncytial virus). Accounts for 20% of community-acquired pneumonias.	Patchy infiltrate, small pleural effusion on chest x-ray. In majority of patients, influenza begins as an acute upper respiratory infection; others have bronchitis, pleurisy, etc., and still others develop gastrointestinal symptoms.	Amantadine; rimantadine; oseltamivir phosphate, ribavirin aerosol. Treated symptomatically. Does not respond to treatment with currently available antimicrobials.	Complications include a superimposed bacterial infection, bronchopneumonia.
Chlamydial pneumonia (TWAR agent)	<i>C. pneumoniae</i>	Reported mainly in college students, military recruits, and the elderly. May be a common cause of community-acquired pneumonia or observed in combination with other pathogens. Mortality rate is low as the majority of cases are relatively mild. The elderly with coexistent infections, comorbidities, and reinfections may require hospitalization.	Hoarseness, fever, chills, pharyngitis, rhinitis, nonproductive cough, myalgias, arthralgias. Single infiltrate on chest x-ray; pleural effusion possible.	Tetracycline, erythromycin, macrolide, quinolone.	Complications include reinfection and acute respiratory failure.

Table 23-1 • Commonly Encountered Pneumonias (Continued)

TYPE	ORGANISM RESPONSIBLE	EPIDEMIOLOGY	CLINICAL FEATURES	TREATMENT	COMMENTS
<b>Hospital-Acquired Pneumonia</b>					
<i>Pseudomonas</i> pneumonia	<i>Pseudomonas aeruginosa</i>	Incidence greatest in those with pre-existing lung disease, cancer (particularly leukemia); those with homograft transplants, burns; debilitated persons; and patients receiving antimicrobial therapy and treatments such as tracheostomy, suctioning, and in postoperative settings. Almost always of nosocomial origin. Accounts for 15% of hospital-acquired pneumonias. Mortality rate: 40% to 60%.	Diffuse consolidation on chest x-ray. Toxic appearance: fever, chills, productive cough, relative bradycardia, leukocytosis.	Aminoglycoside and anti-pseudomonal agents (ticarcillin, piperacillin, mezlocillin, ceftazidime).	Complications include lung cavitation. Has capacity to invade blood vessels, causing hemorrhage and lung infarction. Usually requires hospitalization.
Staphylococcal pneumonia	<i>Staphylococcus aureus</i>	Incidence greatest in immunocompromised patients, IV drug users, and as a complication of epidemic influenza. Commonly nosocomial in origin. Accounts for 10% to 30% of hospital-acquired pneumonias. Mortality rate: 25% to 60%.	Severe hypoxemia, cyanosis, necrotizing infection. Bacteremia is common.	Nafcillin/oxacillin +/- rifampin or gentamicin; methicillin-resistant: vancomycin +/- rifampin or gentamicin.	Complications include pleural effusion/pneumothorax, lung abscess, empyema, meningitis, endocarditis. Frequently requires hospitalization. Treatment must be vigorous and prolonged because disease tends to destroy lung tissue.
Klebsiella pneumonia	<i>Klebsiella pneumoniae</i> (Friedlander's bacillus-encapsulated gram-negative aerobic bacillus)	Incidence greatest in the elderly; alcoholics; patients with chronic disease, such as diabetes, heart failure, COPD; patients in chronic care facilities and nursing homes. Accounts for 2% to 5% of community-acquired and 10% to 30% of hospital-acquired pneumonias. Mortality rate: 40% to 50%.	Tissue necrosis occurs rapidly. Toxic appearance: fever, cough, sputum production, bronchopneumonia, lung abscess. Lobar consolidation, bronchopneumonia pattern on chest x-ray.	Third-generation cephalosporins (cefotaxime, ceftriaxone) plus aminoglycoside, antipseudomonal penicillin, monobactam (aztreonam), or quinolone.	Complications include multiple lung abscesses with cyst formation, empyema, pericarditis, pleural effusion. May be fulminating, progressing to fatal outcome.

Table 23-1 • Commonly Encountered Pneumonias (Continued)

TYPE	ORGANISM RESPONSIBLE	EPIDEMIOLOGY	CLINICAL FEATURES	TREATMENT	COMMENTS
<b>Pneumonia in Immunocompromised Host</b>					
<i>Pneumocystis carinii</i> pneumonia (PCP)	<i>Pneumocystis carinii</i>	Incidence greatest in patients with AIDS and patients receiving immunosuppressive therapy for cancer, organ transplants, and other disorders. Frequently seen with cytomegalovirus infection. Mortality rate 15% to 20% in hospitalized and fatal if not treated.	Pulmonary infiltrates on chest x-ray. Nonproductive cough, fever, dyspnea.	Trimethoprim/sulfamethoxazole (TMP-SMZ), dapsone-trimethoprim, pentamidine, primequine plus clindamycin.	Complications include respiratory failure.
Fungal pneumonia	<i>Aspergillus fumigatus</i>	Incidence greatest in immunocompromised and neutropenic patients. Mortality rate: 15% to 20%.	Cough, hemoptysis, infiltrates, fungus ball on chest x-ray.	Flucytosine with amphotericin B in non-neutropenic patients, amphotericin B, itraconazole, ketoconazole. Lobectomy for fungus ball.	Complications include dissemination to brain, myocardium, and/or thyroid gland.
Tuberculosis	<i>Mycobacterium tuberculosis</i>	Incidence increased in indigent, immigrant, and prison populations, people with AIDS, and the homeless. Mortality rate <1% (depending on comorbidity)	Weight loss, fever, night sweats, cough, sputum production, hemoptysis, non-specific infiltrate (lower lobe), hilar node enlargement, pleural effusion on chest x-ray.	Rifampin, streptomycin, ethambutol, INH (isoniazid), pyrazinamide	Complications include reinfection and acute respiratory infection.

+/- = may add depending upon situation

Hospital-acquired pneumonia (HAP), also known as **nosocomial** pneumonia, is defined as the onset of pneumonia symptoms more than 48 hours after admission to the hospital. HAP accounts for approximately 15% of hospital-acquired infections but is the most lethal nosocomial infection. It is estimated to occur in 0.5% to 1% of all hospitalized patients and in 15% to 20% of intensive care patients. Ventilator-associated pneumonia can be considered a type of nosocomial pneumonia that is associated with endotracheal intubation and mechanical ventilation.

The common organisms responsible for HAP include the pathogens *Enterobacter* species, *Escherichia coli*, *Klebsiella* species, *Proteus*, *Serratia marcescens*, *P. aeruginosa*, and methicillin-sensitive or methicillin-resistant *Staphylococcus aureus*. These respiratory infections occur when at least one of three conditions exists: host defenses are impaired, an inoculum of organisms reaches the patient's lower respiratory tract and overwhelms the host's defenses, or a highly virulent organism is present. Certain illnesses may predispose a patient to HAP because of impaired host defenses. Examples include severe acute or chronic illness, a variety of comorbid conditions, coma, malnutrition, prolonged hospitalization, hypotension, and metabolic disorders. The hospitalized patient is also exposed to potential bacteria from other sources (eg, respira-

tory therapy devices and equipment, transmission of pathogens by the hands of health care personnel). Numerous intervention-related factors also may play a role in the development of HAP (eg, therapeutic agents leading to central nervous system depression with decreased ventilation, impaired removal of secretions, or potential aspiration; prolonged or complicated thoracoabdominal procedures, which may impair mucociliary function and cellular host defenses; endotracheal intubation; prolonged or inappropriate use of antibiotics; use of nasogastric tubes). In addition, immunocompromised patients are at particular risk. HAP is associated with a high mortality rate, in part because of the virulence of the organisms, their resistance to antibiotics, and the patient's underlying disorder.

Dominant pathogens for HAP are gram-negative bacilli (*P. aeruginosa* and *Enterobacteriaceae*/*Klebsiella* species, *Enterobacter*, *Proteus*, *Serratia*) and *S. aureus*. Pseudomonal pneumonia occurs in patients who are debilitated, those with altered mental status, and those with prolonged intubation or with tracheostomies. Staphylococcal pneumonia can occur through inhalation of the organism or spread through the hematogenous route. It is often accompanied by bacteremia and positive blood cultures. Although responsible for less than 10% of cases of CAP,

staphylococcal pneumonia may be responsible for more than 30% of cases of HAP. Its mortality rate is high. Specific strains of staphylococci are resistant to all available antimicrobials except vancomycin. These strains of *S. aureus* are referred to as methicillin-resistant *S. aureus* (MRSA). Overuse and misuse of antimicrobial agents are major risk factors for the emergence of these resistant pathogens. Because MRSA is highly virulent, steps must be taken to prevent the spread of this organism. The patient with MRSA should be isolated in a private room, and contact precautions (gown, mask, glove, and antibacterial soap) are used. The number of people in contact with the patient should be minimized, and appropriate precautions must be taken when transporting the patient within or between facilities.

The usual presentation of an HAP is a new pulmonary infiltrate on chest x-ray combined with evidence of infection such as fever, respiratory symptoms, purulent sputum, and/or leukocytosis. Pneumonias from *Klebsiella* or other gram-negative organisms (*E. coli*, *Proteus*, *Serratia*) are characterized by destruction of lung structure and alveolar walls, consolidation, and bacteremia. Elderly patients and those with alcoholism, chronic lung disease, or diabetes are at particular risk. A sudden onset of cough is a common presentation, and blood-tinged sputum may be present. In the debilitated or dehydrated patient, sputum production may be minimal or absent. Pleural effusions, high fevers, and tachycardia are often observed. Even with treatment, the mortality rate remains high.

Pneumonia in the immunocompromised host is seen with greater frequency because immunocompromised hosts represent a growing portion of the patient population. Examples of pneumonia in the immunocompromised host are *Pneumocystis carinii* pneumonia (PCP), fungal pneumonias, and mycobacterium tuberculosis. These types of pneumonia may also occur in the immunocompetent person and in different settings, but these are less common. Immunocompromised states occur with the use of corticosteroids or other immunosuppressive agents, chemotherapy, nutritional depletion, use of broad-spectrum antimicrobial agents, AIDS, genetic immune disorders, and long-term advanced life-support technology (mechanical ventilation). Patients with compromised immune systems commonly acquire pneumonia from organisms of low virulence. In addition, increasing numbers of patients with impaired defenses develop HAP from gram-negative bacilli (*Klebsiella*, *Pseudomonas*, *E. coli*, *Enterobacteriaceae*, *Proteus*, *Serratia*).

Pneumonia in the compromised host may be caused by the organisms also observed in CAP or HAP (*S. pneumoniae*, *S. aureus*, *H. influenzae*, *P. aeruginosa*, *M. tuberculosis*). PCP is rarely observed in the immunocompetent host and is often an initial AIDS-defining complication. Whether the patient is immunocompromised or immunocompetent, the clinical presentation of pneumonia is similar. PCP has a subtle onset with progressive dyspnea, fever, and a nonproductive cough.

Aspiration pneumonia refers to the pulmonary consequences resulting from the entry of endogenous or exogenous substances into the lower airway. The most common form of aspiration pneumonia is bacterial infection from aspiration of bacteria that normally reside in the upper airways. Aspiration pneumonia may occur in the community or hospital setting; common pathogens are *S. pneumoniae*, *H. influenzae*, and *S. aureus*. Other substances may be aspirated into the lung, such as gastric contents, exogenous chemical contents, or irritating gases. This type of aspiration or ingestion may impair the lung defenses, cause inflammatory changes, and lead to bacterial growth and a resulting pneumonia. (Aspiration is described in more detail at the end of this chapter.)

## Pathophysiology

Upper airway characteristics normally prevent potentially infectious particles from reaching the normally sterile lower respiratory tract. Thus, patients with pneumonia caused by infectious agents often have an acute or chronic underlying disease that impairs host defenses. Pneumonia arises from normally present flora in a patient whose resistance has been altered, or it results from aspiration of flora present in the oropharynx. It may also result from bloodborne organisms that enter the pulmonary circulation and are trapped in the pulmonary capillary bed, becoming a potential source of pneumonia.

Pneumonia often affects both ventilation and diffusion. An inflammatory reaction can occur in the alveoli, producing an exudate that interferes with the diffusion of oxygen and carbon dioxide. White blood cells, mostly neutrophils, also migrate into the alveoli and fill the normally air-containing spaces. Areas of the lung are not adequately ventilated because of secretions and mucosal edema that cause partial occlusion of the bronchi or alveoli, with a resultant decrease in alveolar oxygen tension. Bronchospasm may also occur in patients with reactive airway disease. Because of hypoventilation, a ventilation–perfusion mismatch occurs in the affected area of the lung. Venous blood entering the pulmonary circulation passes through the underventilated area and exits to the left side of the heart poorly oxygenated. The mixing of oxygenated and unoxygenated or poorly oxygenated blood eventually results in arterial hypoxemia.

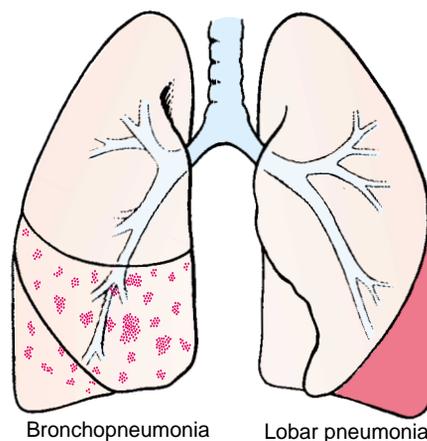

If a substantial portion of one or more lobes is involved, the disease is referred to as “lobar pneumonia.” The term “bronchopneumonia” is used to describe pneumonia that is distributed in a patchy fashion, having originated in one or more localized areas within the bronchi and extending to the adjacent surrounding lung parenchyma. Bronchopneumonia is more common than lobar pneumonia (Fig. 23-2).

## Risk Factors

Being knowledgeable about the factors and circumstances that commonly predispose a person to pneumonia will aid in identifying patients at high risk for this disorder (Chart 23-2).

## Physiology/Pathophysiology

**FIGURE 23-2** Distribution of lung involvement in bronchial and lobar pneumonia. In bronchopneumonia (*left*), patchy areas of consolidation occur. In lobar pneumonia (*right*), an entire lobe is consolidated.

Chart 23-2

## Risk Factors for Pneumonia

**Risk Factor**

Conditions that produce mucus or bronchial obstruction and interfere with normal lung drainage (eg, cancer, cigarette smoking, COPD)

Immunosuppressed patients and those with a low neutrophil count (neutropenic)

Smoking; cigarette smoke disrupts both mucociliary and macrophage activity

Prolonged immobility and shallow breathing pattern

Depressed cough reflex (due to medications, a debilitated state, or weak respiratory muscles); aspiration of foreign material into the lungs during a period of unconsciousness (head injury, anesthesia, depressed level of consciousness), or abnormal swallowing mechanism

Nothing-by-mouth (NPO) status; placement of nasogastric, orogastric, or endotracheal tube

Antibiotic therapy (in very ill people, the oropharynx is likely to be colonized by gram-negative bacteria)

Alcohol intoxication (because alcohol suppresses the body's reflexes, may be associated with aspiration, and decreases white cell mobilization and tracheobronchial ciliary motion)

General anesthetic, sedative, or opioid preparations that promote respiratory depression, which causes a shallow breathing pattern and predisposes to the pooling of bronchial secretions and potential development of pneumonia

Advanced age, because of possible depressed cough and glottic reflexes and nutritional depletion

Respiratory therapy with improperly cleaned equipment

**Preventive Measure**

Promote coughing and expectoration of secretions.  
Encourage smoking cessation.

Initiate special precautions against infection.

Encourage smoking cessation.

Reposition frequently and promote lung expansion exercises and coughing. Initiate suctioning and chest physical therapy if indicated.

Reposition frequently to prevent aspiration and administer medications judiciously, particularly those that increase risk for aspiration.

Perform suctioning and chest physical therapy if indicated.

Promote frequent oral hygiene. Minimize risk for aspiration by checking placement of tube and proper positioning of patient.

Encourage reduced or moderate alcohol intake (in case of alcohol stupor, position patient to prevent aspiration).

Observe the respiratory rate and depth during recovery from general anesthesia and before giving medications. If respiratory depression is apparent, withhold the medication and contact the physician.

Promote frequent turning, early ambulation and mobilization, effective coughing, breathing exercises, and nutritious diet.

Make sure that respiratory equipment is cleaned properly; participate in continuous quality improvement monitoring with the respiratory care department.

Increasing numbers of patients who have compromised defenses against infections are susceptible to pneumonia. Some types of pneumonia, such as those caused by viral infections, occur in previously healthy people and often follow a viral illness.

Pneumonia is common with certain underlying disorders such as heart failure, diabetes, alcoholism, COPD, and AIDS. Certain diseases also have been associated with specific pathogens. For example, staphylococcal pneumonia has been noted after epidemics of influenza, and patients with COPD are at increased risk for developing pneumonia caused by pneumococci or *H. influenzae*. In addition, cystic fibrosis is associated with respiratory infection caused by pseudomonas and staphylococcal organisms, and PCP has been associated with AIDS. Pneumonias occurring in hospitalized patients often involve organisms not usually found in CAP, including enteric gram-negative bacilli and *S. aureus*.

The CDC has identified three specific strategies for preventing HAP: (1) staff education and infection surveillance, (2) interruption of transmission of microorganisms through person-to-person transmission and equipment transmission, and (3) modification of host risk of infection (CDC, 1997). Providing anticipatory and preventive care is an important nursing measure.

To reduce or prevent serious complications of CAP in high-risk groups, vaccination against pneumococcal infection is advised for the following:

- People 65 years of age or older
- Immunocompetent people who are at increased risk for illness and death associated with pneumococcal disease be-

cause of chronic illness (eg, cardiovascular, pulmonary, diabetes mellitus, chronic liver disease)

- People with functional or anatomic asplenia
- People living in environments or social settings in which the risk of disease is high
- Immunocompromised people at high risk for infection (CDC, 1998)

The vaccine provides specific prevention against pneumococcal pneumonia and other infections caused by this organism (otitis media, other upper respiratory tract infections). Vaccines should be avoided in the first trimester of pregnancy.

**Clinical Manifestations**

Pneumonia varies in its signs and symptoms depending on the organism and the patient's underlying disease. However, regardless of the type of pneumonia (CAP, HAP, immunocompromised host, aspiration), a specific type of pneumonia cannot be diagnosed by clinical manifestations alone. For example, the patient with streptococcal (pneumococcal) pneumonia usually has a sudden onset of shaking chills, rapidly rising fever (38.5° to 40.5°C [101° to 105°F]), and pleuritic chest pain that is aggravated by deep breathing and coughing. The patient is severely ill, with marked tachypnea (25 to 45 breaths/min), accompanied by other signs of respiratory distress (eg, shortness of breath, use of accessory muscles in respiration). The pulse is rapid and bounding, and it usually increases about 10 beats/min for every degree

of temperature (Celsius) elevation. A relative bradycardia for the amount of fever may suggest viral infection, mycoplasma infection, or infection with a *Legionella* organism.

Some patients exhibit an upper respiratory tract infection (nasal congestion, sore throat), and the onset of symptoms of pneumonia is gradual and nonspecific. The predominant symptoms may be headache, low-grade fever, pleuritic pain, myalgia, rash, and pharyngitis. After a few days, mucoid or mucopurulent sputum is expectorated. In severe pneumonia, the cheeks are flushed and the lips and nailbeds demonstrate central cyanosis (a late sign of poor oxygenation [hypoxemia]).

Typically, the patient has **orthopnea** (shortness of breath when reclining); he or she prefers to be propped up in bed leaning forward (orthopneic position), trying to achieve adequate gas exchange without coughing or breathing deeply. Appetite is poor, and the patient is diaphoretic and tires easily. Sputum is often purulent; this is not a reliable indicator of the etiologic agent. Rusty, blood-tinged sputum may be expectorated with streptococcal (pneumococcal), staphylococcal, and *Klebsiella* pneumonia.

Signs and symptoms of pneumonia may also depend on underlying conditions. Differing signs occur in patients with other conditions, such as cancer, or in those who are undergoing treatment with immunosuppressants, which lower the resistance to infection. Such patients have fever, crackles, and physical findings that indicate consolidation of lung tissue, including increased tactile fremitus (vocal vibration detected on palpation), percussion dullness, bronchial breath sounds, egophony (when auscultated, the spoken “E” becomes a loud, nasal-sounding “A”), and whispered pectoriloquy (whispered sounds are easily auscultated through the chest wall). These changes occur because sound is transmitted better through solid or dense tissue (consolidation) than through normal air-filled tissue; these sounds are described in Chapter 21.

Purulent sputum or slight changes in respiratory symptoms may be the only sign of pneumonia in patients with COPD. It may be difficult to determine whether an increase in symptoms is an exacerbation of the underlying disease process or an additional infectious process.

## Assessment and Diagnostic Findings

The diagnosis of pneumonia is made by history (particularly of a recent respiratory tract infection), physical examination, chest x-ray studies, blood culture (bloodstream invasion, called bacteremia, occurs frequently), and sputum examination. The sputum sample is obtained by having the patient: (1) rinse the mouth with water to minimize contamination by normal oral flora, (2) breathe deeply several times, (3) cough deeply, and (4) expectorate the raised sputum into a sterile container.

More invasive procedures may be used to collect specimens. Sputum may be obtained by nasotracheal or orotracheal suctioning with a sputum trap or by fiberoptic bronchoscopy (see Chap. 21). Bronchoscopy is often used in patients with acute severe infection, patients with chronic or refractory infection, or immunocompromised patients when a diagnosis cannot be made from an expectorated or induced specimen.

## Medical Management

The treatment of pneumonia includes administration of the appropriate antibiotic as determined by the results of the Gram stain. However, an etiologic agent is not identified in 50% of CAP cases and empiric therapy must be initiated. Therapy for CAP is continuing to evolve. Guidelines exist to guide antibiotic choice; however, the resistance patterns, prevalence of etiologic

agents, patient risk factors, and costs and availability of newer antibiotic agents must all be taken into consideration.

Several organizations have published guidelines for the medical management of CAP (Bartlett et al., 2000; American Thoracic Society, 2001). Recommendations are classified by existing risk factors, setting (inpatient vs. outpatient treatment), or specific pathogens. Examples of risk factors that may increase the risk of infection with certain types of pathogens appear in Chart 23-3.

Recommendations for treatment of outpatients with CAP who have no cardiopulmonary disease or other modifying factors include a macrolide (erythromycin, azithromycin [Zithromax], or clarithromycin [Biaxin]), doxycycline (Vibramycin), or a fluoroquinolone (eg, gatifloxacin [Tequin], levofloxacin [Levaquin]) with enhanced activity against *S. pneumoniae* (Bartlett et al., 2000; American Thoracic Society, 2001). Erythromycin should be avoided in areas where *H. influenzae* and *S. aureus* are more prevalent (Kenreigh & Wagner, 2000; Lynch, 2000). For those outpatients who have cardiopulmonary disease or other modifying factors, treatment should include a beta-lactam (oral cefpodoxime [Vantin], cefuroxime [Zinacef, Ceftin], high-dose amoxicillin or amoxicillin/clavulanate [Augmentin, Clavulin]) plus a macrolide or doxycycline. Also, a beta-lactam plus an antipneumococcal fluoroquinolone can be used (American Thoracic Society, 2001). These are guidelines; treatment for individual patients may be modified.

For patients with CAP who are hospitalized and do not have cardiopulmonary disease or modifying factors, management consists of intravenous azithromycin (Zithromax) or monotherapy with an antipneumococcal fluoroquinolone. For inpatients with cardiopulmonary disease or modifying factors, the treatment involves an intravenous beta-lactam plus an intravenous or oral macrolide or doxycycline. An intravenous antipneumococcal fluoroquinolone may also be used alone (American Thoracic Society, 2001). For acutely ill patients admitted to the intensive care unit, management includes an intravenous beta-lactam plus either an intravenous macrolide or fluoroquinolone. For patients

Chart 23-3

### Risk Factors for Pathogenic Lung Infections

#### Risk Factors for Infection with Penicillin-Resistant and Drug-Resistant Pneumococci

- Age over 65 years
- Alcoholism
- Beta-lactam therapy (eg, cephalosporins) in past 3 months
- Immunosuppressive disorders
- Multiple medical comorbidities
- Exposure to a child in a day care facility

#### Risk Factors for Infection with Enteric Gram-Negative Bacteria

- Nursing home residency
- Underlying cardiopulmonary disease
- Multiple medical comorbidities
- Recent antibiotic therapy

#### Risk Factors for Infection with *Pseudomonas aeruginosa*

- Structural lung disease (eg, bronchiectasis)
- Corticosteroid therapy
- Broad-spectrum antibiotic therapy (more than 7 days in the past month)
- Malnutrition

(American Thoracic Society, 2001)

at high risk for *P. aeruginosa*, more select antipseudomonal antibiotics are administered intravenously.

If specific pathogens have been identified for the CAP, more specific agents may be utilized. *Mycoplasma pneumoniae* is treated with doxycycline or a macrolide. PCP responds best to pentamidine and trimethoprim–sulfamethoxazole (TMP-SMZ). Amantadine and rimantadine are effective with influenza A and have been shown to reduce the duration of fever and other systemic complications when administered within 24 to 48 hours of the onset of an uncomplicated influenza infection. These medications also reduce the duration and quantity of virus shedding in the respiratory secretions. They are most effective when used in combination with influenza vaccine. Ganciclovir is used to treat cytomegalovirus in the non-AIDS patient; cytomegalovirus immunoglobulin may also be used.

HAP has a different etiology from CAP. In suspected HAP or nosocomial pneumonia, empirical treatment is usually initiated with a broad-spectrum intravenous antibiotic and may be monotherapy or combination therapy. In patients who are mildly to moderately ill with a low risk of *Pseudomonas*, the following antibiotics may be used: second-generation cephalosporins (eg, cefuroxime [Ceftin, Zinacef] or cefamandole [Mandol]), non-pseudomonal third-generation cephalosporins (ceftriaxone [Rocephin], cefotaxime [Claforan], ampicillin-sulbactam [Unasyn]), or fluoroquinolones (eg, ciprofloxacin [Cipro], levofloxacin [Lev-aquin]). For combination therapy, any of the above may be used with an aminoglycoside.

For patients at high risk for *Pseudomonas* infection, an antipseudomonal penicillin plus an aminoglycoside (amikacin [Amikin], gentamicin) or beta-lactamase inhibitor (ampicillin/sulbactam [Unasyn], ticarcillin/clavulanate [Timentin]) may be used. Other types of combination therapy may also be used depending upon the individual characteristics of the patient.

Of concern is the rampant rise in respiratory pathogens that are resistant to available antibiotics. Examples include vancomycin-resistant enterococcus (VRE) and drug-resistant *S. pneumoniae* (McGeer & Low, 2000). There is a tendency for clinicians to aggressively use antibiotics inappropriately or to use broad-spectrum agents when narrow-spectrum agents are more appropriate. Mechanisms to monitor and minimize the inappropriate use of antibiotics are in place. Education of clinicians to use evidence-based guidelines in the treatment of respiratory infection is important. Monitoring and surveillance of susceptibility patterns for pathogens are also important.

Therapy with parenteral agents usually is changed to oral antimicrobial agents when there is evidence of a clinical response and the patient is able to tolerate oral medications. The recommended duration of treatment for pneumococcal pneumonia is 72 hours after the patient becomes afebrile. Most other forms of pneumonia caused by bacterial pathogens are treated for 1 to 2 weeks after the patient becomes afebrile. Atypical pneumonia is usually treated for 10 to 21 days (Bartlett, Dowell, Mandell et al., 2000).

Treatment of viral pneumonia is primarily supportive. Antibiotics are ineffective in viral upper respiratory infections and pneumonia and may be associated with adverse effects. Treatment of viral infections with antibiotics is a major reason for the overuse of these medications in the United States. Antibiotics are indicated with a viral respiratory infection *only* when a secondary bacterial pneumonia, bronchitis, or sinusitis is present. Hydration is a necessary part of therapy because fever and tachypnea may result in insensible fluid losses. Antipyretics may be used to treat headache and fever; antitussive medications may be used for the associated cough. Warm, moist inhalations are helpful in relieving bronchial

irritation. Antihistamines may provide benefit with reduced sneezing and rhinorrhea. Nasal decongestants may also be used to treat symptoms and improve sleep; however, excessive use may cause rebound nasal congestion. Treatment of viral pneumonia (with the exception of antimicrobial therapy) is the same as that for bacterial pneumonia. The patient is placed on bed rest until the infection shows signs of clearing. If hospitalized, the patient is observed carefully until the clinical condition improves.

If hypoxemia develops, oxygen is administered. Pulse oximetry or arterial blood gas analysis is performed to determine the need for oxygen and to evaluate the effectiveness of the therapy. A high concentration of oxygen is contraindicated in patients with COPD because it may worsen alveolar ventilation by decreasing the patient's ventilatory drive, leading to further respiratory decompensation. Respiratory support measures include high oxygen concentrations (fraction of inspired oxygen [FiO<sub>2</sub>]), endotracheal intubation, and mechanical ventilation. Different modes of mechanical ventilation may be required; see Chapter 25.

Figure 23-3 provides an algorithm for patients with suspected CAP.

### Gerontologic Considerations

Pneumonia in the elderly patient may occur as a primary problem or as a complication of a chronic disease process. Pulmonary infections in the elderly frequently are difficult to treat and have a higher mortality rate than in younger patients. General deterioration, weakness, abdominal symptoms, anorexia, confusion, tachycardia, and tachypnea may signal the onset of pneumonia. The diagnosis of pneumonia may be missed because the classic symptoms of cough, chest pain, sputum production, and fever may be absent or masked in the elderly patient. Also, the presence of some signs may be misleading. Abnormal breath sounds, for example, may be due to microatelectasis that occurs in the aged as a result of decreased mobility, decreased lung volumes, and other respiratory function changes. Because chronic heart failure is often seen in the elderly, chest x-rays may be obtained to assist in differentiating it from pneumonia as the cause of clinical signs and symptoms.

Supportive treatment includes hydration (with caution and frequent assessment because of the risk of fluid overload in the elderly), supplemental oxygen therapy, assistance with deep breathing, coughing, frequent position changes, and early ambulation. All of these are particularly important in the care of the elderly patient with pneumonia. To reduce or prevent serious complications of pneumonia in the elderly, vaccination against pneumococcal and influenza infections is recommended.

## Complications

### SHOCK AND RESPIRATORY FAILURE

Severe complications of pneumonia include hypotension and shock and respiratory failure (especially with gram-negative bacterial disease in elderly patients). These complications are encountered chiefly in patients who have received no specific treatment or inadequate or delayed treatment. These complications are also encountered when the infecting organism is resistant to therapy and when a comorbid disease complicates the pneumonia.

If the patient is seriously ill, aggressive therapy may include hemodynamic and ventilatory support to combat peripheral collapse, maintain arterial blood pressure, and provide adequate oxygenation. A vasopressor agent may be administered intravenously by continuous infusion and at a rate adjusted in accordance with

**FIGURE 23-3** Treatment algorithm for patient with suspected CAP. From Bartlett, J. G. et al. (2000). Practice guidelines for the management of community-acquired pneumonia in adults. *Clinical Infectious Diseases*, 31 (2), 347–382.

the pressure response. Corticosteroids may be administered parenterally to combat shock and toxicity in patients who are extremely ill with pneumonia and in apparent danger of dying of the infection. Patients may require endotracheal intubation and mechanical ventilation. Congestive heart failure, cardiac dysrhythmias, pericarditis, and myocarditis also are complications of pneumonia that may lead to shock.

### ATELECTASIS AND PLEURAL EFFUSION

Atelectasis (from obstruction of a bronchus by accumulated secretions) may occur at any stage of acute pneumonia. Parapneumonic pleural effusions occur in at least 40% of bacterial pneumonias. A parapneumonic effusion is any pleural effusion associated with bacterial pneumonia, lung abscess, or bronchiectasis. After the pleural effusion is detected on a chest x-ray, a thoracentesis may be performed to remove the fluid. The fluid is sent to the laboratory for analysis. There are three stages of parapneumonic pleural effusions based on pathogenesis: uncomplicated, complicated, and thoracic empyema. An **empyema** occurs when thick, purulent fluid accumulates within the pleural space, often with fibrin development and a loculated (walled-off) area where the infection is located. (Empyema is discussed in greater detail in the section Pleural Conditions, below.) A chest tube may be inserted to treat pleural infection by establishing proper drainage of the empyema. Sterilization of the empyema cavity requires 4 to 6 weeks of antibiotics. Sometimes surgical management is required.

### SUPERINFECTION

Superinfection may occur with the administration of very large doses of antibiotics, such as penicillin, or with combinations of antibiotics. Superinfection may also occur in the patient who has been receiving numerous courses and types of antibiotics. In such cases, bacteria may become resistant to the antibiotic therapy. If the patient improves and the fever diminishes after initial antibiotic therapy, but subsequently there is a rise in temperature with increasing cough and evidence that the pneumonia has spread, a superinfection is likely. Antibiotics are changed appropriately or discontinued entirely in some cases.

## NURSING PROCESS: THE PATIENT WITH PNEUMONIA

### Assessment

Nursing assessment is critical in detecting pneumonia. A fever, chills, or night sweats in a patient who also has respiratory symptoms should alert the nurse to the possibility of bacterial pneumonia. A respiratory assessment will further identify the clinical manifestations of pneumonia: pleuritic-type pain, fatigue, tachypnea, use of accessory muscles for breathing, bradycardia or relative bradycardia, coughing, and purulent sputum. It is important to identify the severity, location, and cause of the chest pain, along

with any medications or procedures that provide relief. The nurse should monitor the following:

- Changes in temperature and pulse
- Amount, odor, and color of secretions
- Frequency and severity of cough
- Degree of tachypnea or shortness of breath
- Changes in physical assessment findings (primarily assessed by inspecting and auscultating the chest)
- Changes in the chest x-ray findings

In addition, it is important to assess the elderly patient for unusual behavior, altered mental status, dehydration, excessive fatigue, and concomitant heart failure.

## Diagnosis

### NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include:

- Ineffective airway clearance related to copious tracheobronchial secretions
- Activity intolerance related to impaired respiratory function
- Risk for deficient fluid volume related to fever and dyspnea
- Imbalanced nutrition: less than body requirements
- Deficient knowledge about the treatment regimen and preventive health measures

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, collaborative problems or potential complications that may occur include:

- Continuing symptoms after initiation of therapy
- Shock
- Respiratory failure
- Atelectasis
- Pleural effusion
- Confusion
- Superinfection

## Planning and Goals

The major goals for the patient may include improved airway patency, rest to conserve energy, maintenance of proper fluid volume, maintenance of adequate nutrition, an understanding of the treatment protocol and preventive measures, and absence of complications.

## Nursing Interventions

### IMPROVING AIRWAY PATENCY

Removing secretions is important because retained secretions interfere with gas exchange and may slow recovery. The nurse encourages hydration (2 to 3 L/day) because adequate hydration thins and loosens pulmonary secretions. Humidification may be used to loosen secretions and improve ventilation. A high-humidity facemask (using either compressed air or oxygen) delivers warm, humidified air to the tracheobronchial tree, helps to liquefy secretions, and relieves tracheobronchial irritation. Coughing can be initiated either voluntarily or by reflex. Lung expansion maneuvers, such as deep breathing with an incentive spirometer, may induce a cough. A directed cough may be necessary to improve airway patency. The nurse encourages the patient to per-

form an effective, directed cough, which includes correct positioning, a deep inspiratory maneuver, glottic closure, contraction of the expiratory muscles against the closed glottis, sudden glottic opening, and an explosive expiration. In some cases, the nurse may assist the patient by placing both hands on the patient's lower rib cage (anteriorly or posteriorly) to focus the patient on a slow deep breath, and then manually assisting the patient by applying external pressure during the expiratory phase.

Chest physiotherapy (percussion and postural drainage) is important in loosening and mobilizing secretions (see Chap. 25). Indications for chest physiotherapy include sputum retention not responsive to spontaneous or directed cough, a history of pulmonary problems previously treated with chest physiotherapy, continued evidence of retained secretions (decreased or abnormal breath sounds, change in vital signs), abnormal chest x-ray findings consistent with atelectasis or infiltrates, or deterioration in oxygenation. The patient is placed in the proper position to drain the involved lung segments, and then the chest is percussed and vibrated either manually or with a mechanical percussor.

After each position change, the nurse encourages the patient to breathe deeply and cough. If the patient is too weak to cough effectively, the nurse may need to remove the mucus by nasotracheal suctioning (see Chap. 25). It may take time for secretions to mobilize and move into the central airways for expectoration. Thus, it is important for the nurse to monitor the patient for cough and sputum production after the completion of chest physiotherapy.

The nurse administers and titrates oxygen therapy as prescribed. The effectiveness of oxygen therapy is monitored by improvement in clinical signs and symptoms, and adequate oxygenation values measured by pulse oximetry or arterial blood gas analysis.

### PROMOTING REST AND CONSERVING ENERGY

The nurse encourages the debilitated patient to rest and avoid overexertion and possible exacerbation of symptoms. The patient should assume a comfortable position to promote rest and breathing (eg, semi-Fowler's) and should change positions frequently to enhance secretion clearance and ventilation/perfusion in the lungs. It is important to instruct outpatients not to overexert themselves and to engage in only moderate activity during the initial phases of treatment.

### PROMOTING FLUID INTAKE

The respiratory rate of a patient with pneumonia increases because of the increased workload imposed by labored breathing and fever. An increased respiratory rate leads to an increase in insensible fluid loss during exhalation and can lead to dehydration. Therefore, it is important to encourage increased fluid intake (at least 2 L/day), unless contraindicated.

### MAINTAINING NUTRITION

Patients with shortness of breath and fatigue often have a decreased appetite and will take only fluids. Fluids with electrolytes (commercially available drinks, such as Gatorade) may help provide fluid, calories, and electrolytes. Other nutritionally enriched drinks or shakes may be helpful. In addition, fluids and nutrients may be administered intravenously if necessary.

### PROMOTING THE PATIENT'S KNOWLEDGE

The patient and family are instructed about the cause of pneumonia, management of symptoms of pneumonia, and the need for follow-up (discussed later). The patient also needs informa-

tion about factors (both patient risk factors and external factors) that may have contributed to developing pneumonia and strategies to promote recovery and to prevent recurrence. If hospitalized for treatment, the patient is instructed about the purpose and importance of management strategies that have been implemented and about the importance of adhering to them during and after the hospital stay. Explanations need to be given simply and in language that the patient can understand. If possible, written instructions and information should be provided. Because of the severity of symptoms, the patient may require that instructions and explanations be repeated several times.

## MONITORING AND MANAGING POTENTIAL COMPLICATIONS

### Continuing Symptoms After Initiation of Therapy

Patients usually begin to respond to treatment within 24 to 48 hours after antibiotic therapy is initiated. The patient is observed for response to antibiotic therapy. The patient is monitored for changes in physical status (deterioration of condition or resolution of symptoms) and for persistent recurrent fever, which may be due to medication allergy (signaled possibly by a rash); medication resistance or slow response (greater than 48 hours) of the susceptible organism to therapy; superinfection; pleural effusion; or pneumonia caused by an unusual organism, such as *P. carinii* or *Aspergillus fumigatus*. Failure of the pneumonia to resolve or persistence of symptoms despite changes on the chest x-ray raises the suspicion of other underlying disorders, such as lung cancer. As described earlier, lung cancers may invade or compress airways, causing an obstructive atelectasis that may lead to a pneumonia.

In addition to monitoring for continuing symptoms of pneumonia, the nurse also monitors for other complications, such as shock and multisystem failure, atelectasis, pleural effusion, and superinfection, which may develop during the first few days of antibiotic treatment.

### Shock and Respiratory Failure

The nurse assesses for signs and symptoms of shock and respiratory failure by evaluating the patient's vital signs, pulse oximetry values, and hemodynamic monitoring parameters. The nurse reports signs of deteriorating patient status and assists in administering intravenous fluids and medications prescribed to combat shock. Intubation and mechanical ventilation may be required if respiratory failure occurs. Shock is described in detail in Chapter 15, and care of the patient receiving mechanical ventilation is described in Chapter 25.

### Atelectasis and Pleural Effusion

The patient is assessed for atelectasis, and preventive measures are initiated to prevent its development. If pleural effusion develops and thoracentesis is performed to remove fluid, the nurse assists in the procedure and explains it to the patient. After thoracentesis, the nurse monitors the patient for pneumothorax or recurrence of pleural effusion. If a chest tube needs to be inserted, the nurse monitors the patient's respiratory status (see Chap. 25 for more information on care of the patient with a chest tube).

### Superinfection

The patient is monitored for manifestations of superinfection (ie, minimal improvement in signs and symptoms, rise in temperature with increasing cough, increasing fremitus and adventitious breath sounds on auscultation of the lungs). These signs are re-

ported, and the nurse assists in implementing therapy to treat superinfection.

### Confusion

The patient with pneumonia is assessed for confusion and other more subtle changes in cognitive status. Confusion and changes in cognitive status resulting from pneumonia are poor prognostic signs. Confusion may be related to hypoxemia, fever, dehydration, sleep deprivation, or developing sepsis. The patient's underlying comorbid conditions may also play a part in the development of confusion. Addressing the underlying factors and ensuring the patient's safety are important nursing interventions.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

Depending on the severity of the pneumonia, treatment may occur in the hospital or in the outpatient setting. Patient education is crucial regardless of the setting, and the proper administration of antibiotics is important. In some instances, the patient may be initially treated with intravenous antibiotics as an inpatient and then be discharged to continue the intravenous antibiotics in the home setting. It is important that a seamless system of care be maintained for the patient from hospital to home; this includes communication between the nurses caring for this patient in both settings. In addition, if oral antibiotics are prescribed, it is important to teach the patient about their proper administration and potential side effects.

After the fever subsides, the patient may gradually increase activities. Fatigue and weakness may be prolonged after pneumonia, especially in the elderly. The nurse encourages breathing exercises to promote secretion clearance and volume expansion. It is important to instruct the patient to return to the clinic or caregiver's office for a follow-up chest x-ray and physical examination. Often improvement in chest x-ray findings lags behind improvement in clinical signs and symptoms.

The nurse encourages the patient to stop smoking. Smoking inhibits tracheobronchial ciliary action, which is the first line of defense of the lower respiratory tract. Smoking also irritates the mucous cells of the bronchi and inhibits the function of alveolar macrophage (scavenger) cells. The patient is instructed to avoid stress, fatigue, sudden changes in temperature, and excessive alcohol intake, all of which lower resistance to pneumonia. The nurse reviews with the patient the principles of adequate nutrition and rest, because one episode of pneumonia may make the patient susceptible to recurring respiratory tract infections.

### Continuing Care

Patients who are severely debilitated or who cannot care for themselves may require referral for home care. During home visits, the nurse assesses the patient's physical status, monitors for complications, assesses the home environment, and reinforces previous teaching. The nurse evaluates the patient's adherence to the therapeutic regimen (ie, taking medications as prescribed, performing breathing exercises, consuming adequate fluid and dietary intake, and avoiding smoking, alcohol, and excessive activity). The nurse stresses to the patient and family the importance of monitoring for complications. The nurse encourages the patient to obtain an influenza vaccine at the prescribed times, because influenza increases susceptibility to secondary bacterial pneumonia, especially that caused by staphylococci, *H. influenzae*, and *S. pneumoniae*. The nurse also encourages the patient to seek medical advice about receiving the vaccine (Pneumovax) against *S. pneumoniae*.

### NURSING RESEARCH PROFILE 23-1

#### Tobacco-Related Nursing Interventions

Sarna, L. P., Brown, J. K., Lillington, L., Rose, M., Wewers, M. E., & Brecht, M. (2000). Tobacco interventions by oncology nurses in clinical practice. *Cancer*, 89(4), 881–889.

#### Purpose

Smoking remains a major cause of death in all populations in the U.S. The purpose of this study was to describe the frequency of interventions related to the use of tobacco used by oncology nurses, using the Agency for Health Care Policy and Research (AHCPR) guidelines as a framework.

#### Study Sample and Design

This was a descriptive study; a self-report questionnaire was mailed to a random sample of 4,000 members of the Oncology Nursing Society. The response rate was 38%, with 1,508 completed questionnaires available for analysis. Subjects were asked to identify those interventions related to tobacco use that they used in their clinical practice.

#### Findings

The majority of respondents were female (98%), with an average age of 44 years. The educational background of respondents was varied, with 39% with baccalaureate preparation, 41% with associate or diploma education, and 20% with master's or doctoral level education. Sixty-two percent of the respondents reported their position as staff nurse. Overall, the sample was characterized as experienced nurses, with average number of years in nursing at  $18 \pm 9.4$  years

and as an oncology nurse for  $11.5 \pm 5.5$  years. Thirty percent of the sample were ex-smokers, while 7% were active smokers. The results demonstrated that most respondents (86%) encountered smokers in their clinical practice on a weekly basis, but only 10% had any knowledge of the AHCPR guidelines for smoking cessation. Sixty-four percent of the respondents assessed and documented smoking status in their clinical patients and 38% assessed readiness to quit. However, fewer nurses reported providing interventions for smoking cessation. The most frequent barriers cited included perceived lack of patient motivation (74%), time (52%), and skills to provide a cessation intervention (53%).

#### Nursing Implications

Nurses have frequent contacts with active smokers in the inpatient and outpatient setting and could have a tremendous impact on smoking prevention and cessation. Even in this sample of oncology nurses, few provided smoking cessation interventions on a regular basis. Nurses need a heightened awareness of the importance of smoking cessation and the potential impact they may have on this growing problem. It is imperative that students and practicing nurses receive improved education regarding smoking cessation techniques and use of evidence-based guidelines like those of the AHCPR.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Demonstrates improved airway patency, as evidenced by adequate oxygenation by pulse oximetry or arterial blood gas analysis, normal temperature, normal breath sounds, and effective coughing
2. Rests and conserves energy by limiting activities and remaining in bed while symptomatic and slowly increasing activities
3. Maintains adequate hydration, as evidenced by an adequate fluid intake and urine output and normal skin turgor
4. Consumes adequate dietary intake, as evidenced by maintenance or increase in body weight without excess fluid gain
5. States explanation for management strategies
6. Complies with management strategies
7. Exhibits no complications
  - a. Has normal vital signs, pulse oximetry, and arterial blood gas measurements
  - b. Reports productive cough that diminishes over time
  - c. Has absence of signs or symptoms of shock, respiratory failure, or pleural effusion
  - d. Remains oriented and aware of surroundings
  - e. Maintains or increases weight
8. Complies with treatment protocol and prevention strategies

## PULMONARY TUBERCULOSIS

Tuberculosis (TB) is an infectious disease that primarily affects the lung parenchyma. It also may be transmitted to other parts of the body, including the meninges, kidneys, bones, and lymph nodes. The primary infectious agent, *Mycobacterium tuberculosis*,

is an acid-fast aerobic rod that grows slowly and is sensitive to heat and ultraviolet light. *Mycobacterium bovis* and *Mycobacterium avium* have rarely been associated with the development of a TB infection.

TB is a worldwide public health problem, and the mortality and morbidity rates continue to rise. *M. tuberculosis* infects an estimated one third of the world's population and remains the leading cause of death from infectious disease in the world. It is the leading cause of death among HIV-positive people (World Health Organization, 2000). TB is closely associated with poverty, malnutrition, overcrowding, substandard housing, and inadequate health care.

In 1952, anti-TB medications were introduced, and the rate of reported cases of TB in the United States declined an average of 6% each year between 1953 and 1985. It was thought that by the early part of the 21st century, TB might be eliminated in the United States. However, since 1985 the trend has reversed and the number of cases has increased. This change has been attributed to several factors, including increased immigration, the HIV epidemic, the emergence of multidrug-resistant strains of TB, increased homelessness, decreased interest and detection by health care providers, and inadequate funding of the U.S. public health system (Small & Fujiwara, 2001).

### Transmission and Risk Factors

TB spreads from person to person by airborne transmission. An infected person releases droplet nuclei (generally particles 1 to 5 micrometers in diameter) through talking, coughing, sneezing, laughing, or singing. Larger droplets settle; smaller droplets remain suspended in the air and are inhaled by the susceptible person. Risk factors for TB are listed in Chart 23-4. Chart 23-5 summarizes the CDC's recommendations for prevention of TB transmission in health care settings.

Chart 23-4

## Risk Factors for Tuberculosis

- Close contact with someone who has active TB. Inhalation of airborne nuclei from an infected person is proportional to the amount of time spent in the same air space, the proximity of the person, and the degree of ventilation.
- Immunocompromised status (eg, those with HIV infection, cancer, transplanted organs, and prolonged high-dose corticosteroid therapy)
- Substance abuse (IV or injection drug users and alcoholics)
- Any person without adequate health care (the homeless; impoverished; minorities, particularly children under age 15 years and young adults between ages 15 and 44 yrs)
- Preexisting medical conditions or special treatment (eg, diabetes, chronic renal failure, malnourishment, selected malignancies, hemodialysis, transplanted organ, gastrectomy, or jejunioileal bypass)
- Immigration from countries with a high prevalence of TB (southeastern Asia, Africa, Latin America, Caribbean)
- Institutionalization (eg, long-term care facilities, psychiatric institutions, prisons)
- Living in overcrowded, substandard housing
- Being a health care worker performing high-risk activities: administration of aerosolized pentamidine and other medications, sputum induction procedures, bronchoscopy, suctioning, coughing procedures, caring for the immunosuppressed patient, home care with the high-risk population, and administering anesthesia and related procedures (eg, intubation, suctioning)

## Pathophysiology

A susceptible person inhales mycobacterium bacilli and becomes infected. The bacteria are transmitted through the airways to the alveoli, where they are deposited and begin to multiply. The bacilli also are transported via the lymph system and bloodstream to other parts of the body (kidneys, bones, cerebral cortex) and other areas of the lungs (upper lobes). The body's immune system responds by initiating an inflammatory reaction. Phagocytes (neutrophils and macrophages) engulf many of the bacteria, and TB-specific lymphocytes lyse (destroy) the bacilli and normal tissue. This tissue reaction results in the accumulation of exudate in the alveoli, causing bronchopneumonia. The initial infection usually occurs 2 to 10 weeks after exposure.

Granulomas, new tissue masses of live and dead bacilli, are surrounded by macrophages, which form a protective wall around the granulomas. Granulomas are then transformed to a fibrous tissue mass, the central portion of which is called a Ghon tubercle. The material (bacteria and macrophages) becomes necrotic, forming a cheesy mass. This mass may become calcified and form a col-

lagenous scar. At this point, the bacteria become dormant, and there is no further progression of active disease.

After initial exposure and infection, the person may develop active disease because of a compromised or inadequate immune system response. Active disease also may occur with reinfection and activation of dormant bacteria. In this case, the Ghon tubercle ulcerates, releasing the cheesy material into the bronchi. The bacteria then become airborne, resulting in further spread of the disease. Then the ulcerated tubercle heals and forms scar tissue. This causes the infected lung to become more inflamed, resulting in further development of bronchopneumonia and tubercle formation.

Unless the process is arrested, it spreads slowly downward to the hilum of the lungs and later extends to adjacent lobes. The process may be prolonged and characterized by long remissions when the disease is arrested, only to be followed by periods of renewed activity. Approximately 10% of people who are initially infected develop active disease. Some people develop reactivation TB (also called adult-type TB). This type of TB results from a breakdown of the host defenses. It most commonly occurs within

Chart 23-5

## CDC Recommendations for Preventing Transmission of Tuberculosis in Health Care Settings

1. Early identification and treatment of persons with active TB
  - a. Maintain a high index of suspicion for TB to identify cases rapidly.
  - b. Promptly initiate effective multidrug anti-TB therapy based on clinical and drug-resistance surveillance data.
2. Prevention of spread of infectious droplet nuclei by source control methods and by reduction of microbial contamination of indoor air
  - a. Initiate acid-fast bacilli (AFB) isolation precautions immediately for all patients who are suspected or confirmed to have active TB and who may be infectious. AFB isolation precautions include use of a private room with negative pressure in relation to surrounding areas and a minimum of six air exchanges per hour. Air from the room should be exhausted directly to the outside. Use of ultraviolet lamps and/or high-efficiency particulate air filters to supplement ventilation may be considered.
  - b. Persons entering the AFB isolation room should use disposable particulate respirators that fit snugly around the face.
  - c. Continue AFB isolation precautions until there is clinical evidence of reduced infectiousness (ie, cough has substantially decreased, and the number of organisms on sequential sputum smears is decreasing). If drug resistance is suspected or confirmed, continue AFB precautions until the sputum smear is negative for AFB.
  - d. Use special precautions during cough-inducing procedures.
3. Surveillance for TB transmission
  - a. Maintain surveillance for TB infection among health care workers (HCWs) by routine, periodic tuberculin skin testing. Recommend appropriate preventive therapy for HCWs when indicated.
  - b. Maintain surveillance for TB cases among patients and HCWs.
  - c. Promptly initiate contact investigation procedures among HCWs, patients, and visitors exposed to an untreated, or ineffectively treated, infectious TB patient for whom appropriate AFB procedures are not in place. Recommend appropriate therapy or preventive therapy for contacts with disease or TB infection without current disease. Therapeutic regimens should be chosen based on the clinical history and local drug-resistance surveillance data.

the lungs, usually in the apical or posterior segments of the upper lobes, or the superior segments of the lower lobes.

## Clinical Manifestations

The signs and symptoms of pulmonary TB are insidious. Most patients have a low-grade fever, cough, night sweats, fatigue, and weight loss. The cough may be nonproductive, or mucopurulent sputum may be expectorated. Hemoptysis also may occur. Both the systemic and pulmonary symptoms are usually chronic and may have been present for weeks to months. The elderly usually present with less pronounced symptoms than do younger patients. Extrapulmonary disease occurs in up to 16% of cases in the United States. In patients with AIDS, extrapulmonary disease is more prevalent and may occur in up to 70% of cases (Niederman & Sarosi, 2000; Small & Fujiwara, 2001).

## Assessment and Diagnostic Findings

A complete history, physical examination, tuberculin skin test, chest x-ray, acid-fast bacillus smear, and sputum culture are used to diagnose TB. If the person is infected with TB, the chest x-ray usually reveals lesions in the upper lobes and the acid-fast bacillus smear contains mycobacterium.

### TUBERCULIN SKIN TEST

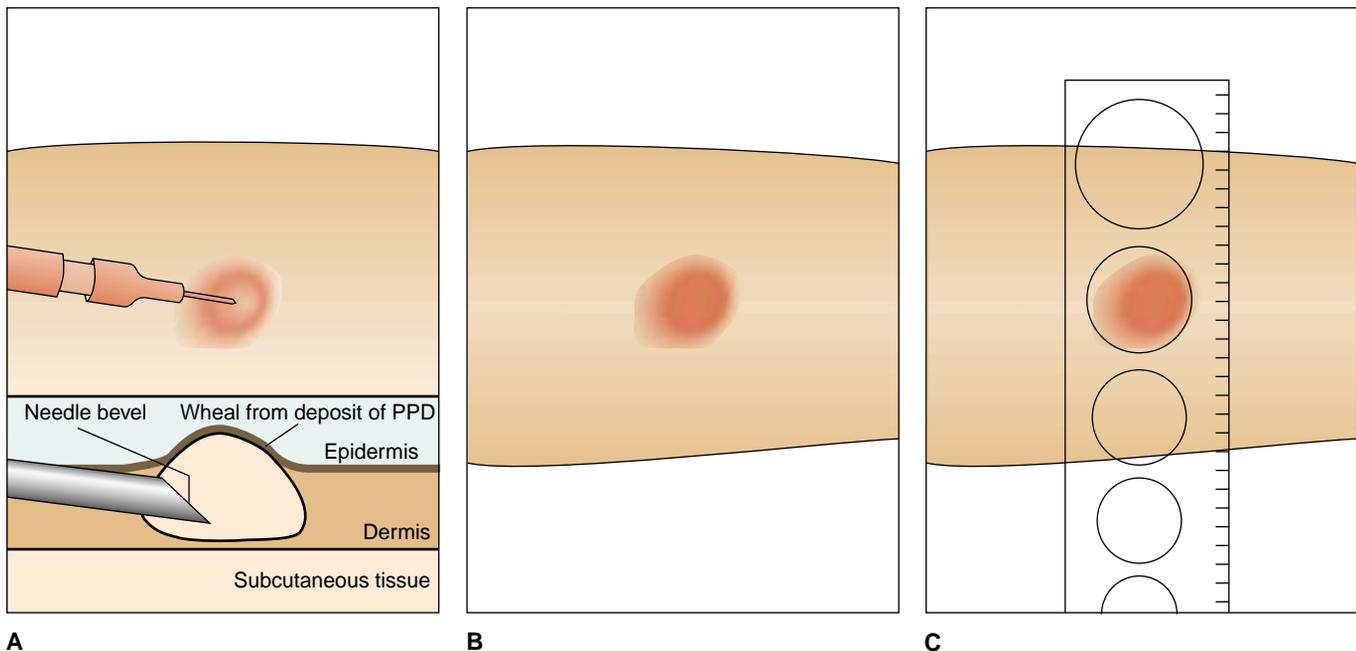

The Mantoux test is used to determine if a person has been infected with the TB bacillus. The Mantoux test is a standardized procedure and should be performed only by those trained in its administration and reading. Tubercle bacillus extract (tuberculin), purified protein derivative (PPD), is injected into the intradermal layer of the inner aspect of the forearm, approximately 4 inches below the elbow (Fig. 23-4). Intermediate-strength (5 TU) PPD in a tuberculin syringe with a half-inch 26- or 27-gauge needle is used.

The needle, with the bevel facing up, is inserted beneath the skin. Then 0.1 mL of PPD is injected, creating an elevation in the skin, a wheal or bleb. The site, antigen name, strength, lot number, date, and time of the test are recorded. The test result is read 48 to 72 hours after injection. Tests read after 72 hours tend to underestimate the true size of **induration** (hardening). A delayed localized reaction indicates that the person is sensitive to tuberculin.

A reaction occurs when both induration and erythema (redness) are noted. After the area is inspected for induration, it is lightly palpated across the injection site, from the area of normal skin to the margins of the induration. The diameter of the induration (not erythema) is measured in millimeters at its widest part (see Fig. 23-4), and the size of the induration is documented. Erythema without induration is not considered significant.

**Interpretation of Results.** The size of the induration determines the significance of the reaction. A reaction of 0 to 4 mm is considered not significant; a reaction of 5 mm or greater may be significant in individuals who are considered at risk. An induration of 10 mm or greater is usually considered significant in individuals who have normal or mildly impaired immunity. A significant reaction indicates that a patient has been exposed to *M. tuberculosis* recently or in the past or has been vaccinated with bacille Calmette-Guerin (BCG) vaccine. The BCG vaccine is given to produce a greater resistance to developing TB. It is effective in up to 76% of those who receive it. The vaccine is used in Europe and Latin America but not routinely in the United States.

A reaction of 5 mm or greater is defined as positive for patients who are HIV-positive or have HIV risk factors and are of unknown HIV status, those who are close contacts with an active case, and those who have chest x-ray results consistent with tuberculosis.

**FIGURE 23-4** The Mantoux test for tuberculosis. (A) Correct technique for inserting the needle involves depositing the PPD subcutaneously with the needle bevel facing upward. (B) The reaction to the Mantoux test usually consists of a wheal, a hivelike, firm welt. (C) To determine the extent of the reaction, the wheal is measured using a commercially prepared gauge. A wheal measuring 5 mm or more is considered significant.

A significant (positive) reaction does not necessarily mean that active disease is present in the body. Most (more than 90%) people who are tuberculin-significant reactors do not develop clinical TB. However, all significant reactors are candidates for active TB. In general, the more intense the reaction, the greater the likelihood of an active infection.

A nonsignificant (negative) skin test does not exclude TB infection or disease because patients who are immunosuppressed cannot develop an immune response adequate to produce a positive skin test. This is referred to as anergy.

The accuracy of the skin test depends on the skill of the person interpreting the test reaction. One study (Kendig, Kirkpatrick, Carter et al., 1998) revealed that health care professionals tend to underestimate the size of induration: only 7% of a sample of 107 health care providers charted the correct size of induration.

### CLASSIFICATION OF TB

Data from the history, physical examination, skin test, chest x-ray, and microbiologic studies are used to classify TB into one of five classes. A classification scheme provides public health officials with a systematic way to monitor epidemiology and treatment of the disease (American Thoracic Society, 2000).

- Class 0: no exposure; no infection
- Class 1: exposure; no evidence of infection
- Class 2: latent infection; no disease (eg, positive PPD reaction but no clinical evidence of active TB)
- Class 3: disease; clinically active
- Class 4: disease; not clinically active
- Class 5: suspected disease; diagnosis pending

### Gerontologic Considerations

TB may have atypical manifestations in elderly patients, whose symptoms may include unusual behavior and altered mental status, fever, anorexia, and weight loss. Many elderly patients may have no reaction (loss of immunologic memory) or delayed reactivity for up to a week (recall phenomenon). A second skin test is performed in 1 to 2 weeks.

### Medical Management

Pulmonary TB is treated primarily with chemotherapeutic agents (antituberculosis agents) for 6 to 12 months. A prolonged treatment duration is necessary to ensure eradication of the organisms and to prevent relapse. A worldwide concern and challenge in TB therapy is the continuing (since the 1950s) and increasing resistance of *M. tuberculosis* to TB medications. Several types of drug resistance must be considered when planning effective therapy:

- Primary drug resistance: resistance to one of the first-line antituberculosis agents in a person who has not had previous treatment
- Secondary or acquired drug resistance: resistance to one or more antituberculosis agents in a patient undergoing therapy
- Multidrug resistance: resistance to two agents, isoniazid (INH) and rifampin. The populations at highest risk for multidrug resistance are those who are HIV-positive, institutionalized, or homeless.

The increasing prevalence of drug resistance points out the need to begin TB treatment with four or more medications, to

ensure completion of therapy, and to develop and evaluate new anti-TB medications.

### PHARMACOLOGIC THERAPY

In current TB therapy, five first-line medications are used (Table 23-2): INH, rifampin, pyrazinamide, and either streptomycin or ethambutol.

Combination medications, such as INH and rifampin (Rifamate) or INH, pyrazinamide and rifampin and medications administered twice a week (eg, rifapentine) are available to help improve patient adherence. Capreomycin, ethionamide, para-aminosalicylate sodium, and cycloserine are second-line medications. Additional potentially effective medications include other aminoglycosides, quinolones, rifabutin, clofazimine, and combinations of medications.

Recommended treatment guidelines for newly diagnosed cases of pulmonary TB (CDC, 2000) consist of a multiple-medication regimen of INH, rifampin, pyrazinamide, and either streptomycin or ethambutol. This initial intensive-treatment regimen is usually administered daily for 8 weeks. If cultures demonstrate that the organism is sensitive to the medications before the 8 weeks of therapy have been completed, either ethambutol or streptomycin can be discontinued. After 8 weeks of this medication regimen, pyrazinamide can be discontinued and INH and rifampin are administered for an additional 4 months. The medication regimen, however, may continue for 12 months. A person is considered noninfectious after 2 to 3 weeks of continuous medication therapy. Vitamin B (pyridoxine) is usually administered with INH to prevent INH-associated peripheral neuropathy (see Table 23-2).

INH also may be used as a prophylactic (preventive) measure for those at risk for significant disease, including:

- Household family members of patients with active disease
- HIV-infected patients with a PPD test reaction of 5 mm of induration or more
- Patients with fibrotic lesions detected on a chest x-ray, suggestive of old TB, and a PPD reaction of 5 mm of induration or more
- Patients whose current PPD test results show a change from former test results, suggesting recent exposure to TB and possible infection (also called skin test converters)
- Drug (intravenous or injectable) users with PPD test results of 10 mm of induration or more
- Patients with high-risk comorbid conditions with a PPD result of 10 mm of induration or more

Other candidates for preventive INH therapy are those age 35 years or younger with PPD test results of 10 mm of induration or more and one of the following criteria:

- Foreign-born individuals from countries with a high prevalence of TB
- High-risk, medically underserved populations
- Institutionalized patients

Prophylactic INH treatment involves taking daily doses for 6 to 12 months. Liver enzyme, blood urea nitrogen, and creatinine levels are monitored monthly. Sputum culture results are monitored for acid-fast bacillus to evaluate the effectiveness of treatment and the patient's compliance with therapy.

In 1998, the federal Advisory Council for the Elimination of Tuberculosis published recommendations for the development of TB vaccines. The recommendations include a focus on a "postinfection vaccine" to prevent people infected with TB from developing active disease (CDC, 1998). To date, this vaccine has

**Table 23-2 • First-Line Antitubercular Medications**

COMMONLY USED AGENTS	ADULT DAILY DOSAGE*	MOST COMMON SIDE EFFECTS	DRUG INTERACTIONS <sup>†</sup>	REMARKS*
isoniazid (INH)	5 mg/kg (300 mg maximum daily)	Peripheral neuritis, hepatic enzyme elevation, hepatitis, hypersensitivity	Phenytoin—synergistic Antabuse Alcohol	Bactericidal. Pyridoxine as prophylaxis for neuritis. Monitor AST (SGOT) and ALT (SGPT).
rifampin (Rifadin)	10 mg/kg (600 mg maximum daily)	Hepatitis, febrile reaction, purpura (rare), nausea, vomiting	Rifampin increases metabolism of oral contraceptives, quinidine, corticosteroids, coumarin derivatives and methadone, digoxin, oral hypoglycemics; PAS may interfere with absorption of rifampin.	Bactericidal. Orange urine and other body secretions. Discoloring of contact lenses. Monitor AST (SGOT) and ALT (SGPT).
rifabutin (Mycobutin)	5 mg/kg (300 mg maximum daily)			
streptomycin	15 mg/kg (1 g maximum daily)*	8th cranial nerve damage (may lead to deafness), nephrotoxicity	Neuromuscular blocking agents; may be potentiated to cause prolonged paralysis	Bactericidal in alkaline pH. Use with caution in elderly or in those with renal disease. Monitor vestibular function, audiograms, BUN and creatinine.
pyrazinamide	15 to 30 mg/kg (2.0 g maximum daily)*	Hyperuricemia, hepatotoxicity, skin rash, arthralgias, GI distress		Bactericidal. Monitor uric acid, AST (SGOT), ALT (SGPT).
ethambutol (Myambutol)	15 to 25 mg/kg (no maximum daily dose, but base on lean body wt)*	Optic neuritis (may lead to blindness; very rare at 15 mg/kg), skin rash		Bacteriostatic. Use with caution with renal disease or when eye testing is not feasible. Monitor visual acuity, color discrimination. <sup>‡</sup>
Combinations: INH + rifampin (eg, Rifamate)	150-mg & 300-mg caps (2 caps daily)			

\*Check product labeling for detailed information on dose, contraindications, drug interaction, adverse reactions, and monitoring.

<sup>†</sup>Refer to current literature, particularly on rifampin, because it increases hepatic microenzymes and therefore interacts with many drugs.

<sup>‡</sup>Initial examination should be performed at start of treatment.

not become clinically available. In 2000, recommendations were released regarding the treatment of latent TB infection (American Thoracic Society and CDC, 2000). Isoniazid (INH) for 6 to 12 months has been the mainstay of treatment for latent TB infection. However, this long duration of treatment has been limited due to poor adherence and concerns of toxicity. The American Thoracic Society and CDC released newer guidelines in the 2000 document, which focused on treating a latent infection over a shorter period of time. The CDC released case reports of liver injury associated with the 2-month rifampin-pyrazinamide (RIF-PZA) dosing regimen in August 2001 (MMWR, 2001). This prompted a review and changes to the 2000 guidelines. In summary, a 2-month RIF-PZA treatment regimen for latent TB infection should be used with caution, especially in patients who are concurrently taking medications for liver disease or those with a history of alcoholism. For patients not infected with HIV, 9 months of daily INH remains the preferred treatment, and 4 months of daily RIF is an acceptable alternative. No more than

a 2-week supply of RIF-PZA should be dispensed at any one time to facilitate periodic clinical assessments. Lastly, serum aminotransferase and bilirubin should be measured at baseline and at 2, 4, and 6 weeks of treatment in patients taking RIF-PZA (MMWR, 2001).

## NURSING PROCESS: THE PATIENT WITH TUBERCULOSIS

### Assessment

The nurse performs a complete history and physical examination. Clinical manifestations of fever, anorexia, weight loss, night sweats, fatigue, cough, and sputum production prompt a more thorough assessment of respiratory function—for example, assessing the lungs for consolidation by evaluating breath sounds (diminished, bronchial sounds, crackles), fremitus, egophony, and dullness on percussion. Enlarged, painful lymph nodes may be palpated as well. The nurse also assesses the patient's living

arrangements, perceptions and understanding of TB and its treatment, and readiness to learn.

## Nursing Diagnoses

Based on the assessment data, the nursing diagnoses may include:

- Ineffective airway clearance related to copious tracheo-bronchial secretions
- Deficient knowledge about treatment regimen and preventive health measures and related ineffective individual management of the therapeutic regimen (noncompliance)
- Activity intolerance related to fatigue, altered nutritional status, and fever

## Collaborative Problems/ Potential Complications

Based on the assessment data, collaborative problems or potential complications that may occur include:

- Malnutrition
- Adverse side effects of medication therapy: hepatitis, neurologic changes (deafness or neuritis), skin rash, gastrointestinal upset
- Multidrug resistance
- Spread of TB infection (miliary TB)

## Planning and Goals

The major goals for the patient include maintenance of a patent airway, increased knowledge about the disease and treatment regimen and adherence to the medication regimen, increased activity tolerance, and absence of complications.

## Nursing Interventions

### PROMOTING AIRWAY CLEARANCE

Copious secretions obstruct the airways in many patients with TB and interfere with adequate gas exchange. Increasing fluid intake promotes systemic hydration and serves as an effective expectorant. The nurse instructs the patient about correct positioning to facilitate airway drainage (postural drainage); this is described in Chapter 25.

### ADVOCATING ADHERENCE TO TREATMENT REGIMEN

The multiple-medication regimen that a patient must follow can be quite complex. Understanding the medications, schedule, and side effects is important. The patient must understand that TB is a communicable disease and that taking medications is the most effective means of preventing transmission. The major reason treatment fails is that patients do not take their medications regularly and for the prescribed duration. The nurse carefully instructs the patient about important hygiene measures, including mouth care, covering the mouth and nose when coughing and sneezing, proper disposal of tissues, and hand hygiene.

### PROMOTING ACTIVITY AND ADEQUATE NUTRITION

Patients with TB are often debilitated from a prolonged chronic illness and impaired nutritional status. The nurse plans a progressive activity schedule that focuses on increasing activity tolerance and muscle strength. Anorexia, weight loss, and malnutrition are common in patients with TB. The patient's willingness to eat may

be altered by fatigue from excessive coughing, sputum production, chest pain, generalized debilitated state, or cost, if the person has few resources. A nutritional plan that allows for small, frequent meals may be required. Liquid nutritional supplements may assist in meeting basic caloric requirements.

## MONITORING AND MANAGING POTENTIAL COMPLICATIONS

### Malnutrition

This may be a consequence of the patient's lifestyle, lack of knowledge about adequate nutrition and its role in health maintenance, lack of resources, fatigue, or lack of appetite because of coughing and mucus production. To counter the effects of these factors, the nurse collaborates with the dietitian, physician, social worker, family, and patient to identify strategies to ensure an adequate nutritional intake and availability of nutritious food. Identifying facilities (eg, shelters, soup kitchens, Meals on Wheels, and other community resources) that provide meals in the patient's neighborhood may increase the likelihood that the patient with limited resources and energy will have access to a more nutritious intake. High-calorie nutritional supplements may be suggested as a strategy for increasing dietary intake using food products normally found in the home. Purchasing food supplements may be beyond the patient's budget, but a dietitian can help develop recipes to increase caloric intake despite minimal resources.

### Side Effects of Medication Therapy

It is important to assess medication side effects because they are often a reason the patient fails to adhere to the prescribed medication regimen. Efforts are made to reduce the side effects to increase the patient's willingness to take the medications as prescribed.

The nurse instructs the patient to take the medication either on an empty stomach or at least 1 hour before meals, because food interferes with medication absorption (although taking medications on an empty stomach frequently results in gastrointestinal upset). Patients taking INH should avoid foods containing tyramine and histamine (tuna, aged cheese, red wine, soy sauce, yeast extracts). Eating these types of foods while taking INH may result in headache, flushing, hypotension, light-headedness, palpitations, and diaphoresis.

In addition, rifampin can increase the metabolism of other medications, making them less effective. These medications include beta-blockers, oral anticoagulants such as warfarin (Coumadin), digoxin, quinidine, corticosteroids, oral hypoglycemic agents, oral contraceptives, theophylline, and verapamil. This issue should be discussed with the physician and pharmacist so that medication dosages can be adjusted accordingly. The nurse informs the patient that rifampin may discolor contact lenses, so the patient may want to wear eyeglasses during treatment. The nurse monitors for other side effects of anti-TB medications, including hepatitis, neurologic changes (hearing loss, neuritis), and rash. Liver enzyme, blood urea nitrogen, and serum creatinine levels are monitored to detect medication-related changes in liver and kidney function. Sputum culture results are monitored for acid-fast bacillus to evaluate the effectiveness of the treatment regimen and adherence to therapy.

### Multidrug Resistance

The nurse carefully monitors vital signs and observes for spikes in temperature or changes in the clinical status. The nurse reports any change in the patient's respiratory status to the primary

health care provider. The nurse instructs the patient about the risk of drug resistance if the medication regimen is not strictly and continuously followed.

### Spread of TB Infection

Spread of TB infection to nonpulmonary sites of the body is known as miliary TB. It is the result of invasion of the bloodstream by the tubercle bacillus (*Ghon tubercle*). Usually it results from late reactivation of a dormant infection in the lung or elsewhere. The origin of the bacilli that enter the bloodstream is either a chronic focus that has ulcerated into a blood vessel or multitudes of miliary tubercles lining the inner surface of the thoracic duct. The organisms migrate from these foci into the bloodstream, are carried throughout the body, and disseminate throughout all tissues, with tiny miliary tubercles developing in the lungs, spleen, liver, kidneys, meninges, and other organs.

The clinical course of miliary TB may vary from an acute, rapidly progressive infection with high fever to an indolent process with low-grade fever, anemia, and debilitation. At first, there may be no localizing signs except an enlarged spleen and a reduced number of leukocytes. Within a few weeks, however, the chest x-ray reveals small densities scattered diffusely throughout both lung fields; these are the miliary tubercles, which gradually grow.

The possibility of TB in nonpulmonary sites in the body requires careful monitoring for this very serious form of the infection. The nurse monitors vital signs and observes for spikes in temperature as well as changes in renal and cognitive function. Few physical signs may be elicited on physical examination of the chest, but at this stage the patient has a severe cough and dyspnea. Treatment of miliary TB is the same as for pulmonary TB.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

The nurse plays a vital role in caring for the patient with TB and the family, which includes assessing the patient's ability to continue therapy at home. The nurse instructs the patient and family about infection control procedures, such as proper disposal of tissues, covering the mouth during coughing, and hand hygiene. Assessment of the patient's adherence to the medication regimen is imperative because of the risk of developing resistant strains of TB if the regimen is not followed faithfully. In some cases, when the patient's ability to comply with the medication regimen is in question, referral to an outpatient clinic for daily medication administration may be required. This is referred to as directly observed therapy (DOT).

### Continuing Care

The nurse evaluates the patient's environment, including home or workplace and social setting, to identify other people who may have been in contact with the patient during the infectious stage. It is important to arrange follow-up screening for any contacts of the infected person. Nurses who have contact with the patient in home, shelter, hospital, clinic, or work settings assess the patient's physical and psychological status and ability to adhere to the prescribed treatment. The nurse assesses the patient for adverse effects of medications and adherence to the therapeutic regimen (eg, taking medications as prescribed, practicing safe hygiene, consuming a nutritious and adequate diet, and participating in an appropriate level of activity). The nurse reinforces previous teaching and emphasizes the importance of

keeping scheduled appointments with the primary health care provider. In addition, the patient is reminded of the importance of other health promotion activities and recommended health screening.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Maintains a patent airway by managing secretions with hydration, humidification, coughing, and postural drainage
2. Demonstrates an adequate level of knowledge
  - a. Lists medications by name and the correct schedule for taking them
  - b. Names expected side effects of medications
  - c. Identifies how and when to contact health care provider
3. Adheres to treatment regimen by taking medications as prescribed and reporting for follow-up screening
4. Participates in preventive measures
  - a. Disposes of used tissues properly
  - b. Encourages people who are close contacts to report for testing
  - c. Adheres to hand hygiene recommendations
5. Maintains activity schedule
6. Exhibits no complications
  - a. Maintains adequate weight or gains weight if indicated
  - b. Exhibits normal results of tests of liver and kidney function
7. Takes steps to minimize side effects of medications
  - a. Takes supplemental vitamins (vitamin B), as prescribed, to minimize peripheral neuropathy
  - b. Avoids use of alcohol
  - c. Avoids foods containing tyramine and histamine
  - d. Has regular physical examinations and blood tests to evaluate liver and kidney function, neuropathy, hearing and visual acuity

## LUNG ABSCESS

A lung abscess is a localized necrotic lesion of the lung parenchyma containing purulent material that collapses and forms a cavity. It is generally caused by aspiration of anaerobic bacteria. By definition, the chest x-ray will demonstrate a cavity of at least 2 cm. Patients who have impaired cough reflexes and cannot close the glottis, or those with swallowing difficulties, are at risk for aspirating foreign material and developing a lung abscess. Other at-risk patients include those with central nervous system disorders (seizure, stroke), drug addiction, alcoholism, esophageal disease, or compromised immune function, those without teeth, as well as patients receiving nasogastric tube feedings and those with an altered state of consciousness from anesthesia.

## Pathophysiology

Most lung abscesses are a complication of bacterial pneumonia or are caused by aspiration of oral anaerobes into the lung. Abscesses also may occur secondary to mechanical or functional obstruction of the bronchi by a tumor, foreign body, or bronchial stenosis, or from necrotizing pneumonias, TB, pulmonary embolism, or chest trauma.

Most abscesses are found in areas of the lung that may be affected by aspiration. The site of the lung abscess is related to gravity and is determined by the patient's position. For patients who

are confined to bed, the posterior segment of an upper lobe and the superior segment of the lower lobe are the most common areas in which lung abscess occurs. However, atypical presentations may occur, depending on the position of the patient when the aspiration occurred.

Initially, the cavity in the lung may or may not extend directly into a bronchus. Eventually the abscess becomes surrounded, or encapsulated, by a wall of fibrous tissue. The necrotic process may extend until it reaches the lumen of a bronchus or the pleural space and establishes communication with the respiratory tract, the pleural cavity, or both. If the bronchus is involved, the purulent contents are expectorated continuously in the form of sputum. If the pleura is involved, an empyema results. A communication or connection between the bronchus and pleura is known as a bronchopleural fistula.

The organisms frequently associated with lung abscesses are *S. aureus*, *Klebsiella*, and other gram-negative species. Anaerobic organisms, however, may also be present. The organism varies depending on the underlying predisposing factors.

### Clinical Manifestations

The clinical manifestations of a lung abscess may vary from a mild productive cough to acute illness. Most patients have a fever and a productive cough with moderate to copious amounts of foul-smelling, often bloody, sputum. Leukocytosis may be present. Pleurisy or dull chest pain, dyspnea, weakness, anorexia, and weight loss are common. Fever and cough may develop insidiously and may have been present for several weeks before diagnosis.

### Assessment and Diagnostic Findings

Physical examination of the chest may reveal dullness on percussion and decreased or absent breath sounds with an intermittent **pleural friction rub** (grating or rubbing sound) on auscultation. Crackles may be present. Confirmation of the diagnosis is made by chest x-ray, sputum culture, and in some cases fiberoptic bronchoscopy. The chest x-ray reveals an infiltrate with an air–fluid level. A computed tomography (CT) scan of the chest may be required to provide more detailed pictures of different cross-sectional areas of the lung.

### Prevention

The following measures will reduce the risk of lung abscess:

- Appropriate antibiotic therapy before any dental procedures in patients who must have teeth extracted while their gums and teeth are infected
- Adequate dental and oral hygiene, because anaerobic bacteria play a role in the pathogenesis of lung abscess
- Appropriate antimicrobial therapy for patients with pneumonia

### Medical Management

The findings of the history, physical examination, chest x-ray, and sputum culture indicate the type of organism and the treatment required. Adequate drainage of the lung abscess may be achieved through postural drainage and chest physiotherapy. The patient should be assessed for an adequate cough. A few patients need a percutaneous chest catheter placed for long-term drainage of the abscess. Therapeutic use of bronchoscopy to drain an abscess is uncommon. A diet high in protein and calories is necessary because

chronic infection is associated with a catabolic state, necessitating increased intake of calories and protein to facilitate healing. Surgical intervention is rare, but pulmonary resection (lobectomy) is performed when there is massive **hemoptysis** (coughing up of blood) or little or no response to medical management.

### PHARMACOLOGIC THERAPY

Intravenous antimicrobial therapy depends on the results of the sputum culture and sensitivity and is administered for an extended period. Penicillin G or clindamycin (Cleocin) is the medication of choice, followed by penicillin with metronidazole. Large intravenous doses are generally required because the antibiotic must penetrate the necrotic tissue and the fluid in the abscess. The intravenous dose is continued until there is evidence of symptom improvement.

Long-term therapy with oral antibiotics replaces intravenous therapy after the patient shows signs of improvement (usually 3 to 5 days). Improvement is demonstrated by normal temperature, decreased white blood cell count, and improvement on the chest x-ray (resolution of surrounding infiltrate, reduction in cavity size, absence of fluid). Oral administration of antibiotic therapy is continued for an additional 4 to 8 weeks. If treatment stops too soon, a relapse may occur.

### Nursing Management

The nurse administers antibiotics and intravenous therapies as prescribed and monitors for adverse effects. Chest physiotherapy is initiated as prescribed to facilitate drainage of the abscess. The nurse teaches the patient to perform deep-breathing and coughing exercises to help expand the lungs. To ensure proper nutritional intake, the nurse encourages a diet high in protein and calories. The nurse also offers emotional support because the abscess may take a long time to resolve.

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** The patient who has had surgery may return home before the wound closes entirely or with a drain or tube in place. Thus, the patient or a caregiver needs instruction on how to change the dressings to prevent skin excoriation and odor, how to monitor for signs and symptoms of infection, and how to care for and maintain the drain or tube. The nurse instructs the patient to perform deep-breathing and coughing exercises every 2 hours during the day and shows a caregiver how to perform chest percussion and postural drainage to facilitate expectoration of lung secretions.

**Continuing Care.** Referral for home care may be required by some patients whose condition requires therapy at home. During visits to the patient at home, the nurse assesses the patient's physical condition, nutritional status, and home environment as well as the patient's and family's ability to carry out the therapeutic regimen. Patient teaching is reinforced during home visits, and nutrition counseling is provided with the goal of attaining and maintaining an optimal state of nutrition. To prevent a relapse, the nurse emphasizes the importance of completing the antibiotic regimen and of following the suggestions for rest and appropriate activity. If intravenous antibiotic therapy is to continue at home, the services of a home care nurse may be arranged to initiate intravenous therapy and to evaluate its administration by the patient or family. Although most outpatient intravenous therapy

is administered in the home setting, a patient may visit a nearby clinic or physician's office for this treatment. In some cases the patient with lung abscess may have ignored his or her health. Therefore, it is important to use this opportunity to address health promotion strategies and health screening with the patient.

## Pleural Conditions

Pleural conditions are disorders that involve the membranes covering the lungs (visceral pleura) and the surface of the chest wall (parietal pleura) or disorders affecting the pleural space.

### PLEURISY

#### Pathophysiology

Pleurisy (pleuritis) refers to inflammation of both layers of the pleurae (parietal and visceral). Pleurisy may develop in conjunction with pneumonia or an upper respiratory tract infection, TB, or collagen disease; after trauma to the chest, pulmonary infarction, or pulmonary embolism; in patients with primary and metastatic cancer; and after thoracotomy. The parietal pleura has nerve endings; the visceral pleura does not. When the inflamed pleural membranes rub together during respiration (intensified on inspiration), the result is severe, sharp, knifelike pain.

#### Clinical Manifestations

The key characteristic of pleuritic pain is its relationship to respiratory movement. Taking a deep breath, coughing, or sneezing worsens the pain. Pleuritic pain is restricted in distribution rather than diffuse; it usually occurs only on one side. The pain may become minimal or absent when the breath is held, or it may be localized or radiate to the shoulder or abdomen. Later, as pleural fluid develops, the pain decreases.

#### Assessment and Diagnostic Findings

In the early period, when little fluid has accumulated, a pleural friction rub can be heard with the stethoscope, only to disappear later as more fluid accumulates and separates the inflamed pleural surfaces. Diagnostic tests may include chest x-rays, sputum examinations, thoracentesis to obtain a specimen of pleural fluid for examination, and less commonly a pleural biopsy.

#### Medical Management

The objectives of treatment are to discover the underlying condition causing the pleurisy and to relieve the pain. As the underlying disease (pneumonia, infection) is treated, the pleuritic inflammation usually resolves. At the same time, it is necessary to monitor for signs and symptoms of pleural effusion, such as shortness of breath, pain, assumption of a position that decreases pain, and decreased chest wall excursion.

Prescribed analgesics and topical applications of heat or cold provide symptomatic relief. Indomethacin (Indocin), a non-steroidal anti-inflammatory drug (NSAID), may provide pain relief while allowing the patient to take deep breaths and cough more effectively. If the pain is severe, an intercostal nerve block may be required.

### Nursing Management

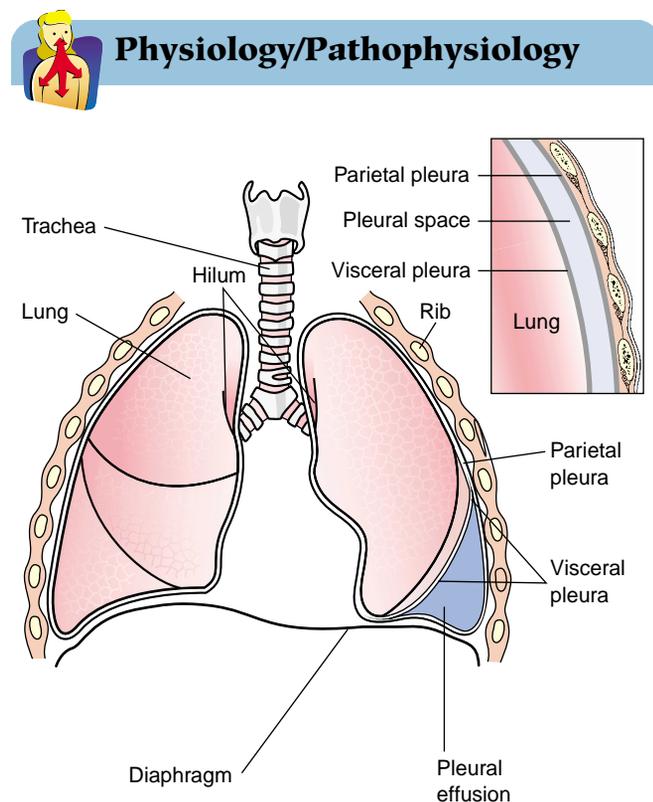

Because the patient has considerable pain on inspiration, the nurse can offer suggestions to enhance comfort, such as turning frequently onto the affected side to splint the chest wall and reduce the stretching of the pleurae. The nurse also can teach the patient to use the hands or a pillow to splint the rib cage while coughing.

### PLEURAL EFFUSION

Pleural effusion, a collection of fluid in the pleural space, is rarely a primary disease process but is usually secondary to other diseases. Normally, the pleural space contains a small amount of fluid (5 to 15 mL), which acts as a lubricant that allows the pleural surfaces to move without friction (Fig. 23-5). Pleural effusion may be a complication of heart failure, TB, pneumonia, pulmonary infections (particularly viral infections), nephrotic syndrome, connective tissue disease, pulmonary embolism, and neoplastic tumors. Bronchogenic carcinoma is the most common malignancy associated with a pleural effusion.

#### Pathophysiology

In certain disorders, fluid may accumulate in the pleural space to a point where it becomes clinically evident. This almost always has pathologic significance. The effusion can be composed of a relatively clear fluid, or it can be bloody or purulent. An effusion

**FIGURE 23-5** In pleural effusion, an abnormal volume of fluid collects in the pleural space, causing pain and shortness of breath. Pleural effusion is usually secondary to other disease processes.

of clear fluid may be a transudate or an exudate. A transudate (filtrates of plasma that move across intact capillary walls) occurs when factors influencing the formation and reabsorption of pleural fluid are altered, usually by imbalances in hydrostatic or oncotic pressures. The finding of a transudative effusion generally implies that the pleural membranes are not diseased. The most common cause of a transudative effusion is heart failure. An exudate (extravasation of fluid into tissues or a cavity) usually results from inflammation by bacterial products or tumors involving the pleural surfaces.

## Clinical Manifestations

Usually the clinical manifestations are those caused by the underlying disease. Pneumonia causes fever, chills, and pleuritic chest pain, whereas a malignant effusion may result in dyspnea and coughing. The size of the effusion and the patient's underlying lung disease determine the severity of symptoms. A large pleural effusion causes shortness of breath. When a small to moderate pleural effusion is present, dyspnea may be absent or only minimal. The severity of the symptoms assessed depends on the time course of the development of the pleural effusion and the patient's underlying disease.

## Assessment and Diagnostic Findings

Assessment of the area of the pleural effusion reveals decreased or absent breath sounds, decreased fremitus, and a dull, flat sound when percussed. In an extremely large pleural effusion, the assessment reveals a patient in acute respiratory distress. Tracheal deviation away from the affected side may also be noted.

Physical examination, chest x-ray, chest CT scan, and thoracentesis confirm the presence of fluid. In some instances, a lateral decubitus x-ray is obtained. For this x-ray, the patient lies on the affected side in a side-lying position. A pleural effusion can be diagnosed because this position allows for the "layering out" of the fluid, and an air-fluid line is visible.

Pleural fluid is analyzed by bacterial culture, Gram stain, acid-fast bacillus stain (for TB), red and white blood cell counts, chemistry studies (glucose, amylase, lactic dehydrogenase, protein), cytologic analysis for malignant cells, and pH. A pleural biopsy also may be performed.

## Medical Management

The objectives of treatment are to discover the underlying cause, to prevent reaccumulation of fluid, and to relieve discomfort, dyspnea, and respiratory compromise. Specific treatment is directed at the underlying cause (eg, heart failure, pneumonia, lung cancer, cirrhosis). If the pleural fluid is an exudate, more extensive diagnostic procedures are performed to determine the cause. Treatment for the primary cause is then instituted.

Thoracentesis is performed to remove fluid, to obtain a specimen for analysis, and to relieve dyspnea and respiratory compromise (see Chap. 21). Thoracentesis may be performed under ultrasound guidance. Depending on the size of the pleural effusion, the patient may be treated by removing the fluid during the thoracentesis procedure or by inserting a chest tube connected to a water-seal drainage system or suction to evacuate the pleural space and re-expand the lung.

If the underlying cause is a malignancy, however, the effusion tends to recur within a few days or weeks. Repeated thoracente-

ses result in pain, depletion of protein and electrolytes, and sometimes pneumothorax. Once the pleural space is adequately drained, a chemical pleurodesis may be performed to obliterate the pleural space and prevent reaccumulation of fluid. Pleurodesis may be performed using a thoracoscopic approach or via a chest tube. Chemically irritating agents (eg., bleomycin or talc) are instilled in the pleural space. With the chest tube insertion approach, after the agent is instilled, the chest tube is clamped for 60 to 90 minutes and the patient is assisted to assume various positions to promote uniform distribution of the agent and to maximize its contact with the pleural surfaces. The tube is unclamped as prescribed, and chest drainage may be continued several days longer to prevent reaccumulation of fluid and to promote the formation of adhesions between the visceral and parietal pleurae.

Other treatments for malignant pleural effusions include surgical pleurectomy, insertion of a small catheter attached to a drainage bottle for outpatient management, or implantation of a pleuroperitoneal shunt. A pleuroperitoneal shunt consists of two catheters connected by a pump chamber containing two one-way valves. Fluid moves from the pleural space to the pump chamber and then to the peritoneal cavity. The patient manually pumps on the reservoir daily to move fluid from the pleural space to the peritoneal space (Taubert & Wright, 2000).

## Nursing Management

The nurse's role in the care of the patient with a pleural effusion includes implementing the medical regimen. The nurse prepares and positions the patient for thoracentesis and offers support throughout the procedure. Pain management is a priority, and the nurse assists the patient to assume positions that are the least painful. However, frequent turning and ambulation are important to facilitate drainage. The nurse administers analgesics as prescribed and as needed.

If a chest tube drainage and water-seal system is used, the nurse is responsible for monitoring the system's function and recording the amount of drainage at prescribed intervals. Nursing care related to the underlying cause of the pleural effusion is specific to the underlying condition. Care of the patient with a chest tube is discussed in Chapter 25.

If the patient is to be managed as an outpatient with a pleural catheter for drainage, the nurse is responsible for educating the patient and family regarding management and care of the catheter and drainage system.

## EMPHYEMA

An empyema is an accumulation of thick, purulent fluid within the pleural space, often with fibrin development and a loculated (walled-off) area where infection is located. Most empyemas occur as complications of bacterial pneumonia or lung abscess. Other causes include penetrating chest trauma, hematogenous infection of the pleural space, nonbacterial infections, or iatrogenic causes (after thoracic surgery or thoracentesis).

## Pathophysiology

At first the pleural fluid is thin, with a low leukocyte count, but it frequently progresses to a fibropurulent stage and, finally, to a stage where it encloses the lung within a thick exudative membrane (loculated empyema).

## Clinical Manifestations

With an empyema, the patient is acutely ill and has signs and symptoms similar to those of an acute respiratory infection or pneumonia (fever, night sweats, pleural pain, cough, dyspnea, anorexia, weight loss). If the patient is immunocompromised, the symptoms may be more vague. If the patient has received antimicrobial therapy, the clinical manifestations may be less obvious.

## Assessment and Diagnostic Findings

Chest auscultation demonstrates decreased or absent breath sounds over the affected area, and there is dullness on chest percussion as well as decreased fremitus. The diagnosis is established by a chest x-ray or chest CT scan. Usually a diagnostic thoracentesis is performed, often under ultrasound guidance.

## Medical Management

The objectives of treatment are to drain the pleural cavity and to achieve full expansion of the lung. The fluid is drained and appropriate antibiotics, in large doses, are prescribed based on the causative organism. Sterilization of the empyema cavity requires 4 to 6 weeks of antibiotics. Drainage of the pleural fluid depends on the stage of the disease and is accomplished by one of the following methods:

- Needle aspiration (thoracentesis) with a thin percutaneous catheter, if the volume is small and the fluid not too purulent or thick
- Tube thoracostomy (chest drainage using a large-diameter intercostal tube attached to water-seal drainage [see Chap. 25]) with fibrinolytic agents instilled through the chest tube in patients with loculated or complicated pleural effusions
- Open chest drainage via thoracotomy, including potential rib resection, to remove the thickened pleura, pus, and debris and to remove the underlying diseased pulmonary tissue

With long-standing inflammation, an exudate can form over the lung, trapping it and interfering with its normal expansion. This exudate must be removed surgically (decortication). The drainage tube is left in place until the pus-filled space is obliterated completely. The complete obliteration of the pleural space is monitored by serial chest x-rays, and the patient should be informed that treatment may be long term. Patients are frequently discharged from the hospital with a chest tube in place, with instructions to monitor fluid drainage at home.

## Nursing Management

Resolution of empyema is a prolonged process. The nurse helps the patient cope with the condition and instructs the patient in lung-expanding breathing exercises to restore normal respiratory function. The nurse also provides care specific to the method of drainage of the pleural fluid (eg, needle aspiration, closed chest drainage, or rib resection and drainage). When a patient is discharged to home with a drainage tube or system in place, the nurse instructs the patient and family on care of the drainage system and drain site, measurement and observation of drainage, signs and symptoms of infection, and how and when to contact the health care provider. (See Nursing Process: The Patient Undergoing Thoracic Surgery in Chapter 25.)

## Pulmonary Edema

**Pulmonary edema** is defined as abnormal accumulation of fluid in the lung tissue and/or alveolar space. It is a severe, life-threatening condition.

## Pathophysiology

Pulmonary edema most commonly occurs as a result of increased microvascular pressure from abnormal cardiac function. The backup of blood into the pulmonary vasculature resulting from inadequate left ventricular function causes an increased microvascular pressure, and fluid begins to leak into the interstitial space and the alveoli. Other causes of pulmonary edema are hypervolemia or a sudden increase in the intravascular pressure in the lung. One example of this is in the patient who has undergone pneumonectomy. When one lung has been removed, all the cardiac output then goes to the remaining lung. If the patient's fluid status is not monitored closely, pulmonary edema can quickly develop in the postoperative period as the patient's pulmonary vasculature attempts to adapt. This type of pulmonary edema is sometimes termed "flash" pulmonary edema. A second example is called re-expansion pulmonary edema. This may be due to a rapid reinflation of the lung after removal of air from a pneumothorax or evacuation of fluid from a large pleural effusion.

## Clinical Manifestations

The patient has increasing respiratory distress, characterized by dyspnea, air hunger, and central cyanosis. The patient is usually very anxious and often agitated. As the fluid leaks into the alveoli and mixes with air, a foam or froth is formed. The patient coughs up or the nurse suction out these foamy, frothy, and often blood-tinged secretions. The patient has acute respiratory distress and may become confused or stuporous.

## Assessment and Diagnostic Findings

Auscultation reveals crackles in the lung bases (especially in the posterior bases) that rapidly progress toward the apices of the lungs. These crackles are due to the movement of air through the alveolar fluid. The chest x-ray reveals increased interstitial markings. The patient may be tachycardic, the pulse oximetry values begin to fall, and arterial blood gas analysis demonstrates increasing hypoxemia.

## Medical Management

Management focuses on correcting the underlying disorder. If the pulmonary edema is cardiac in origin, then improvement in left ventricular function is the goal. Vasodilators, inotropic medications, afterload or preload agents, or contractility medications may be given. Additional cardiac measures (eg, intra-aortic balloon pump) may be indicated if the patient does not respond. If the problem is fluid overload, diuretics are given and the patient is placed on fluid restrictions. Oxygen is administered to correct the hypoxemia; in some circumstances, intubation and mechanical ventilation are necessary. The patient is extremely anxious, and morphine is administered to reduce anxiety and control pain.

## Nursing Management

Nursing management of the patient with pulmonary edema includes assisting with administration of oxygen and intubation and mechanical ventilation if respiratory failure occurs. The nurse also administers medications (ie, morphine, vasodilators, inotropic medications, preload and afterload agents) as prescribed and monitors the patient's response. Nursing management in pulmonary edema is described in more detail in Chapter 30.

## Acute Respiratory Failure

Respiratory failure is a sudden and life-threatening deterioration of the gas exchange function of the lung. It exists when the exchange of oxygen for carbon dioxide in the lungs cannot keep up with the rate of oxygen consumption and carbon dioxide production by the cells of the body.

Acute respiratory failure (ARF) is defined as a fall in arterial oxygen tension ( $\text{PaO}_2$ ) to less than 50 mm Hg (hypoxemia) and a rise in arterial carbon dioxide tension ( $\text{PaCO}_2$ ) to greater than 50 mm Hg (hypercapnia), with an arterial pH of less than 7.35. In ARF, the ventilation or perfusion mechanisms in the lung are impaired. Respiratory system mechanisms leading to ARF include:

- Alveolar hypoventilation
- Diffusion abnormalities
- Ventilation–perfusion mismatching
- Shunting

It is important to distinguish between ARF and chronic respiratory failure. Chronic respiratory failure is defined as a deterioration in the gas exchange function of the lung that has developed insidiously or has persisted for a long period after an episode of ARF. The absence of acute symptoms and the presence of a chronic respiratory acidosis suggest the chronicity of the respiratory failure. Two causes of chronic respiratory failure are COPD (discussed in Chap. 24) and neuromuscular diseases (discussed in Chap. 65). Patients with these disorders develop a tolerance to the gradually worsening hypoxemia and hypercapnia. However, a patient with chronic respiratory failure may develop ARF. This is seen in the COPD patient who develops an exacerbation or infection that causes additional deterioration of the gas exchange mechanism. The principles of management of acute versus chronic respiratory failure are different; the following discussion will be limited to ARF.

## Pathophysiology

Common causes of ARF can be classified into four categories: decreased respiratory drive, dysfunction of the chest wall, dysfunction of the lung parenchyma, and other causes.

### DECREASED RESPIRATORY DRIVE

Decreased respiratory drive may occur with severe brain injury, large lesions of the brain stem (multiple sclerosis), use of sedative medications, and metabolic disorders such as hypothyroidism. These disorders impair the normal response of chemoreceptors in the brain to normal respiratory stimulation.

### DYSFUNCTION OF THE CHEST WALL

The impulses arising in the respiratory center travel through nerves that extend from the brain stem down the spinal cord to receptors in the muscles of respiration. Thus, any disease or disorder of the nerves, spinal cord, muscles, or neuromuscular junction

involved in respiration seriously affects ventilation and may ultimately lead to ARF. These include musculoskeletal disorders (muscular dystrophy, polymyositis), neuromuscular junction disorders (myasthenia gravis, poliomyelitis), some peripheral nerve disorders, and spinal cord disorders (amyotrophic lateral sclerosis, Guillain-Barré syndrome, and cervical spinal cord injuries).

### DYSFUNCTION OF LUNG PARENCHYMA

Pleural effusion, hemothorax, pneumothorax, and upper airway obstruction are conditions that interfere with ventilation by preventing expansion of the lung. These conditions, which may cause respiratory failure, usually are produced by an underlying lung disease, pleural disease, or trauma and injury. Other diseases and conditions of the lung that lead to ARF include pneumonia, status asthmaticus, lobar atelectasis, pulmonary embolism, and pulmonary edema.

### OTHER CAUSES

In the postoperative period, especially after major thoracic or abdominal surgery, inadequate ventilation and respiratory failure may occur because of several factors. During this period, for example, ARF may be caused by the effects of anesthetic agents, analgesics, and sedatives, which may depress respiration as described earlier or enhance the effects of opioids and lead to hypoventilation. Pain may interfere with deep breathing and coughing. A mismatch of ventilation to perfusion is the usual cause of respiratory failure after major abdominal, cardiac, or thoracic surgery.

## Clinical Manifestations

Early signs are those associated with impaired oxygenation and may include restlessness, fatigue, headache, dyspnea, air hunger, tachycardia, and increased blood pressure. As the hypoxemia progresses, more obvious signs may be present, including confusion, lethargy, tachycardia, tachypnea, central cyanosis, diaphoresis, and finally respiratory arrest. Physical findings are those of acute respiratory distress, including use of accessory muscles, decreased breath sounds if the patient cannot adequately ventilate, and other findings related specifically to the underlying disease process and cause of ARF.

## Medical Management

The objectives of treatment are to correct the underlying cause and to restore adequate gas exchange in the lung. Intubation and mechanical ventilation may be required to maintain adequate ventilation and oxygenation while the underlying cause is corrected.

## Nursing Management

Nursing management of the patient with ARF includes assisting with intubation and maintaining mechanical ventilation (described in Chap. 25). The nurse assesses the patient's respiratory status by monitoring the patient's level of response, arterial blood gases, pulse oximetry, and vital signs and assessing the respiratory system. The nurse implements strategies (eg, turning schedule, mouth care, skin care, range of motion of extremities) to prevent complications. The nurse also assesses the patient's understanding of the management strategies that are used and initiates some form of communication to enable the patient to express his or her needs to the health care team. Nursing care also addresses the problems

that led to ARF. As the patient's status improves, the nurse assesses the patient's knowledge of the underlying disorder and provides teaching as appropriate to address the underlying disorder.

## Acute Respiratory Distress Syndrome

**Acute respiratory distress syndrome** (ARDS; previously called adult respiratory distress syndrome) is a clinical syndrome characterized by a sudden and progressive pulmonary edema, increasing bilateral infiltrates on chest x-ray, hypoxemia refractory to oxygen supplementation, and reduced lung compliance. These signs occur in the absence of left-sided heart failure. Patients with ARDS usually require mechanical ventilation with a higher-than-normal airway pressure. A wide range of factors are associated with the development of ARDS (Chart 23-6), including direct injury to the lungs (eg, smoke inhalation) or indirect insult to the lungs (eg, shock). ARDS has been associated with a mortality rate as high as 50% to 60%. The major cause of death in ARDS is nonpulmonary multiple-system organ failure, often with sepsis.

### Pathophysiology

ARDS occurs as a result of an inflammatory trigger that initiates the release of cellular and chemical mediators, causing injury to the alveolar capillary membrane. This results in leakage of fluid into the alveolar interstitial spaces and alterations in the capillary bed.

Severe ventilation-perfusion mismatching occurs in ARDS. Alveoli collapse because of the inflammatory infiltrate, blood, fluid, and surfactant dysfunction. Small airways are narrowed because of interstitial fluid and bronchial obstruction. The lung compliance becomes markedly decreased (stiff lungs), and the result is a characteristic decrease in functional residual capacity and severe hypoxemia. The blood returning to the lung for gas exchange is pumped through the nonventilated, nonfunctioning areas of the lung, causing a shunt to develop. This means that blood is interfacing with nonfunctioning alveoli and gas exchange is markedly impaired, resulting in severe, refractory hypoxemia. Figure 23-6 shows the sequence of pathophysiologic events leading to ARDS.

Chart  
23-6

### Etiologic Factors Related to ARDS

- Aspiration (gastric secretions, drowning, hydrocarbons)
- Drug ingestion and overdose
- Hematologic disorders (disseminated intravascular coagulopathy [DIC], massive transfusions, cardiopulmonary bypass)
- Prolonged inhalation of high concentrations of oxygen, smoke, or corrosive substances
- Localized infection (bacterial, fungal, viral pneumonia)
- Metabolic disorders (pancreatitis, uremia)
- Shock (any cause)
- Trauma (pulmonary contusion, multiple fractures, head injury)
- Major surgery
- Fat or air embolism
- Systemic sepsis

### Clinical Manifestations

Clinically, the acute phase of ARDS is marked by a rapid onset of severe dyspnea that usually occurs 12 to 48 hours after the initiating event. A characteristic feature is arterial hypoxemia that does not respond to supplemental oxygen. On chest x-ray, the findings are similar to those seen with cardiogenic pulmonary edema and present as bilateral infiltrates that quickly worsen. The acute lung injury then progresses to fibrosing alveolitis with persistent, severe hypoxemia. The patient also has increased alveolar dead space (ventilation to alveoli, but poor perfusion) and decreased pulmonary compliance ("stiff lungs," which are difficult to ventilate). Clinically, a patient is thought to be in the recovery phase if the hypoxemia gradually resolves, the chest x-ray improves, and the lungs become more compliant (Ware & Matthay, 2000).

### Assessment and Diagnostic Findings

Intercostal retractions and crackles, as the fluid begins to leak into the alveolar interstitial space, are evident on physical examination. A diagnosis of ARDS may be made based on the following crite-

## Physiology/Pathophysiology

**FIGURE 23-6** Pathogenesis and pathophysiology of acute respiratory distress syndrome. Adapted from Farzan, S. (1997). *A concise handbook of respiratory diseases* (4th ed.). Stamford, CT: Appleton & Lange.

ria; a history of systemic or pulmonary risk factors, acute onset of respiratory distress, bilateral pulmonary infiltrates, clinical absence of left-sided heart failure, and a ratio of partial pressure of oxygen of arterial blood to fraction of inspired oxygen ( $\text{PaO}_2/\text{FiO}_2$ ) less than 200 mm Hg (severe refractory hypoxemia).

## Medical Management

The primary focus in the management of ARDS includes identification and treatment of the underlying condition. Aggressive, supportive care must be provided to compensate for the severe respiratory dysfunction. This supportive therapy almost always includes intubation and mechanical ventilation. In addition, circulatory support, adequate fluid volume, and nutritional support are important. Supplemental oxygen is used as the patient begins the initial spiral of hypoxemia. As the hypoxemia progresses, intubation and mechanical ventilation are instituted. The concentration of oxygen and ventilator settings and modes are determined by the patient's status. This is monitored by arterial blood gas analysis, pulse oximetry, and bedside pulmonary function testing.

Positive end-expiratory pressure (PEEP) is a critical part of the treatment of ARDS. PEEP usually improves oxygenation, but it does not influence the natural history of the syndrome. Use of PEEP helps to increase functional residual capacity and reverse alveolar collapse by keeping the alveoli open, resulting in improved arterial oxygenation and a reduction in the severity of the ventilation–perfusion imbalance. By using PEEP, a lower  $\text{FiO}_2$  may be required. The goal is a  $\text{PaO}_2$  greater than 60 mm Hg or an oxygen saturation level of greater than 90% at the lowest possible  $\text{FiO}_2$ . PEEP and modes of mechanical ventilation are discussed in Chapter 25.

Systemic hypotension may occur in ARDS as a result of hypovolemia secondary to leakage of fluid into the interstitial spaces and depressed cardiac output from high levels of PEEP therapy. Hypovolemia must be carefully treated without causing further overload. Intravenous crystalloid solutions are administered, with careful monitoring of pulmonary status. Inotropic or vasopressor agents may be required. Pulmonary artery pressure catheters are used to monitor the patient's fluid status and the severe and progressive pulmonary hypertension sometimes observed in ARDS.

## PHARMACOLOGIC THERAPY

Numerous pharmacologic treatments are under investigation to stop the cascade of events leading to ARDS. These include human recombinant interleukin-1 receptor antagonist, neutrophil inhibitors, pulmonary-specific vasodilators, surfactant replacement therapy, antisepsis agents, antioxidant therapy, and corticosteroids late in the course of ARDS (Ware & Matthay, 2000).

## NUTRITIONAL THERAPY

Adequate nutritional support is vital in the treatment of ARDS. Patients with ARDS require 35 to 45 kcal/kg per day to meet caloric requirements. Enteral feeding is the first consideration; however, parenteral nutrition also may be required.

## Nursing Management

### GENERAL MEASURES

The patient with ARDS is critically ill and requires close monitoring because the condition could quickly change to a life-

threatening situation. Most of the respiratory modalities discussed in Chapter 25 are used in this situation (oxygen administration, nebulizer therapy, chest physiotherapy, endotracheal intubation or tracheostomy, mechanical ventilation, suctioning, bronchoscopy). Frequent assessment of the patient's status is necessary to evaluate the effectiveness of treatment.

In addition to implementing the medical plan of care, the nurse considers other needs of the patient. Positioning is important. The nurse should turn the patient frequently to improve ventilation and perfusion in the lungs and enhance secretion drainage. However, the nurse must closely monitor the patient for deterioration in oxygenation with changes in position. Oxygenation in the ARDS patient is sometimes improved in the prone position and may be used in special circumstances; studies to assess the benefits and problems of such positioning are ongoing (Curley, 2000; Marion, 2001).

The patient is extremely anxious and agitated because of the increasing hypoxemia and dyspnea. The nurse should explain all procedures and provide care in a calm, reassuring manner. It is important to reduce the patient's anxiety because anxiety prevents rest and increases oxygen expenditure. Rest is essential to reduce oxygen consumption, thereby reducing oxygen needs.

## VENTILATOR CONSIDERATIONS

If the patient is intubated and receiving mechanical ventilation with PEEP, several considerations must be addressed. PEEP, which causes increased end-expiratory pressure, is an unnatural pattern of breathing and feels strange to the patient. The patient may be anxious and “fight” the ventilator. Nursing assessment is important to assess for problems with ventilation that may be causing the anxiety reaction: tube blockage by kinking or retained secretions; other acute respiratory problems (eg, pneumothorax, pain); a sudden drop in the oxygen level; the patient's level of dyspnea; or ventilator malfunction. In some cases, sedation may be required to decrease the patient's oxygen consumption, allow the ventilator to provide full support of ventilation, and decrease the patient's anxiety. Possible sedatives are lorazepam (Ativan), midazolam (Versed), haloperidol (Haldol), propofol (Diprivan), and short-acting barbiturates.

If the PEEP level cannot be maintained despite the use of sedatives, neuromuscular blocking agents, such as pancuronium (Pavulon), vecuronium (Norcuron), atracurium (Tracrium), and rocuronium (Zemuron), may be given to paralyze the patient. This allows the patient to be ventilated more easily. With paralysis, the patient appears unconscious, loses motor function, and cannot breathe, talk, or blink independently. However, the patient retains sensation and is awake and able to hear. The nurse must reassure the patient that the paralysis is a result of the medication and is temporary. Paralysis should be used for the shortest possible time and never without adequate sedation.

Use of paralytic agents has many dangers and side effects. The nurse must be sure the patient does not become disconnected from the ventilator, because respiratory muscles are paralyzed and the patient will be apneic. Consequently, the nurse ensures that the patient is closely monitored at all times. All ventilator and patient alarms should be on at all times. Eye care is important as well because the patient cannot blink, increasing the risk of corneal abrasions. Neuromuscular blockers predispose patients to the development of deep venous thrombi, muscle atrophy, and skin breakdown. Nursing assessment is essential to minimize the complications related to neuromuscular blockade. The patient may have discomfort or pain but cannot communicate these sensations.

Analgesia is usually administered concurrently with neuromuscular blocking agents. The nurse must anticipate the patient's needs regarding pain and comfort. The nurse checks the patient's position to ensure it is comfortable and in normal alignment and talks to, and not about, the patient while in the patient's presence.

In addition, it is important for the nurse to describe the purpose and effects of the paralytic agents to the family. This experience can be very frightening to family members if they are unaware that these agents have been administered.

## Pulmonary Hypertension

Pulmonary hypertension is a condition that is not clinically evident until late in its progression. Pulmonary hypertension exists when the systolic pulmonary artery pressure exceeds 30 mm Hg or the mean pulmonary artery pressure exceeds 25 mm Hg. These pressures cannot be measured indirectly as can systemic blood pressure; instead, they must be measured during right-sided heart catheterization. In the absence of these measurements, clinical recognition becomes the only indicator for the presence of pulmonary hypertension.

There are two forms of pulmonary hypertension: primary (or idiopathic) and secondary. Primary pulmonary hypertension is an uncommon disease in which the diagnosis is made by excluding all other possible causes. The exact cause is unknown, but there are several possible causes (Chart 23-7). The clinical presentation of primary pulmonary hypertension exists with no evidence of pulmonary and cardiac disease or pulmonary embolism. It occurs most often in women 20 to 40 years of age and is usually fatal within 5 years of diagnosis.

Chart  
23-7

### Causes of Pulmonary Hypertension

#### Primary or Idiopathic

- Altered immune mechanisms
- Silent pulmonary emboli
- Raynaud's phenomenon
- Oral contraceptive use
- Sickle cell disease
- Collagen diseases

#### Secondary

- Pulmonary vasoconstriction due to hypoxemia
- Chronic obstructive pulmonary disease
- Kyphoscoliosis
- Obesity
- Smoke inhalation
- High altitude
- Neuromuscular disorders
- Diffuse interstitial pneumonia
- Reduction of the pulmonary vascular bed (must impair 50% to 75% of the vascular bed)
  - Pulmonary emboli
  - Vasculitis
  - Widespread interstitial lung disease (sarcoidosis, systemic sclerosis)
  - Tumor emboli
- Primary cardiac disease
  - Congenital (patent ductus arteriosus, atrial septal defect, ventricular septal defect)
  - Acquired (rheumatic valvular disease, mitral stenosis, myxoma, left ventricular failure)

Secondary pulmonary hypertension is more common and results from existing cardiac or pulmonary disease. The prognosis depends on the severity of the underlying disorder and the changes in the pulmonary vascular bed. A common cause of secondary pulmonary hypertension is pulmonary artery constriction due to hypoxemia from COPD.

## Pathophysiology

The underlying process of pulmonary hypertension varies, and multiple factors are often responsible. Normally, the pulmonary vascular bed can handle the blood volume delivered by the right ventricle. It has a low resistance to blood flow and compensates for increased blood volume by dilation of the vessels in the pulmonary circulation. However, if the pulmonary vascular bed is destroyed or obstructed, as in pulmonary hypertension, the ability to handle whatever flow or volume of blood it receives is impaired, and the increased blood flow then increases the pulmonary artery pressure. As the pulmonary arterial pressure increases, the pulmonary vascular resistance also increases. Both pulmonary artery constriction (as in hypoxemia or hypercapnia) and a reduction of the pulmonary vascular bed (which occurs with pulmonary emboli) result in an increase in pulmonary vascular resistance and pressure. This increased workload affects right ventricular function. The myocardium ultimately cannot meet the increasing demands imposed on it, leading to right ventricular hypertrophy (enlargement and dilation) and failure.

## Clinical Manifestations

Dyspnea is the main symptom of pulmonary hypertension, occurring at first with exertion and eventually at rest. Substernal chest pain also is common, affecting 25% to 50% of patients. Other signs and symptoms include weakness, fatigue, syncope, occasional hemoptysis, and signs of right-sided heart failure (peripheral edema, ascites, distended neck veins, liver engorgement, crackles, heart murmur).

## Assessment and Diagnostic Findings

A complete diagnostic evaluation includes a history, physical examination, chest x-ray, pulmonary function studies, electrocardiogram (ECG), echocardiogram, ventilation-perfusion scan, and cardiac catheterization. In some cases, a lung biopsy, performed by thoracotomy or thoracoscopy, may be needed to make a definite diagnosis. Cardiac catheterization of the right side of the heart reveals elevated pulmonary arterial pressure. An echocardiogram can assess the progression of the disease and rule out other conditions with similar signs and symptoms. The ECG reveals right ventricular hypertrophy, right axis deviation, and tall peaked P waves in inferior leads, tall anterior R waves, and ST-segment depression and/or T-wave inversion anteriorly. The PaO<sub>2</sub> also is decreased (hypoxemia). A ventilation-perfusion scan or pulmonary angiography detects defects in pulmonary vasculature, such as pulmonary emboli. Pulmonary function studies may be normal or show a slight decrease in vital capacity (VC) and lung compliance, with a mild decrease in the diffusing capacity.

## Medical Management

The goal of treatment is to manage the underlying cardiac or pulmonary condition. Most patients with primary pulmonary hypertension do not have hypoxemia at rest but require supplemental

oxygen with exercise. However, patients with severe right ventricular failure, decreased cardiac output, and progressive disease may have resting hypoxemia and require continuous oxygen supplementation. Appropriate oxygen therapy (see Chap. 25) reverses the vasoconstriction and reduces the pulmonary hypertension in a relatively short time.

In the presence of cor pulmonale, which is discussed in the section that follows, treatment should include fluid restriction, diuretics to decrease fluid accumulation, cardiac glycosides (eg, digitalis) in an attempt to improve cardiac function, calcium channel blockers for vasodilation, and rest. In primary pulmonary hypertension, vasodilators have been administered with variable success (eg, calcium channel blockers, intravenous prostacyclin). Prostacyclin (PGX [Flolan]) is one of the prostaglandins produced by the pulmonary endothelium. Intravenous prostacyclin (epoprostenol) helps to decrease pulmonary hypertension by reducing pulmonary vascular resistance and pressures and increasing cardiac output. Anticoagulants such as warfarin (Coumadin) have been given to patients because of chronic pulmonary emboli. Heart–lung transplantation has been successful in select patients with primary hypertension who have not been responsive to other therapies.

## Nursing Management

The major nursing goal is to identify patients at high risk for pulmonary hypertension, such as those with COPD, pulmonary emboli, congenital heart disease, and mitral valve disease. The nurse also must be alert for signs and symptoms, administer oxygen therapy appropriately, and instruct patients and their families about the use of home oxygen supplementation.

## Pulmonary Heart Disease (Cor Pulmonale)

**Cor pulmonale** is a condition in which the right ventricle of the heart enlarges (with or without right-sided heart failure) as a result of diseases that affect the structure or function of the lung or its vasculature. Any disease affecting the lungs and accompanied by hypoxemia may result in cor pulmonale. The most frequent cause is severe COPD (see Chap. 24), in which changes in the airway and retained secretions reduce alveolar ventilation. Other causes are conditions that restrict or compromise ventilatory function, leading to hypoxemia or acidosis (deformities of the thoracic cage, massive obesity), or conditions that reduce the pulmonary vascular bed (primary idiopathic pulmonary arterial hypertension, pulmonary embolus). Certain disorders of the nervous system, respiratory muscles, chest wall, and pulmonary arterial tree also may be responsible for cor pulmonale.

## Pathophysiology

Pulmonary disease can produce physiologic changes that in time affect the heart and cause the right ventricle to enlarge and eventually fail. Any condition that deprives the lungs of oxygen can cause hypoxemia and hypercapnia, resulting in ventilatory insufficiency. Hypoxemia and hypercapnia cause pulmonary arterial vasoconstriction and possibly reduction of the pulmonary vascular bed, as in emphysema or pulmonary emboli. The result is increased resistance in the pulmonary circulatory system, with a subsequent rise in pulmonary blood pressure (pulmonary hypertension). A mean pulmonary arterial pressure of 45 mm Hg or more may occur in cor pulmonale. Right ventricular hypertrophy

may result, followed by right ventricular failure. In short, cor pulmonale results from pulmonary hypertension, which causes the right side of the heart to enlarge because of the increased work required to pump blood against high resistance through the pulmonary vascular system.

## Clinical Manifestations

Symptoms of cor pulmonale are usually related to the underlying lung disease, such as COPD. With right ventricular failure, the patient may develop increasing edema of the feet and legs, distended neck veins, an enlarged palpable liver, pleural effusion, ascites, and a heart murmur. Headache, confusion, and somnolence may occur as a result of increased levels of carbon dioxide (hypercapnia). Patients often complain of increasing shortness of breath, wheezing, cough, and fatigue.

## Medical Management

The objectives of treatment are to improve the patient's ventilation and to treat both the underlying lung disease and the manifestations of heart disease. Supplemental oxygen is administered to improve gas exchange and to reduce pulmonary arterial pressure and pulmonary vascular resistance. Improved oxygen transport relieves the pulmonary hypertension that is causing the cor pulmonale.

Better survival rates and greater reduction in pulmonary vascular resistance have been reported with continuous, 24-hour oxygen therapy for patients with severe hypoxemia. Substantial improvement may require 4 to 6 weeks of oxygen therapy, usually in the home. Periodic assessment of pulse oximetry and arterial blood gases is necessary to determine the adequacy of alveolar ventilation and to monitor the effectiveness of oxygen therapy.

Ventilation is further improved with chest physical therapy and bronchial hygiene maneuvers as indicated to remove accumulated secretions, and the administration of bronchodilators. Further measures depend on the patient's condition. If the patient is in respiratory failure, endotracheal intubation and mechanical ventilation may be necessary. If the patient is in heart failure, hypoxemia and hypercapnia must be relieved to improve cardiac function and output. Bed rest, sodium restriction, and diuretic therapy also are instituted judiciously to reduce peripheral edema (to lower pulmonary arterial pressure through a decrease in total blood volume) and the circulatory load on the right side of the heart. Digitalis may be prescribed to relieve pulmonary hypertension if the patient also has left ventricular failure, a supraventricular dysrhythmia, or right ventricular failure that does not respond to other therapy.

ECG monitoring may be indicated because of the high incidence of dysrhythmias in patients with cor pulmonale. Any pulmonary infection must be treated promptly to avoid further impaired gas exchange and exacerbations of hypoxemia and pulmonary heart disease. The prognosis depends on whether the pulmonary hypertension is reversible. (Management of acute respiratory failure was presented earlier in this chapter.)

## Nursing Management

Nursing care of the patient with cor pulmonale addresses the underlying disorder leading to cor pulmonale as well as the problems related to pulmonary hyperventilation and right-sided cardiac failure. If intubation and mechanical ventilation are required to manage ARF, the nurse assists with the intubation procedure

and maintains mechanical ventilation. The nurse assesses the patient's respiratory and cardiac status and administers medications as prescribed.

During the patient's hospital stay, the nurse instructs the patient about the importance of close monitoring (fluid retention, weight gain, edema) and adherence to the therapeutic regimen, especially the 24-hour use of oxygen. Factors that affect the patient's adherence to the treatment regimen are explored and addressed.

## PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** Most of the care and monitoring of the patient with cor pulmonale is performed by the patient and family in the home because it is a chronic disorder. If supplemental oxygen is administered, the nurse instructs the patient and the family in its use. Nutrition counseling is warranted if the patient is on a sodium-restricted diet or is taking diuretics. The nurse teaches the family to monitor for signs and symptoms of right ventricular failure and about emergency interventions and when to call for assistance. Most importantly, the nurse urges the patient to stop smoking.

**Continuing Care.** A referral for home care may be warranted for the patient who cannot manage self-care or for the patient whose physical condition warrants close assessment. During the home visit, the home care nurse evaluates the patient's status and the patient's and family members' understanding of the therapeutic regimen and their adherence to it. If oxygen is used in the home, the nurse determines if it is being administered safely and as prescribed. It is important to assess the patient's progress in stopping smoking and to reinforce the importance of smoking cessation with the patient and family. The nurse identifies strategies to assist with smoking cessation and refers the patient and family to community support groups. In addition, the patient is reminded about the importance of other health promotion and screening practices.

## Pulmonary Embolism

**Pulmonary embolism (PE)** refers to the obstruction of the pulmonary artery or one of its branches by a thrombus (or thrombi) that originates somewhere in the venous system or in the right side of the heart. Most commonly, PE is due to a blood clot or thrombus. However, there are other types of emboli: air, fat, amniotic fluid, and septic (from bacterial invasion of the thrombus). It is estimated that more than half a million people develop PE yearly, resulting in more than 50,000 deaths. PE is a common disorder and often is associated with trauma, surgery (orthopedic, major abdominal, pelvic, gynecologic), pregnancy, heart failure, age older than 50 years, hypercoagulable states, and prolonged immobility. It also may occur in an apparently healthy person. Risk factors for developing PE are identified in Chart 23-8.

Although most thrombi originate in the deep veins of the legs, other sites include the pelvic veins and the right atrium of the heart. A venous thrombosis can result from slowing of blood flow (stasis), secondary to damage to the blood vessel wall (particularly the endothelial lining) or changes in the blood coagulation mechanism. Atrial fibrillation is also a cause of pulmonary embolism. An enlarged right atrium in fibrillation causes blood to stagnate and form clots in this area. These clots are prone to travel into the pulmonary circulation.

Chart 23-8

### Risk Factors for Pulmonary Embolus

#### Venous Stasis (slowing of blood flow in veins)

- Prolonged immobilization (especially postoperative)
- Prolonged periods of sitting/traveling
- Varicose veins
- Spinal cord injury

#### Hypercoagulability (due to release of tissue thromboplastin after injury/surgery)

- Injury
- Tumor (pancreatic, GI, GU, breast, lung)
- Increased platelet count (polycythemia, splenectomy)

#### Venous Endothelial Disease

- Thrombophlebitis
- Vascular disease
- Foreign bodies (IV/central venous catheters)

#### Certain Disease States (combination of stasis, coagulation alterations, and venous injury)

- Heart disease (especially heart failure)
- Trauma (especially fracture of hip, pelvis, vertebra, lower extremities)
- Postoperative state/postpartum period
- Diabetes mellitus
- Chronic obstructive pulmonary disease

#### Other Predisposing Conditions

- Advanced age
- Obesity
- Pregnancy
- Oral contraceptive use
- History of previous thrombophlebitis, pulmonary embolism
- Constrictive clothing

## Pathophysiology

When a thrombus completely or partially obstructs a pulmonary artery or its branches, the alveolar dead space is increased. The area, although continuing to be ventilated, receives little or no blood flow. Thus, gas exchange is impaired or absent in this area. In addition, various substances are released from the clot and surrounding area, causing regional blood vessels and bronchioles to constrict. This causes an increase in pulmonary vascular resistance. This reaction compounds the ventilation-perfusion imbalance.

The hemodynamic consequences are increased pulmonary vascular resistance from the regional vasoconstriction and reduced size of the pulmonary vascular bed. This results in an increase in pulmonary arterial pressure and, in turn, an increase in right ventricular work to maintain pulmonary blood flow. When the work requirements of the right ventricle exceed its capacity, right ventricular failure occurs, leading to a decrease in cardiac output followed by a decrease in systemic blood pressure and the development of shock.

## Clinical Manifestations

The symptoms of PE depend on the size of the thrombus and the area of the pulmonary artery occluded by the thrombus; they may be nonspecific. Dyspnea is the most frequent symptom; tachypnea (very rapid respiratory rate) is the most frequent sign (Goldhaber, 1998). The duration and intensity of the dyspnea depend on the extent of embolization. Chest pain is common and is usually sud-

den and pleuritic. It may be substernal and mimic angina pectoris or a myocardial infarction. Other symptoms include anxiety, fever, tachycardia, apprehension, cough, diaphoresis, hemoptysis, and syncope.

A massive embolism is best defined by the degree of hemodynamic instability rather than the percentage of pulmonary vasculature occlusion. It is described as an occlusion of the outflow tract of the main pulmonary artery or the bifurcation of the pulmonary arteries that produces pronounced dyspnea, sudden substernal pain, rapid and weak pulse, shock, syncope, and sudden death. Multiple small emboli can lodge in the terminal pulmonary arterioles, producing multiple small infarctions of the lungs. A pulmonary infarction causes ischemic necrosis of an area of the lung and occurs in less than 10% of cases of PE (Arroliga, Matthay & Matthay, 2000). The clinical picture may mimic that of bronchopneumonia or heart failure. In atypical instances, the disease causes few signs and symptoms, whereas in other instances it mimics various other cardiopulmonary disorders.

### Assessment and Diagnostic Findings

Death from PE commonly occurs within 1 hour of symptoms; thus, early recognition and diagnosis are priorities. Because the symptoms of PE can vary from few to severe, a diagnostic workup is performed to rule out other diseases. Deep venous thrombosis is closely associated with the development of PE. Typically, patients report sudden onset of pain and/or swelling and warmth of the proximal or distal extremity, skin discoloration, and superficial vein distention. The pain is usually relieved with elevation. The diagnostic workup includes a ventilation–perfusion scan, pulmonary angiography, chest x-ray, ECG, peripheral vascular studies, impedance plethysmography, and arterial blood gas analysis.

The chest x-ray is usually normal but may show infiltrates, atelectasis, elevation of the diaphragm on the affected side, or a pleural effusion. The chest x-ray is most helpful in excluding other possible causes. The ECG usually shows sinus tachycardia, PR-interval depression, and nonspecific T-wave changes. Peripheral vascular studies may include impedance plethysmography, Doppler ultrasonography, or venography (see Chap. 31). Test results confirm or exclude the diagnosis of PE. Arterial blood gas analysis may show hypoxemia and hypocapnia (from tachypnea); however, arterial blood gas measurements are normal in up to 20% of patients with PE.

A ventilation–perfusion scan is the test of choice in patients with suspected PE. The perfusion portion of the scan may indicate areas of diminished or absent blood flow and is the most useful test to rule out clinically important PE. A ventilation scan may show whether there is also a ventilation abnormality present. A normal perfusion scan rules out the diagnosis of PE. If there is a ventilation–perfusion mismatch, the probability of PE is high. Spiral CT of the chest may also assist in the diagnosis.

If lung scan results are not definitive, pulmonary angiography, considered the gold standard for the diagnosis of PE, can be used. This test is invasive and is performed in the interventional radiology department. A contrast agent is injected into the pulmonary arterial system, allowing visualization of obstructions to blood flow and abnormalities.

### Prevention

For those at risk, the most effective approach to preventing PE is to prevent deep venous thrombosis. Active leg exercises to avoid venous stasis, early ambulation, and use of elastic compression stockings are general preventive measures. Additional strategies for prevention are listed in the checklist in Chart 23-9.

Chart 23-9

#### Home Care Checklist • Prevention of Recurrent Pulmonary Embolism

*At the completion of the home care instruction, the patient or caregiver will be able to:*

	Patient	Caregiver
• Describe the underlying process leading to pulmonary embolism.	✓	✓
• Describe the need for continued anticoagulant therapy after the initial embolism.	✓	✓
• Name the anticoagulant prescribed and identify dosage and schedule of administration.	✓	✓
• Describe potential side effects of coagulation such as bruising and bleeding and identify ways to prevent bleeding.	✓	✓
Avoid the use of sharps (razors, knives, etc.) to prevent cuts; shave with an electric shaver.		
Use a toothbrush with soft bristles to prevent gum injury.		
Do not take aspirin or antihistamines while taking warfarin sodium (Coumadin).		
Always check with health care provider before taking any medicine, including over-the-counter medications.		
Avoid laxatives, because they may affect vitamin K absorption.		
Report the occurrence of dark, tarry stools to the health care provider immediately.		
Wear an identification bracelet or carry a medicine card stating that you are taking anticoagulants.		
• Describe strategies to prevent recurrent deep venous thrombosis and pulmonary emboli:	✓	✓
Continue to wear elastic pressure stockings (compression hose) as long as directed.		
Avoid sitting with legs crossed or sitting for prolonged periods of time.		
When traveling, change position regularly, walk occasionally, and do active exercises of moving the legs and ankles while sitting.		
Drink fluids, especially while traveling and in warm weather, to avoid hemoconcentration due to fluid deficit.		
• Describe the signs and symptoms of lower extremity circulatory compromise and potential deep venous thrombosis: calf or leg pain, swelling, pedal edema.	✓	✓
• Describe the signs and symptoms of pulmonary compromise related to recurrent pulmonary embolism.	✓	✓
• Describe how and when to contact the health care provider if symptoms of circulatory compromise or pulmonary compromise are identified.	✓	✓

Patients who are older than 40, whose hemostasis is adequate, and who are undergoing major elective abdominal or thoracic surgery may receive anticoagulant therapy. Low doses of heparin may be given before surgery to reduce the risk of postoperative deep venous thrombus and PE. Heparin should be administered subcutaneously 2 hours before surgery and continued every 8 to 12 hours until the patient is discharged. Low-dose heparin is thought to enhance the activity of antithrombin III, a major plasma inhibitor of clotting factor X. This regimen is not recommended for patients with an active thrombotic process or for those undergoing major orthopedic surgery, open prostatectomy, or surgery on the eye or brain. Low-molecular-weight heparin (eg, enoxaparin [Lovenox]) is an alternative therapy. It has a longer half-life, enhanced subcutaneous absorption, a reduced incidence of thrombocytopenia, and reduced interaction with platelets as compared to unfractionated heparin (Ansell, Hickey, Kleinschmidt et al., 2000).

The intermittent pneumatic leg compression device is useful in preventing thromboembolism. The device inflates a bag that intermittently compresses the leg from the calf to the thigh, thereby improving venous return. It may be applied before surgery and continued until the patient is ambulatory. The device is particularly useful for patients who are not candidates for anticoagulant therapy (Clagett, Anderson, Geerts et al., 1998).

## Medical Management

Because PE is often a medical emergency, emergency management is of primary concern. After emergency measures have been taken and the patient's condition stabilizes, the treatment goal is to dissolve (lyse) the existing emboli and prevent new ones from forming. The treatment of PE may include a variety of modalities:

- General measures to improve respiratory and vascular status
- Anticoagulation therapy
- Thrombolytic therapy
- Surgical intervention

## EMERGENCY MANAGEMENT

Massive PE is a life-threatening emergency. The immediate objective is to stabilize the cardiopulmonary system. A sudden rise in pulmonary resistance increases the work of the right ventricle, which can cause acute right-sided heart failure with cardiogenic shock. Most patients who die of massive PE do so in the first 1 to 2 hours after the embolic event. Emergency management consists of the following:

- Nasal oxygen is administered immediately to relieve hypoxemia, respiratory distress, and central cyanosis.
- Intravenous infusion lines are started to establish routes for medications or fluids that will be needed.
- A perfusion scan, hemodynamic measurements, and arterial blood gas determinations are performed. Spiral (helical) CT or pulmonary angiography may be performed. Spiral CT is more advanced and quicker than routine tomography. With spiral CT, the patient continuously moves as the x-ray tube rotates. With this type of CT, images can be reconstructed at select levels and locations for diagnostic purposes.
- Hypotension is treated by a slow infusion of dobutamine (Dobutrex) (which has a dilating effect on the pulmonary vessels and bronchi) or dopamine (Intropin).

- The ECG is monitored continuously for dysrhythmias and right ventricular failure, which may occur suddenly.
- Digitalis glycosides, intravenous diuretics, and antiarrhythmic agents are administered when appropriate.
- Blood is drawn for serum electrolytes, complete blood count, and hematocrit.
- If clinical assessment and arterial blood gas analysis indicate the need, the patient is intubated and placed on a mechanical ventilator.
- If the patient has suffered massive embolism and is hypotensive, an indwelling urinary catheter is inserted to monitor urinary output.
- Small doses of intravenous morphine or sedatives are administered to relieve the patient's anxiety, to alleviate chest discomfort, to improve tolerance of the endotracheal tube, and to ease adaptation to the mechanical ventilator.

## GENERAL MANAGEMENT

Measures are initiated to improve the patient's respiratory and vascular status. Oxygen therapy is administered to correct the hypoxemia, relieve the pulmonary vascular vasoconstriction, and reduce the pulmonary hypertension. Using elastic compression stockings or intermittent pneumatic leg compression devices reduces venous stasis. These measures compress the superficial veins and increase the velocity of blood in the deep veins by redirecting the blood through the deep veins. Elevating the leg (above the level of the heart) also increases venous flow.

## PHARMACOLOGIC THERAPY

**Anticoagulation Therapy.** Anticoagulant therapy (heparin, warfarin sodium) has traditionally been the primary method for managing acute deep vein thrombosis and PE (Goldhaber, 1998). Heparin is used to prevent recurrence of emboli but has no effect on emboli that are already present. It is administered as an intravenous bolus of 5,000 to 10,000 units, followed by a continuous infusion initiated at a dose of 18 U/kg per hour, not to exceed 1,600 U/hour in otherwise healthy patients (Goldhaber, 1998). The rate is reduced in patients with a high risk of bleeding. The goal is to keep the partial thromboplastin time 1.5 to 2.5 times normal (or 46 to 70 seconds). Heparin is usually administered for 5 to 7 days. Low-molecular-weight heparin (eg, enoxaparin [Lovenox]) may also be used.

Warfarin sodium (Coumadin) administration is begun within 24 hours after the start of heparin therapy because its onset of action is 4 to 5 days. Warfarin is usually continued for 3 to 6 months. The prothrombin time is maintained at 1.5 to 2.5 times normal (or an INR [international normalized ratio] of 2.0 to 3.0). Anticoagulation therapy is contraindicated in patients who are at risk for bleeding (eg, those with gastrointestinal conditions or with postoperative or postpartum bleeding).

**Thrombolytic Therapy.** Thrombolytic therapy (urokinase, streptokinase, alteplase, anistreplase, reteplase) also may be used in treating PE, particularly in patients who are severely compromised (eg, those who are hypotensive and have significant hypoxemia despite oxygen supplementation). Thrombolytic therapy resolves the thrombi or emboli more quickly and restores more normal hemodynamic functioning of the pulmonary circulation, thereby reducing pulmonary hypertension.

and improving perfusion, oxygenation, and cardiac output. Bleeding, however, is a significant side effect. Contraindications to thrombolytic therapy include a cerebrovascular accident within the past 2 months, other active intracranial processes, active bleeding, surgery within the past 10 days of the thrombotic event, recent labor and delivery, trauma, or severe hypertension. Consequently, thrombolytic agents are advocated only for PE affecting a significant area of blood flow to the lung and causing hemodynamic instability.

Before thrombolytic therapy is started, prothrombin time, partial thromboplastin time, hematocrit values, and platelet counts are obtained. Heparin is stopped prior to administration of a thrombolytic agent. During therapy, all but essential invasive procedures are avoided because of potential bleeding. If necessary, fresh whole blood, packed red cells, cryoprecipitate, or frozen plasma is administered to replace blood loss and reverse the bleeding tendency. After the thrombolytic infusion is completed (which varies in duration according to the agent used and the condition being treated), the patient is given anticoagulants.

### SURGICAL MANAGEMENT

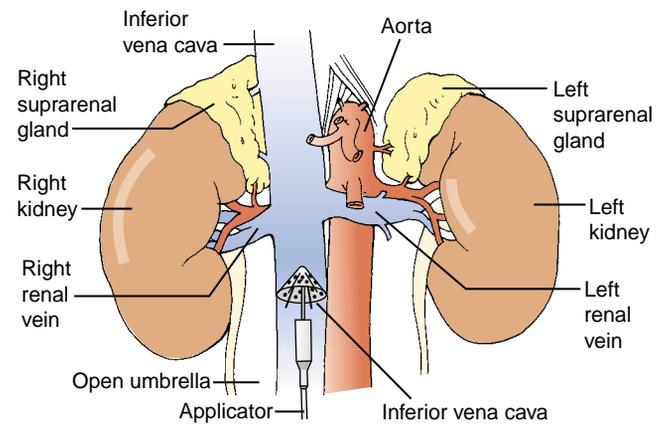

A surgical embolectomy is rarely performed but may be indicated if the patient has a massive PE or hemodynamic instability or if there are contraindications to thrombolytic therapy. Pulmonary embolectomy requires a thoracotomy with cardiopulmonary bypass technique. Transvenous catheter embolectomy is a technique in which a vacuum-cupped catheter is introduced transvenously into the affected pulmonary artery. Suction is applied to the end of the embolus and the embolus is aspirated into the cup. The surgeon maintains suction to hold the embolus within the cup, and the entire catheter is withdrawn through the right side of the heart and out the femoral vein. Catheters are available that pulverize the clot with high-velocity jets of normal saline solution (Goldhaber, 1998). An inferior caval filter is usually inserted at the time of surgery to protect against a recurrence.

Interrupting the inferior vena cava is another surgical technique used when PE recurs or when the patient is intolerant of anticoagulant therapy. This approach prevents dislodged thrombi from being swept into the lungs while allowing adequate blood flow. The preferred approach is the application of Teflon clips to the inferior vena cava to divide the lumen into small channels without occluding caval blood flow. Also, the use of transvenous devices that occlude or filter the blood through the inferior vena cava is a fairly safe way to prevent recurrent PE. One such technique involves inserting a filter (eg, Greenfield filter) through the internal jugular vein or common femoral vein (Fig. 23-7). This filter is advanced into the inferior vena cava, where it is opened. The perforated umbrella permits the passage of blood but prevents the passage of large thrombi. It is recommended that anticoagulation be continued in patients with a caval filter, if there are no contraindications to its use.

## Nursing Management

### MINIMIZING THE RISK OF PULMONARY EMBOLISM

A key role of the nurse is to identify patients at high risk for PE and to minimize the risk of PE in all patients. The nurse must have a high degree of suspicion for PE in any patient, but particularly in those with conditions predisposing to a slowing of venous return (see Chart 23-8).

**FIGURE 23-7** An umbrella filter is in place in the inferior vena cava to prevent pulmonary embolism. The filter (compressed within an applicator catheter) is inserted through an incision in the right internal jugular vein. The applicator is withdrawn when the filter fixes itself to the wall of the inferior vena cava after ejection from the applicator.

### PREVENTING THROMBUS FORMATION

Preventing thrombus formation is a major nursing responsibility. The nurse encourages ambulation and active and passive leg exercises to prevent venous stasis in patients on bed rest. The nurse instructs the patient to move the legs in a “pumping” exercise so that the leg muscles can help increase venous flow. The nurse also advises the patient not to sit or lie in bed for prolonged periods, not to cross the legs, and not to wear constricting clothing. Legs should not be dangled or feet placed in a dependent position while the patient sits on the edge of the bed; instead, the patient’s feet should rest on the floor or on a chair. In addition, intravenous catheters (for parenteral therapy or measurements of central venous pressure) should not be left in place for prolonged periods.

### ASSESSING POTENTIAL FOR PULMONARY EMBOLISM

The nurse examines patients who are at risk for developing PE for a positive Homans’ sign, which may or may not indicate impending thrombosis of the leg veins (see Chap. 31). To test for Homans’ sign, the patient assumes a supine position, lifts the leg, and dorsiflexes the foot. The nurse asks the patient to report whether calf pain occurs during this maneuver. The occurrence of pain—a positive Homans’ sign—may indicate deep venous thrombosis.

### MONITORING THROMBOLYTIC THERAPY

The nurse is responsible for monitoring thrombolytic and anticoagulant therapy. Thrombolytic therapy (streptokinase, urokinase, tissue plasminogen activator) causes lysis of deep vein thrombi and pulmonary emboli, which helps dissolve the clots. During thrombolytic infusion, the patient remains on bed rest, vital signs are assessed every 2 hours, and invasive procedures are limited. Tests to determine prothrombin time or partial thromboplastin time are performed 3 to 4 hours after the thrombolytic infusion is started to confirm that the fibrinolytic systems have been activated. Because of the prolonged clotting time, only essential arterial punctures or venipunctures are performed, and manual pressure is applied to any puncture site for at least 30 minutes. Pulse oximetry is used to monitor changes in oxygenation. The nurse immediately discontinues the infusion if uncontrolled bleeding occurs.

See Chapter 31 for nursing management for the patient receiving anticoagulant or thrombolytic therapy.

### MANAGING PAIN

Chest pain, if present, is usually pleuritic rather than cardiac in origin. A semi-Fowler's position provides a more comfortable position for breathing. However, it is important to continue to turn the patient frequently and reposition the patient to improve the **ventilation–perfusion ratio** in the lung. The nurse administers opioid analgesics as prescribed for severe pain.

### MANAGING OXYGEN THERAPY

Careful attention is given to the proper use of oxygen. It is important to ensure that the patient understands the need for continuous oxygen therapy. The nurse assesses the patient frequently for signs of hypoxemia and monitors the pulse oximetry values to evaluate the effectiveness of the oxygen therapy. Deep breathing and incentive spirometry are indicated for all patients to minimize or prevent atelectasis and improve ventilation. Nebulizer therapy or percussion and postural drainage may be used for management of secretions.

### RELIEVING ANXIETY

The nurse encourages the stabilized patient to talk about any fears or concerns related to this frightening episode, answers the patient's and family's questions concisely and accurately, explains the therapy, and describes how to recognize untoward effects early.

### MONITORING FOR COMPLICATIONS

When caring for a patient who has had PE, the nurse must be alert for the potential complication of cardiogenic shock or right ventricular failure subsequent to the effect of PE on the cardiovascular system. Nursing activities for managing shock are found in Chapter 15.

### PROVIDING POSTOPERATIVE NURSING CARE

After surgery, the nurse measures the patient's pulmonary arterial pressure and urinary output. The nurse assesses the insertion site of the arterial catheter for hematoma formation and infection. It is important to maintain the blood pressure at a level that supports perfusion of vital organs. To prevent peripheral venous stasis and edema of the lower extremities, the nurse elevates the foot of the bed and encourages isometric exercises, use of elastic compression stockings, and walking when the patient is permitted out of bed. Sitting is discouraged because hip flexion compresses the large veins in the legs.

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** Before hospital discharge and at follow-up visits to the clinic or during home visits, the nurse instructs the patient about how to prevent recurrence and what signs and symptoms to report immediately. Patient instructions, as presented in Chart 23-9, are intended to help prevent recurrences and side effects of treatment.

## Sarcoidosis

Sarcoidosis is a multisystem, granulomatous disease of unknown etiology. It may involve almost any organ or tissue but most commonly involves the lungs, lymph nodes, liver, spleen, central nervous system, skin, eyes, fingers, and parotid glands. The disease is not gender-specific, but some manifestations are more

common in women. In the United States, the disease is 10 times more common in African Americans (40 cases per 100,000) than in Caucasians (5 cases per 100,000), and the disease usually begins in the third or fourth decade of life (American Thoracic Society, 1999).

### Pathophysiology

Sarcoidosis is thought to be a hypersensitivity response to one or more agents (bacteria, fungi, virus, chemicals) in people with an inherited or acquired predisposition to the disorder. The hypersensitivity response results in granuloma formation due to the release of cytokines and other substances that promote replication of fibroblasts. In the lung, granuloma infiltration and fibrosis may occur, resulting in low lung compliance, impaired diffusing capacity, and reduced lung volumes (American Thoracic Society, 1999).

### Clinical Manifestations

A hallmark of this disease is its insidious onset and lack of prominent clinical signs or symptoms. The clinical picture depends on the systems involved. With pulmonary involvement, signs and symptoms may include dyspnea, cough, hemoptysis, and congestion. Generalized symptoms include anorexia, fatigue, and weight loss. Other signs include uveitis, joint pain, fever, and granulomatous lesions of the skin, liver, spleen, kidney, and central nervous system. The granulomas may disappear or gradually convert to fibrous tissue. With multisystem involvement, the patient has fatigue, fever, anorexia, weight loss, and joint pain.

### Assessment and Diagnostic Findings

Chest x-rays and CT scans are used to assess pulmonary adenopathy. The chest x-ray may show hilar adenopathy and disseminated miliary and nodular lesions in the lungs. A mediastinoscopy or **transbronchial** biopsy (in which a tissue specimen is obtained through the bronchial wall) may be used to confirm the diagnosis. In rare cases, an **open lung biopsy** is performed. Diagnosis is confirmed by a biopsy that shows noncaseating granulomas. Pulmonary function test results are abnormal if there is restriction of lung function (reduction in total lung capacity). Arterial blood gas measurements may be normal or may show reduced oxygen levels (hypoxemia) and increased carbon dioxide levels (hypercapnia).

### Medical Management

Many patients undergo remission without specific treatment. Corticosteroid therapy may benefit some patients because of its anti-inflammatory effect, which relieves symptoms and improves organ function. It is useful for patients with ocular and myocardial involvement, skin involvement, extensive pulmonary disease that compromises pulmonary function, hepatic involvement, and hypercalcemia. Other cytotoxic and immunosuppressive agents have been used, but without the benefit of controlled clinical trials. There is no single test that monitors the progression or recurrence of sarcoidosis. Multiple tests are used to monitor the involved systems.

## Occupational Lung Diseases: Pneumoconioses

Diseases of the lungs occur in numerous occupations as a result of exposure to organic and inorganic (mineral) dusts and noxious gases (fumes and aerosols). The effects of inhaling these materi-

als depend on the composition of the substance, its concentration, its ability to initiate an immune response, its irritating properties, the duration of exposure, and the individual's response or susceptibility to the irritant. Smoking may compound the problem and may increase the risk of lung cancers in people exposed to the mineral asbestos. Key aspects of any assessment of patients with a potential occupational respiratory history include job and job activities, exposure levels, general hygiene, time frame of exposure, amount of respiratory protection used, and direct versus indirect exposures.

Pneumoconiosis refers to a nonneoplastic alteration of the lung resulting from inhalation of mineral or inorganic dust (eg, "dusty lung"). The most common pneumoconioses are silicosis, asbestosis, and coal workers' pneumoconiosis.

## SILICOSIS

Silicosis is a chronic fibrotic pulmonary disease caused by inhalation of silica dust (crystalline silicon dioxide particles). Exposure to silica and silicates occurs in almost all mining, quarrying, and tunneling operations. Glass manufacturing, stone-cutting, the manufacture of abrasives and pottery, and foundry work are other occupations with exposure hazards. Finely ground silica, such as that found in soaps, polishes and filters, is extremely dangerous.

### Pathophysiology

When the silica particles, which have fibrogenic properties, are inhaled, nodular lesions are produced throughout the lungs. With the passage of time and further exposure, the nodules enlarge and coalesce. Dense masses form in the upper portion of the lungs, resulting in the loss of pulmonary volume. **Restrictive lung disease** (inability of the lungs to expand fully) and obstructive lung disease from secondary emphysema result. Cavities can form as a result of superimposed TB. Exposure of 15 to 20 years is usually required before the onset of the disease and shortness of breath are manifested. Fibrotic destruction of pulmonary tissue can lead to emphysema, pulmonary hypertension, and cor pulmonale.

### Clinical Manifestations

Patients with acute silicosis present with dyspnea, fever, cough, and weight loss and have a rapid progression of the disease. Symptoms are more severe in patients whose disease is complicated by progressive massive fibrosis. More commonly, this disease is a chronic problem with a long latency period. The patient may have slowly progressive symptoms indicative of hypoxemia, severe air-flow obstruction, and right-sided heart failure. Edema may occur because of the cardiac failure.

### Medical Management

There is no specific treatment for silicosis, because the fibrotic process in the lung is irreversible. Supportive therapy is directed at managing complications and preventing infection. Testing is performed to rule out other lung diseases, such as TB, lung cancer, and sarcoidosis. If TB is present, it is aggressively treated. Additional therapy might include oxygen, diuretics, inhaled beta-adrenergic agonists, anticholinergics, and bronchodilator therapy.

## ASBESTOSIS

**Asbestosis** is a disease characterized by diffuse pulmonary fibrosis from the inhalation of asbestos dust. Current laws restrict the use of asbestos, but many industries used it in the past. Therefore, exposure occurred, and may still occur, in numerous occupations, including asbestos mining and manufacturing, shipbuilding, demolition of structures containing asbestos, and roofing. Materials such as shingles, cement, vinyl asbestos tile, fireproof paint and clothing, brake linings, and filters all contained asbestos at one time, and many of these materials are still in existence. Additional diseases related to asbestos exposure include lung cancer, mesothelioma, and asbestos pleural effusion.

### Pathophysiology

Inhaled asbestos fibers enter the alveoli, where they are surrounded by fibrous tissue. The fibrous tissue eventually obliterates the alveoli. Fibrous changes also affect the pleura, which thickens and develops plaque. The result of these physiologic changes is a restrictive lung disease, with a decrease in lung volume, diminished exchange of oxygen and carbon dioxide, and hypoxemia.

### Clinical Manifestations

The onset of the disease is insidious, and the patient has progressive dyspnea, persistent, dry cough, mild to moderate chest pain, anorexia, weight loss, and malaise. Early physical findings include bibasilar fine, end-inspiratory crackles and in more advanced cases clubbing of the fingers. Cor pulmonale and respiratory failure occur as the disease progresses. A high proportion of workers who have been exposed to asbestos dust die of lung cancer, especially those who smoke or have a history of smoking. Malignant mesotheliomas may also occur. These are rare cancers of the pleura or peritoneum that are strongly associated with asbestos exposure.

### Medical Management

There is no effective treatment for asbestosis as the lung damage is permanent and often progressive. Management is directed at controlling infection and treating the lung disease. When oxygen-carbon dioxide exchange becomes severely impaired, continuous oxygen therapy may help improve activity tolerance. The patient must be instructed to avoid additional exposure to asbestos and to stop smoking. A significant contributing cause to mortality in this population is the high incidence of lung carcinoma.

## COAL WORKERS' PNEUMOCONIOSIS

Coal workers' pneumoconiosis ("black lung disease") includes a variety of respiratory diseases found in coal workers who have inhaled coal dust over the years. Coal miners are exposed to dusts that are mixtures of coal, kaolin, mica, and silica.

### Pathophysiology

When coal dust is deposited in the alveoli and respiratory bronchioles, macrophages engulf the particles (by phagocytosis) and transport them to the terminal bronchioles, where they are removed by mucociliary action. In time, the clearance mechanisms cannot handle the excessive dust load, and the macrophages aggregate in the respiratory bronchioles and alveoli. Fibroblasts appear and a network of reticulin is laid down surrounding the

dust-laden macrophages. The bronchioles and the alveoli become clogged with coal dust, dying macrophages, and fibroblasts. This leads to the formation of the coal macule, the primary lesion of the disorder. Macules appear as blackish dots on the lungs. Fibrotic lesions develop and, as the macules enlarge, the weakening bronchioles dilate, with subsequent development of a localized emphysema. The disease begins in the upper lobes of the lungs but may progress to the lower lobes.

## Clinical Manifestations

The first signs are a chronic cough and sputum production, similar to the signs encountered in chronic bronchitis. As the disease progresses, the patient develops dyspnea and coughs up large amounts of sputum with varying amounts of black fluid (melanoptysis), particularly if the individual is a smoker. Eventually, cor pulmonale and respiratory failure result. The diagnosis may first be made based on chest x-ray findings and a history of exposure.

## Medical Management

Preventing this disease is key because there is no effective treatment. Instead, treatment focuses on early diagnosis and management of complications. (See Chap. 24 for discussion of emphysema.)

## Nursing Management

### TEACHING ABOUT PREVENTION

The occupational health nurse serves as an employee advocate, making every effort to promote measures to reduce the exposure of workers to industrial products. Laws require that the work environment be ventilated properly to remove any noxious agent. Dust control can prevent many of the pneumoconioses. Dust control includes ventilation, spraying an area with water to control dust, and effective and frequent floor cleaning. Air samples need to be monitored. Toxic substances should be enclosed and placed in restricted areas. Workers must wear or use protective devices (facemasks, hoods, industrial respirators) to provide a safe air supply when a toxic element is present. Employees who are at risk should be carefully screened and followed. There is a risk of developing serious smoking-related illness (cancer) in industries in which there are unsafe levels of certain gases, dusts, fumes, fluids, and other toxic substances. Additionally, there is the potential for second-hand exposure. Asbestos and toxic dusts and substances may be transferred to others through the handling of clothing or shoes that have been exposed. Ongoing educational programs should be designed to teach workers to take responsibility for their own health and to stop smoking and receive an influenza vaccination.

The Right to Know law stipulates that employees must be informed about all hazardous and toxic substances in the workplace. Specifically, they must be educated about any hazardous or toxic substances they work with, what effects these substances can have on their health, and the measures they can take to protect themselves. The responsibility for implementing these controls inevitably falls on the federal or state government.

## Chest Tumors

Tumors of the lung may be benign or malignant. A malignant chest tumor can be primary, arising within the lung, chest wall, or mediastinum, or it can be a metastasis from a primary tumor site elsewhere in the body. Metastatic lung tumors occur fre-

quently because the bloodstream transports cancer cells from primary cancers elsewhere in the body to the lungs.

## LUNG CANCER (BRONCHOGENIC CARCINOMA)

Lung cancer is the number-one cancer killer among men and women in the United States, accounting for 31% of cancer deaths in men and 25% in women (American Cancer Society, 2002; Greenlee et al., 2001). For men, the incidence of lung cancer has remained relatively constant, but in women it continues to rise. Lung cancer affects primarily those in the sixth or seventh decade of life; less than 5% of patients are under the age of 40. In approximately 70% of lung cancer patients, the disease has spread to regional lymphatics and other sites by the time of diagnosis. As a result, the long-term survival rate for lung cancer patients is low. Evidence indicates that carcinoma tends to arise at sites of previous scarring (TB, fibrosis) in the lung. More than 85% of lung cancers are caused by the inhalation of carcinogenic chemicals, most commonly cigarette smoke (Schottenfeld, 2000).

## Pathophysiology

Lung cancers arise from a single transformed epithelial cell in the tracheobronchial airways. A carcinogen (cigarette smoke, radon gas, other occupational and environmental agents) binds to a cell's DNA and damages it. This damage results in cellular changes, abnormal cell growth, and eventually a malignant cell. As the damaged DNA is passed on to daughter cells, the DNA undergoes further changes and becomes unstable. With the accumulation of genetic changes, the pulmonary epithelium undergoes malignant transformation from normal epithelium to eventual invasive carcinoma.

Squamous cell carcinoma is more centrally located and arises more commonly in the segmental and subsegmental bronchi in response to repetitive carcinogenic exposures. Adenocarcinoma is the most prevalent carcinoma of the lung for both men and women; it presents more peripherally as peripheral masses or nodules and often metastasizes. Large cell carcinoma (also called undifferentiated carcinoma) is a fast-growing tumor that tends to arise peripherally. Bronchioalveolar cell cancer arises from the terminal bronchus and alveoli and is usually slower growing as compared to other bronchogenic carcinomas. Lastly, small cell carcinomas arise primarily as a proximal lesion or lesions but may arise in any part of the tracheobronchial tree.

## Classification and Staging

Non-small cell carcinoma represents 70% to 75% of tumors; small cell carcinoma represents 15% to 20% of tumors. For non-small cell carcinoma, the cell types include squamous cell carcinoma (30%), large cell carcinoma (10% to 16%), and adenocarcinoma (31% to 34%), including bronchioalveolar carcinoma (3% to 4%). Most small cell carcinomas arise in the major bronchi and spread by infiltration along the bronchial wall. Small cell cancers account for 20% to 25% of all bronchogenic cancers (Matthay, Tanoue & Carter, 2000).

In addition to cell type, lung cancers also are staged. The stage of the tumor refers to the size of the tumor, its location, whether lymph nodes are involved, and whether the cancer has spread (American Joint Committee on Cancer, 2002). Non-small cell lung cancer is staged as I to IV. Stage I is the earliest stage with the highest cure rates, while stage IV designates metastatic spread.

Small cell lung cancers are classified as limited or extensive. Diagnostic tools and further information on staging are described in Chapter 16.

## Risk Factors

Various factors have been associated with the development of lung cancer, including tobacco smoke, second-hand (passive) smoke, environmental and occupational exposures, gender, genetics, and dietary deficits. Other factors that have been associated with lung cancer include genetic predisposition and other underlying respiratory diseases, such as COPD and TB.

### TOBACCO SMOKE

Tobacco use is responsible for more than one of every six deaths in the United States from pulmonary and cardiovascular diseases. Smoking is the most important single preventable cause of death and disease in this country. More than 85% of lung cancers are attributable to inhalation of carcinogenic chemicals, such as cigarette smoke (American Cancer Society, 2002). Lung cancer is 10 times more common in cigarette smokers than nonsmokers. Risk is determined by the pack-year history (number of packs of cigarettes used each day, multiplied by the number of years smoked), the age of initiation of smoking, the depth of inhalation, and the tar and nicotine levels in the cigarettes smoked. The younger a person is when he or she starts smoking, the greater the risk of developing lung cancer. The risk of lung cancer decreases as the duration of smoking cessation increases.

### SECOND-HAND SMOKE

Passive smoking has been identified as a possible cause of lung cancer in nonsmokers. In other words, people who are involuntarily exposed to tobacco smoke in a closed environment (home, car, building) are at increased risk for developing lung cancer as compared to unexposed nonsmokers. An average lifetime passive smoke exposure to a smoking spouse or partner increases a nonsmoker's risk of lung cancer by about 35% compared to the risk of 100% for a lifetime of active smoking (Matthay, Tanoue & Carter, 2000).

### ENVIRONMENTAL AND OCCUPATIONAL EXPOSURE

Various carcinogens have been identified in the atmosphere, including motor vehicle emissions and pollutants from refineries and manufacturing plants. Evidence suggests that the incidence of lung cancer is greater in urban areas as a result of the buildup of pollutants and motor vehicle emissions.

Radon is a colorless, odorless gas found in soil and rocks. For many years it has been associated with uranium mines, but it is now known to seep into homes through ground rock. High levels of radon have been associated with the development of lung cancer, especially when combined with cigarette smoking. Homeowners are advised to have radon levels checked in their houses and to arrange for special venting if the levels are high.

Chronic exposure to industrial carcinogens, such as arsenic, asbestos, mustard gas, chromates, coke oven fumes, nickel, oil, and radiation, has been associated with the development of lung cancer. Laws have been passed to control exposure to such elements in the workplace.

### GENETICS

Some familial predisposition to lung cancer seems apparent, because the incidence of lung cancer in close relatives of patients

with lung cancer appears to be two to three times that of the general population regardless of smoking status.

### DIETARY FACTORS

Prior research has demonstrated that smokers who eat a diet low in fruits and vegetables have an increased risk of developing lung cancer (Bast, Kufe, Pollock et al., 2000). The actual active agents in a diet rich in fruits and vegetables have yet to be determined. It has been hypothesized that carotenoids, particularly carotene or vitamin A, may be important. Several ongoing trials may help to determine if carotene supplementation has anticancer properties. Other nutrients, including vitamin E, selenium, vitamin C, fat, and retinoids, are also being evaluated regarding their protective role against lung cancer (Bast, Kufe, Pollock et al., 2000).

## Clinical Manifestations

Often, lung cancer develops insidiously and is asymptomatic until late in its course. The signs and symptoms depend on the location and size of the tumor, the degree of obstruction, and the existence of metastases to regional or distant sites.

The most frequent symptom of lung cancer is cough or change in a chronic cough. People frequently ignore this symptom and attribute it to smoking or a respiratory infection. The cough starts as a dry, persistent cough, without sputum production. When obstruction of airways occurs, the cough may become productive due to infection.

**NURSING ALERT** A cough that changes in character should arouse suspicion of lung cancer.

Wheezing is noted (occurs when a bronchus becomes partially obstructed by the tumor) in about 20% of patients with lung cancer. Patients also may report dyspnea. Hemoptysis or blood-tinged sputum may be expectorated. In some patients, a recurring fever occurs as an early symptom in response to a persistent infection in an area of pneumonitis distal to the tumor. In fact, cancer of the lung should be suspected in people with repeated unresolved upper respiratory tract infections. Chest or shoulder pain may indicate chest wall or pleural involvement by a tumor. Pain also is a late manifestation and may be related to metastasis to the bone.

If the tumor spreads to adjacent structures and regional lymph nodes, the patient may present with chest pain and tightness, hoarseness (involving the recurrent laryngeal nerve), dysphagia, head and neck edema, and symptoms of pleural or pericardial effusion. The most common sites of metastases are lymph nodes, bone, brain, contralateral lung, adrenal glands, and liver. Non-specific symptoms of weakness, anorexia, and weight loss also may be diagnostic.

## Assessment and Diagnostic Findings

If pulmonary symptoms occur in a heavy smoker, cancer of the lung is suspected. A chest x-ray is performed to search for pulmonary density, a solitary peripheral nodule (coin lesion), atelectasis, and infection. CT scans of the chest are used to identify small nodules not visualized on the chest x-ray and also to examine serially areas of the thoracic cage not clearly visible on the chest x-ray.

Sputum cytology is rarely used to make a diagnosis of lung cancer; however, fiberoptic bronchoscopy is more commonly

used and provides a detailed study of the tracheobronchial tree and allows for brushings, washings, and biopsies of suspicious areas. For peripheral lesions not amenable to bronchoscopic biopsy, a transthoracic **fine-needle aspiration** may be performed under CT or fluoroscopic guidance to aspirate cells from a suspicious area. In some circumstances, an endoscopy with esophageal ultrasound (EUS) may be used to obtain a transesophageal biopsy of enlarged subcarinal lymph nodes that are not easily accessible by other means.

A variety of scans may be used to assess for metastasis of the cancer. These may include bone scans, abdominal scans, positron emission tomography (PET) scans, or liver ultrasound or scans. CT of the brain, magnetic resonance imaging (MRI), and other neurologic diagnostic procedures are used to detect central nervous system metastases. Mediastinoscopy or mediastinotomy may be used to obtain biopsy samples from lymph nodes in the mediastinum.

If surgery is a potential treatment, the patient is evaluated to determine whether the tumor is resectable and whether the physiologic impairment resulting from such surgery can be tolerated. Pulmonary function tests, arterial blood gas analysis, ventilation–perfusion scans, and exercise testing may all be used as part of the preoperative assessment (Knippel, 2001).

## Medical Management

The objective of management is to provide a cure, if possible. Treatment depends on the cell type, the stage of the disease, and the physiologic status (particularly cardiac and pulmonary status) of the patient. In general, treatment may involve surgery, radiation therapy, or chemotherapy—or a combination of these. Newer and more specific therapies to modulate the immune system (gene therapy, therapy with defined tumor antigens) are under study and show promise in treating lung cancer.

### SURGICAL MANAGEMENT

Surgical resection is the preferred method of treating patients with localized non-small cell tumors, no evidence of metastatic spread, and adequate cardiopulmonary function. If the patient's cardiovascular status, pulmonary function, and functional status are satisfactory, surgery is generally well tolerated. Coronary artery disease, pulmonary insufficiency, and other comorbidities, however, may contraindicate surgical intervention. The cure rate of surgical resection depends on the type and stage of the cancer. Surgery is primarily used for non-small cell carcinomas because small cell cancer of the lung grows rapidly and metastasizes early and extensively. Unfortunately, in many patients with bronchogenic cancer, the lesion is inoperable at the time of diagnosis.

Several different types of lung resections may be performed (Chart 23-10). The most common surgical procedure for a small, apparently curable tumor of the lung is lobectomy (removal of a lobe of the lung). In some cases, an entire lung may be removed (pneumonectomy) (see Chap. 25 for further details).

### RADIATION THERAPY

Radiation therapy may cure a small percentage of patients. It is useful in controlling neoplasms that cannot be surgically resected but are responsive to radiation. Radiation also may be used to reduce the size of a tumor, to make an inoperable tumor operable, or to relieve the pressure of the tumor on vital structures. It can control symptoms of spinal cord metastasis and superior vena caval compression. Also, prophylactic brain irradiation is used in certain patients to treat microscopic metastases to the brain. Radiation may help relieve cough, chest pain, dyspnea, hemoptysis,

Chart  
23-10

## Types of Lung Resections

- Lobectomy: a single lobe of lung is removed
- Bilobectomy: two lobes of the lung are removed
- Sleeve resection: cancerous lobe(s) is removed and a segment of the main bronchus is resected
- Pneumonectomy: removal of entire lung
- Segmentectomy: a segment of the lung is removed\*
- Wedge resection: removal of a small, pie-shaped area of the segment\*
- Chest wall resection with removal of cancerous lung tissue: for cancers that have invaded the chest wall

\*Not recommended as curative resection for lung cancer.

and bone and liver pain. Relief of symptoms may last from a few weeks to many months and is important in improving the quality of the remaining period of life.

Radiation therapy usually is toxic to normal tissue within the radiation field, and this may lead to complications such as esophagitis, pneumonitis, and radiation lung fibrosis. These may impair ventilatory and diffusion capacity and significantly reduce pulmonary reserve. The patient's nutritional status, psychological outlook, fatigue level, and signs of anemia and infection are monitored throughout the treatment. See Chapter 16 for management of the patient receiving radiation therapy.

### CHEMOTHERAPY

Chemotherapy is used to alter tumor growth patterns, to treat patients with distant metastases or small cell cancer of the lung, and as an adjunct to surgery or radiation therapy. Combinations of two or more medications may be more beneficial than single-dose regimens. A large number of medications are active against lung cancer. A variety of chemotherapeutic agents are used, including alkylating agents (ifosfamide), platinum analogues (cisplatin and carboplatin), taxanes (paclitaxel, docetaxel), vinca alkaloids (vinblastine and vindesine), doxorubicin, gemcitabine, vinorelbine, irinotecan (CPT-11), and etoposide (VP-16). The choice of agent depends on the growth of the tumor cell and the specific phase of the cell cycle that the medication affects. Numerous combinations of chemotherapy are undergoing investigation to identify the optimal regimen to treat differing types of lung cancer.

Chemotherapy may provide relief, especially of pain, but it does not usually cure the disease, nor does it often prolong life to any great degree. Chemotherapy is also accompanied by side effects. It is valuable in reducing pressure symptoms of lung cancer and in treating brain, spinal cord, and pericardial metastasis. See Chapter 16 for a discussion of chemotherapy for the patient with cancer.

### PALLIATIVE THERAPY

Palliative therapy may include radiation therapy to shrink the tumor to provide pain relief, a variety of bronchoscopic interventions to open a narrowed bronchus or airway, and pain management and other comfort measures. Evaluation and referral for hospice care are important in planning for comfortable and dignified end-of-life care for the patient and family.

## Treatment-Related Complications

A variety of complications may occur as a result of lung cancer treatments. Radiation therapy may result in diminished cardiopulmonary function and other complications, such as pulmonary

fibrosis, pericarditis, myelitis, and cor pulmonale. Chemotherapy, particularly in combination with radiation therapy, can cause pneumonitis. Pulmonary toxicity is a potential side effect of chemotherapy. Surgical resection may result in respiratory failure, particularly when the cardiopulmonary system is compromised before surgery. Surgical complications and prolonged mechanical ventilation are potential outcomes.

## Nursing Management

Nursing care of the patient with lung cancer is similar to that of other patients with cancer (see Chap. 16) and addresses the physiologic and psychological needs of the patient. The physiologic problems are primarily due to the respiratory manifestations of the disease. Nursing care includes strategies to ensure relief of pain and discomfort and to prevent complications.

### MANAGING SYMPTOMS

The nurse instructs the patient and family about the potential side effects of the specific treatment and strategies to manage them. Strategies for managing such symptoms as dyspnea, fatigue, nausea and vomiting, and anorexia will assist the patient and family to cope with the therapeutic measures.

### RELIEVING BREATHING PROBLEMS

Airway clearance techniques are key to maintaining airway patency through the removal of excess secretions. This may be accomplished through deep-breathing exercises, chest physiotherapy, directed cough, suctioning, and in some instances bronchoscopy. Bronchodilator medications may be prescribed to promote bronchial dilation. As the tumor enlarges or spreads, it may compress a bronchus or involve a large area of lung tissue, resulting in an impaired breathing pattern and poor gas exchange. At some stage of the disease, supplemental oxygen will probably be necessary.

Nursing measures focus on decreasing dyspnea by encouraging the patient to assume positions that promote lung expansion, breathing exercises for lung expansion and relaxation, and educating the patient on energy conservation and airway clearance techniques (Connolly & O'Neill, 1999). Many of the techniques used in pulmonary rehabilitation can be applied to the lung cancer patient. Depending on the severity of disease and the patient's wishes, a referral to a pulmonary rehabilitation program may be helpful in managing respiratory symptoms.

### REDUCING FATIGUE

Fatigue is a devastating symptom that affects quality of life in the cancer patient. It is commonly experienced by the lung cancer patient and may be related to the disease itself, the cancer treatment and complications (eg, anemia), sleep disturbances, pain and discomfort, hypoxemia, poor nutrition, or the psychological ramifications of the disease (eg, anxiety, depression). The nurse is pivotal in thoroughly assessing the patient's level of fatigue, identifying potentially treatable causes, and validating with the patient that fatigue is indeed an important symptom. Educating the patient in energy conservation techniques or referring the patient to a physical therapy, occupational therapy, or pulmonary rehabilitation program may be helpful. In addition, guided exercise has been recently identified as a potential intervention for treating fatigue in cancer patients. This is an important area for research because few studies have been conducted, and only in select populations of cancer patients.

## PROVIDING PSYCHOLOGICAL SUPPORT

Another important part of the nursing care of the patient with lung cancer is psychological support and identification of potential resources for the patient and family. Often, the nurse must help the patient and family deal with the poor prognosis and relatively rapid progression of this disease. The nurse must help the patient and family with informed decision making regarding the possible treatment options, methods to maintain the patient's quality of life during the course of this disease, and end-of-life treatment options.

## TUMORS OF THE MEDIASTINUM

Tumors of the mediastinum include neurogenic tumors, tumors of the thymus, lymphomas, germ cell, cysts, and mesenchymal tumors. These tumors may be malignant or benign. These tumors are usually described in relation to location: anterior, middle, or posterior masses or tumors.

### Clinical Manifestations

Nearly all the symptoms of mediastinal tumors result from the pressure of the mass against important intrathoracic organs. Symptoms may include cough, wheezing, dyspnea, anterior chest or neck pain, bulging of the chest wall, heart palpitations, angina, other circulatory disturbances, central cyanosis, superior vena caval syndrome (ie, swelling of the face, neck, and upper extremities), marked distention of the veins of the neck and the chest wall (evidence of the obstruction of large veins of the mediastinum by extravascular compression or intravascular invasion), and dysphagia and weight loss from pressure or invasion into the esophagus.

### Assessment and Diagnostic Findings

Chest x-rays are the major method used initially to diagnose mediastinal tumors and cysts. CT scans are the gold standard for assessment of the mediastinum and surrounding structures. MRI may be used in some circumstances, as well as PET scans.

### Medical Management

If the tumor is malignant and has infiltrated surrounding tissue, radiation therapy and/or chemotherapy are the therapeutic modalities used when complete surgical removal (discussed below) is not feasible.

### SURGICAL MANAGEMENT

Many mediastinal tumors are benign and operable. The location of the tumor (anterior, middle, or posterior compartments) in the mediastinum dictates the type of incision. The common incision used is a median sternotomy; however, a thoracotomy may be used, depending on the location of the tumor. Additional approaches may include a bilateral anterior thoracotomy (clamshell incision) or video-assisted thoracoscopic surgery (see Chap. 25). The care is the same as for any patient undergoing thoracic surgery. The major complications include hemorrhage, injury to the phrenic or recurrent laryngeal nerve, and infection.

## Chest Trauma

Approximately 60% of all multisystem trauma victims have some type of chest or thoracic trauma (Owens, Chaudry, Eggerstedt & Smith, 2000). Chest trauma is classified as either blunt or

penetrating. Blunt chest trauma results from sudden compression or positive pressure inflicted to the chest wall. Motor vehicle crashes (trauma due to steering wheel, seat belt), falls, and bicycle crashes (trauma due to handlebars) are the most common causes of blunt chest trauma. Penetrating trauma occurs when a foreign object penetrates the chest wall. The most common causes of penetrating chest trauma include gunshot wounds and stabbings.

## BLUNT TRAUMA

Although blunt chest trauma is more common, it is often difficult to identify the extent of the damage because the symptoms may be generalized and vague. In addition, patients may not seek immediate medical attention, which may complicate the problem.

### Pathophysiology

Injuries to the chest are often life-threatening and result in one or more of the following pathologic mechanisms:

- Hypoxemia from disruption of the airway; injury to the lung parenchyma, rib cage, and respiratory musculature; massive hemorrhage; collapsed lung; and pneumothorax
- Hypovolemia from massive fluid loss from the great vessels, cardiac rupture, or hemothorax
- Cardiac failure from cardiac tamponade, cardiac contusion, or increased intrathoracic pressure

These mechanisms frequently result in impaired ventilation and perfusion leading to ARF, hypovolemic shock, and death.

### Assessment and Diagnostic Findings

Time is critical in treating chest trauma. Therefore, it is essential to assess the patient immediately to determine the following:

- When the injury occurred
- Mechanism of injury
- Level of responsiveness
- Specific injuries
- Estimated blood loss
- Recent drug or alcohol use
- Prehospital treatment

The initial assessment of thoracic injuries includes assessment of the patient for airway obstruction, tension pneumothorax, open pneumothorax, massive hemothorax, flail chest, and cardiac tamponade. These injuries are life-threatening and need immediate treatment. Secondary assessment would include simple pneumothorax, hemothorax, pulmonary contusion, traumatic aortic rupture, tracheobronchial disruption, esophageal perforation, traumatic diaphragmatic injury, and penetrating wounds to the mediastinum (Owens, Chaudry, Eggerstedt & Smith, 2000). Although listed as secondary, these injuries may be life-threatening as well depending upon the circumstances.

The physical examination includes inspection of the airway, thorax, neck veins, and breathing difficulty. Specifics include assessing the rate and depth of breathing for abnormalities, such as stridor, cyanosis, nasal flaring, use of accessory muscles, drooling, and overt trauma to the face, mouth, or neck. The chest should be assessed for symmetric movement, symmetry of breath sounds, open chest wounds, entrance or exit wounds, impaled objects, tracheal shift, distended neck veins, subcutaneous emphysema, and paradoxical chest wall motion. In addition, the chest wall

should be assessed for bruising, petechiae, lacerations, and burns. The vital signs and skin color are assessed for signs of shock. The thorax is palpated for tenderness and crepitus; the position of the trachea is also assessed.

The initial diagnostic workup includes a chest x-ray, CT scan, complete blood count, clotting studies, type and cross-match, electrolytes, oxygen saturation, arterial blood gas analysis, and ECG. The patient is completely undressed to avoid missing additional injuries that can complicate care. Many patients with injuries involving the chest have associated head and abdominal injuries that require attention. Ongoing assessment is essential to monitor the patient's response to treatment and to detect early signs of clinical deterioration.

### Medical Management

The goals of treatment are to evaluate the patient's condition and to initiate aggressive resuscitation. An airway is immediately established with oxygen support and, in some cases, intubation and ventilatory support. Re-establishing fluid volume and negative intrapleural pressure and draining intrapleural fluid and blood are essential.

The potential for massive blood loss and exsanguination with blunt or penetrating chest injuries is high because of injury to the great blood vessels. Many patients die at the scene or are in shock by the time help arrives. Agitation and irrational and combative behavior are signs of decreased oxygen delivery to the cerebral cortex. Strategies to restore and maintain cardiopulmonary function include ensuring an adequate airway and ventilation, stabilizing and re-establishing chest wall integrity, occluding any opening into the chest (open pneumothorax), and draining or removing any air or fluid from the thorax to relieve pneumothorax, hemothorax, or cardiac tamponade. Hypovolemia and low cardiac output must be corrected. Many of these treatment efforts, along with the control of hemorrhage, are usually carried out simultaneously at the scene of the injury or in the emergency department. Depending on the success of efforts to control the hemorrhage in the emergency department, the patient may be taken immediately to the operating room. Principles of management are essentially those pertaining to care of the postoperative thoracic patient (see Chap. 25).

### Sternal and Rib Fractures

Sternal fractures are most common in motor vehicle crashes with a direct blow to the sternum via the steering wheel and are most common in women, patients over age 50, and those using shoulder restraints (Owens, Chaudry, Eggerstedt & Smith, 2000).

Rib fractures are the most common type of chest trauma, occurring in more than 60% of patients admitted with blunt chest injury. Most rib fractures are benign and are treated conservatively. Fractures of the first three ribs are rare but can result in a high mortality rate because they are associated with laceration of the subclavian artery or vein. The fifth through ninth ribs are the most common sites of fractures. Fractures of the lower ribs are associated with injury to the spleen and liver, which may be lacerated by fragmented sections of the rib.

### CLINICAL MANIFESTATIONS

The patient with sternal fractures has anterior chest pain, overlying tenderness, ecchymosis, crepitus, swelling, and the potential of a chest wall deformity. For the patient with rib fractures, clinical manifestations are similar: severe pain, point tenderness,

and muscle spasm over the area of the fracture, which is aggravated by coughing, deep breathing, and movement. The area around the fracture may be bruised. To reduce the pain, the patient splints the chest by breathing in a shallow manner and avoids sighs, deep breaths, coughing, and movement. This reluctance to move or breathe deeply results in diminished ventilation, collapse of unaerated alveoli (atelectasis), pneumonitis, and hypoxemia. Respiratory insufficiency and failure can be the outcomes of such a cycle.

### ASSESSMENT AND DIAGNOSTIC FINDINGS

The patient with a sternal fracture must be closely evaluated for underlying cardiac injuries. A crackling, grating sound in the thorax (subcutaneous crepitus) may be detected with auscultation. The diagnostic workup may include a chest x-ray, rib films of a specific area, ECG, continuous pulse oximetry, and arterial blood gas analysis.

### MEDICAL MANAGEMENT

Medical management of the patient with a sternal fracture is directed toward controlling pain, avoiding excessive activity, and treating any associated injuries. Surgical fixation is rarely necessary unless fragments are grossly displaced and pose a potential for further injury.

The goals of treatment for rib fractures are to control pain and to detect and treat the injury. Sedation is used to relieve pain and to allow deep breathing and coughing. Care must be taken to avoid oversedation and suppression of the respiratory drive. Alternative strategies to relieve pain include an intercostal nerve block and ice over the fracture site; a chest binder may decrease pain on movement. Usually the pain abates in 5 to 7 days, and discomfort can be controlled with epidural analgesia, patient-controlled analgesia, or nonopioid analgesia. Most rib fractures heal in 3 to 6 weeks. The patient is monitored closely for signs and symptoms of associated injuries.

### Flail Chest

Flail chest is frequently a complication of blunt chest trauma from a steering wheel injury. It usually occurs when three or more adjacent ribs (multiple contiguous ribs) are fractured at two or more sites, resulting in free-floating rib segments. It may also re-

sult as a combination fracture of ribs and costal cartilages or sternum (Owens, Chaudry, Eggerstedt & Smith, 2000). As a result, the chest wall loses stability and there is subsequent respiratory impairment and usually severe respiratory distress.

### PATHOPHYSIOLOGY

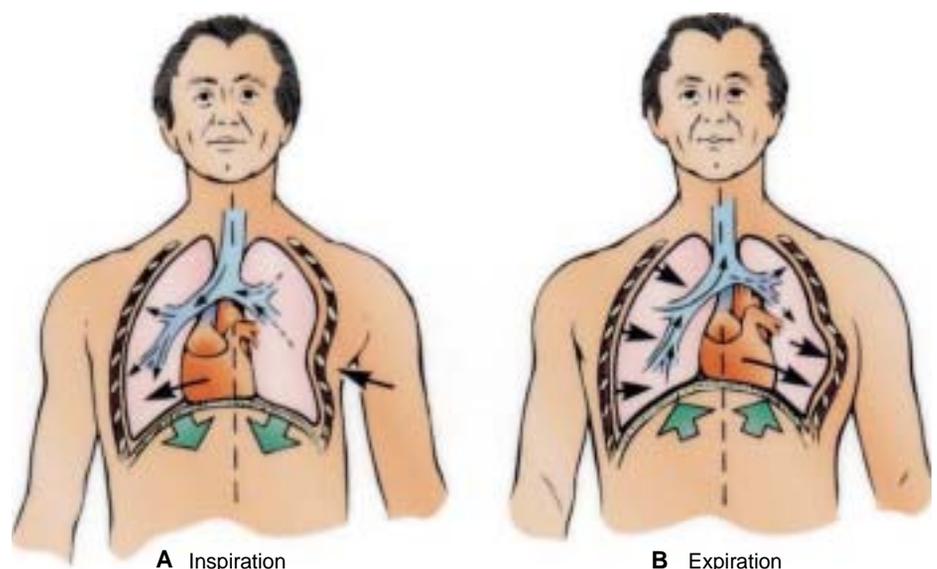

During inspiration, as the chest expands, the detached part of the rib segment (flail segment) moves in a paradoxical manner (pendelluft movement) in that it is pulled inward during inspiration, reducing the amount of air that can be drawn into the lungs. On expiration, because the intrathoracic pressure exceeds atmospheric pressure, the flail segment bulges outward, impairing the patient's ability to exhale. The mediastinum then shifts back to the affected side (Fig. 23-8). This paradoxical action results in increased dead space, a reduction in alveolar ventilation, and decreased compliance. Retained airway secretions and atelectasis frequently accompany flail chest. The patient has hypoxemia, and if gas exchange is greatly compromised, respiratory acidosis develops as a result of CO<sub>2</sub> retention. Hypotension, inadequate tissue perfusion, and metabolic acidosis often follow as the paradoxical motion of the mediastinum decreases cardiac output.

### MEDICAL MANAGEMENT

As with rib fracture, treatment of flail chest is usually supportive. Management includes providing ventilatory support, clearing secretions from the lungs, and controlling pain. The specific management depends on the degree of respiratory dysfunction. If only a small segment of the chest is involved, the objectives are to clear the airway through positioning, coughing, deep breathing, and suctioning to aid in the expansion of the lung, and to relieve pain by intercostal nerve blocks, high thoracic epidural blocks, or cautious use of intravenous opioids.

For mild to moderate flail chest injuries, the underlying pulmonary contusion is treated by monitoring fluid intake and appropriate fluid replacement, while at the same time relieving chest pain. Pulmonary physiotherapy focusing on lung volume expansion and secretion management techniques are performed. The patient is closely monitored for further respiratory compromise.

When a severe flail chest injury is encountered, endotracheal intubation and mechanical ventilation are required to provide internal pneumatic stabilization of the flail chest and to correct abnormalities in gas exchange. This helps to treat the underlying

**FIGURE 23-8** Flail chest is caused by a free-floating segment of rib cage resulting from multiple rib fractures. (A) Paradoxical movement on inspiration occurs when the flail rib segment is sucked inward and the mediastinal structures shift to the unaffected side. The amount of air drawn into the affected lung is reduced. (B) On expiration, the flail segment bulges outward and the mediastinal structures shift back to the affected side.

pulmonary contusion, serves to stabilize the thoracic cage to allow the fractures to heal, and improves alveolar ventilation and intrathoracic volume by decreasing the work of breathing. This treatment modality requires endotracheal intubation and ventilator support. Differing modes of ventilation are used depending on the patient's underlying disease and specific needs.

In rare circumstances, surgery may be required to more quickly stabilize the flail segment. This may be used in the patient who is difficult to ventilate or the high-risk patient with underlying lung disease who may be difficult to wean from mechanical ventilation.

Regardless of the type of treatment, the patient is carefully monitored by serial chest x-rays, arterial blood gas analysis, pulse oximetry, and bedside pulmonary function monitoring. Pain management is key to successful treatment. Patient-controlled analgesia, intercostal nerve blocks, epidural analgesia, and intrapleural administration of opioids may be used to control thoracic pain.

## Pulmonary Contusion

Pulmonary contusion is observed in about 20% of adult patients with multiple traumatic injuries and in a higher percentage of children due to increased compliance of the chest wall. It is defined as damage to the lung tissues resulting in hemorrhage and localized edema. It is associated with chest trauma when there is rapid compression and decompression to the chest wall (ie, blunt trauma). It may not be evident initially on examination but will develop in the posttraumatic period.

### PATHOPHYSIOLOGY

The primary pathologic defect is an abnormal accumulation of fluid in the interstitial and intra-alveolar spaces. It is thought that injury to the lung parenchyma and its capillary network results in a leakage of serum protein and plasma. The leaking serum protein exerts an osmotic pressure that enhances loss of fluid from the capillaries. Blood, edema, and cellular debris (from cellular response to injury) enter the lung and accumulate in the bronchioles and alveolar surface, where they interfere with gas exchange. An increase in pulmonary vascular resistance and pulmonary artery pressure occurs. The patient has hypoxemia and carbon dioxide retention. Occasionally, a contused lung occurs on the other side of the point of body impact; this is called a contrecoup contusion.

### CLINICAL MANIFESTATIONS

Pulmonary contusion may be mild, moderate, or severe. The clinical manifestations vary from tachypnea, tachycardia, pleuritic chest pain, hypoxemia, and blood-tinged secretions to more severe tachypnea, tachycardia, crackles, frank bleeding, severe hypoxemia, and respiratory acidosis. Changes in sensorium, including increased agitation or combative irrational behavior, may be signs of hypoxemia.

In addition, the patient with moderate pulmonary contusion has a large amount of mucus, serum, and frank blood in the tracheobronchial tree; the patient often has a constant cough but cannot clear the secretions. A patient with severe pulmonary contusion has the signs and symptoms of ARDS; these may include central cyanosis, agitation, combativeness, and productive cough with frothy, bloody secretions.

### ASSESSMENT AND DIAGNOSTIC FINDINGS

The efficiency of gas exchange is determined by pulse oximetry and arterial blood gas measurements. Pulse oximetry is also used

to measure oxygen saturation continuously. The chest x-ray may show pulmonary infiltration. The initial chest x-ray may show no changes; in fact, changes may not appear for 1 or 2 days after the injury.

### MEDICAL MANAGEMENT

Treatment priorities include maintaining the airway, providing adequate oxygenation, and controlling pain. In mild pulmonary contusion, adequate hydration via intravenous fluids and oral intake is important to mobilize secretions. However, fluid intake must be closely monitored to avoid hypervolemia. Volume expansion techniques, postural drainage, physiotherapy including coughing, and endotracheal suctioning are used to remove the secretions. Pain is managed by intercostal nerve blocks or by opioids via patient-controlled analgesia or other methods. Usually, antimicrobial therapy is administered because the damaged lung is susceptible to infection. Supplemental oxygen is usually given by mask or cannula for 24 to 36 hours.

The patient with moderate pulmonary contusion may require bronchoscopy to remove secretions; intubation and mechanical ventilation with PEEP may also be necessary to maintain the pressure and keep the lungs inflated. Diuretics may be given to reduce edema. A nasogastric tube is inserted to relieve gastrointestinal distention.

The patient with severe contusion may develop respiratory failure and may require aggressive treatment with endotracheal intubation and ventilatory support, diuretics, and fluid restriction. Colloids and crystalloid solutions may be used to treat hypovolemia.

Antimicrobial medications may be prescribed for the treatment of pulmonary infection. This is a common complication of pulmonary contusion (especially pneumonia in the contused segment), because the fluid and blood that extravasates into the alveolar and interstitial spaces serve as an excellent culture medium.

## PENETRATING TRAUMA: GUNSHOT AND STAB WOUNDS

Gunshot and stab wounds are the most common types of penetrating chest trauma. They are classified according to their velocity. Stab wounds are generally considered of low velocity because the weapon destroys a small area around the wound. Knives and switchblades cause most stab wounds. The appearance of the external wound may be very deceptive, because pneumothorax, hemothorax, lung contusion, and cardiac tamponade, along with severe and continuing hemorrhage, can occur from any small wound, even one caused by a small-diameter instrument such as an ice pick.

Gunshot wounds to the chest may be classified as of low, medium, or high velocity. The factors that determine the velocity and resulting extent of damage include the distance from which the gun was fired, the caliber of the gun, and construction and size of the bullet. A gunshot wound can produce a variety of pathophysiologic changes. A bullet can cause damage at the site of penetration and along its pathway. It also may ricochet off bony structures and damage the chest organs and great vessels. If the diaphragm is involved in either a gunshot wound or a stab wound, injury to the chest cavity must be considered.

### Medical Management

The objective of immediate management is to restore and maintain cardiopulmonary function. After an adequate airway is ensured and ventilation is established, the patient is examined for

shock and intrathoracic and intra-abdominal injuries. The patient is undressed completely so that additional injuries will not be missed. There is a high risk for associated intra-abdominal injuries with stab wounds below the level of the fifth anterior intercostal space. Death can result from exsanguinating hemorrhage or intra-abdominal sepsis.

After the status of the peripheral pulses is assessed, a large-bore intravenous line is inserted. The diagnostic workup includes a chest x-ray, chemistry profile, arterial blood gas analysis, pulse oximetry, and ECG. Blood typing and cross-matching are done in case blood transfusion is required. An indwelling catheter is inserted to monitor urinary output. A nasogastric tube is inserted to prevent aspiration, minimize leakage of abdominal contents, and decompress the gastrointestinal tract.

Shock is treated simultaneously with colloid solutions, crystalloids, or blood, as indicated by the patient's condition. Chest x-rays are obtained, and other diagnostic procedures are carried out as dictated by the needs of the patient (eg, CT scans of chest or abdomen, flat plate x-ray of the abdomen, abdominal tap to check for bleeding).

A chest tube is inserted into the pleural space in most patients with penetrating wounds of the chest to achieve rapid and continuing re-expansion of the lungs. The insertion of the chest tube frequently results in a complete evacuation of the blood and air. The chest tube also allows early recognition of continuing intrathoracic bleeding, which would make surgical exploration necessary. If the patient has a penetrating wound of the heart and great vessels, the esophagus, or the tracheobronchial tree, surgical intervention is required.

## PNEUMOTHORAX

Pneumothorax occurs when the parietal or visceral pleura is breached and the pleural space is exposed to positive atmospheric pressure. Normally the pressure in the pleural space is negative or subatmospheric compared to atmospheric pressure; this negative pressure is required to maintain lung inflation. When either pleura is breached, air enters the pleural space, and the lung or a portion of it collapses. Types of pneumothorax include simple, traumatic, and tension pneumothorax.

### Simple Pneumothorax

A simple, or spontaneous, pneumothorax occurs when air enters the pleural space through a breach of either the parietal or visceral pleura. Most commonly this occurs as air enters the pleural space through the rupture of a bleb or a bronchopleural fistula. A spontaneous pneumothorax may occur in an apparently healthy person in the absence of trauma due to rupture of an air-filled bleb, or blister, on the surface of the lung, allowing air from the airways to enter the pleural cavity. It may be associated with diffuse interstitial lung disease and severe emphysema.

### Traumatic Pneumothorax

Traumatic pneumothorax occurs when air escapes from a laceration in the lung itself and enters the pleural space or enters the pleural space through a wound in the chest wall. It can occur with blunt trauma (eg, rib fractures) or penetrating chest trauma. It may also occur from abdominal trauma (eg, stab wounds or gunshot wounds to the abdomen) and from diaphragmatic tears. Traumatic pneumothorax may occur with invasive thoracic procedures (ie, thoracentesis, transbronchial lung biopsy, insertion

of a subclavian line) in which the pleura is inadvertently punctured, or with barotrauma from mechanical ventilation.

Traumatic pneumothorax resulting from major injury to the chest is often accompanied by hemothorax (collection of blood in the pleural space resulting from torn intercostal vessels, lacerations of the great vessels, and lacerations of the lungs). Often both blood and air are found in the chest cavity (hemothorax) after major trauma. Chest surgery can cause what is classified as a traumatic pneumothorax as a result of the entry into the pleural space and the accumulation of air and fluid in the pleural space.

Open pneumothorax is one form of traumatic pneumothorax. It occurs when a wound in the chest wall is large enough to allow air to pass freely in and out of the thoracic cavity with each attempted respiration. Because the rush of air through the hole in the chest wall produces a sucking sound, such injuries are termed sucking chest wounds. In such patients, not only does the lung collapse, but the structures of the mediastinum (heart and great vessels) also shift toward the uninjured side with each inspiration and in the opposite direction with expiration. This is termed mediastinal flutter or swing, and it produces serious circulatory problems.

## Clinical Manifestations

The signs and symptoms associated with pneumothorax depend on its size and cause. Pain is usually sudden and may be pleuritic. The patient may have only minimal respiratory distress with slight chest discomfort and tachypnea with a small simple or uncomplicated pneumothorax. If the pneumothorax is large and the lung collapses totally, acute respiratory distress occurs. The patient is anxious, has dyspnea and air hunger, has increased use of the accessory muscles, and may develop central cyanosis from severe hypoxemia. Severe chest pain may occur, accompanied by tachypnea, decreased movement of the affected side of the thorax, a tympanic sound on percussion of the chest wall, and decreased or absent breath sounds and tactile fremitus on the affected side.

## Medical Management

Medical management of pneumothorax depends on its cause and severity. The goal of treatment is to evacuate the air or blood from the pleural space. A small chest tube (28 French) is inserted near the second intercostal space; this space is used because it is the thinnest part of the chest wall, minimizes the danger of contacting the thoracic nerve, and leaves a less visible scar. If the patient also has a hemothorax, a large-diameter chest tube (32 French or greater) is inserted, usually in the fourth or fifth intercostal space at the midaxillary line. The tube is directed posteriorly to drain the fluid and air. Once the chest tube or tubes are inserted and suction is applied (usually to 20 mm Hg suction), effective decompression of the pleural cavity (drainage of blood or air) occurs.

If an excessive amount of blood enters the chest tube in a relatively short period, an autotransfusion may be needed. This technique involves taking the patient's own blood that has been drained from the chest, filtering it, and then transfusing it back into the patient's vascular system.

**NURSING ALERT** Traumatic open pneumothorax calls for emergency interventions. Stopping the flow of air through the opening in the chest wall is a life-saving measure.

In such an emergency, anything may be used that is large enough to fill the chest wound—a towel, a handkerchief, or the heel of the hand. If conscious, the patient is instructed to inhale and strain against a closed glottis. This action assists in re-expanding the lung and ejecting the air from the thorax. In the hospital, the opening is plugged by sealing it with gauze impregnated with petrolatum. A pressure dressing is applied. Usually, a chest tube connected to water-seal drainage is inserted to permit air and fluid to drain. Antibiotics usually are prescribed to combat infection from contamination.

The severity of open pneumothorax depends on the amount and rate of thoracic bleeding and the amount of air in the pleural space. The pleural cavity can be decompressed by needle aspiration (thoracentesis) or chest tube drainage of the blood or air. The lung is then able to re-expand and resume the function of gas exchange. As a rule of thumb, the chest wall is opened surgically (thoracotomy) when more than 1,500 mL of blood is aspirated initially by thoracentesis (or is the initial chest tube output) or when chest tube output continues at greater than 200 mL/hour. The urgency with which the blood must be removed is determined by the respiratory compromise. An emergency thoracotomy may also be performed in the emergency department if there is suggested cardiovascular injury secondary to chest or penetrating trauma.

### Tension Pneumothorax

A **tension pneumothorax** occurs when air is drawn into the pleural space from a lacerated lung or through a small hole in the chest wall. It may be a complication of other types of pneumothorax. In contrast to open pneumothorax, the air that enters the chest cavity with each inspiration is trapped; it cannot be expelled during expiration through the air passages or the hole in the chest wall. In effect, a one-way valve or ball valve mechanism occurs where air enters the pleural space but cannot escape. With each breath, tension (positive pressure) is increased within the affected pleural space. This causes the lung to collapse and the heart, the great vessels, and the trachea to shift toward the unaffected side of the chest (mediastinal shift). Both respiration and circulatory function are compromised because of the increased intrathoracic pressure. The increased intrathoracic pressure decreases venous return to the heart, causing decreased cardiac output and impairment of peripheral circulation. In extreme cases, the pulse may be undetectable—this is known as pulseless electrical activity.

### CLINICAL MANIFESTATIONS

The clinical picture is one of air hunger, agitation, increasing hypoxemia, central cyanosis, hypotension, tachycardia, and profuse diaphoresis. A comparison of open and tension pneumothorax is shown in Figure 23-9.

**NURSING ALERT** Relief of tension pneumothorax is considered an emergency measure.

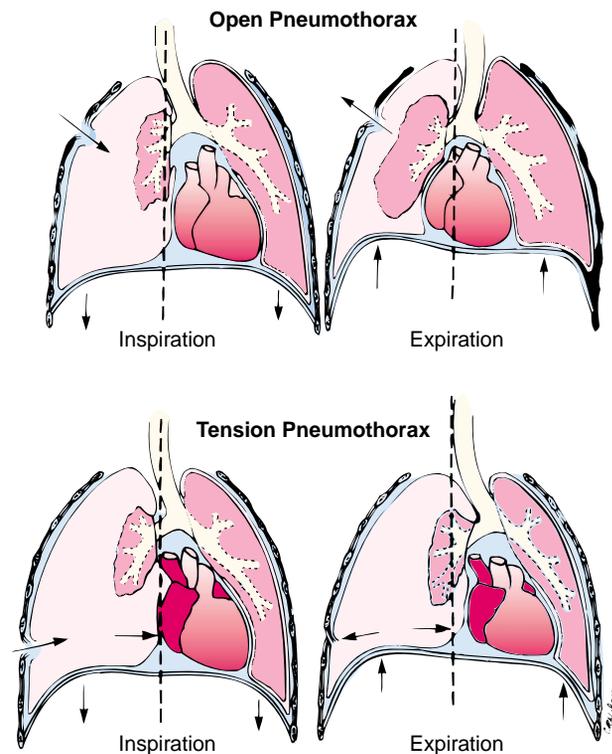

### MEDICAL MANAGEMENT

If a tension pneumothorax is suspected, the patient should immediately be given a high concentration of supplemental oxygen to treat the hypoxemia, and pulse oximetry should be used to monitor oxygen saturation.

In an emergency situation, a tension pneumothorax can be decompressed or quickly converted to a simple pneumothorax by inserting a large-bore needle (14-gauge) at the second intercostal

## Physiology/Pathophysiology

**FIGURE 23-9** Open pneumothorax (*top*) and tension pneumothorax (*bottom*). In open pneumothorax, air enters the chest during inspiration and exits during expiration. A slight shift of the affected lung may occur because of a decrease in pressure as air moves out of the chest. In tension pneumothorax, air enters but cannot leave the chest. As the pressure increases, the heart and great vessels are compressed and the mediastinal structures are shifted toward the opposite side of the chest. The trachea is pushed from its normal midline position toward the opposite side of the chest, and the unaffected lung is compressed.

space, midclavicular line on the affected side. This relieves the pressure and vents the positive pressure to the external environment. A chest tube is then inserted and connected to suction to remove the remaining air and fluid, re-establish the negative pressure, and re-expand the lung. If the lung re-expands and air leakage from the lung parenchyma stops, further drainage may be unnecessary. If a prolonged air leak continues despite chest tube drainage to underwater seal, surgery may be necessary to close the leak.

### CARDIAC TAMPONADE

Cardiac tamponade is the compression of the heart as a result of fluid within the pericardial sac. It usually is caused by blunt or penetrating trauma to the chest. A penetrating wound of the heart is associated with a high mortality rate. Cardiac tamponade also may follow diagnostic cardiac catheterization, angiographic procedures, and pacemaker insertion, which can produce perforations of the heart and great vessels. Pericardial effusion with fluid compressing the heart also may develop from metastases to the pericardium from malignant tumors of the breast, lung, and mediastinum and may occur with lymphomas and leukemias,

renal failure, TB, and high-dose radiation to the chest. Cardiac tamponade is discussed in detail in Chapter 30.

## SUBCUTANEOUS EMPHYSEMA

No matter what kind of chest trauma the patient has, when the lung or the air passages are injured, air may enter the tissue planes and pass for some distance under the skin (eg, neck, chest). The tissues give a crackling sensation when palpated, and the subcutaneous air produces an alarming appearance as the face, neck, body, and scrotum become misshapen by subcutaneous air. Fortunately, subcutaneous emphysema is of itself usually not a serious complication. The subcutaneous air is spontaneously absorbed if the underlying air leak is treated or stops spontaneously. In severe cases in which there is widespread subcutaneous emphysema, a tracheostomy is indicated if airway patency is threatened.

## Aspiration

Aspiration of stomach contents into the lungs is a serious complication that may cause pneumonia and result in the following clinical picture: tachycardia, dyspnea, central cyanosis, hypertension, hypotension, and finally death. It can occur when the protective airway reflexes are decreased or absent from a variety of factors (Chart 23-11).

**NURSING ALERT** When a nonfunctioning nasogastric tube allows the gastric contents to accumulate in the stomach, a condition known as silent aspiration may result. Silent aspiration often occurs unobserved and may be more common than suspected. If untreated, massive inhalation of gastric contents develops in a period of several hours.

## Pathophysiology

The primary factors responsible for death and complications after aspiration of gastric contents are the volume and character of the aspirated gastric contents. For example, a small, localized aspiration from regurgitation can cause pneumonia and acute respiratory distress; a massive aspiration is usually fatal.

A full stomach contains solid particles of food. If these are aspirated, the problem then becomes one of mechanical blockage of the airways and secondary infection. During periods of fasting, the stomach contains acidic gastric juice, which, if aspirated, may be very destructive to the alveoli and capillaries. Fecal contamination (more likely seen in intestinal obstruction) increases the

likelihood of death because the endotoxins produced by intestinal organisms may be absorbed systemically, or the thick proteinaceous material found in the intestinal contents may obstruct the airway, leading to atelectasis and secondary bacterial invasion.

Aspiration pneumonitis may develop from aspiration of substances with a pH of less than 2.5 and a volume of gastric aspirate greater than 0.3 mL per kilogram of body weight (20 to 25 mL in adults) (Marik, 2001). Aspiration of gastric contents causes a chemical burn of the tracheobronchial tree and pulmonary parenchyma (Marik, 2001). An inflammatory response occurs. This results in the destruction of alveolar–capillary endothelial cells, with a consequent outpouring of protein-rich fluids into the interstitial and intra-alveolar spaces. As a result, surfactant is lost, which in turn causes the airways to close and the alveoli to collapse. Finally, the impaired exchange of oxygen and carbon dioxide causes respiratory failure.

Aspiration pneumonia develops following inhalation of colonized oropharyngeal material. The pathologic process involves an acute inflammatory response to bacteria and bacterial products. Most commonly, the bacteriologic findings include gram-positive cocci, gram-negative rods, and occasionally anaerobic bacteria (Marik, 2001).

## Prevention

Prevention is the primary goal when caring for patients at risk for aspiration.

## COMPENSATING FOR ABSENT REFLEXES

Aspiration is likely to occur if the patient cannot adequately coordinate protective glottic, laryngeal, and cough reflexes. This hazard is increased if the patient has a distended abdomen, is in a supine position, has the upper extremities immobilized by intravenous infusions or hand restraints, receives local anesthetics to the oropharyngeal or laryngeal area for diagnostic procedures, has been sedated, or has had long-term intubation.

When vomiting, a person can normally protect the airway by sitting up or turning on the side and coordinating breathing, coughing, gag, and glottic reflexes. If these reflexes are active, an oral airway should not be inserted. If an airway is in place, it should be pulled out the moment the patient gags so as not to stimulate the pharyngeal gag reflex and promote vomiting and aspiration. Suctioning of oral secretions with a catheter should be performed with minimal pharyngeal stimulation.

## ASSESSING FEEDING TUBE PLACEMENT

Even when the patient is intubated, aspiration may occur even with a nasogastric tube in place. This aspiration may result in nosocomial pneumonia. Assessment of tube placement is key to prevent aspiration. The best method for determining tube placement is via an x-ray. There are other nonradiologic methods that have been studied. Observation of the aspirate and testing of its pH are the most reliable. Gastric fluid may be grassy green, brown, clear, or colorless. An aspirate from the lungs may be off-white or tan mucus. Pleural fluid is watery and usually straw-colored (Metheny & Titler, 2001). Gastric pH values are typically lower or more acidic than that of the intestinal or respiratory tract. Gastric pH is usually between 1 and 5, while intestinal or respiratory pH is 7 or higher (Metheny & Titler, 2001). There are differences in assessing tube placement with continuous versus intermittent feedings. For intermittent feedings with small-bore tubes, observation of aspirated contents and pH evaluation should be performed. For continuous feedings, the pH method

### Chart 23-11 Risk Factors for Aspiration

- Seizure activity
- Decreased level of consciousness from trauma, drug or alcohol intoxication, excessive sedation, or general anesthesia
- Nausea and vomiting in the patient with a decreased level of consciousness
- Stroke
- Swallowing disorders
- Cardiac arrest
- Silent aspiration

### NURSING RESEARCH PROFILE 23-2

#### Pulmonary Aspiration

Elpern, E. H., Okonek, M. B., Bacon, M., Gerstung, C., & Skrzyński, M. (2000). Effect of the Passy-Muir tracheostomy speaking valve on pulmonary aspiration in adults. *Heart Lung, 29*(4), 287–293.

#### Purpose

The purpose of this study was to investigate the frequency of aspiration in adults with tracheostomies and to investigate the effect of the Passy-Muir speaking valve on aspiration occurrences.

#### Study Sample and Design

Fifteen subjects were included in this study. Inclusion criteria were that there was a tracheostomy in place and the patient was scheduled for a videofluoroscopic swallowing examination. During the swallowing examination, six presentations of thin liquids were recorded: three with and three without the Passy-Muir tracheostomy speaking valve applied.

#### Findings

Seven of the 15 subjects (47%) aspirated material on one or more presentations of the thin liquid. Five subjects aspirated without the valve and two subjects aspirated with and without the valve. No subjects aspirated only when the valve was applied. Aspiration occurred less frequently with the Passy-Muir tracheostomy speaking valve on than with it off.

#### Nursing Implications

Aspiration is a common problem that can lead to severe pulmonary complications. Potential complications of aspiration include obstruction, inflammation (pneumonitis), and infection (aspiration pneumonia). Nursing assessment and knowledge of risk factors are key in evaluating patients at risk for potential aspiration problems and preventing this complication.

is not clinically useful due to the infused formula (Metheny & Titler, 2001).

The patient who is receiving continuous or timed-interval tube feedings must be positioned properly. The patient receiving a continuous infusion is given small volumes under low pressure in an upright position, which helps to prevent aspiration. Patients receiving tube feedings at timed intervals are maintained in an upright position during the feeding and for a minimum of 30 minutes afterward to allow the stomach to empty partially. Tube feedings must be given only when it is certain that the feeding tube is positioned correctly in the stomach. Many patients today receive enteral feeding directly into the duodenum through a small-bore flexible feeding tube or surgically implanted tube. Feedings are given slowly and regulated by a feeding pump. Correct placement is confirmed by chest x-ray.

### IDENTIFYING DELAYED STOMACH EMPTYING

A full stomach may cause aspiration because of increased intragastric or extragastric pressure. The following clinical situations cause a delayed emptying time of the stomach and may contribute to aspiration: intestinal obstruction; increased gastric secretions in gastroesophageal reflux disease; increased gastric secretions during anxiety, stress, or pain; or abdominal distention because of ileus, ascites, peritonitis, use of opioids and sedatives, severe illness, or vaginal delivery.

When a feeding tube is present, contents are aspirated, usually every 4 hours, to determine the amount of the last feeding left in the stomach (residual volume). If more than 50 mL is aspirated, there may be a problem with delayed emptying, and the next

feeding should be delayed or the continuous feeding stopped for a period of time.

### MANAGING EFFECTS OF PROLONGED INTUBATION

Prolonged endotracheal intubation or tracheostomy can depress the laryngeal and glottic reflexes because of disuse. Patients with prolonged tracheostomies are encouraged to phonate and exercise their laryngeal muscles. For patients who have had long-term intubation or tracheostomies, it may be helpful to have a rehabilitation therapist experienced in speech and swallowing disorders work with the patient to assess the swallowing reflex.

### Critical Thinking Exercises

1. Your patient, a 44-year-old unemployed man who lives with his 80-year-old mother, has recently been diagnosed with active TB. He has been started on treatment and given specific instructions about his medications. What strategies would you initiate to be sure that he takes his medications correctly? What strategies would you use to ensure that his mother is not infected? How would your care differ if the patient lived alone or were homeless?
2. You are working on a surgical unit. Your patient is a 67-year-old woman who has had surgery to repair a fractured hip that occurred following a fall associated with heavy alcohol use. She has been a heavy smoker for over 35 years and is reluctant to move in bed because of pain. What are the potential postoperative pulmonary complications? What assessment criteria would you use to assess her respiratory status? What interventions would you implement to prevent pulmonary complications in this patient? What changes, if any, would you implement if she had a history of deep vein thrombosis?
3. Your patient has experienced blunt chest trauma following a motor vehicle crash. A chest tube has been inserted to treat a pneumothorax. The chest drainage system has drained 400 mL of light-red fluid during the first 6 hours following the tube's insertion. The patient is unable to recall how he was injured or what has happened to him over the last 24 hours. The patient is experiencing pain requiring opioids and is asking that the chest tube be removed to enable him to walk to the bathroom. What additional information would you obtain through assessment and what actions would you take? How would you explain to the patient and his family the purpose of the chest tubes? How would you modify your explanation and teaching if he has little understanding of English?

# ● Management of Patients With Chronic Obstructive Pulmonary Disease

## **LEARNING OBJECTIVES**

*On completion of this chapter, the learner will be able to:*

1. Describe the pathophysiology of chronic obstructive pulmonary disease (COPD).
2. Discuss the major risk factors for developing COPD and nursing interventions to minimize or prevent these risk factors.
3. Use the nursing process as a framework for care of the patient with COPD.
4. Develop a teaching plan for patients with COPD.
5. Describe the pathophysiology of asthma.
6. Discuss the medications used in asthma management.
7. Describe asthma self-management strategies.
8. Describe the pathophysiology of cystic fibrosis.

Chronic obstructive pulmonary disease (COPD) is a leading cause of morbidity and mortality in the United States. Nurses are involved with COPD patients across the spectrum of care, from outpatient and home care to critical care and the hospice setting. Patients with COPD or asthma need care from nurses who not only have astute assessment and clinical management skills, but who also understand how these disorders can affect patients' quality of life. Patient and family teaching is an important nursing intervention to enhance self-management of COPD, asthma, and cystic fibrosis.

## Chronic Obstructive Pulmonary Disease

**Chronic obstructive pulmonary disease (COPD)** is a disease state characterized by airflow limitation that is not fully reversible. This newest definition of COPD, provided by the Global Initiative for Chronic Obstructive Lung Disease, provides a broad description that better explains this disorder and its signs and symptoms (National Institutes of Health [NIH], 2001). While previous definitions have included emphysema and chronic bronchitis under the umbrella classification of COPD, this was often confusing because most patients with COPD present with overlapping signs and symptoms of these two distinct disease processes.

COPD may include diseases that cause airflow obstruction (eg, emphysema, chronic bronchitis) or a combination of these disorders. Other diseases such as cystic fibrosis, bronchiectasis, and asthma were previously classified as types of chronic obstructive lung disease. However, asthma is now considered a separate disorder and is classified as an abnormal airway condition characterized primarily by reversible inflammation. COPD can coexist with asthma. Both of these diseases have the same major symptoms; however, symptoms are generally more variable in asthma than in COPD. This chapter discusses COPD as a disease and briefly describes chronic bronchitis and emphysema as distinct disease states, providing a foundation for understanding the pathophysiology of COPD. Bronchiectasis, asthma, and cystic fibrosis are discussed separately.

COPD is the fifth leading cause of death in the United States for all ages and both genders; fifth for men and fourth for women (National Center for Health Statistics [NCHS], 2000). In 1998, more than 12,000 persons died of COPD. This represents a rise in the mortality rate for this disorder at a time when death rates

from other serious illnesses, such as heart disease and cerebral vascular disease, were declining. Approximately 16 million people in the United States have some form of COPD; it is responsible for over 13.4 million office visits per year and is the third most frequent justification for home care services (NCHS, 2000; National Heart, Lung and Blood Institute [NHLBI], 1998). People with COPD commonly become symptomatic during the middle adult years, and the incidence of COPD increases with age. Although certain aspects of lung function normally decrease with age (eg, vital capacity and forced expiratory volume in 1 second [FEV<sub>1</sub>]), COPD accentuates and accelerates these physiologic changes.

## Pathophysiology

In COPD, the airflow limitation is both progressive and associated with an abnormal inflammatory response of the lungs to noxious particles or gases. The inflammatory response occurs throughout the airways, parenchyma, and pulmonary vasculature (NIH, 2001). Because of the chronic inflammation and the body's attempts to repair it, narrowing occurs in the small peripheral airways. Over time, this injury-and-repair process causes scar tissue formation and narrowing of the airway lumen. Airflow obstruction may also be due to parenchymal destruction as seen with emphysema, a disease of the alveoli or gas exchange units.

In addition to inflammation, processes relating to imbalances of proteinases and antiproteinases in the lung may be responsible for airflow limitation. When activated by chronic inflammation, proteinases and other substances may be released, damaging the parenchyma of the lung. The parenchymal changes may also be consequences of inflammation, environmental, or genetic factors (eg, alpha<sub>1</sub> antitrypsin deficiency).

Early in the course of COPD, the inflammatory response causes pulmonary vasculature changes that are characterized by thickening of the vessel wall. These changes may occur as a result of exposure to cigarette smoke or use of tobacco products or as a result of the release of inflammatory mediators (NIH, 2001).

## Chronic Bronchitis

Chronic **bronchitis**, a disease of the airways, is defined as the presence of cough and sputum production for at least 3 months in each of 2 consecutive years. In many cases, smoke or other environmental pollutants irritate the airways, resulting in hypersecretion

## Glossary

**air trapping:** incomplete emptying of alveoli during expiration due to loss of lung tissue elasticity (emphysema), bronchospasm (asthma), or airway obstruction

**alpha<sub>1</sub> antitrypsin deficiency:** genetic disorder resulting from deficiency of alpha<sub>1</sub> antitrypsin, a protective agent for the lung; increases patient's risk for developing panacinar emphysema even in the absence of smoking

**asthma:** a disease with multiple precipitating mechanisms resulting in a common clinical outcome of reversible airflow obstruction; no longer considered a category of COPD

**bronchiectasis:** chronic dilation of a bronchus or bronchi; the dilated airways

become saccular and are a medium for chronic infection. Is no longer considered a category of COPD.

**bronchitis:** a disease of the airways defined as the presence of cough and sputum production for at least a combined total of 3 months in each of 2 consecutive years; is a category of COPD

**chronic obstructive pulmonary disease:** disease state characterized by airflow limitation that is not fully reversible; sometimes referred to as chronic airway obstruction or chronic obstructive lung disease

**emphysema:** a disease of the airways characterized by destruction of the walls of

overdistended alveoli; is a category of COPD

**metered-dose inhaler (MDI):** patient-activated medication canister that provides aerosolized medication that the patient inhales into the lungs

**polycythemia:** increase in the red blood cell concentration in the blood; in COPD, the body attempts to improve oxygen carrying capacity by producing increasing amounts of red blood cells

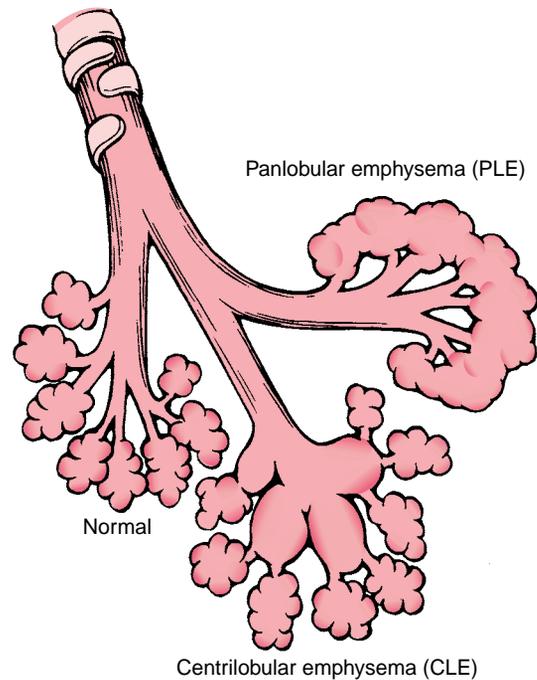

**spirometry:** pulmonary function tests that measure specific lung volumes (eg, FEV<sub>1</sub>, FVC) and rates (FEF<sub>25-75%</sub>); may be measured before and after bronchodilator administration

of mucus and inflammation. This constant irritation causes the mucus-secreting glands and goblet cells to increase in number, ciliary function is reduced, and more mucus is produced. The bronchial walls become thickened, the bronchial lumen is narrowed, and mucus may plug the airway (Fig. 24-1). Alveoli adjacent to the bronchioles may become damaged and fibrosed, resulting in altered function of the alveolar macrophages. This is significant because the macrophages play an important role in destroying foreign particles, including bacteria. As a result, the patient becomes more susceptible to respiratory infection. A wide range of viral, bacterial, and mycoplasmal infections can produce acute episodes of bronchitis. Exacerbations of chronic bronchitis are most likely to occur during the winter.

## Emphysema

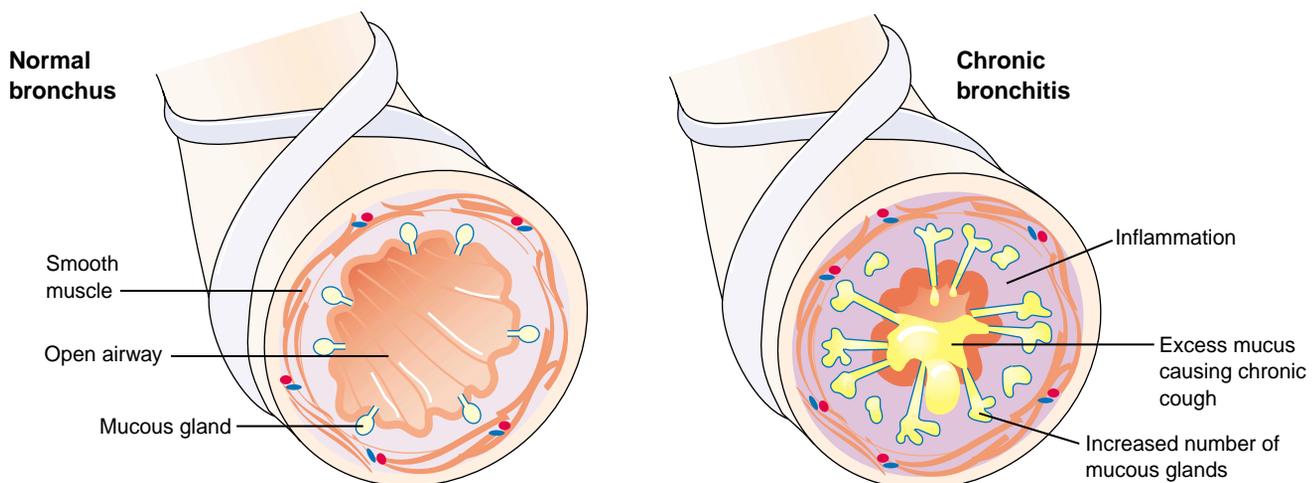

In **emphysema**, impaired gas exchange (oxygen, carbon dioxide) results from destruction of the walls of overdistended alveoli. “Emphysema” is a pathological term that describes an abnormal distention of the air spaces beyond the terminal bronchioles, with destruction of the walls of the alveoli. It is the end stage of a process that has progressed slowly for many years. As the walls of the alveoli are destroyed (a process accelerated by recurrent infections), the alveolar surface area in direct contact with the pulmonary capillaries continually decreases, causing an increase in dead space (lung area where no gas exchange can occur) and impaired oxygen diffusion, which leads to hypoxemia. In the later stages of the disease, carbon dioxide elimination is impaired, resulting in increased carbon dioxide tension in arterial blood (hypercapnia) and causing respiratory acidosis. As the alveolar walls continue to break down, the pulmonary capillary bed is reduced. Consequently, pulmonary blood flow is increased, forcing the right ventricle to maintain a higher blood pressure in the pulmonary artery. Hypoxemia may further increase pulmonary artery pressure. Thus, right-sided heart failure (*cor pulmonale*) is one of the complications of emphysema. Congestion, dependent edema, distended neck veins, or pain in the region of the liver suggests the development of cardiac failure.

There are two main types of emphysema, based on the changes taking place in the lung: panlobular (panacinar) and centrilobular (centroacinar) (Fig. 24-2). Both types may occur in the same pa-

**FIGURE 24-2** Changes in alveolar structure in centrilobular and panlobular emphysema. In panlobular emphysema, the bronchioles, alveolar ducts, and alveoli are destroyed and the air spaces within the lobule are enlarged. In centrilobular emphysema, the pathologic changes occur in the lobule, while the peripheral portions of the acinus are preserved.

tient. In the panlobular (panacinar) type, there is destruction of the respiratory bronchiole, alveolar duct, and alveoli. All air spaces within the lobule are essentially enlarged, but there is little inflammatory disease. The patient with this type of emphysema typically has a hyperinflated (hyperexpanded) chest (barrel chest on physical examination), marked dyspnea on exertion, and weight loss. To move air into and out of the lungs, negative pressure is required during inspiration, and an adequate level of positive pressure must be attained and maintained during expiration. The resting position is one of inflation. Instead of being an involuntary passive act, expiration becomes active and requires mus-

**FIGURE 24-1** Pathophysiology of chronic bronchitis as compared to a normal bronchus. The bronchus in chronic bronchitis is narrowed and has impaired air flow due to multiple mechanisms: inflammation, excess mucus production, and potential smooth muscle constriction (bronchospasm).

cular effort. The patient becomes increasingly short of breath, the chest becomes rigid, and the ribs are fixed at their joints.

In the centrilobular (centroacinar) form, pathologic changes take place mainly in the center of the secondary lobule, preserving the peripheral portions of the acinus. Frequently, there is a derangement of ventilation–perfusion ratios, producing chronic hypoxemia, hypercapnia (increased  $\text{CO}_2$  in the arterial blood), **polycythemia**, and episodes of right-sided heart failure. This leads to central cyanosis, peripheral edema, and respiratory failure. The patient may receive diuretic therapy for edema.

## Risk Factors

Risk factors for COPD include environmental exposures and host factors (Chart 24-1). The most important risk factor for COPD is cigarette smoking. Pipe, cigar, and other types of tobacco smoking are also risk factors. In addition, passive smoking contributes to respiratory symptoms and COPD (NIH, 2001). Smoking depresses the activity of scavenger cells and affects the respiratory tract's ciliary cleansing mechanism, which keeps breathing passages free of inhaled irritants, bacteria, and other foreign matter. When smoking damages this cleansing mechanism, airflow is obstructed and air becomes trapped behind the obstruction. The alveoli greatly distend, diminishing lung capacity. Smoking also irritates the goblet cells and mucus glands, causing an increased accumulation of mucus, which in turn produces more irritation, infection, and damage to the lung. In addition, carbon monoxide (a byproduct of smoking) combines with hemoglobin to form carboxyhemoglobin. Hemoglobin that is bound by carboxyhemoglobin cannot carry oxygen efficiently.

Smoking is not the only risk factor for COPD. Other factors include prolonged and intense exposure to occupational dusts and chemicals, indoor air pollution, and outdoor air pollution, which adds to the total burden of inhaled particles on the lung (NIH, 2001).

A host risk factor for COPD is a deficiency of  $\alpha_1$  antitrypsin, an enzyme inhibitor that protects the lung parenchyma from injury. This deficiency predisposes young patients to rapid development of lobular emphysema even in the absence of smoking. **Alpha<sub>1</sub> antitrypsin deficiency** is one of the most common genetically linked lethal diseases among Caucasians and affects approximately one in every 3,000 Americans or approximately 80,000 to 100,000 cases (George, San Pedro & Stoller, 2000). The genetically susceptible person is sensitive to environmental factors (smoking, air pollution, infectious agents, allergens) and in time develops chronic obstructive symptoms. Carriers of this genetic defect must be identified so that they can modify environmental risk factors to delay or prevent overt symptoms of dis-

ease. Genetic counseling should also be offered. Alpha-protease inhibitor replacement therapy, which slows the progression of the disease, is available for patients with this genetic defect and for those with severe disease. This intermittent infusion therapy is costly and is required on an ongoing basis.

## Clinical Manifestations

COPD is characterized by three primary symptoms: cough, sputum production, and dyspnea on exertion (NIH, 2001). These symptoms often worsen over time. Chronic cough and sputum production often precede the development of airflow limitation by many years. However, not all individuals with cough and sputum production will develop COPD. Dyspnea may be severe and often interferes with the patient's activities. Weight loss is common because dyspnea interferes with eating, and the work of breathing is energy-depleting. Often the patient cannot participate in even mild exercise because of dyspnea; as COPD progresses, dyspnea occurs even at rest. As the work of breathing increases over time, the accessory muscles are recruited in an effort to breathe. The patient with COPD is at risk for respiratory insufficiency and respiratory infections, which in turn increase the risk for acute and chronic respiratory failure.

In COPD patients with a primary emphysematous component, chronic hyperinflation leads to the “barrel chest” thorax configuration. This results from fixation of the ribs in the inspiratory position (due to hyperinflation) and from loss of lung elasticity (Fig. 24-3). Retraction of the supraclavicular fossae occurs on inspiration, causing the shoulders to heave upward (Fig. 24-4). In advanced emphysema, the abdominal muscles also contract on inspiration.

## Assessment and Diagnostic Findings

The nurse should obtain a thorough health history for a patient with known or potential COPD. Chart 24-2 lists the key factors to assess. Pulmonary function studies are used to help confirm the diagnosis of COPD, determine disease severity, and follow disease progression. **Spirometry** is used to evaluate airflow obstruction, which is determined by the ratio of  $\text{FEV}_1$  (volume of air that the patient can forcibly exhale in 1 second) to forced vital capacity (FVC). Spirometric results are expressed as an absolute volume and as percent-predicted using appropriate normal values for gender, age, and height. With obstruction, the patient either has difficulty exhaling or cannot forcibly exhale air from the lungs, reducing the  $\text{FEV}_1$ . Obstructive lung disease is defined as a  $\text{FEV}_1/\text{FVC}$  ratio of less than 70%.

In addition, bronchodilator reversibility testing may be performed to rule out the diagnosis of asthma and to guide initial treatment. With this type of testing, spirometry is first obtained, then the patient is given an inhaled bronchodilator per a protocol, and finally spirometry is repeated. The patient demonstrates a degree of reversibility if the pulmonary function values improve after administration of the bronchodilator.

Arterial blood gas measurements may also be obtained to assess baseline oxygenation and gas exchange. In addition, a chest x-ray may be obtained to exclude alternative diagnoses. Lastly,  $\alpha_1$  antitrypsin deficiency screening may be performed for patients under age 45 or for those with a strong family history of COPD.

The severity of COPD is classified into four stages (Table 24-1) (National Institutes of Health, 2001). Factors that determine the clinical course and survival of patients with COPD include history

Chart 24-1

### Risk Factors for COPD

- Exposure to tobacco smoke accounts for an estimated 80% to 90% of COPD cases (Rennard, 1998)
- Passive smoking
- Occupational exposure
- Ambient air pollution
- Genetic abnormalities, including a deficiency of  $\alpha_1$ -antitrypsin, an enzyme inhibitor that normally counteracts the destruction of lung tissue by certain other enzymes

### NURSING RESEARCH PROFILE 24-1

## Physical Activity in Patients With COPD

Belza, B., Steele, B. G., Hunziker, J., Lakshminaryan, S., Holt, L., & Buchner, D. M. (2001). Correlates of physical activity in chronic obstructive pulmonary disease. *Nursing Research*, 50(4), 195–202.

### Purpose

For patients with chronic obstructive pulmonary disease (COPD), physical activity is an important part of their quality of life. Yet little is known about the contributions of psychological and physiologic variables to physical activity in this population. The purpose of this study was to determine the relationships among differing functional performance measures (physical activity, functional capacity, symptom experience, and health-related quality of life) in this population.

### Study Sample and Design

This cross-sectional, descriptive study evaluated 63 outpatients with COPD prior to entry into a pulmonary rehabilitation program. The sample was predominantly male (60 men and 3 women) with a mean age of  $65.4 \pm 8.0$  years. None of the participants had been hospitalized in the past 2 months for a respiratory problem, and none was engaged in a formalized exercise program. Functional performance was measured by physical activity (evaluated by an accelerometer and self-report). Functional capacity was measured by three measures of impairment (pulmonary function tests [FEV<sub>1</sub>], 6-minute walk test, and

a self-efficacy questionnaire for walking). The symptom experiences of dyspnea and fatigue as well as health-related quality of life were measured by widely used reliable and valid questionnaires.

### Findings

Sixty-nine subjects were initially enrolled in the study but six were withdrawn due to missing data. Daily physical activity as measured by the accelerometer was strongly associated with the maximal distance walked in the 6-minute walk test, the level of airway obstruction as measured by pulmonary function tests, walking self-efficacy, and physical health status. Physical activity was not correlated with the subjects' self-report of functional status. The 6-minute walk test was the only predictor of physical activity in this sample.

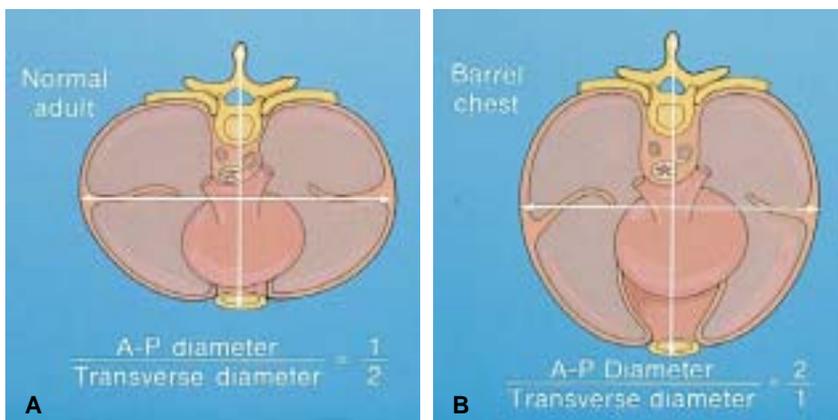

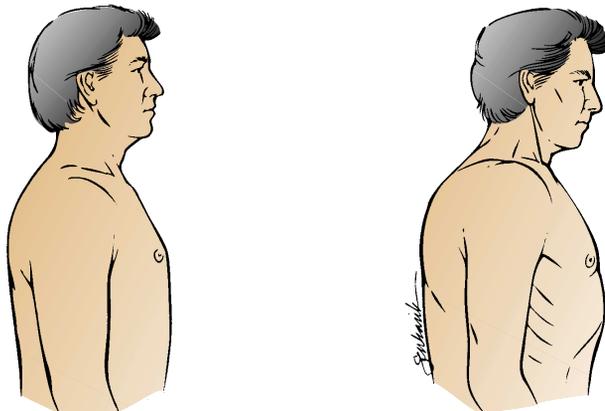

### Nursing Implications

Functional performance status is an important multidimensional outcome measure for both nursing and medicine. This study demonstrates that the multiple measures of functional performance status, which are frequently used in clinical practice and research, may differ in their relationship to the actual physical activity level of the patient.

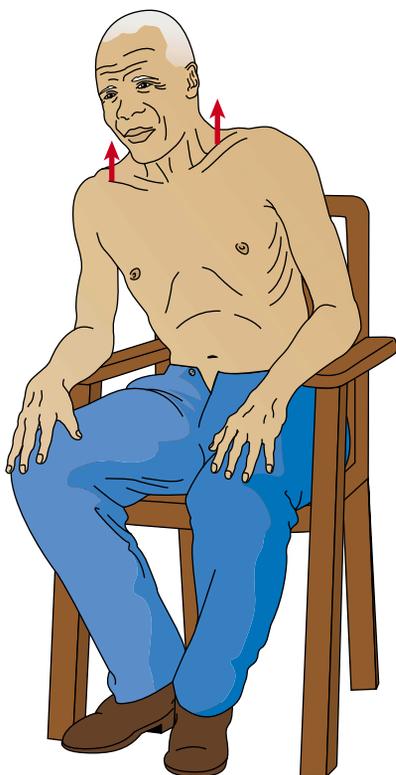

of cigarette smoking, passive smoking exposure, age, rate of decline of FEV<sub>1</sub>, hypoxemia, pulmonary artery pressure, resting heart rate, weight loss, and reversibility of airflow obstruction (George, San Pedro & Stoller, 2000).

In diagnosing COPD, several differential diagnoses must be ruled out. The primary differential diagnosis is asthma. Key char-

acteristics of asthma include onset often early in life, variation in daily symptoms and day-to-day occurrence or timing of symptoms, family history of asthma, and a largely reversible airflow obstruction. It may be difficult to differentiate between a patient with COPD and one with chronic asthma. A key part of differentiation is the patient history, as well as the patient's respon-

**FIGURE 24-3** Characteristics of normal chest wall and chest wall in emphysema. The normal chest wall and its cross section are illustrated on the left (A). The barrel-shaped chest of emphysema and its cross section are illustrated on the right (B).

**FIGURE 24-4** Typical posture of person with COPD—primarily emphysema. The person tends to lean forward and uses the accessory muscles of respiration to breathe, forcing the shoulder girdle upward and causing the supraclavicular fossae to retract on inspiration.

siveness to bronchodilators. Other diseases that must be considered in the differential diagnosis include heart failure, bronchiectasis, and tuberculosis (NIH, 2001).

## Complications

Respiratory insufficiency and failure are major life-threatening complications of COPD. The acuity of the onset and the severity of respiratory failure depend on the patient's baseline pulmonary function, pulse oximetry or arterial blood gas values, comorbid conditions, and the severity of other complications of COPD. Respiratory insufficiency and failure may be chronic

**Table 24-1 • Stages of COPD**

STAGE	CHARACTERISTICS
0	Normal spirometry Chronic symptoms of cough, sputum production
I (mild COPD)	$FEV_1/FVC < 70\%$ $FEV_1 \geq 80\%$ predicted May or may not have chronic symptoms of cough, sputum production
II (moderate COPD)	$FEV_1/FVC < 70\%$ $FEV_1$ between 30% and 80% predicted May or may not have chronic symptoms of cough, sputum production
III (severe COPD)	$FEV_1/FVC < 70\%$ $FEV_1 < 30\%$ predicted or $FEV_1 < 50\%$ predicted plus respiratory failure or clinical signs of right heart failure

National Institutes of Health (2001). *Global initiative for chronic obstructive lung disease: Global strategy for the diagnosis, management, and prevention of chronic obstructive pulmonary disease*. U.S. Department of Health and Human Services, NIH Publication Number 2701B.

(with severe COPD) or acute (with severe bronchospasm or pneumonia in the patient with severe COPD). Acute respiratory insufficiency and failure may necessitate ventilatory support until other acute complications, such as infection, can be treated. Management of the patient requiring ventilatory support is discussed in Chapter 25. Other complications of COPD include pneumonia, atelectasis, pneumothorax, and cor pulmonale.

## Medical Management

### RISK REDUCTION

Smoking cessation is the single most effective intervention to prevent COPD or slow its progression (NIH, 2001). Recent surveys indicate that 25% of all American adults smoke (USPHS, 2000). Nurses play a key role in promoting smoking cessation and educating patients about ways to do so. Patients diagnosed with COPD who continue to smoke must be encouraged and assisted to quit. Factors associated with continued smoking vary among patients and may include the strength of nicotine addiction, continued exposure to smoking-associated stimuli (at work or in social settings), stress, depression, and habit. Continued smoking is also more prevalent among those with low incomes, a low level of education, and psychosocial problems (Pohl, 2000).

Because there are multiple factors associated with continued smoking, successful cessation often requires multiple strategies. The health care provider should promote cessation by explaining the risks of smoking and personalizing the “at-risk” message to the patient. After giving a strong warning about smoking, the health care provider should work with the patient to set a definite “quit date.” Referral to a smoking cessation program may be helpful. Follow-up within 3 to 5 days after the quit date to review progress and to address any problems is associated with an increased rate of success; this should be repeated as needed. Continued reinforcement with telephone calls or clinic visits is extremely beneficial. Relapses should be analyzed, and the patient and health care provider should jointly identify possible solutions to prevent future backsliding. It is important to emphasize successes rather

### Chart 24-2 • ASSESSMENT

#### Key Factors to Assess in the COPD Patient's Health History

- Exposure to risk factors—types, intensity, duration
- Past medical history—respiratory diseases/problems, including asthma, allergy, sinusitis, nasal polyps, history of respiratory infections
- Family history of COPD or other chronic respiratory diseases
- Pattern of symptom development
- History of exacerbations or previous hospitalizations for respiratory problems
- Presence of comorbidities
- Appropriateness of current medical treatments
- Impact of the disease on quality of life
- Available social and family support for patient
- Potential for reducing risk factors (eg, smoking cessation)

than failures. First-line pharmacotherapies that reliably increase long-term smoking abstinence rates are bupropion SR (Zyban, Wellbutrin), nicotine gum, nicotine inhaler, nicotine nasal spray, or nicotine patches. Second-line pharmacotherapies include clonidine (Catapres) and nortriptyline (Aventyl) (USPHS, 2000).

Smoking cessation can begin in a variety of health care settings—outpatient clinic, pulmonary rehabilitation, community, hospital, and the patient’s home. Regardless of the setting, the nurse has the opportunity to teach the patient about the risks of smoking and the benefits of smoking cessation. A variety of materials, resources, and programs are available to assist with this effort (eg, Agency for Healthcare Research and Quality [formerly Agency for Healthcare Policy and Research], United States Public Health Service, Centers for Disease Control and Prevention, National Cancer Institute, American Lung Association, American Cancer Society).

### PHARMACOLOGIC THERAPY

**Bronchodilators.** Bronchodilators relieve bronchospasm and reduce airway obstruction by allowing increased oxygen distribution throughout the lungs and improving alveolar ventilation. These medications, which are central in the management of COPD (NIH, 2001), are delivered through a metered-dose inhaler, by nebulization, or via the oral route in pill or liquid form. Bronchodilators are often administered regularly throughout the day as well as on an as-needed basis. They may also be used prophylactically to prevent breathlessness by having the patient use them before an activity, such as eating or walking.

A **metered-dose inhaler** (MDI) is a pressurized device containing an aerosolized powder of medication. A precise amount of medication is released with each activation of the canister (Dhand, 2000). Patients need to be instructed on the correct use

of the device. A spacer (holding chamber) may also be used to enhance deposition of the medication in the lung and help the patient coordinate activation of the MDI with inspiration. Spacers come in several designs, but all are attached to the MDI and have a mouthpiece on the opposite end (Fig. 24-5). Once the canister is activated, the spacer holds the aerosol in the chamber until the patient inhales (Dhand, 2000). The patient should take a slow, 3- to 5-second inhalation immediately following activation of the MDI (Expert Panel Report II, 1997).

Several classes of bronchodilators are used: beta-adrenergic agonists, anticholinergic agents, and methylxanthines. These medications may be used in combination to optimize the bronchodilation effect. Some of these medications are short-acting; others are long-acting. Long-acting bronchodilators are more convenient for patient use. Examples of medications in these differing classes are shown in Table 24-2. Nebulized medications (nebulization of medication via an air compressor) may also be effective in patients who cannot use an MDI properly or who prefer this method of administration.

**Corticosteroids.** Inhaled and systemic corticosteroids (oral or intravenous) may also be used in COPD but are used more frequently in asthma. Although it has been shown that corticosteroids do not slow the decline in lung function, these medications may improve symptoms. A short trial course of oral corticosteroids may be prescribed for patients with stage II or III COPD to see if pulmonary function improves and symptoms decrease. Inhaled corticosteroids via MDI may also be used. Examples of corticosteroids in the inhaled form are beclomethasone (Beclonvent, Vanceril), budesonide (Pulmicort), fluticasone (AeroBid), fluticasone (Flovent), and triamcinolone (Azmacort).

Medication regimens used to manage COPD are based on disease severity. For stage I or mild COPD, a short-acting bron-

Table 24-2 • Types of Bronchodilator Medications

CLASS/DRUG	METHOD OF ADMINISTRATION			DURATION OF ACTION
	Metered-Dose Inhaler	Nebulizer	Oral	
<b>Beta-Adrenergic Agonist Agents</b>				
Albuterol (Proventil, Ventolin, Volmax)	X	X	X	Short
Bitolerol (Tornate)	X	X		Medium
Levalbuterol (Xopenax)		X		Medium
Metaproterenol (Alupent)	X	X	X	Short
Pirbuterol (Maxair)	X			Short
Salbutamol (Asmavent)	X	X	X	Short
Salmeterol (Serevent)	X			Long
Terbutaline (Brethaire)			X	Short
<b>Anticholinergic Agents</b>				
Ipratropium bromide (Atrovent)	X	X		Short
Oxipropium bromide (Oxivent)	X			Medium
<b>Methylxanthines</b>				
Aminophylline (Phyllocontin)			X	Variable
Theophylline (Slo-bid, Theo-Dur)			X	Variable

Short-acting: 4–6 hours

Medium-acting: 6–9 hours

Long-acting: 12+ hours

chodilator may be prescribed. For stage II or moderate COPD, one or more bronchodilators may be prescribed along with inhaled corticosteroids, if symptoms are significant. For stage III or severe COPD, medication therapy includes regular treatment with one or more bronchodilators and inhaled corticosteroids (NIH, 2001).

**Other Medications.** Patients should receive a yearly influenza vaccine and the pneumococcal vaccine every 5 to 7 years as preventive measures. In most healthy adults, pneumococcal vaccine titers persist for 5 or more years (George, San Pedro & Stoller, 2000). Other pharmacologic treatments that may be used in COPD include  $\alpha_1$  antitrypsin augmentation therapy, antibiotic agents, mucolytic agents, and antitussive agents.

### MANAGEMENT OF EXACERBATION

An exacerbation of COPD is difficult to diagnose, but signs and symptoms may include increased dyspnea, increased sputum production and purulence, respiratory failure, changes in mental status, or worsening blood gas abnormalities. Primary causes for an acute exacerbation include tracheobronchial infection and air pollution (NIH, 2001). Secondary causes are pneumonia; pulmonary embolism; pneumothorax; rib fractures or chest trauma; inappropriate use of sedative, opioid, or beta-blocking agents; and right- or left-sided heart failure. First, the primary cause of the exacerbation is identified, and then specific treatment is administered. Optimization of bronchodilator medications is the first-line therapy and involves identifying the best medication or combinations of medications taken on a regular schedule for that patient. Depending on the signs and symptoms, corticosteroids, antibiotic agents, oxygen therapy, and intensive respiratory interventions may also be used. Indications for hospitalization of a patient with an acute exacerbation of COPD include severe dyspnea that does not respond adequately to initial therapy, confu-

sion or lethargy, respiratory muscle fatigue, paradoxical chest wall movement, peripheral edema, worsening or new onset of central cyanosis, persistent or worsening hypoxemia, and/or need for noninvasive or invasive assisted mechanical ventilation (Celli, Snider, Heffner et al., 1995; NIH, 2001).

### OXYGEN THERAPY

Oxygen therapy can be administered as long-term continuous therapy, during exercise, or to prevent acute dyspnea. Long-term oxygen therapy has been shown to improve the patient's quality of life and survival (NIH, 2001). For patients with an arterial oxygen pressure ( $\text{PaO}_2$ ) of 55 mm Hg or less on room air, maintaining a constant and adequate oxygen saturation ( $>90\%$ ) is associated with significantly reduced mortality and improved quality of life. Indications for oxygen supplementation include a  $\text{PaO}_2$  of 55 mm Hg or less or evidence of tissue hypoxia and organ damage such as cor pulmonale, secondary polycythemia, edema from right heart failure, or impaired mental status. In patients with exercise-induced hypoxemia, oxygen supplementation during exercise can improve performance. Patients who are hypoxemic while awake are likely to be so during sleep. Therefore, nighttime oxygen therapy is recommended as well, and the prescription for oxygen therapy is for continuous, 24-hour use. Intermittent oxygen therapy is indicated for those who desaturate only during exercise or sleep.

**NURSING ALERT** Because hypoxemia stimulates respiration in the patient with severe COPD, increasing the oxygen flow to a high rate may greatly raise the patient's blood oxygen level. At the same time, this will suppress the respiratory drive, causing increased retention of carbon dioxide and  $\text{CO}_2$  narcosis. The nurse should closely monitor the patient's respiratory response to oxygen administration via physical assessment, pulse oximetry, and/or arterial blood gases.

### NURSING RESEARCH PROFILE 24-2

## Oxygen Administration and Dyspnea Management in Patients With AAT Deficiency

Knebel, A. R., Bentz, E., & Barnes, P. (2000). Dyspnea management in alpha-1 antitrypsin deficiency: Effect of oxygen administration. *Nursing Research, 49*(6), 333–338.

### Purpose

Limitations in activity due to dyspnea are common in persons with emphysema, including patients with alpha<sub>1</sub> antitrypsin (AAT) deficiency. The purpose of this study was to examine whether short-term oxygen administration decreased dyspnea and improved exercise tolerance in nonhypoxemic patients with emphysema caused by AAT deficiency.

### Study Sample and Design

Thirty-one Caucasian subjects participated in a double-blind, crossover study. The subjects' mean age was  $47 \pm 7$  years; 62% were male and 38% were female. Twenty-four percent had used oxygen supplementation at some point during their illness. Oxygen saturation, 6-minute walk distance, and end-of-walk dyspnea were measured during three practice walks and during walks with nasal cannula administration of oxygen (intervention) and compressed air (control).

### Findings

Researchers found significant differences in subjects' oxygen saturation during walks with oxygen vs. walks with compressed air ( $p = 0.0001$ ),

with oxygen saturation higher with oxygen supplementation than with compressed air. There was no difference in subjects' walk distance and severity of self-reported dyspnea between oxygen and compressed air use. However, some gender differences were noted. Men showed no benefit from oxygen supplementation while walking, but women experienced less dyspnea, which corresponded with an increased walking distance.

### Nursing Implications

The findings demonstrated that oxygen supplementation did not significantly improve the sensation of dyspnea or the distance walked in 6 minutes in the total sample of patients with AAT deficiency. However, there were trends in gender differences in relation to dyspnea levels and distance walked while receiving the intervention (oxygen supplementation). Future studies should examine subjects with differing levels of room air hypoxemia and explore potential gender differences in exercise performance with oxygen supplementation. Nurses should be aware that patients may respond differently to oxygen supplementation depending upon the underlying disease process, level of hypoxemia, and gender.

## SURGICAL MANAGEMENT

**Bullectomy.** A bullectomy is a surgical option for select patients with bullous emphysema. Bullae are enlarged airspaces that do not contribute to ventilation but occupy space in the thorax; these areas may be surgically excised. Many times these bullae compress areas of the lung that do have adequate gas exchange. Bullectomy may help reduce dyspnea and improve lung function. It can be done thoracoscopically (with a video-assisted thoracoscope) or via a limited thoracotomy incision (see Chap. 25).

**Lung Volume Reduction Surgery.** Treatment options for patients with end-stage COPD (stage III) with a primary emphysematous component are limited, although lung volume reduction surgery is an option for a specific subset of patients. This subset includes patients with homogenous disease or disease that is focused in one area and not widespread throughout the lungs. Lung volume reduction surgery involves the removal of a portion of the diseased lung parenchyma. This allows the functional tissue to expand, resulting in improved elastic recoil of the lung and improved chest wall and diaphragmatic mechanics. This type of surgery does not cure the disease, but it may decrease dyspnea, improve lung function, and improve the patient's overall quality of life. Careful selection of patients for this procedure is essential to decrease the morbidity and mortality. The long-term outcomes of this surgery are unknown.

The National Emphysema Treatment Trial (NETT) is a large, multicenter randomized clinical trial that began in 1997 and is ongoing. It is attempting to answer many questions regarding the risks and benefits of lung volume reduction surgery in the treatment of severe emphysema. All patients in this trial receive a 6- to 10-week pulmonary rehabilitation program and comprehensive medical management. Following completion of pulmonary rehabilitation, patients are randomized to continue medical management or undergo lung volume reduction surgery. The results

of this trial will help to determine the role of lung volume reduction surgery for patients with severe emphysema (NIH, 2001). It is expected that 2,500 patients will be entered into the study.

**Lung Transplantation.** Lung transplantation is a viable alternative for definitive surgical treatment of end-stage emphysema. It has been shown to improve quality of life and functional capacity (NIH, 2001). Specific criteria exist for referral for lung transplantation; however, organs are in short supply and many patients die while waiting for a transplant.

## PULMONARY REHABILITATION

Pulmonary rehabilitation for patients with COPD is well established and widely accepted as a means to alleviate symptoms and optimize functional status. In both randomized and nonrandomized clinical trials, pulmonary rehabilitation has been shown to improve exercise tolerance, reduce dyspnea, and increase health-related quality of life (Rochester, 2000). The primary goal of rehabilitation is to restore patients to the highest level of independent function possible and to improve their quality of life. A successful rehabilitation program is individualized for each patient, is multidisciplinary, and attends to both the physiologic and emotional needs of the patient. Most pulmonary rehabilitation programs include educational, psychosocial, behavioral, and physical components. Breathing exercises and retraining and exercise programs are used to improve functional status, and the patient is taught methods to alleviate symptoms.

Pulmonary rehabilitation may be used therapeutically in other diseases besides COPD, including asthma, cystic fibrosis, lung cancer, interstitial lung disease, thoracic surgery, and lung transplantation. It may be conducted in the inpatient, outpatient, or home setting; the lengths of programs vary. Selection of a program depends upon the patient's physical, functional, and psychosocial status; insurance coverage; changing health care trends; availability of programs; and patient preference (Rochester, 2000).

## Nursing Management

The nurse plays a key role in identifying potential candidates for pulmonary rehabilitation and in facilitating and reinforcing the material learned in the rehabilitation program. Not all patients have access to a formal rehabilitation program. However, the nurse can be instrumental in teaching the patient and family as well as facilitating specific services for the patient (eg, respiratory therapy education, physical therapy for exercise and breathing retraining, occupational therapy for conserving energy during activities of daily living, and nutritional counseling). In addition, numerous educational materials are available to assist the nurse in teaching patients with COPD. Potential resources include the American Lung Association, the American Association of Cardiovascular and Pulmonary Rehabilitation, the American Thoracic Society, the American College of Chest Physicians, and the American Association for Respiratory Therapy.

### PATIENT EDUCATION

Patient education is a major component of pulmonary rehabilitation and includes a broad variety of topics. Depending on the length and setting of the program, topics may include normal anatomy and physiology of the lung, pathophysiology and changes with COPD, medications and home oxygen therapy, nutrition, respiratory therapy treatments, symptom alleviation, smoking cessation, sexuality and COPD, coping with chronic disease, communicating with the health care team, and planning for the future (advance directives, living wills, informed decision making about health care alternatives).

**Breathing Exercises.** The breathing pattern of most people with COPD is shallow, rapid, and inefficient; the more severe the disease, the more inefficient the breathing pattern. With practice, this type of upper chest breathing can be changed to diaphragmatic breathing, which reduces the respiratory rate, increases alveolar ventilation, and sometimes helps expel as much air as possible during expiration (see Chap. 25 for technique). Pursed-lip breathing helps to slow expiration, prevents collapse of small airways, and helps the patient to control the rate and depth of respiration. It also promotes relaxation, enabling the patient to gain control of dyspnea and reduce feelings of panic.

**Inspiratory Muscle Training.** Once the patient masters diaphragmatic breathing, a program of inspiratory muscle training may be prescribed to help strengthen the muscles used in breathing. This program requires that the patient breathe against resistance for 10 to 15 minutes every day. As the resistance is gradually increased, the muscles become better conditioned. Conditioning of the respiratory muscles takes time, and the patient is instructed to continue practicing at home (Larson, Covey, Wirtz et al., 1999; NIH, 2001).

**Activity Pacing.** A patient with COPD has decreased exercise tolerance during specific periods of the day. This is especially true on arising in the morning, because bronchial secretions collect in the lungs during the night while the person is lying down. The patient may have difficulty bathing or dressing. Activities requiring the arms to be supported above the level of the thorax may produce fatigue or respiratory distress but may be tolerated better after the patient has been up and moving around for an hour or more. Working with the nurse, the patient can reduce these

limitations by planning self-care activities and determining the best time for bathing, dressing, and daily activities.

**Self-Care Activities.** As gas exchange, airway clearance, and the breathing pattern improve, the patient is encouraged to assume increasing participation in self-care activities. The patient is taught to coordinate diaphragmatic breathing with activities such as walking, bathing, bending, or climbing stairs. The patient should bathe, dress, and take short walks, resting as needed to avoid fatigue and excessive dyspnea. Fluids should always be readily available, and the patient should begin to drink fluids without having to be reminded. If postural drainage is to be done at home, the nurse instructs and supervises the patient before discharge or in the outpatient setting.

**Physical Conditioning.** Physical conditioning techniques include breathing exercises and general exercises intended to conserve energy and increase pulmonary ventilation. There is a close relationship between physical fitness and respiratory fitness. Graded exercises and physical conditioning programs using treadmills, stationary bicycles, and measured level walks can improve symptoms and increase work capacity and exercise tolerance. Any physical activity that can be done regularly is helpful. Lightweight portable oxygen systems are available for ambulatory patients who require oxygen therapy during physical activity.

**Oxygen Therapy.** Oxygen supplied to the home comes in compressed gas, liquid, or concentrator systems. Portable oxygen systems allow the patient to exercise, work, and travel. To help the patient adhere to the oxygen prescription, the nurse explains the proper flow rate and required number of hours for oxygen use as well as the dangers of arbitrary changes in flow rates or duration of therapy. The nurse cautions the patient that smoking with or near oxygen is extremely dangerous. The nurse also reassures the patient that oxygen is not “addictive” and explains the need for regular evaluations of blood oxygenation by pulse oximetry or arterial blood gas analysis.

**Nutritional Therapy.** Nutritional assessment and counseling are important aspects in the rehabilitation process for the patient with COPD. Approximately 25% of patients with COPD are undernourished (NIH, 2001; Ferreira, Brooks, Lacasse & Goldstein, 2001). A thorough assessment of caloric needs and counseling about meal planning and supplementation are part of the rehabilitation process.

**Coping Measures.** Any factor that interferes with normal breathing quite naturally induces anxiety, depression, and changes in behavior. Many patients find the slightest exertion exhausting. Constant shortness of breath and fatigue may make the patient irritable and apprehensive to the point of panic. Restricted activity (and reversal of family roles due to loss of employment), the frustration of having to work to breathe, and the realization that the disease is prolonged and unrelenting may cause the patient to react with anger, depression, and demanding behavior. Sexual function may be compromised, which also diminishes self-esteem. In addition, the nurse needs to provide education and support to the spouse/significant other and family because the caregiver role in end-stage COPD can be difficult.

## NURSING PROCESS: THE PATIENT WITH COPD

### Assessment

Assessment involves obtaining information about current symptoms as well as previous disease manifestations. Chart 24-3 lists sample questions that may be used to obtain a clear history of the disease process. In addition to the history, the nurse also reviews the results of available diagnostic tests.

### Diagnosis

#### NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include the following:

- Impaired gas exchange and airway clearance due to chronic inhalation of toxins
- Impaired gas exchange related to ventilation–perfusion inequality

- Ineffective airway clearance related to bronchoconstriction, increased mucus production, ineffective cough, bronchopulmonary infection, and other complications
- Ineffective breathing pattern related to shortness of breath, mucus, bronchoconstriction, and airway irritants
- Activity intolerance due to fatigue, ineffective breathing patterns, and hypoxemia
- Deficient knowledge of self-care strategies to be performed at home.
- Ineffective coping related to reduced socialization, anxiety, depression, lower activity level, and the inability to work

#### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include:

- Respiratory insufficiency or failure
- Atelectasis
- Pulmonary infection
- Pneumonia
- Pneumothorax
- Pulmonary hypertension

**Chart 24-3 • ASSESSMENT**

### Chronic Obstructive Pulmonary Disease

#### Health History

- How long has the patient had respiratory difficulty?
- Does exertion increase the dyspnea? What type of exertion?
- What are limits of the patient's tolerance for exercise?
- At what times during the day does the patient complain most of fatigue and shortness of breath?
- Which eating and sleeping habits have been affected?
- What does the patient know about the disease and his or her condition?
- What is the patient's smoking history (primary and secondary)?
- Is there occupational exposure to smoke or other pollutants?
- What are the triggering events (exertion, strong odors, dust, exposure to animals, etc.)?

#### Inspection and Examination Findings

- What position does the patient assume during the interview?
- What are the pulse and the respiratory rates?
- What is the character of respirations? Even and without effort? Other?
- Can the patient complete a sentence without having to take a breath?
- Does the patient contract the abdominal muscles during inspiration?
- Does the patient use accessory muscles of the shoulders and neck when breathing?
- Does the patient take a long time to exhale (prolonged expiration)?
- Is central cyanosis evident?
- Are the patient's neck veins engorged?
- Does the patient have peripheral edema?
- Is the patient coughing?
- What is the color, amount, and consistency of the sputum?
- Is clubbing of the fingers present?
- What types of breath sounds (ie, clear, diminished or distant, crackles, wheezes) are heard? Describe and document findings and locations.
- What is the status of the patient's sensorium?
- Is there short-term or long-term memory impairment?
- Is there increasing stupor?
- Is the patient apprehensive?

### Planning and Goals

The major goals for the patient may include smoking cessation, improved gas exchange, airway clearance, improved breathing pattern, improved activity tolerance, maximal self-management, improved coping ability, adherence to the therapeutic program and home care, and absence of complications.

### Nursing Interventions

#### PROMOTING SMOKING CESSATION

Because smoking has such a detrimental effect on the lungs, the nurse must discuss smoking cessation strategies with patients. Although patients may believe that it is too late to reverse the damage from years of smoking and that smoking cessation is futile, they should be informed that continuing to smoke impairs the mechanisms that clear the airways and keep them free of irritants. The nurse should educate the patient regarding the hazards of smoking and cessation strategies and provide resources regarding smoking cessation, counseling, and formalized programs available in the community.

#### IMPROVING GAS EXCHANGE

Bronchospasm, which occurs in many pulmonary diseases, reduces the caliber of the small bronchi and may cause dyspnea, static secretions, and infection. Bronchospasm can sometimes be detected when wheezing or diminished breath sounds are heard on auscultation with a stethoscope. Increased mucus production, along with decreased mucociliary action, contributes to further reduction in the caliber of the bronchi and results in decreased airflow and decreased gas exchange. This is further aggravated by the loss of lung elasticity that occurs with COPD (NIH, 2001).

These changes in the airway require that the nurse monitor the patient for dyspnea and hypoxemia. If bronchodilators or corticosteroids are prescribed, the nurse must administer the medications properly and be alert for potential side effects. The relief of bronchospasm is confirmed by measuring improvement in expiratory flow rates and volumes (the force of expiration, how long it takes to exhale, and the amount of air exhaled) and assessing whether the patient has less dyspnea.

### ACHIEVING AIRWAY CLEARANCE

Diminishing the quantity and viscosity of sputum can clear the airway and improve pulmonary ventilation and gas exchange. All pulmonary irritants should be eliminated or reduced, particularly cigarette smoking, which is the most persistent source of pulmonary irritation. The nurse instructs the patient in directed or controlled coughing, which is more effective and reduces the fatigue associated with undirected forceful coughing. Directed coughing consists of a slow, maximal inspiration followed by breath-holding for several seconds and then two or three coughs. “Huff” coughing may also be effective. The technique consists of one or two forced exhalations (“huffs”) from low to medium lung volumes with the glottis open.

Chest physiotherapy with postural drainage, intermittent positive-pressure breathing, increased fluid intake, and bland aerosol mists (with normal saline solution or water) may be useful for some patients with COPD. The use of these measures must be based on the patient’s response and tolerance.

### IMPROVING BREATHING PATTERNS

Ineffective breathing patterns and shortness of breath are due to the ineffective respiratory mechanics of the chest wall and lung resulting from **air trapping**, ineffective diaphragmatic movement, airway obstruction, the metabolic cost of breathing, and stress. Inspiratory muscle training and breathing retraining may help to improve breathing patterns. Training in diaphragmatic breathing reduces the respiratory rate, increases alveolar ventilation, and sometimes helps expel as much air as possible during expiration. Pursed-lip breathing helps to slow expiration, prevents collapse of small airways, and helps the patient to control the rate and depth of respiration. It also promotes relaxation, which enables the patient to gain control of dyspnea and reduce feelings of panic.

### IMPROVING ACTIVITY TOLERANCE

Patients with COPD experience progressive activity and exercise intolerance. Education is focused on rehabilitative therapies to promote independence in executing activities of daily living. These may include pacing activities throughout the day or using supportive devices to decrease energy expenditure. The nurse evaluates the patient’s activity tolerance and limitations and teaching strategies to promote independent activities of daily living. Also, the patient may be a candidate for exercise training to strengthen the muscles of the upper and lower extremities and improve exercise tolerance and endurance. Other health care professionals (rehabilitation therapy, occupational therapy, physical therapy) may be consulted as additional resources.

### ENHANCING SELF-CARE STRATEGIES

In addition to a pulmonary rehabilitation program, the nurse helps the patient manage self-care by emphasizing the importance of setting realistic goals, avoiding temperature extremes, and modifying lifestyle (particularly stopping smoking) as applicable.

#### Setting Realistic Goals

A major area of teaching is the importance of setting and accepting realistic short-term and long-range goals. If the patient is severely disabled, the objectives of treatment are to preserve current pulmonary function and relieve symptoms as much as possible. If the disease is mild, the objectives are to increase exercise tolerance and prevent further loss of pulmonary function. It is important to plan and share the goals and expectations of treatment with the patient. The patient and those providing care need patience to achieve these goals.

### Avoiding Temperature Extremes

The nurse instructs the patient to avoid extremes of heat and cold. Heat increases the body temperature, thereby raising oxygen requirements; cold tends to promote bronchospasm. Air pollutants such as fumes, smoke, dust, and even talcum, lint, and aerosol sprays may initiate bronchospasm. High altitudes aggravate hypoxemia.

### Modifying Lifestyle

Patients with COPD should adopt a lifestyle of moderate activity, ideally in a climate with minimal shifts in temperature and humidity. As much as possible, the patient should avoid emotional disturbances and stressful situations that might trigger a coughing episode. The medication regimen for patients with COPD can be quite complex; patients receiving aerosol medications by an MDI may be particularly challenged. It is crucial to review this material and to have the patient perform a return demonstration before discharge, during follow-up visits to the caregiver’s office or clinic, and during home visits (Chart 24-4).

Smoking cessation goes hand in hand with lifestyle changes, and reinforcement of the patient’s efforts is a key nursing activity. Smoking cessation is the single most important therapeutic intervention for patients with COPD. There are many strategies, including prevention, cessation with or without oral or topical patch medications, and behavior modification techniques.

### ENHANCING INDIVIDUAL COPING STRATEGIES

COPD and its progression promote a cycle of physical, social, and psychological consequences, all which are interrelated. Patients experience depression, altered mood states, social isolation, and altered functional status. The nurse is key to identifying this cycle and promoting interventions for improved physical functioning, psychological and emotional stability, and social support. Following the initial assessment of the patient, the nurse may provide referrals to health care professionals in these specific areas.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

The nurse caring for the patient with COPD must assess for various complications, such as life-threatening respiratory insufficiency and failure and respiratory infection and atelectasis, which may increase the patient’s risk for respiratory failure. The nurse also monitors for cognitive changes (personality and behavioral changes, memory impairment), increasing dyspnea, tachypnea, and tachycardia, which may indicate increasing hypoxemia and impending respiratory failure.

The nurse monitors pulse oximetry values to assess the patient’s need for oxygen and administers supplemental oxygen as prescribed. The nurse also instructs the patient about signs and symptoms of respiratory infection that may worsen hypoxemia and reports changes in the patient’s physical and cognitive status to the physician. Other activities require assisting with the management of developing complications, with possible intubation and mechanical ventilation (see Chap. 25).

Bronchopulmonary infections must be controlled to diminish inflammatory edema and to permit recovery of normal ciliary action. Minor respiratory infections that are of no consequence to the person with normal lungs can be life-threatening to the person with COPD. The cough associated with bronchial infection introduces a vicious cycle with further trauma and damage to the lungs, progression of symptoms, increased bronchospasm, and increased susceptibility to bronchial infection. Infection compromises lung

## Chart 24-4

## Home Care Checklist • Use of Metered-Dose Inhaler (MDI)

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• Describe the rationale for using the MDI to administer inhaled medicine.	✓	✓
• Describe how the medication enters the lungs.	✓	✓
• Demonstrate the correct steps in administering medication with an MDI:		
Remove the cap and hold the inhaler upright.	✓	
Shake the inhaler.	✓	
Tilt your head back slightly and breathe out slowly.	✓	
Position the inhaler approximately 1–2 inches away from the open mouth, or use a spacer/holding chamber.	✓	
When using a medicine chamber, place the lips around the mouthpiece.	✓	
Press down on the inhaler to release the medication as you start to breathe in slowly through the mouth.	✓	
Continue breathing in as the medication is released (press the cartridge down).		

Nurse teaches patient to use a metered dose inhaler. © B. Proud.

Breathe in slowly and deeply for 3–5 seconds.	✓	
Hold your breath for 8–10 seconds to allow the medication to reach down into your airways.	✓	
Repeat puffs as directed, allowing 1–2 minutes between puffs.	✓	
Apply the cap to the MDI for storage.	✓	
After inhalation, rinse mouth with water when using a corticosteroid-containing MDI.	✓	
• Describe how to clean the MDI.	✓	✓
• Describe how to assess the amount of medication remaining in the MDI.	✓	✓
• Describe how and when to contact the health care provider for assessment, and how to obtain a refill of the MDI prescription.	✓	✓

Expert Panel Report II. (1997). *Guidelines for the diagnosis and management of asthma*. National Asthma Education and Prevention Program, National Institutes of Health.

function and is a common cause of respiratory failure in patients with COPD.

In COPD, infection may be accompanied by subtle changes. The nurse instructs the patient to report any signs of infection, such as a fever or change in sputum color, character, consistency, or amount. Any worsening of symptoms (increased tightness of the chest, increased dyspnea and fatigue) also suggests infection and must be reported. Viral infections are hazardous to these patients because they are often followed by infections caused by bacterial organisms, such as *Streptococcus pneumoniae* and *Haemophilus influenzae*.

The nurse should encourage patients with COPD to be immunized against influenza and *S. pneumoniae* because these patients are prone to respiratory infection. It is important to caution patients to avoid going outdoors if the pollen count is high or if there is significant air pollution because of the risk of bron-

chospasm. The patient also should avoid exposure to high outdoor temperatures with high humidity.

Pneumothorax is a potential complication of COPD. Patients with severe emphysematous changes can develop large bullae, which may rupture and cause a pneumothorax. The development of a pneumothorax may be spontaneous or related to an activity such as severe coughing or large intrathoracic pressure changes. If the patient develops a rapid onset of shortness of breath, the nurse should quickly evaluate the patient for a potential pneumothorax by assessing the symmetry of chest movement, differences in breath sounds, and pulse oximetry. A pneumothorax is a life-threatening event in the patient with COPD who has minimal pulmonary reserve.

Over time, pulmonary hypertension may occur as a result of chronic hypoxemia. The pulmonary arteries respond to hypoxemia by constriction, thus leading to pulmonary hypertension.

The complication may be prevented by maintaining adequate oxygenation through an adequate hemoglobin level, improved ventilation/perfusion of the lungs, or continuous administration of supplemental oxygen (if needed).

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

Teaching is essential throughout the course of COPD and should be part of the nursing care given to every patient with COPD. Patients' and family members' knowledge and comfort level with their knowledge should be assessed and considered when providing instructions about self-management strategies. In addition to the aspects of patient education previously described, patients and family members must become familiar with the medications that are prescribed and knowledgeable about potential side effects. Patients and family members need to learn the early signs and symptoms of infection and other complications so that they seek appropriate health care promptly.

### Continuing Care

Referral for home care is important to enable the nurse to assess the patient's home environment and physical and psychological status, to evaluate the patient's adherence to the prescribed regimen, and to assess the patient's ability to cope with changes in lifestyle and physical status. The nurse assesses the patient's and family's understanding of the complications and side effects of medications. The home care visit provides an opportunity to reinforce the information and activities learned in the inpatient or outpatient pulmonary rehabilitation program and to have the patient and family demonstrate correct administration of medications and oxygen, if indicated, and performance of exercises. If the patient does not have access to a formal pulmonary rehabilitation program, it is important for the nurse to provide the education and breathing retraining necessary to optimize the patient's functional status.

The nurse may direct patients to community resources such as pulmonary rehabilitation programs and smoking cessation programs to help improve their ability to cope with their chronic condition and the therapeutic regimen and to give them a sense of worth, hope, and well-being. In addition, the nurse reminds the patient and family about the importance of participating in general health promotion activities and health screening.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Demonstrates knowledge of hazards of smoking
  - a. Verbalizes willingness/interest to quit smoking
  - b. Verbalizes information about smoking, risks of continuing, benefits of quitting, and techniques to optimize cessation efforts
2. Demonstrates improved gas exchange
  - a. Shows no signs of restlessness, confusion, or agitation
  - b. Has stable pulse oximetry or arterial blood gas values (but not necessarily normal values due to chronic changes in the gas exchange ability of the lungs)
3. Achieves maximal airway clearance
  - a. Stops smoking
  - b. Avoids noxious substances and extremes of temperature
  - c. Maintains adequate hydration
  - d. If indicated, performs postural drainage correctly

- e. Knows signs of early infection and is aware of how and when to report them if they occur
  - f. Performs controlled coughing without experiencing excessive fatigue
4. Improves breathing pattern
    - a. Practices and uses pursed-lip and diaphragmatic breathing
    - b. Shows signs of decreased respiratory effort (decreased respiratory rate, less dyspnea)
  5. Demonstrates knowledge of strategies to improve activity tolerance and maintain maximum level of self-care
    - a. Performs self-care activities within tolerance range
    - b. Paces self to avoid fatigue and dyspnea
    - c. Uses controlled breathing while performing activities
    - d. Uses devices to assist with activity tolerance and decrease energy expenditure
  6. Demonstrates knowledge of self-care strategies
    - a. Participates in determining the therapeutic program
    - b. Understands the rationale for activities and medications
    - c. Follows the medication plan
    - d. Uses bronchodilators and oxygen therapy as prescribed
    - e. Stops smoking
    - f. Maintains acceptable activity level
  7. Uses effective coping mechanisms for dealing with consequences of disease
    - a. Uses self-care strategies to lessen stress associated with disease
    - b. Verbalizes resources available to deal with psychological burden of disease
    - c. Participates in pulmonary rehabilitation, if appropriate
  8. Uses community resources and home-based care
    - a. Verbalizes knowledge of community resources (eg, smoking cessation, hospital/community-based support groups)
    - b. Participates in pulmonary rehabilitation, if appropriate
  9. Avoids or reduces complications
    - a. Has no evidence of respiratory failure or insufficiency
    - b. Maintains adequate pulse oximetry and arterial blood gas values
    - c. Shows no signs or symptoms of infection, pneumothorax, or pulmonary hypertension

For more information, see Plan of Nursing Care: Care of the Patient With COPD.

## Bronchiectasis

**Bronchiectasis** is a chronic, irreversible dilation of the bronchi and bronchioles. Under the new definition of COPD, it is considered a separate disease process from COPD (NIH, 2001). Bronchiectasis may be caused by a variety of conditions, including:

- Airway obstruction
- Diffuse airway injury
- Pulmonary infections and obstruction of the bronchus or complications of long-term pulmonary infections
- Genetic disorders such as cystic fibrosis
- Abnormal host defense (eg, ciliary dyskinesia or humoral immunodeficiency)
- Idiopathic causes

(text continues on page 586)

## Plan of Nursing Care

### Care of the Patient With COPD

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Impaired gas exchange and airway clearance due to chronic inhalation of toxins

**Goal:** Improvement in gas exchange

Instruct and encourage patient in diaphragmatic breathing and effective coughing.</li> </ol> | <ol style="list-style-type: none"> <li>1. Bronchodilators dilate the airways. The medication dosage is carefully adjusted for each patient, in accordance with clinical response.</li> <li>2. Combining medication with aerosolized bronchodilators is typically used to control bronchoconstriction in an acute exacerbation. Generally, however, the MDI with spacer is the preferred route (less cost and time to treatment).</li> <li>3. These techniques improve ventilation by opening airways to facilitate clearing the airways of sputum. Gas exchange is improved and fatigue is minimized.</li> </ol> | <ul style="list-style-type: none"> <li>• Verbalizes need for bronchodilators and for taking as prescribed</li> <li>• Evidences minimal side effects; heart rate near normal, absence of dysrhythmias, normal mentation</li> <li>• Reports a decrease in dyspnea</li> <li>• Shows an improved expiratory flow rate</li> <li>• Uses and cleans respiratory therapy equipment as applicable</li> <li>• Demonstrates diaphragmatic breathing and coughing</li> <li>• Uses oxygen equipment appropriately when indicated</li> <li>• Evidences improved arterial blood gases or pulse oximetry</li> <li>• Demonstrates correct technique for use of MDI</li> </ul> |
|--|--|--|

(continued)

## Plan of Nursing Care

### Care of the Patient With COPD (Continued)

#### Nursing Interventions

4. Administer oxygen by the method prescribed.
  - a. Explain rationale and importance to patient.
  - b. Evaluate effectiveness; observe for signs of hypoxemia. Notify physician if restlessness, anxiety, somnolence, cyanosis, or tachycardia is present.
  - c. Analyze arterial blood gases and compare with baseline values. When arterial puncture is performed and a blood sample is obtained, hold puncture site for 5 minutes to prevent arterial bleeding and development of ecchymoses.
  - d. Initiate pulse oximetry to monitor oxygen saturation.
  - e. Explain that no smoking is permitted by patient or visitors while oxygen is in use.

#### Rationale

4. Oxygen will correct the hypoxemia. Careful observation of the liter flow or the percentage administered and its effect on the patient is important. If the patient has chronic CO<sub>2</sub> retention, excessive oxygen could suppress the hypoxic drive and respirations. These patients generally need low-flow oxygen rates of 1 to 2 L/min. Periodic arterial blood gases and pulse oximetry help to evaluate adequacy of oxygenation. Smoking may render pulse oximetry inaccurate because the carbon monoxide from cigarette smoke also saturates hemoglobin.

#### Expected Outcomes

**Nursing Diagnosis:** Ineffective airway clearance related to bronchoconstriction, increased mucus production, ineffective cough, bronchopulmonary infection, and other complications

**Goal:** Achievement of airway clearance

- |   |  |  |
|---|--|--|
| <ol style="list-style-type: none"> <li>1. Adequately hydrate the patient.</li> <li>2. Teach and encourage the use of diaphragmatic breathing and coughing techniques.</li> <li>3. Assist in administering nebulizer or MDI.</li> <li>4. If indicated, perform postural drainage with percussion and vibration in the morning and at night as prescribed.</li> <li>5. Instruct patient to avoid bronchial irritants such as cigarette smoke, aerosols, extremes of temperature, and fumes.</li> <li>6. Teach early signs of infection that are to be reported to the clinician immediately:           <ol style="list-style-type: none"> <li>a. Increased sputum production</li> <li>b. Change in color of sputum</li> <li>c. Increased thickness of sputum</li> <li>d. Increased shortness of breath, tightness in chest, or fatigue</li> <li>e. Increased coughing</li> <li>f. Fever or chills</li> </ol> </li> <li>7. Administer antibiotics as prescribed.</li> <li>8. Encourage patient to be immunized against influenza and <i>Streptococcus pneumoniae</i>.</li> </ol> | <ol style="list-style-type: none"> <li>1. Systemic hydration keeps secretions moist and easier to expectorate. Fluids must be given with caution if right- or left-sided heart failure is present.</li> <li>2. These techniques help to improve ventilation and mobilize secretions without causing breathlessness and fatigue.</li> <li>3. This ensures adequate delivery of medication to the airways.</li> <li>4. Uses gravity to help raise secretions so they can be more easily expectorated or suctioned.</li> <li>5. Bronchial irritants cause bronchoconstriction and increased mucus production, which then interferes with airway clearance.</li> <li>6. Minor respiratory infections that are of no consequence to the person with normal lungs can produce fatal disturbances in the lungs of the person with emphysema. Early recognition is crucial.</li> <li>7. Antibiotics may be prescribed to prevent or treat infection.</li> <li>8. People with respiratory conditions are prone to respiratory infections and are encouraged to be immunized.</li> </ol> | <ul style="list-style-type: none"> <li>• Verbalizes need to drink fluids</li> <li>• Demonstrates diaphragmatic breathing and coughing</li> <li>• Performs postural drainage correctly</li> <li>• Coughing is minimized</li> <li>• Does not smoke</li> <li>• Verbalizes that pollens, fumes, gases, dusts, and extremes of temperature and humidity are irritants to be avoided</li> <li>• Identifies signs of early infection</li> <li>• Is free of infection (no fever, no change in sputum, lessening of dyspnea)</li> <li>• Verbalizes need to notify health care provider at the earliest sign of infection</li> <li>• Verbalizes need to stay away from crowds or people with colds in flu season</li> <li>• Discusses flu and pneumonia vaccines with clinician to help prevent infection</li> </ul> |
|---|--|--|

(continued)

## Plan of Nursing Care

### Care of the Patient With COPD (Continued)

#### Nursing Interventions

#### Rationale

#### Expected Outcomes

**Nursing Diagnosis:** Ineffective breathing pattern related to shortness of breath, mucus, bronchoconstriction, and airway irritants

**Goal:** Improvement in breathing pattern

- |  |  |  |
|--|--|--|
| <ol style="list-style-type: none"> <li>1. Teach patient diaphragmatic and pursed-lip breathing.</li> <li>2. Encourage alternating activity with rest periods. Allow patient to make some decisions (bath, shaving) about care based on tolerance level.</li> <li>3. Encourage use of an inspiratory muscle trainer if prescribed.</li> </ol> | <ol style="list-style-type: none"> <li>1. Helps patient prolong expiration time and decreases air trapping. With these techniques, patient will breathe more efficiently and effectively.</li> <li>2. Pacing activities permits patient to perform activities without excessive distress.</li> <li>3. Strengthens and conditions the respiratory muscles.</li> </ol> | <ul style="list-style-type: none"> <li>• Practices pursed-lip and diaphragmatic breathing and uses them when short of breath and with activity</li> <li>• Shows signs of decreased respiratory effort and paces activities</li> <li>• Uses inspiratory muscle trainer as prescribed</li> </ul> |
|--|--|--|

**Nursing Diagnosis:** Self-care deficits related to fatigue secondary to increased work of breathing and insufficient ventilation and oxygenation

**Goal:** Independence in self-care activities

- |  |  |  |
|--|--|--|
| <ol style="list-style-type: none"> <li>1. Teach patient to coordinate diaphragmatic breathing with activity (eg, walking, bending).</li> <li>2. Encourage patient to begin to bathe self, dress self, walk, and drink fluids. Discuss energy conservation measures.</li> <li>3. Teach postural drainage if appropriate.</li> </ol> | <ol style="list-style-type: none"> <li>1. This will allow the patient to be more active and to avoid excessive fatigue or dyspnea during activity.</li> <li>2. As condition resolves, patient will be able to do more but needs to be encouraged to avoid increasing dependence.</li> <li>3. Encourages patient to become involved in own care. Prepares patient to manage at home.</li> </ol> | <ul style="list-style-type: none"> <li>• Uses controlled breathing while bathing, bending, and walking</li> <li>• Paces activities of daily living to alternate with rest periods to reduce fatigue and dyspnea</li> <li>• Describes energy conservation strategies</li> <li>• Performs same self-care activities as before</li> <li>• Performs postural drainage correctly</li> </ul> |
|--|--|--|

**Nursing Diagnosis:** Activity intolerance due to fatigue, hypoxemia, and ineffective breathing patterns

**Goal:** Improvement in activity tolerance

- |   |   |  |
|---|---|--|
| <ol style="list-style-type: none"> <li>1. Support patient in establishing a regular regimen of exercise using treadmill and exercycle, walking, or other appropriate exercises, such as mall walking.             <ol style="list-style-type: none"> <li>a. Assess the patient's current level of functioning and develop exercise plan based on baseline functional status.</li> <li>b. Suggest consultation with a physical therapist or pulmonary rehabilitation program to determine an exercise program specific to the patient's capability. Have portable oxygen unit available if oxygen is prescribed for exercise.</li> </ol> </li> </ol> | <ol style="list-style-type: none"> <li>1. Muscles that are deconditioned consume more oxygen and place an additional burden on the lungs. Through regular, graded exercise, these muscle groups become more conditioned, and the patient can do more without getting as short of breath. Graded exercise breaks the cycle of debilitation.</li> </ol> | <ul style="list-style-type: none"> <li>• Performs activities with less shortness of breath</li> <li>• Verbalizes need to exercise daily and demonstrates an exercise plan to be carried out at home</li> <li>• Walks and gradually increases walking time and distance to improve physical condition</li> <li>• Exercises both upper and lower body muscle groups</li> </ul> |
|---|---|--|

**Nursing Diagnosis:** Ineffective coping related to reduced socialization, anxiety, depression, lower activity level, and the inability to work

**Goal:** Attainment of an optimal level of coping

- |  |   |   |
|--|---|---|
| <ol style="list-style-type: none"> <li>1. Help the patient develop realistic goals.</li> <li>2. Encourage activity to level of symptom tolerance.</li> </ol> | <ol style="list-style-type: none"> <li>1. Developing realistic goals will promote a sense of hope and accomplishment rather than defeat and hopelessness.</li> <li>2. Activity reduces tension and decreases degree of dyspnea as patient becomes conditioned.</li> </ol> | <ul style="list-style-type: none"> <li>• Expresses interest in the future</li> <li>• Participates in the discharge plan</li> <li>• Discusses activities or methods that can be performed to ease shortness of breath</li> <li>• Uses relaxation techniques appropriately</li> <li>• Expresses interest in a pulmonary rehabilitation program</li> </ul> |
|--|---|---|

(continued)

## Plan of Nursing Care

### Care of the Patient With COPD (Continued)

#### Nursing Interventions

3. Teach relaxation technique or provide a relaxation tape for patient.
4. Enroll patient in pulmonary rehabilitation program where available.

#### Rationale

3. Relaxation reduces stress, anxiety, and dyspnea and helps patient to cope with disability.
4. Pulmonary rehabilitation programs have been shown to promote a subjective improvement in a patient's status and self-esteem as well as increased exercise tolerance and decreased hospitalizations.

#### Expected Outcomes

**Nursing Diagnosis:** Deficient knowledge about self-management to be performed at home.

**Goal:** Adherence to therapeutic program and home care

1. Help patient understand short- and long-term goals.
  - a. Teach the patient about disease, medications, procedures, and how and when to seek help.
  - b. Refer patient to pulmonary rehabilitation.
2. Give strong message to stop smoking. Discuss smoking cessation strategies. Provide information about resource groups (eg, SmokEnders, American Cancer Society, American Lung Association).

1. Patient needs to be a partner in developing the plan of care and needs to know what to expect. Teaching about the condition is one of the most important aspects of care; it will prepare the patient to live and cope with the condition and improve quality of life.
2. Smoking causes permanent damage to the lung and diminishes the lungs' protective mechanisms. Air flow is obstructed and lung capacity is reduced. Smoking increases morbidity and mortality and is also a risk factor for lung cancer.

- Understands disease and what affects it
- Verbalizes the need to preserve existing lung function by adhering to the prescribed program
- Understands purposes and proper administration of medications
- Stops smoking or enrolls in a smoking cessation program
- Identifies when and whom to call for assistance

**Collaborative Problem:** Atelectasis

**Goal:** Absence of atelectasis on x-ray and physical examination

1. Monitor respiratory status, including rate and pattern of respirations, breath sounds, signs and symptoms of respiratory distress, and pulse oximetry.
2. Instruct in and encourage diaphragmatic breathing and effective coughing techniques.
3. Promote use of lung expansion techniques (eg, deep-breathing exercises, incentive spirometry) as prescribed.

1. A change in respiratory status, including tachypnea, dyspnea, and diminished or absent breath sounds, may indicate atelectasis.
2. These techniques improve ventilation and lung expansion and ideally improve gas exchange.
3. Deep-breathing exercises and incentive spirometry promote maximal lung expansion.

- Normal (baseline for patient) respiratory rate and pattern
- Normal breath sounds for patient
- Demonstrates diaphragmatic breathing and effective coughing
- Performs deep-breathing exercises, incentive spirometry as prescribed
- Pulse oximetry is  $\geq 90\%$

**Collaborative Problem:** Pneumothorax

**Goal:** Absence of signs and symptoms of pneumothorax

1. Monitor respiratory status, including rate and pattern of respirations, symmetry of chest wall movement, breath sounds, signs and symptoms of respiratory distress, and pulse oximetry.
2. Assess pulse.
3. Assess for chest pain and precipitating factors.
4. Palpate for tracheal deviation/shift away from the affected side.

1. Dyspnea, tachypnea, tachycardia, acute pleuritic chest pain, tracheal deviation away from the affected side, absence of breath sounds on the affected side, and decreased tactile fremitus may indicate pneumothorax.
2. Tachycardia is associated with pneumothorax and anxiety.
3. Pain may accompany pneumothorax.
4. Early detection of pneumothorax and prompt intervention will prevent other serious complications.

- Normal respiratory rate and pattern for patient
- Normal breath sounds bilaterally
- Normal pulse for patient
- Normal tactile fremitus
- Absence of pain
- Tracheal position is midline
- Pulse oximetry  $\geq 90\%$
- Maintains normal oxygen saturation and arterial blood gas measurements for patient
- Exhibits no hypoxemia and hypercapnia (or returns to baseline values)

(continued)

## Plan of Nursing Care

### Care of the Patient With COPD (Continued)

Nursing Interventions	Rationale	Expected Outcomes
5. Monitor pulse oximetry and if indicated arterial blood gases.	5. Recognition of a deterioration in respiratory function will prevent serious complications.	<ul style="list-style-type: none"> <li>• Absence of pain</li> <li>• Symmetric chest wall movement</li> <li>• Lung is reexpanded on chest x-ray</li> <li>• Breath sounds are heard on the affected side</li> </ul>
6. Administer supplemental oxygen therapy, as indicated.	6. Oxygen will correct hypoxemia; administer it with caution.	
7. Administer analgesics, as indicated, for chest pain.	7. Pain interferes with deep breathing, resulting in a decrease in lung expansion.	
8. Assist with chest tube insertion and use pleural drainage system, as prescribed.	8. Removal of air from the pleural space will reexpand the lung.	

#### Collaborative Problem: Respiratory failure

**Goal:** Absence of signs and symptoms of respiratory failure; no evidence of respiratory failure on laboratory tests

1. Monitor respiratory status, including rate and pattern of respirations, breath sounds, and signs and symptoms of acute respiratory distress.	1. Early recognition of a deterioration in respiratory function will avert further complications, such as respiratory failure, severe hypoxemia, and hypercapnia.	<ul style="list-style-type: none"> <li>• Normal respiratory rate and pattern for patient with no acute distress</li> <li>• Recognizes symptoms of hypoxemia and hypercapnia</li> <li>• Maintains normal arterial blood gases/pulse oximetry or returns to baseline values</li> </ul>
2. Monitor pulse oximetry and arterial blood gases.	2. Recognition of changes in oxygenation and acid-base balance will guide in correcting and preventing complications.	
3. Administer supplemental oxygen and initiate mechanisms for mechanical ventilation, as prescribed.	3. Acute respiratory failure is a medical emergency. Hypoxemia is a hallmark sign. Administration of oxygen therapy and mechanical ventilation (if indicated) are critical to survival.	

#### Collaborative Problem: Pulmonary hypertension

**Goal:** Absence of evidence of pulmonary hypertension on physical examination or laboratory tests

1. Monitor respiratory status, including rate and pattern of respirations, breath sounds, pulse oximetry, and signs and symptoms of acute respiratory distress.	1. Dyspnea is the primary symptom of pulmonary hypertension. Other symptoms include fatigue, angina, near syncope, edema, and palpitations.	<ul style="list-style-type: none"> <li>• Normal respiratory rate and pattern for patient</li> <li>• Exhibits no signs and symptoms of right-sided failure</li> <li>• Maintains baseline pulse oximetry values and arterial blood gases</li> </ul>
2. Assess for signs and symptoms of right-sided heart failure, including peripheral edema, ascites, distended neck veins, crackles, and heart murmur.	2. Right-sided heart failure is a common clinical manifestation of pulmonary hypertension due to increased right ventricular workload.	
3. Administer oxygen therapy, as prescribed.	3. Continuous oxygen therapy is a major component of management of pulmonary hypertension by preventing hypoxemia and thereby reducing pulmonary vascular constriction (resistance) secondary to hypoxemia.	

A person may be predisposed to bronchiectasis as a result of recurrent respiratory infections in early childhood, measles, influenza, tuberculosis, and immunodeficiency disorders.

### Pathophysiology

The inflammatory process associated with pulmonary infections damages the bronchial wall, causing a loss of its supporting structure and resulting in thick sputum that ultimately obstructs the bronchi. The walls become permanently distended and distorted, impairing mucociliary clearance. The inflammation and infection

extend to the peribronchial tissues; in the case of sacular bronchiectasis, each dilated tube virtually amounts to a lung abscess, the exudate of which drains freely through the bronchus. Bronchiectasis is usually localized, affecting a segment or lobe of a lung, most frequently the lower lobes.

The retention of secretions and subsequent obstruction ultimately cause the alveoli distal to the obstruction to collapse (atelectasis). Inflammatory scarring or fibrosis replaces functioning lung tissue. In time the patient develops respiratory insufficiency with reduced vital capacity, decreased ventilation, and an increased ratio of residual volume to total lung capacity. There is impair-

ment in the matching of ventilation to perfusion (ventilation–perfusion imbalance) and hypoxemia.

## Clinical Manifestations

Characteristic symptoms of bronchiectasis include chronic cough and the production of purulent sputum in copious amounts. Many patients with this disease have hemoptysis. Clubbing of the fingers also is common because of respiratory insufficiency. The patient usually has repeated episodes of pulmonary infection. Even with modern treatment approaches, the average age at death is approximately 55 years.

## Assessment and Diagnostic Findings

Bronchiectasis is not readily diagnosed because the symptoms can be mistaken for those of simple chronic bronchitis. A definite sign is offered by the prolonged history of productive cough, with sputum consistently negative for tubercle bacilli. The diagnosis is established by a computed tomography (CT) scan, which demonstrates either the presence or absence of bronchial dilation.

## Medical Management

Treatment objectives are to promote bronchial drainage to clear excessive secretions from the affected portion of the lungs and to prevent or control infection. Postural drainage is part of all treatment plans because draining the bronchiectatic areas by gravity reduces the amount of secretions and the degree of infection. Sometimes mucopurulent sputum must be removed by bronchoscopy. Chest physiotherapy, including percussion and postural drainage, is important in secretion management.

Smoking cessation is important because smoking impairs bronchial drainage by paralyzing ciliary action, increasing bronchial secretions, and causing inflammation of the mucous membranes, resulting in hyperplasia of the mucous glands. Infection is controlled with antimicrobial therapy based on the results of sensitivity studies on organisms cultured from sputum. A year-round regimen of antibiotic agents may be prescribed, with different types of antibiotics at intervals. Some clinicians prescribe antibiotic agents throughout the winter or when acute upper respiratory tract infections occur. Patients should be vaccinated against influenza and pneumococcal pneumonia. Bronchodilators, which may be prescribed for patients who also have reactive airway disease, may also assist with secretion management.

Surgical intervention, although used infrequently, may be indicated for the patient who continues to expectorate large amounts of sputum and has repeated bouts of pneumonia and hemoptysis despite adhering to the treatment regimen. However, the disease must involve only one or two areas of the lung that can be removed without producing respiratory insufficiency. The goals of surgical treatment are to conserve normal pulmonary tissue and to avoid infectious complications. Diseased tissue is removed, provided that the postoperative lung function will be adequate. It may be necessary to remove a segment of a lobe (segmental resection), a lobe (lobectomy), or rarely an entire lung (pneumonectomy). (See Chart 25-16 for further information.) Segmental resection is the removal of an anatomic subdivision of a pulmonary lobe. The chief advantage is that only diseased tissue is removed and healthy lung tissue is conserved.

The surgery is preceded by a period of careful preparation. The objective is to obtain a dry (free of infection) tracheo-bronchial tree to prevent complications (atelectasis, pneumonia,

bronchopleural fistula, and empyema). This is accomplished by postural drainage or, depending on the location, by direct suction through a bronchoscope. A course of antibacterial therapy may be prescribed. After surgery, the care is the same as for any patient undergoing chest surgery (see Chap. 25).

## Nursing Management

Nursing management of the patient with bronchiectasis focuses on alleviating symptoms and assisting the patient to clear pulmonary secretions. Smoking and other factors that increase the production of mucus and hamper its removal are targeted in patient teaching. The patient and family are taught to perform postural drainage and to avoid exposure to others with upper respiratory and other infections. If the patient experiences fatigue and dyspnea, strategies to conserve energy while maintaining as active a lifestyle as possible are discussed. The patient needs to become knowledgeable about early signs of respiratory infection and the progression of the disorder so that appropriate treatment can be implemented promptly. Because the presence of a large amount of mucus may decrease the patient's appetite and result in an inadequate dietary intake, the patient's nutritional status is assessed and strategies are implemented to ensure an adequate diet.

## Asthma

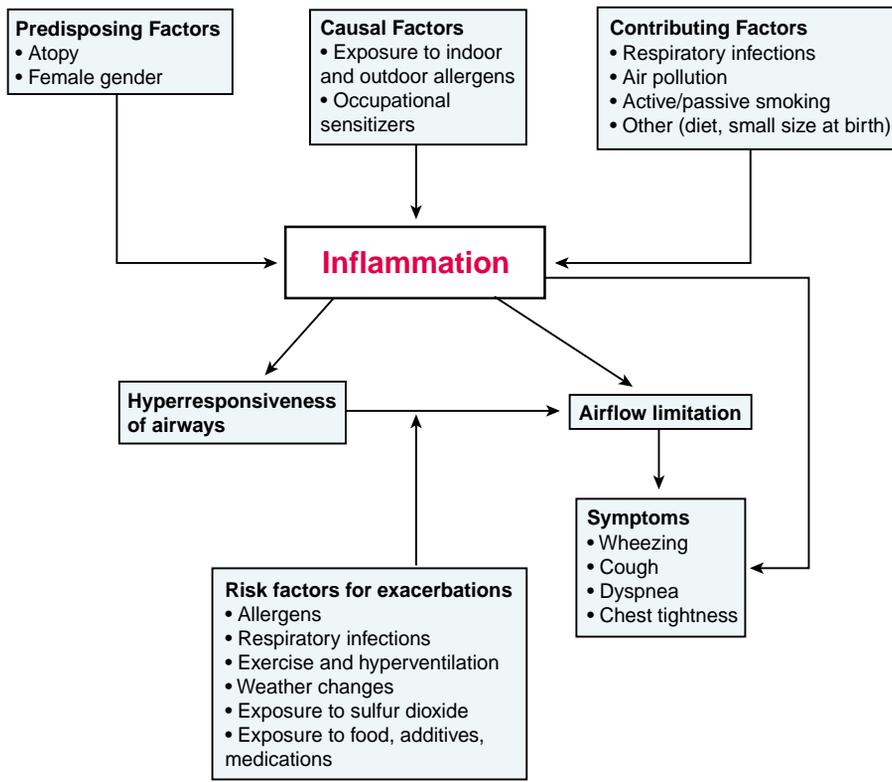

**Asthma** is a chronic inflammatory disease of the airways that causes airway hyperresponsiveness, mucosal edema, and mucus production. This inflammation ultimately leads to recurrent episodes of asthma symptoms: cough, chest tightness, wheezing, and dyspnea (Fig. 24-6). Estimates show that nearly 17 million Americans have asthma, and more than 5,000 die from this disease annually (Centers for Disease Control and Prevention [CDC], 1998; CDC, 1999; NCHS, 2001). In 1998, asthma accounted for over 13.9 million outpatient visits to physician offices or hospital clinics and over 2.0 million emergency room visits (NCHS, 2001).

Asthma differs from the other obstructive lung diseases in that it is largely reversible, either spontaneously or with treatment. Patients with asthma may experience symptom-free periods alternating with acute exacerbations, which last from minutes to hours or days. Asthma can occur at any age and is the most common chronic disease of childhood. Despite increased knowledge regarding the pathology of asthma and the development of better medications and management plans, the death rate from asthma continues to increase. For most patients it is a disruptive disease, affecting school and work attendance, occupational choices, physical activity, and general quality of life.

Allergy is the strongest predisposing factor for asthma. Chronic exposure to airway irritants or allergens also increases the risk for developing asthma. Common allergens can be seasonal (eg, grass, tree, and weed pollens) or perennial (eg, mold, dust, roaches, or animal dander). Common triggers for asthma symptoms and exacerbations in patients with asthma include airway irritants (eg, air pollutants, cold, heat, weather changes, strong odors or perfumes, smoke), exercise, stress or emotional upsets, sinusitis with postnasal drip, medications, viral respiratory tract infections, and gastroesophageal reflux. Most people who have asthma are sensitive to a variety of triggers. A patient's asthma condition will change depending upon the environment, activities, management practices, and other factors (NHLBI, 1998).

## Physiology/Pathophysiology

**FIGURE 24-6** Pathophysiology of asthma. Adapted from materials developed for the Global Initiative for Asthma (GINA): Global Strategy for Asthma Management and Prevention, National Institutes of Health–National Heart, Lung, and Blood Institute, revised 2002.

## Pathophysiology

The underlying pathology in asthma is reversible and diffuse airway inflammation. The inflammation leads to obstruction from the following: swelling of the membranes that line the airways (mucosal edema), reducing the airway diameter; contraction of the bronchial smooth muscle that encircles the airways (bronchospasm), causing further narrowing; and increased mucus production, which diminishes airway size and may entirely plug the bronchi.

The bronchial muscles and mucus glands enlarge; thick, tenacious sputum is produced; and the alveoli hyperinflate. Some patients may have airway subbasement membrane fibrosis. This is called airway “remodeling” and occurs in response to chronic inflammation. The fibrotic changes in the airway lead to airway narrowing and potentially irreversible airflow limitation (NIH, 2001; NHLBI, 1998).

Cells that play a key role in the inflammation of asthma are mast cells, neutrophils, eosinophils, and lymphocytes. Mast cells, when activated, release several chemicals called mediators. These chemicals, which include histamine, bradykinin, prostaglandins, and leukotrienes, perpetuate the inflammatory response, causing increased blood flow, vasoconstriction, fluid leak from the vasculature, attraction of white blood cells to the area, and bronchoconstriction (NHLBI, 1998). Regulation of these chemicals is the aim of much of the current research regarding pharmacologic therapy for asthma.

Further, alpha- and beta<sub>2</sub>-adrenergic receptors of the sympathetic nervous system are located in the bronchi. When the alpha-adrenergic receptors are stimulated, bronchoconstriction occurs; when the beta<sub>2</sub>-adrenergic receptors are stimulated, bronchodila-

tion results. The balance between alpha and beta<sub>2</sub> receptors is controlled primarily by cyclic adenosine monophosphate (cAMP). Alpha-adrenergic receptor stimulation results in a decrease in cAMP, which leads to an increase of chemical mediators released by the mast cells and bronchoconstriction. Beta<sub>2</sub>-receptor stimulation results in increased levels of cAMP, which inhibits the release of chemical mediators and causes bronchodilation (NHLBI, 1998).

## Clinical Manifestations

The three most common symptoms of asthma are cough, dyspnea, and wheezing. In some instances, cough may be the only symptom. Asthma attacks often occur at night or early in the morning, possibly due to circadian variations that influence airway receptor thresholds.

An asthma exacerbation may begin abruptly but most frequently is preceded by increasing symptoms over the previous few days. There is cough, with or without mucus production. At times the mucus is so tightly wedged in the narrowed airway that the patient cannot cough it up. There may be generalized wheezing (the sound of airflow through narrowed airways), first on expiration and then possibly during inspiration as well. Generalized chest tightness and dyspnea occur. Expiration requires effort and becomes prolonged. As the exacerbation progresses, diaphoresis, tachycardia, and a widened pulse pressure may occur along with hypoxemia and central cyanosis (a late sign of poor oxygenation). Although life-threatening and severe hypoxemia can occur in asthma, it is relatively uncommon. The hypoxemia is secondary to a ventilation–perfusion mismatch and readily responds to supplemental oxygenation.

Symptoms of exercise-induced asthma include maximal symptoms during exercise, absence of nocturnal symptoms, and sometimes only a description of a “choking” sensation during exercise.

Asthma is categorized according to symptoms and objective measures of airflow obstruction (Table 24-3) (Expert Panel Report II, 1997).

### Assessment and Diagnostic Findings

A complete family, environmental, and occupational history is essential. To establish the diagnosis, the clinician must determine that periodic symptoms of airflow obstruction are present, airflow is at least partially reversible, and other etiologies have been excluded. A positive family history and environmental factors, including seasonal changes, high pollen counts, mold, climate changes (particularly cold air), and air pollution, are primarily associated with asthma. In addition, asthma is associated with a variety of occupation-related chemicals and compounds, including metal salts, wood and vegetable dust, medications (eg, aspirin, antibiotics, piperazine, cimetidine), industrial chemicals and plastics, biologic enzymes (eg, laundry detergents), animal and insect dusts, sera, and secretions. Comorbid conditions that may accompany asthma include gastroesophageal reflux, drug-induced asthma, and allergic bronchopulmonary aspergillosis. Other possible allergic reactions that may accompany asthma include eczema, rashes, and temporary edema.

During acute episodes, sputum and blood tests may disclose eosinophilia (elevated levels of eosinophils). Serum levels of immunoglobulin E may be elevated if allergy is present. Arterial blood gas analysis and pulse oximetry reveal hypoxemia during acute attacks. Initially, hypocapnia and respiratory alkalosis are present. As the condition worsens and the patient becomes more fatigued, the PaCO<sub>2</sub> may rise. A normal PaCO<sub>2</sub> value may be a signal of impending respiratory failure. Because CO<sub>2</sub> is 20 times more diffusible than oxygen, it is rare for PaCO<sub>2</sub> to be normal or elevated in a person who is breathing very rapidly. During an exacerbation, the FEV<sub>1</sub> and FVC are markedly decreased but improve with bronchodilator administration (demonstrating reversibility). Pulmonary function is usually normal between exacerbations.

The occurrence of a severe, continuous reaction is referred to as status asthmaticus and is considered life-threatening (see below).

### Prevention

Patients with recurrent asthma should undergo tests to identify the substances that precipitate the symptoms. Possible causes are dust, dust mites, roaches, certain types of cloth, pets, horses, detergents, soaps, certain foods, molds, and pollens. If the attacks are seasonal, pollens can be strongly suspected. The patient is instructed to avoid the causative agents whenever possible.

Knowledge is the key to quality asthma care. Although national guidelines are available for the care of the asthma patient, unfortunately health care providers may not follow them. Failure to follow the guidelines in the following areas has been noted: lack of treatment of patients who have symptoms more than 2 days per week with a regular medication schedule, lack of patient-specific advice on improving the environment and an explanation about the importance of doing so, lack of encouragement for patients to monitor their peak flow measurements with a diary, and lack of written, up-to-date educational materials (Plaut, 2001).

A 1998 survey by a group called “Asthma in America” found that 11% of physicians were unaware of the national asthma guidelines. Only 35% of patients with asthma who were surveyed reported having pulmonary function testing in the past year.

While 83% of physicians reported prescribing peak flow meter monitoring, only 62% of patients had ever heard of a peak flow meter (Rickard & Stempel, 1999). All health care providers caring for asthma patients need to be aware of the national guidelines and use them (Expert Panel Report II, 1997).

### Complications

Complications of asthma may include status asthmaticus, respiratory failure, pneumonia, and atelectasis. Airway obstruction, particularly during acute asthmatic episodes, often results in hypoxemia, requiring the administration of oxygen and the monitoring of pulse oximetry and arterial blood gases. Fluids are administered because people with asthma are frequently dehydrated from diaphoresis and insensible fluid loss with hyperventilation.

### Medical Management

Immediate intervention is necessary because the continuing and progressive dyspnea leads to increased anxiety, aggravating the situation.

#### PHARMACOLOGIC THERAPY

Two general classes of asthma medications are long-acting medications to achieve and maintain control of persistent asthma and quick-relief medications for immediate treatment of asthma symptoms and exacerbations (Table 24-4). Because the underlying pathology of asthma is inflammation, control of persistent asthma is accomplished primarily with regular use of anti-inflammatory medications. These medications have systemic side effects when used long term. The route of choice for administration of these medications is the MDI because it allows for topical administration. Critical to the success of inhaled therapy is the proper use of the MDI (see Chart 24-4). If the patient has difficulty with this procedure, the use of a spacer device is indicated. Table 24-3 presents a stepwise approach for managing asthma (Expert Panel Report II, 1997). Information on use of the MDI and spacer device is given in the previous section on COPD.

**Long-Acting Control Medications.** Corticosteroids are the most potent and effective anti-inflammatory medications currently available. They are broadly effective in alleviating symptoms, improving airway function, and decreasing peak flow variability. Initially, the inhaled form is used. A spacer should be used with inhaled corticosteroids and the patient should rinse the mouth after administration to prevent thrush, a common complication of inhaled corticosteroid use. A systemic preparation may be used to gain rapid control of the disease; to manage severe, persistent asthma; to treat moderate to severe exacerbations; to accelerate recovery; and to prevent recurrence (Dhand, 2000).

Cromolyn sodium (Intal) and nedocromil (Tilade) are mild to moderate anti-inflammatory agents that are used more commonly in children. They also are effective on a prophylactic basis to prevent exercise-induced asthma or in unavoidable exposure to known triggers. These medications are contraindicated in acute asthma exacerbations.

Long-acting beta<sub>2</sub>-adrenergic agonists are used with anti-inflammatory medications to control asthma symptoms, particularly those that occur during the night. These agents are also effective for preventing exercise-induced asthma. Long-acting beta<sub>2</sub>-adrenergic agonists are not indicated for immediate relief of symptoms.

Table 24-3 • Stepwise Approach for Managing Asthma in Adults and Children Over 5 Years Old

**Goals of Asthma Treatment**

- Prevent chronic and troublesome symptoms (eg, coughing or breathlessness in the night, in the early morning, or after exertion)
- Maintain near-normal pulmonary function
- Maintain normal activity levels (including exercise and other physical activity)
- Prevent recurrent exacerbations of asthma and minimize the need for emergency department visits or hospitalizations
- Provide optimal pharmacotherapy with minimal or no adverse effects
- Meet patients' and families' expectation of and satisfaction with asthma care

Table 24-3 • Stepwise Approach for Managing Asthma in Adults and Children Over 5 Years Old (Continued)

	SYMPTOMS**	NIGHTTIME SYMPTOMS	LUNG FUNCTION	LONG-TERM CONTROL	QUICK RELIEF	EDUCATION
<b>STEP 1</b>				<ul style="list-style-type: none"> <li>Sustained-release theophylline to serum concentration of 5–15 µg/mL is an alternative. Zafirlukast or zileuton may also be considered for patients ≥12 years of age, although their position in therapy is not fully established.</li> </ul>	<ul style="list-style-type: none"> <li>Use of short-acting inhaled beta<sub>2</sub>-agonists on a daily basis, or increasing use, indicates the need for additional long-term-control therapy.</li> </ul>	<ul style="list-style-type: none"> <li>Review and update self-management plan</li> </ul>
<b>Mild Intermittent</b>	<ul style="list-style-type: none"> <li>Symptoms ≤2 times a week</li> <li>Asymptomatic and normal PEF between exacerbations</li> <li>Exacerbations brief (from a few hours to a few days); intensity may vary</li> </ul>	≤2 times a month	<ul style="list-style-type: none"> <li>FEV<sub>1</sub> or PEF ≥80% predicted</li> <li>PEF variability &lt;20%</li> </ul>	<ul style="list-style-type: none"> <li>No daily medication needed.</li> </ul>	<ul style="list-style-type: none"> <li>Short-acting bronchodilator: inhaled beta<sub>2</sub>-agonists as needed for symptoms.</li> <li>Intensity of treatment will depend on severity of exacerbation.</li> <li>Use of short-acting inhaled beta<sub>2</sub>-agonists more than 2 times a week may indicate the need to initiate long-term control therapy.</li> </ul>	<ul style="list-style-type: none"> <li>Teach basic facts about asthma</li> <li>Teach inhaler/spacer/holding chamber technique</li> <li>Discuss roles of medications</li> <li>Develop self-management plan</li> <li>Develop action plan for when and how to take rescue actions</li> <li>Discuss appropriate environmental control measures to avoid exposure to known allergens and irritants</li> </ul>
<b>↓ Step Down</b>	Review treatment every 1 to 6 months; a gradual stepwise reduction in treatment may be possible.					
<b>Notes:</b>	<ul style="list-style-type: none"> <li>The stepwise approach presents general guidelines to assist clinical decision making; it is not intended to be a specific prescription. Asthma is highly variable; clinicians should tailor specific medication plans to the needs and circumstances of individual patients.</li> <li>Gain control as quickly as possible; then decrease treatment to the least medication necessary to maintain control. Gaining control may be accomplished either by starting treatment at the step most appropriate to the initial severity of the condition or by starting at a higher level of therapy (eg, a course of systemic corticosteroids or higher dose of inhaled corticosteroids).</li> </ul>					
<b>↑ Step Up</b>	<p>If control is not maintained, consider step up. First, review patient medication technique, adherence, and environmental control (avoidance of allergens or other factors that contribute to asthma severity).</p> <ul style="list-style-type: none"> <li>A rescue course of systemic corticosteroid may be needed at any time and at any step.</li> <li>Some patients with intermittent asthma experience severe and life-threatening exacerbations separated by long periods of normal lung function and no symptoms. This may be especially common with exacerbations provoked by respiratory infections. A short course of systemic corticosteroids is recommended.</li> <li>At each step, patients should control their environment to avoid or control factors that make their asthma worse (eg, allergens, irritants); this requires specific diagnosis and education.</li> </ul>					

PEF, peak expiratory flow

\*The presence of one of the features of severity is sufficient to place a patient in that category. An individual should be assigned to the most severe grade in which any feature occurs. The characteristics noted in this table are general and may overlap because asthma is highly variable. Furthermore, an individual's classification may change over time.

\*\*Patients at any level of severity can have mild, moderate, or severe exacerbations. Some patients with intermittent asthma experience severe and life-threatening exacerbations separated by long periods of normal lung function and no symptoms.

Highlights of the Expert Panel Report 2. (1997). *Guidelines for the diagnosis and management of asthma*. National Institutes of Health, National Heart, Lung and Blood Institute, NIH Publication No 97-4051A, p. 29.

**Table 24-4 • Classifications of Medications Used in Asthma**

MEDICATION CLASS	DRUG (BRAND NAME)
<b>Long-Acting Control Medications</b>	
Corticosteroids	beclomethasone (Beclivent, Vanceril), budesonide (Pulmicort), flunisolide (AeroBid), fluticasone propionate (Flovent), triamcinolone acetonide (Azmacort), prednisone
Mast cell stabilizers	cromolyn sodium (Intal), nedocromil sodium (Tilade)
Long-acting beta <sub>2</sub> -adrenergic agents	salmeterol (Serevent), albuterol (sustained release) (Volmax ER), formoterol fumarate (Foradil)
Xanthine derivatives	aminophylline, theophylline (Slo-bid, Theo-24, Theo-Dur)
Leukotriene modifiers (inhibitors)	zafirlukast (Accolate), zileuton (Zyflo), montelukast (Singulair)
Combination products	albuterol sulfate + ipratropium bromide (Combivent); fluticasone propionate + salmeterol inhalation powder (Advair Diskus)
<b>Quick-Relief Medications</b>	
Short-acting beta <sub>2</sub> -adrenergic agents	Albuterol (Proventil), levalbuterol (Xopenex), pirbuterol (Maxair), bitolterol (Tornalate)
Anticholinergics	ipratropium bromide (Atrovent)

Expert Panel Report II. (1997). *Guidelines for the diagnosis and management of asthma*. National Asthma Education and Prevention Program, National Institutes of Health.

Methylxanthines (theophylline [Slo-bid, Theo-24, Theo-Dur]) are mild to moderate bronchodilators usually used in addition to inhaled corticosteroids, mainly for relief of nighttime asthma symptoms. There is some evidence that theophylline may have a mild anti-inflammatory effect (NHLBI, 1998).

Leukotriene modifiers (inhibitors) or antileukotrienes are a new class of medications. Leukotrienes are potent bronchoconstrictors that also dilate blood vessels and alter permeability. Leukotriene inhibitors act by either interfering with leukotriene synthesis or blocking the receptors where leukotrienes exert their action (Boushey, Fick, Lazarus & Martin, 2000). At this time, they may provide an alternative to inhaled corticosteroids for mild persistent asthma or may be added to a regimen of inhaled corticosteroids in more severe asthma to attain further control.

In addition, combination products are also available (eg, albuterol/ipratropium [Combivent]) and offer ease of use for the patient.

**Quick-Relief Medications.** Short-acting beta-adrenergic agonists are the medications of choice for relieving acute symptoms and preventing exercise-induced asthma. They have a rapid onset of action. Anticholinergics (eg, ipratropium bromide [Atrovent]) may bring added benefit in severe exacerbations, but they are used more frequently in COPD patients.

### MANAGEMENT OF ASTHMA EXACERBATION

Asthma exacerbations are best managed by early treatment and education of the patient (Expert Panel Report II, 1997). Quick-acting beta-adrenergic medications are first used for prompt re-

lief of airflow obstruction. Systemic corticosteroids may be necessary to decrease airway inflammation in patients who fail to respond to inhaled beta-adrenergic medications. In some patients, oxygen supplementation may be required to relieve hypoxemia associated with a moderate to severe exacerbation (Expert Panel Report II, 1997). Also, response to treatment may be monitored by serial measurements of lung function.

A written action plan is the most useful tool for the patient (Fig. 24-7). This helps to guide the patient in self-management strategies regarding an exacerbation and also provides instructions regarding recognition of early warning signs of worsening asthma. Patient self-management and early recognition of problems lead to more efficient communication with health care providers regarding an asthma exacerbation (Expert Panel Report II, 1997).

### PEAK FLOW MONITORING

Peak flow meters measure the highest airflow during a forced expiration (Fig. 24-8). Daily peak flow monitoring is recommended for all patients with moderate or severe asthma because it helps measure asthma severity and, when added to symptom monitoring, indicates the current degree of asthma control. The patient is instructed in the proper technique, particularly to give maximal effort. The “personal best” is determined after monitoring peak flows for 2 or 3 weeks after receiving optimal asthma therapy. The green (80% to 100% of personal best), yellow (60% to 80%), and red (less than 60%) zones are determined, and specific actions are delineated for each zone, enabling the patient to monitor and manipulate his or her own therapy after careful instruction (Expert Panel Report II, 1997). This reinforces compliance, independence, and self-efficacy (Reinke, 2000).

### Nursing Management

The immediate nursing care of the patient with asthma depends on the severity of the symptoms. The patient may be treated successfully as an outpatient if asthma symptoms are relatively mild, or he or she may require hospitalization and intensive care for acute and severe asthma.

The patient and family are often frightened and anxious because of the patient’s dyspnea. Thus, an important aspect of care is a calm approach. The nurse assesses the patient’s respiratory status by monitoring the severity of symptoms, breath sounds, peak flow, pulse oximetry, and vital signs. The nurse obtains a history of allergic reactions to medications before administering medications and identifies the patient’s current use of medications. The nurse administers medications as prescribed and monitors the patient’s responses to those medications. Fluids may be administered if the patient is dehydrated, and antibiotic agents may be prescribed if the patient has an underlying respiratory infection. If the patient requires intubation because of acute respiratory failure, the nurse assists with the intubation procedure, continues close monitoring of the patient, and keeps the patient and family informed about procedures.

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** A major challenge is to implement basic asthma management principles at the community level (Reinke, 2000). Key issues include education of health care providers, establishment of programs for asthma education (for patients and providers), use of outpatient follow-up care for patients, and a focus on chronic management versus acute episodic care. The nurse is pivotal to achieving all of these objectives.

ASTHMA ACTION PLAN FOR \_\_\_\_\_

Doctor's Name \_\_\_\_\_

Date \_\_\_\_\_

Doctor's Phone Number \_\_\_\_\_

Hospital/Emergency Room Phone Number \_\_\_\_\_

**GREEN ZONE: Doing Well**

- No cough, wheeze, chest tightness, or shortness of breath during the day or night
- Can do usual activities

And, if a peak flow meter is used,  
Peak flow: more than \_\_\_\_\_  
(80% or more of my best peak flow)

My best peak flow is: \_\_\_\_\_

**Before exercise**

\_\_\_\_\_  2 or  4 puffs  5 to 60 minutes before exercise

**Take These Long-Term-Control Medicines Each Day (include an anti-inflammatory)**

Medicine	How much to take	When to take it

**YELLOW ZONE: Asthma Is Getting Worse**

- Cough, wheeze, chest tightness, or shortness of breath, or
- Waking at night due to asthma, or
- Can do some, but not all, usual activities

-Or-

Peak flow: \_\_\_\_\_ to \_\_\_\_\_  
(50% - 80% of my best peak flow)

**ADD: Quick-Relief Medicine - and keep taking your GREEN ZONE medicine**

**FIRST**  \_\_\_\_\_ (short-acting beta<sub>2</sub>-agonist)

**SECOND**  2 or  4 puffs, every 20 minutes for up to 1 hour  
 Nebulizer, once

If your symptoms (and peak flow, if used) return to GREEN ZONE after 1 hour of above treatment:

- Take the quick-relief medicine every 4 hours for 1 to 2 days.
- Double the dose of your inhaled steroid for \_\_\_\_\_ (7-10) days.

-Or-

If your symptoms (and peak flow, if used) do **not** return to GREEN ZONE after 1 hour of above treatment:

- Take: \_\_\_\_\_ (short-acting beta<sub>2</sub>-agonist)  2 or  4 puffs or  Nebulizer
- Add: \_\_\_\_\_ mg. per day For \_\_\_\_\_ (3-10) days  
(oral steroid)
- Call the doctor  before/  within \_\_\_\_\_ hours after taking the oral steroid.

**RED ZONE: Medical Alert!**

- Very short of breath, or
- Quick-relief medicines have not helped, or
- Cannot do usual activities, or
- Symptoms are same or get worse after 24 hours in Yellow Zone

-Or-

Peak flow: less than \_\_\_\_\_  
(50% of my best peak flow)

**DANGER SIGNS**

- Trouble walking and talking due to shortness of breath
- Lips or fingernails are blue

**Take this medicine:**

- \_\_\_\_\_ (short-acting beta<sub>2</sub>-agonist)  4 or  6 puffs or  Nebulizer
- \_\_\_\_\_ mg.  
(oral steroid)

**Then call your doctor NOW.** Go to the hospital or call for an ambulance if:

- You are still in the red zone after 15 minutes AND
- You have not reached your doctor.

Take  4 or  6 puffs of your quick-relief medicine AND  
Go to the hospital or call for an ambulance ( \_\_\_\_\_ ) NOW!

**FIGURE 24-7** Asthma action plan. From *Facts about controlling asthma*, National Asthma Education and Prevention Program, National Heart, Lung, and Blood Institute. NIH Publication No. 97-2339.

**FIGURE 24-8** Peak flow meters measure the highest volume of air flow during a forced expiration (*left*). Volume is measured in color-coded zones (*right*): the green zone signifies 80% to 100% of personal best; yellow, 60% to 80%; and red, less than 60%. If peak flow falls below the red zone, the patient should take the appropriate actions prescribed by his or her health care provider.

Patient teaching is a critical component of care for the patient with asthma (Plaut, 2001). Multiple inhalers, different types of inhalers, antiallergy therapy, antireflux medications, and avoidance measures are all integral for long-term control. This complex therapy requires a patient–provider partnership to determine the desired outcomes and to formulate a plan to achieve those outcomes. The patient then carries out daily therapy as part of self-care management, with input and guidance by the health care provider. Before a partnership can be established, the patient needs to understand the following:

- The nature of asthma as a chronic inflammatory disease
- The definition of inflammation and bronchoconstriction
- The purpose and action of each medication
- Triggers to avoid, and how to do so
- Proper inhalation technique
- How to perform peak flow monitoring (Chart 24-5)
- How to implement an action plan
- When to seek assistance, and how to do so

An assortment of excellent educational materials is available from the Expert Panel Report II (1997) and the National Heart,

### Chart 24-5

#### Home Care Checklist • Use of Peak Flow Meter

At the completion of the home care instruction, the patient or caregiver will be able to:

- |  | Patient | Caregiver |
|--|---------|-----------|
| • Describe the rationale for using a peak flow meter in asthma management.                                 | ✓       | ✓         |
| • Explain how peak flow monitoring is used along with symptoms to determine severity of asthma.            | ✓       | ✓         |
| • Demonstrate steps for using the peak flow meter correctly:   |         |           |
| • Move the indicator to the bottom of the numbered scale.  | ✓       |           |
| • Stand up.  | ✓       |           |
| • Take a deep breath and fill the lungs completely.  | ✓       |           |
| • Place mouthpiece in mouth and close lips around mouthpiece (do not put tongue inside opening).           | ✓       |           |
| • Blow out hard and fast with a single blow.   | ✓       |           |
| • Record the number achieved on the indicator.   | ✓       |           |
| • Repeat steps 1–5 two more times and write the highest number in the asthma diary.                        | ✓       |           |
| • Explain how to determine the “personal best” peak flow reading.  | ✓       | ✓         |
| • Describe the significance of the color zones for peak flow monitoring.                                   | ✓       | ✓         |
| • Demonstrate how to clean the peak flow meter.  | ✓       | ✓         |
| • Discuss how and when to contact the health care provider about changes or decreases in peak flow values. | ✓       | ✓         |

Lung and Blood Institute. The nurse should obtain current educational materials for the patient based on the patient's diagnosis, causative factors, educational level, and cultural factors.

**Continuing Care.** The nurse who has contact with the patient in the hospital, clinic, school, or office uses the opportunity to assess the patient's respiratory status and ability to manage self-care to prevent serious exacerbations. The nurse emphasizes adherence to the prescribed therapy, preventive measures, and the need to keep follow-up appointments with the primary health care provider. A home visit to assess the home environment for allergens may be indicated for the patient with recurrent exacerbations. The nurse refers the patient to community support groups. In addition, the nurse reminds the patient and family about the importance of health promotion strategies and recommended health screening.

## STATUS ASTHMATICUS

Status asthmaticus is severe and persistent asthma that does not respond to conventional therapy. The attacks can last longer than 24 hours. Infection, anxiety, nebulizer abuse, dehydration, increased adrenergic blockage, and nonspecific irritants may contribute to these episodes. An acute episode may be precipitated by hypersensitivity to aspirin.

### Pathophysiology

The basic characteristics of asthma (constriction of the bronchiolar smooth muscle, swelling of the bronchial mucosa, and thickened secretions) decrease the diameter of the bronchi and are apparent in status asthmaticus. A ventilation–perfusion abnormality results in hypoxemia and respiratory alkalosis initially, followed by respiratory acidosis. There is a reduced PaO<sub>2</sub> and an initial respiratory alkalosis, with a decreased PaCO<sub>2</sub> and an increased pH. As status asthmaticus worsens, the PaCO<sub>2</sub> increases and the pH falls, reflecting respiratory acidosis.

### Clinical Manifestations

The clinical manifestations are the same as those seen in severe asthma: labored breathing, prolonged exhalation, engorged neck veins, and wheezing. However, the extent of wheezing does not indicate the severity of the attack. As the obstruction worsens, the wheezing may disappear, and this is frequently a sign of impending respiratory failure.

### Assessment and Diagnostic Findings

Pulmonary function studies are the most accurate means of assessing acute airway obstruction. Arterial blood gas measurements are obtained if the patient cannot perform pulmonary function maneuvers because of severe obstruction or fatigue, or if the patient does not respond to treatment. Respiratory alkalosis (low PaCO<sub>2</sub>) is the most common finding in patients with asthma. A rising PaCO<sub>2</sub> (to normal levels or levels indicating respiratory acidosis) frequently is a danger sign of impending respiratory failure.

### Medical Management

In the emergency setting, the patient is treated initially with a short-acting beta-adrenergic agonist and corticosteroids. The pa-

tient usually requires supplemental oxygen and intravenous fluids for hydration. Oxygen therapy is initiated to treat dyspnea, central cyanosis, and hypoxemia. Humidified oxygen by either Venturi mask or nasal catheter is administered. The flow is based on pulse oximetry or arterial blood gas values. The PaO<sub>2</sub> is maintained at 65 to 85 mm Hg. Sedative medications are contraindicated. If there is no response to repeated treatments, hospitalization is required. Other criteria indicating the need for hospitalization include poor pulmonary function test results and deteriorating blood gas levels (respiratory acidosis), which may indicate that the patient is tiring and will require mechanical ventilation. Although most patients do not need mechanical ventilation, it is used for patients in respiratory failure, for those who tire and are too fatigued by the attempt to breathe, or for those whose conditions do not respond to initial treatment.

Death from asthma is associated with several risk factors, including the following:

- Past history of sudden and severe exacerbations
- Prior endotracheal intubation for asthma
- Prior admission to the intensive care unit for an asthma exacerbation
- Two or more hospitalizations for asthma within the past year
- Three or more emergency care visits for asthma in the past year
- Excessive use of short-acting beta-adrenergic inhalers (more than two canisters per month)
- Recent withdrawal from systemic corticosteroids
- Comorbidity of cardiovascular disease or COPD
- Psychiatric disease
- Low socioeconomic status
- Urban residence (Expert Panel Report II, 1997)

### Nursing Management

The nurse constantly monitors the patient for the first 12 to 24 hours, or until status asthmaticus is under control. The nurse also assesses the patient's skin turgor to identify signs of dehydration. Fluid intake is essential to combat dehydration, to loosen secretions, and to facilitate expectoration. The nurse administers intravenous fluids as prescribed, up to 3 to 4 L/day, unless contraindicated. The patient's energy needs to be conserved, and the room should be quiet and free of respiratory irritants, including flowers, tobacco smoke, perfumes, or odors of cleaning agents. A nonallergenic pillow should be used.

## Cystic Fibrosis

Cystic fibrosis (CF) is the most common fatal autosomal recessive disease among the Caucasian population. An individual must inherit a defective copy of the CF gene (one from each parent) to have CF. One in 31 Americans are unknowing symptom carriers of this gene (Katkin, 2002). The frequency of CF is 1 in 2,000 to 3,000 live births, and there are approximately 30,000 children and adults with this disease in the United States (Cystic Fibrosis Foundation, 2002). Although CF was once considered a fatal childhood disease, approximately 38% of people living with the disease are 18 years of age or older (Cystic Fibrosis Foundation, 2002). Cystic fibrosis is usually diagnosed in infancy or early childhood, but patients may be diagnosed later in life. For individuals diagnosed later in life, respiratory symptoms are frequently the major manifestation of the disease.

## Pathophysiology

This disease is caused by mutations in the CF transmembrane conductance regulator protein, which is a chloride channel found in all exocrine tissues (Katkin, 2002). Chloride transport problems lead to thick, viscous secretions in the lungs, pancreas, liver, intestine, and reproductive tract as well as increased salt content in sweat gland secretions. In 1989, major breakthroughs were made in this disease with the identification of the CF gene. The ability to detect the common mutations of this gene allows for routine screening for this disease as well as the detection of carriers. Genetic counseling is an important part of health care for couples at risk.

Airflow obstruction is a key feature in the presentation of CF. This obstruction is due to bronchial plugging by purulent secretions, bronchial wall thickening due to inflammation, and, over time, airway destruction (Katkin, 2002). These chronic retained secretions in the airways set up an excellent reservoir for continued bronchial infections.

## Clinical Manifestations

The pulmonary manifestations of this disease include a productive cough, wheezing, hyperinflation of the lung fields on chest x-ray, and pulmonary function test results consistent with obstructive airways disease (Katkin, 2002). Colonization of the airways with pathogenic bacteria usually occurs early in life. *Staphylococcus aureus* and *Haemophilus influenzae* are common organisms during early childhood. As the disease progresses, *Pseudomonas aeruginosa* is ultimately isolated from the sputum of most patients. Upper respiratory manifestations of the disease include sinusitis and nasal polyps.

Nonpulmonary clinical manifestations include gastrointestinal problems (eg, pancreatic insufficiency, recurrent abdominal pain, biliary cirrhosis, vitamin deficiencies, recurrent pancreatitis, weight loss), genitourinary problems (male and female infertility), and clubbing of the extremities. (See Chap. 40 for a discussion of pancreatitis.)

## Assessment and Diagnostic Findings

Most of the time, the diagnosis of CF is made based on an elevated result of a sweat chloride concentration test, along with clinical signs and symptoms consistent with the disease. Repeated sweat chloride values of greater than 60 mEq/L distinguish most individuals with CF from those with other obstructive diseases. A molecular diagnosis may also be used in evaluating common genetic mutations of the CF gene.

## Medical Management

Pulmonary problems remain the leading cause of morbidity and mortality in CF. Because chronic bacterial infection of the airways occurs in individuals with CF, control of infections is key in the treatment. Antibiotic medications are routinely prescribed for acute pulmonary exacerbations of the disease. Depending upon the severity of the exacerbation, aerosolized, oral, or intravenous antibiotic therapy may be used. Antibiotic agents are selected based upon the results of a sputum culture and sensitivity. Patients with CF have problems with bacteria that are resistant to multiple drugs and require multiple courses of antibiotic agents over long periods of time.

Bronchodilators are frequently administered to decrease airway obstruction. Differing pulmonary techniques are used to enhance secretion clearance. Examples include manual postural drainage and chest physical therapy, high-frequency chest wall oscillation, and other devices that assist in airway clearance (PEP masks [masks that generate positive expiratory pressure], “flutter devices” [devices that provide an oscillatory expiratory pressure pattern with positive expiratory pressure and assist with expectoration of secretions]).

Inhaled mucolytic agents such as dornase alfa (Pulmozyme) or N-acetylcysteine (Mucomyst) may also be used. These agents help to decrease the viscosity of the sputum and promote expectoration of secretions.

To decrease the inflammation and ongoing destruction of the airways, anti-inflammatory agents may also be used. These may include inhaled corticosteroids or systemic therapy. Other anti-inflammatory medications have also been studied in CF. Ibuprofen was studied in children with CF and some benefit was demonstrated, but there is little information on its use in young or older adults with CF (Katkin, 2002).

Supplemental oxygen is used to treat the progressive hypoxemia that occurs with CF. It helps to correct the hypoxemia and may minimize the complications seen with chronic hypoxemia (pulmonary hypertension).

Lung transplantation is an option for a small, select population of CF patients. A double lung transplant technique is used due to the chronically infected state of the lungs seen in end-stage CF. Because there is a long waiting list for lung transplant recipients, many patients die while awaiting a transplant.

Gene therapy is a promising approach to management, with many clinical trials underway. It is hoped that various methods of administering gene therapy will carry healthy genes to the damaged cells and correct defective CF cells. Efforts are underway to develop innovative methods of delivering therapy to the CF cells of the airways.

## Nursing Management

Nursing care of the adult with CF includes assisting the patient to manage pulmonary symptoms and to prevent complications of CF. Specific nursing measures include strategies that promote removal of pulmonary secretions; chest physiotherapy, including postural drainage, chest percussion, and vibration, and breathing exercises are implemented and are taught to the patient and to the family when the patient is very young. The patient is reminded of the need to reduce risk factors associated with respiratory infections (eg, exposure to crowds and to persons with known infections). The patient is taught the early signs and symptoms of respiratory infection and disease progression that indicate the need to notify the primary health care provider.

The nurse emphasizes the importance of an adequate fluid and dietary intake to promote removal of secretions and to ensure an adequate nutritional status. Because CF is a life-long disorder, patients often have learned to modify their daily activities to accommodate their symptoms and treatment modalities. As the disease progresses, however, assessment of the home environment may be warranted to identify modifications required to address changes in the patient's needs, increasing dyspnea and fatigue, and nonpulmonary symptoms.

Although gene therapy and double lung transplantation are promising therapies for CF, they are limited in availability and largely experimental. As a result, the life expectancy of adults with CF is shortened. Therefore, end-of-life issues and concerns need

to be addressed in patients when warranted. For the patient whose disease is progressing and who is developing increasing hypoxemia, preferences for end-of-life care should be discussed, documented, and honored (see Chap. 17). Patients and family members need support as they face a shortened life span and an uncertain future.

### Critical Thinking Exercises

1. A 75-year-old woman with end-stage COPD was recently admitted to your unit from the emergency room. She cannot lie flat in bed, she is extremely short of breath, and she has decreased breath sounds throughout the chest and crackles in the posterior basilar areas. What is the pathophysiology associated with these findings? What medical and nursing interventions might be used to decrease or alleviate these signs/symptoms?
2. Your patient at an outpatient asthma clinic is a 35-year-old inner-city Mexican-American mother with asthma. Use of an MDI on a regular daily schedule has been repeatedly prescribed for her, but she reports that she does not use the MDI except as needed when extremely short of breath. Describe teaching techniques you might use to assess the patient's knowledge of the medication and provide education about the action of the MDI, frequency of use, and correct administration of the medication. What methods would you use to monitor use of the MDI and reinforce education?
3. As a nurse in your hospital's community outreach clinic, you are responsible for providing group education and counseling to patients with asthma. What areas would you address regarding triggers for asthma? How might you have patients assess their home environments?
4. Your 64-year-old patient has a history of bronchiectasis and heart failure following two myocardial infarctions. To promote removal of pulmonary secretions, his physician has prescribed chest physiotherapy and postural drainage. The patient reports that he is able to breathe easily only in a sitting position. Describe how you would modify chest physiotherapy and postural drainage given his statement that he cannot breathe in a supine or prone position.
5. Your 22-year-old patient is a college student with a history of cystic fibrosis; he has been admitted to your unit for intravenous antibiotic therapy. Describe what pulmonary rehabilitation techniques would be appropriate for his disease process, which are age-specific and consistent with his activity level.

# ● Respiratory Care Modalities

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Describe the nursing management for patients receiving oxygen therapy, intermittent positive-pressure breathing, mini-nebulizer therapy, incentive spirometry, chest physiotherapy, and breathing retraining.
2. Describe the patient education and home care considerations for patients receiving oxygen therapy.
3. Describe the nursing care for a patient with an endotracheal tube and for a patient with a tracheostomy.
4. Demonstrate the procedure of tracheal suctioning.
5. Use the nursing process as a framework for care of patients who are mechanically ventilated.
6. Describe the process of weaning the patient from mechanical ventilation.
7. Describe the significance of preoperative nursing assessment and patient teaching for the patient who is to have thoracic surgery.
8. Explain the principles of chest drainage and the nursing responsibilities related to the care of the patient with a chest drainage system.
9. Describe the patient education and home care considerations for patients who have had thoracic surgery.

Numerous treatment modalities are used when caring for patients with various respiratory conditions. The choice of modality is based on the oxygenation disorder and whether there is a problem with gas ventilation, diffusion, or both. Therapies range from simple and noninvasive modalities (oxygen and nebulizer therapy, chest physiotherapy, breathing retraining) to complex and highly invasive treatments (intubation, mechanical ventilation, surgery). Assessment and management of the patient with respiratory disorders are best accomplished when the approach is multidisciplinary and collaborative.

## Noninvasive Respiratory Therapies

### OXYGEN THERAPY

Oxygen therapy is the administration of oxygen at a concentration greater than that found in the environmental atmosphere. At sea level, the concentration of oxygen in room air is 21%. The goal of oxygen therapy is to provide adequate transport of oxygen in the blood while decreasing the work of breathing and reducing stress on the myocardium.

Oxygen transport to the tissues depends on factors such as cardiac output, arterial oxygen content, concentration of hemoglobin, and metabolic requirements. These factors must be kept in mind when oxygen therapy is considered. (Respiratory physiology and oxygen transport are discussed in Chap. 21.)

### Indications

A change in the patient's respiratory rate or pattern may be one of the earliest indicators of the need for oxygen therapy. The change in respiratory rate or pattern may result from hypoxemia

or hypoxia. **Hypoxemia** (a decrease in the arterial oxygen tension in the blood) is manifested by changes in mental status (progressing through impaired judgment, agitation, disorientation, confusion, lethargy, and coma), dyspnea, increase in blood pressure, changes in heart rate, dysrhythmias, central cyanosis (late sign), diaphoresis, and cool extremities. Hypoxemia usually leads to **hypoxia**, which is a decrease in oxygen supply to the tissues. Hypoxia, if severe enough, can be life-threatening.

The signs and symptoms signaling the need for oxygen may depend on how suddenly this need develops. With rapidly developing hypoxia, changes occur in the central nervous system because the higher neurologic centers are very sensitive to oxygen deprivation. The clinical picture may resemble that of alcohol intoxication, with the patient exhibiting lack of coordination and impaired judgment. Longstanding hypoxia (as seen in chronic obstructive pulmonary disease [COPD] and chronic heart failure) may produce fatigue, drowsiness, apathy, inattentiveness, and delayed reaction time. The need for oxygen is assessed by arterial blood gas analysis and pulse oximetry as well as by clinical evaluation. For more information about hypoxia, see Chart 25-1.

### Cautions in Oxygen Therapy

As with other medications, the nurse administers oxygen with caution and carefully assesses its effects on each patient. Oxygen is a medication and except in emergency situations is administered only when prescribed by a physician.

In general, patients with respiratory conditions are given oxygen therapy only to raise the arterial oxygen pressure (PaO<sub>2</sub>) back to the patient's normal baseline, which may vary from 60 to 95 mm Hg. In terms of the oxyhemoglobin dissociation curve (see Chap. 21),

## Glossary

**assist-control ventilation:** mode of mechanical ventilation in which the patient's breathing pattern may trigger the ventilator to deliver a preset tidal volume; in the absence of spontaneous breathing, the machine delivers a controlled breath at a preset minimum rate and tidal volume

**chest drainage system:** use of a chest tube and closed drainage system to reexpand the lung and to remove excess air, fluid, and blood

**chest percussion:** manually cupping over the chest wall to mobilize secretions by mechanically dislodging viscous or adherent secretions in the lungs

**chest physiotherapy (CPT):** therapy used to remove bronchial secretions, improve ventilation, and increase the efficiency of the respiratory muscles. Types include postural drainage, chest percussion, and vibration.

**controlled ventilation:** mode of mechanical ventilation in which the ventilator completely controls the patient's ventilation according to preset tidal volumes and respiratory rate. Because of problems with synchrony, it is rarely used except in paralyzed or anesthetized patients.

**endotracheal intubation:** insertion of a breathing tube through the nose or mouth into the trachea

**fraction of inspired oxygen (FiO<sub>2</sub>):** concentration of oxygen delivered (1.0 = 100% oxygen)

**hypoxemia:** decrease in arterial oxygen tension in the blood

**hypoxia:** decrease in oxygen supply to the tissues and cells

**incentive spirometry:** method of deep breathing that provides visual feedback to help the patient inhale deeply and slowly and achieve maximum lung inflation

**mechanical ventilator:** a positive- or negative-pressure breathing device that supports ventilation and oxygenation

**pneumothorax:** partial or complete collapse of the lung due to positive pressure in the pleural space

**positive end-expiratory pressure (PEEP):** positive pressure maintained by the ventilator at the end of exhalation (instead of a normal zero pressure) to increase functional residual capacity and open collapsed alveoli; improves oxygenation with lower FiO<sub>2</sub>

**postural drainage:** positioning the patient to allow drainage from all the lobes of the lungs and airways

**pressure support ventilation (PSV):** mode of mechanical ventilation in which preset positive pressure is delivered with spontaneous breaths to decrease work of breathing

**respiratory weaning:** process of gradual, systematic withdrawal and/or removal of ventilator, breathing tube, and oxygen

**synchronized intermittent mandatory ventilation (SIMV):** mode of mechanical ventilation in which the ventilator allows the patient to breathe spontaneously while providing a preset number of breaths to ensure adequate ventilation; ventilated breaths are synchronized with spontaneous breathing

**thoracotomy:** surgical opening into the chest cavity

**tracheotomy:** surgical opening into the trachea

**tracheostomy tube:** indwelling tube inserted directly into the trachea to assist with ventilation

**vibration:** a type of massage administered by quickly tapping the chest with the fingertips or alternating the fingers in a rhythmic manner, or by using a mechanical device to assist in mobilizing lung secretions

25-1

## Types of Hypoxia

Hypoxia can occur from either severe pulmonary disease (inadequate oxygen supply) or from extrapulmonary disease (inadequate oxygen delivery) affecting gas exchange at the cellular level. The four general types of hypoxia are hypoxemic hypoxia, circulatory hypoxia, anemic hypoxia, and histotoxic hypoxia.

**Hypoxemic Hypoxia**

Hypoxemic hypoxia is a decreased oxygen level in the blood resulting in decreased oxygen diffusion into the tissues. It may be caused by hypoventilation, high altitudes, ventilation–perfusion mismatch (as in pulmonary embolism), shunts in which the alveoli are collapsed and cannot provide oxygen to the blood (commonly caused by atelectasis), and pulmonary diffusion defects. It is corrected by increasing alveolar ventilation or providing supplemental oxygen.

**Circulatory Hypoxia**

Circulatory hypoxia is hypoxia resulting from inadequate capillary circulation. It may be caused by decreased cardiac output, local vascular obstruction, low-flow states such as shock, or cardiac arrest. Although tissue partial pressure of oxygen ( $PO_2$ ) is reduced, arterial oxygen ( $PaO_2$ ) remains normal. Circulatory hypoxia is corrected by identifying and treating the underlying cause.

**Anemic Hypoxia**

Anemic hypoxia is a result of decreased effective hemoglobin concentration, which causes a decrease in the oxygen-carrying capacity of the blood. It is rarely accompanied by hypoxemia. Carbon monoxide poisoning, because it reduces the oxygen-carrying capacity of hemoglobin, produces similar effects but is not strictly anemic hypoxia because hemoglobin levels may be normal.

**Histotoxic Hypoxia**

Histotoxic hypoxia occurs when a toxic substance, such as cyanide, interferes with the ability of tissues to use available oxygen.

the blood at these levels is 80% to 98% saturated with oxygen; higher inspired oxygen flow ( $FiO_2$ ) values add no further significant amounts of oxygen to the red blood cells or plasma. Instead of helping, increased amounts of oxygen may produce toxic effects on the lungs and central nervous system or may depress ventilation (see discussion below).

It is important to observe for subtle indicators of inadequate oxygenation when oxygen is administered by any method. Therefore, the nurse assesses the patient frequently for confusion, restlessness progressing to lethargy, diaphoresis, pallor, tachycardia, tachypnea, and hypertension. Intermittent or continuous pulse oximetry is used to monitor oxygen levels.

**OXYGEN TOXICITY**

Oxygen toxicity may occur when too high a concentration of oxygen (greater than 50%) is administered for an extended period (longer than 48 hours). It is caused by overproduction of oxygen free radicals, which are byproducts of cell metabolism. If oxygen toxicity is untreated, these radicals can severely damage or kill cells. Antioxidants such as vitamin E, vitamin C, and beta-carotene may help defend against oxygen free radicals (Scanlan, Wilkins & Stoller, 1999). The dietitian can adjust the patient's diet so that it is rich in antioxidants; supplements are also available for patients who have a decreased appetite or who are unable to eat.

Signs and symptoms of oxygen toxicity include substernal discomfort, paresthesias, dyspnea, restlessness, fatigue, malaise, progressive respiratory difficulty, and alveolar infiltrates evident on chest x-rays.

Prevention of oxygen toxicity is achieved by using oxygen only as prescribed. If high concentrations of oxygen are necessary, it is important to minimize the duration of administration and reduce its concentration as soon as possible. Often, **positive end-expiratory pressure** (PEEP) or continuous positive airway pressure (CPAP) is used with oxygen therapy to reverse or prevent microatelectasis, thus allowing a lower percentage of oxygen to be used. The level of PEEP that allows the best oxygenation without hemodynamic compromise is known as “best PEEP.”

**SUPPRESSION OF VENTILATION**

In patients with COPD, the stimulus for respiration is a decrease in blood oxygen rather than an elevation in carbon dioxide levels. Thus, administration of a high concentration of oxygen removes the respiratory drive that has been created largely by the patient's chronic low oxygen tension. The resulting decrease in alveolar ventilation can cause a progressive increase in arterial carbon dioxide pressure ( $PaCO_2$ ), ultimately leading to the patient's death from carbon dioxide narcosis and acidosis. Oxygen-induced hypoventilation is prevented by administering oxygen at low flow rates (1 to 2 L/min).

**OTHER COMPLICATIONS**

Because oxygen supports combustion, there is always a danger of fire when it is used. It is important to post “no smoking” signs when oxygen is in use. Oxygen therapy equipment is also a potential source of bacterial cross-infection; thus, the nurse changes the tubing according to infection control policy and the type of oxygen delivery equipment.

**Methods of Oxygen Administration**

Oxygen is dispensed from a cylinder or a piped-in system. A reduction gauge is necessary to reduce the pressure to a working level, and a flow meter regulates the flow of oxygen in liters per minute. When oxygen is used at high flow rates, it should be moistened by passing it through a humidification system to prevent it from drying the mucous membranes of the respiratory tract.

The use of oxygen concentrators is another means of providing varying amounts of oxygen, especially in the home setting. These devices are relatively portable, easy to operate, and cost-effective. However, they require more maintenance than tank or liquid systems and probably cannot deliver oxygen flows in excess of 4 L, which provides an  $FiO_2$  of about 36%.

Many different oxygen devices are used, and all deliver oxygen if they are used as prescribed and maintained correctly (Table 25-1). The amount of oxygen delivered is expressed as a percentage concentration (eg, 70%). The appropriate form of oxygen therapy is best determined by arterial blood gas levels, which indicate the patient's oxygenation status.

Oxygen delivery systems are classified as low-flow or high-flow delivery systems. Low-flow systems contribute partially to the inspired gas the patient breathes. This means the patient breathes some room air along with the oxygen. These systems do not provide a constant or known concentration of inspired oxygen. The amount of inspired oxygen changes as the patient's breathing changes. Examples of low-flow systems include nasal cannula, oropharyngeal catheter, simple mask, and partial-rebreather and non-rebreather masks. High-flow systems provide the total amount of inspired air. A specific percentage of oxygen is delivered independent of the patient's breathing. High-flow systems are indicated for patients who require a constant and precise amount of oxygen. Examples of such systems include transtracheal catheters, Venturi

Table 25-1 • Oxygen Administration Devices

DEVICE	SUGGESTED FLOW RATE (L/MIN)	O <sub>2</sub> PERCENTAGE SETTING	ADVANTAGES	DISADVANTAGES
<b>Low-Flow Systems</b>				
Cannula	1–2 3–5 6	23–30 30–40 42	Lightweight, comfortable, inexpensive, continuous use with meals and activity	Nasal mucosal drying, variable FiO <sub>2</sub>
Oropharyngeal catheter	1–6	23–42	Inexpensive, does not require a tracheostomy	Nasal mucosa irritation; catheter should be changed frequently to alternate nostril
Mask, simple	6–8	40–60	Simple to use, inexpensive	Poor fitting, variable FiO <sub>2</sub> , must remove to eat
Mask, partial rebreather	8–11	50–75	Moderate O <sub>2</sub> concentration	Warm, poorly fitting, must remove to eat
Mask, non-rebreather	12	80–100	High O <sub>2</sub> concentration	Poorly fitting
<b>High-Flow Systems</b>				
Transtacheal catheter	¼–4	60–100	More comfortable, concealed by clothing, less oxygen liters per minute needed than nasal cannula	Requires frequent and regular cleaning, requires surgical intervention
Mask, Venturi	4–6 6–8	24, 26, 28 30, 35, 40	Provides low levels of supplemental O <sub>2</sub> Precise FiO <sub>2</sub> , additional humidity available	Must remove to eat
Mask, aerosol	8–10	30–100	Good humidity, accurate FiO <sub>2</sub>	Uncomfortable for some
Tracheostomy collar	8–10	30–100	Good humidity, comfortable, fairly accurate FiO <sub>2</sub>	
T-piece	8–10	30–100	Same as tracheostomy collar	Heavy with tubing
Face tent	8–10	30–100	Good humidity, fairly accurate FiO <sub>2</sub>	Bulky and cumbersome

masks, aerosol masks, tracheostomy collars, T-piece, and face tents (Cairo & Philbeam, 1999; Scanlan, Wilkins & Stoller, 1999).

A nasal cannula is used when the patient requires a low to medium concentration of oxygen for which precise accuracy is not essential. This method is relatively simple and allows the patient to move about in bed, talk, cough, and eat without interrupting oxygen flow. Flow rates in excess of 6 to 8 L/min may lead to swallowing of air; this may cause irritation and drying of the nasal and pharyngeal mucosa.

The oropharyngeal catheter is rarely used but may be prescribed for short-term therapy to administer low to moderate concentrations of oxygen. The catheter should be changed every 8 hours, alternating nostrils to prevent infection and nasal irritation.

When oxygen is administered via cannula or catheter, the percentage of oxygen reaching the lungs varies with the depth and rate of respirations, particularly if the nasal mucosa is swollen or if the patient is a mouth breather.

Oxygen masks come in several forms. Each is used for different purposes (Fig. 25-1). *Simple masks* are used for low to moderate concentrations of oxygen. The body of the mask itself gathers and stores oxygen between breaths. The patient exhales directly through openings or ports in the body of the mask. If oxygen flow ceases, the patient can draw air in through these openings around the mask edges (Scanlan, Wilkins & Stoller, 1999). Although widely used, these masks cannot be used for controlled oxygen concentrations and must be adjusted for proper fit. They should not press too tightly against the skin, because this may cause a sense of claustrophobia and skin breakdown; adjustable elastic bands are provided to ensure comfort and security.

*Partial-rebreathing masks* have a reservoir bag that must remain inflated during both inspiration and expiration. The nurse

should adjust the liter flow to ensure that the bag does not collapse during inhalation. A higher concentration of oxygen can be delivered because both the mask and bag serve as reservoirs for oxygen. Oxygen enters the mask through small-bore tubing that connects at the junction of the mask and bag. As the patient inhales, gas is drawn from the mask, the bag, and potentially from room air through the exhalation ports. As the patient exhales, the first third of the exhalation fills the reservoir bag. This is mainly dead space and does not participate in gas exchange in the lungs. Therefore, it has a high oxygen concentration. The remainder of the exhaled gas is vented through the exhalation ports. The actual percentage of oxygen delivered is influenced by the patient's ventilatory pattern (Cairo & Pilbeam, 1999).

*Non-rebreathing masks* are similar in design to partial-rebreathing masks except that they have two valves. The first valve is a one-way valve located between the reservoir bag and the base of the mask. The valve allows gas from the reservoir bag to enter the mask on inhalation and prevents gas in the mask from flowing back into the reservoir bag during exhalation. The second valve is a set of valves located at the exhalation ports. These one-way valves prevent room air from entering the mask during inhalation. They also allow the patient's exhaled gases to exit the mask on exhalation (Cairo & Pilbeam, 1999). As with the partial-rebreathing mask, it is important to adjust the liter flow so that the reservoir bag does not completely collapse on inspiration. In theory, if the non-rebreather mask fits the patient snugly and both side exhalation ports have one-way valves, it is possible for the patient to receive 100% oxygen, making the non-rebreather a high-flow oxygen system. However, because it is difficult to get an exact fit from the mask on every patient, and some non-rebreather masks have only one one-way exhalation valve, it is nearly impossible to ensure 100% oxygen delivery, making it a low-flow oxygen system.

**FIGURE 25-1** Types of oxygen masks used to deliver varying concentrations of oxygen. Photos © Ken Kaspar.

The *Venturi mask* is the most reliable and accurate method for delivering precise concentrations of oxygen through noninvasive means. The mask is constructed in a way that allows a constant flow of room air blended with a fixed flow of oxygen. It is used primarily for patients with COPD because it can provide low levels of supplemental oxygen, thus avoiding the risk of suppressing the hypoxic drive.

The Venturi mask employs the Bernoulli principle of air entrainment (trapping the air like a vacuum), which provides a high air flow with controlled oxygen enrichment. For each liter of oxygen that passes through a jet orifice, a fixed proportion of room air will be entrained. A precise volume of oxygen can be delivered by varying the size of the jet orifice and adjusting the flow of oxygen. Excess gas leaves the mask through the two exhalation ports, carrying with it the exhaled carbon dioxide. This method allows a constant oxygen concentration to be inhaled regardless of the depth or rate of respiration.

The mask should fit snugly enough to prevent oxygen from flowing into the patient's eyes. The nurse should check the patient's skin for irritation. It is necessary to remove the mask so that the patient can eat, drink, and take medications.

The *transtracheal oxygen catheter* is inserted directly into the trachea and is indicated for patients with chronic oxygen therapy needs. These catheters are more comfortable, less dependent on breathing patterns, and less obvious than other oxygen delivery methods. Because no oxygen is lost into the surrounding environment, the patient achieves adequate oxygenation at lower rates, making this method less expensive and more efficient.

The *T-piece* connects to the endotracheal tube and is useful in weaning patients from mechanical ventilation (Fig. 25-2).

Other oxygen devices include *aerosol masks*, *tracheostomy collars*, and *face tents*, all of which are used with aerosol devices (nebulizers) that can be adjusted for oxygen concentrations from 27% to 100% (0.27 to 1.00). If the gas mixture flow falls below patient demand, room air is pulled in, diluting the concentration. The aerosol mist must be available for the patient during the entire inspiratory phase.

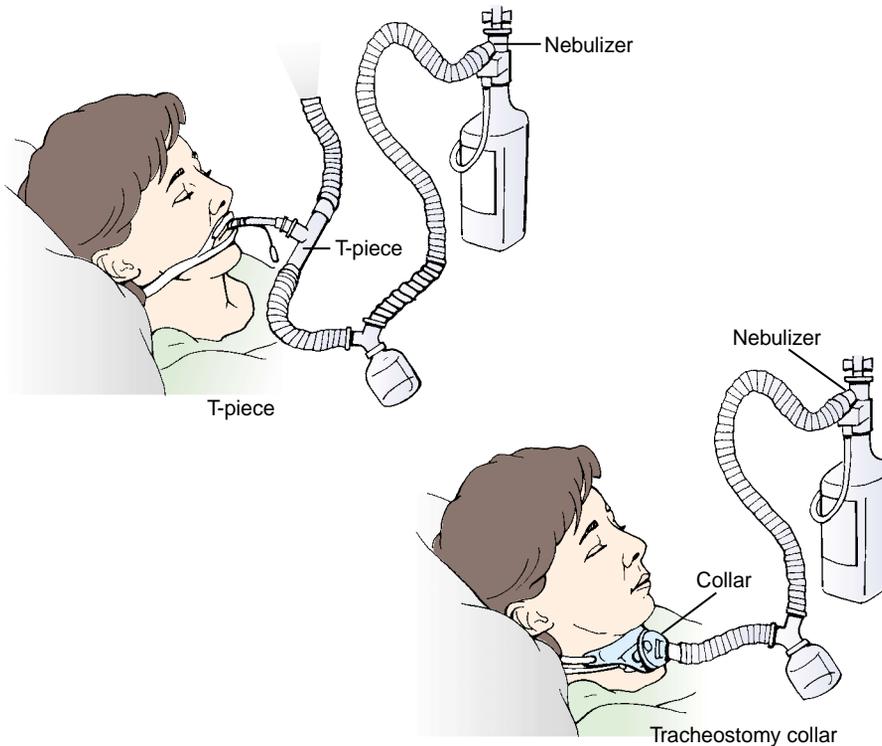

Although most oxygen therapy is administered as continuous flow oxygen, new methods of oxygen conservation are coming

into use. *Demand oxygen delivery systems* (DODS) interrupt the flow of oxygen during exhalation, when the oxygen flow is otherwise mostly wasted. Several versions of DODS are being researched for their effectiveness. Studies show that DODS models conserve oxygen and maintain oxygen saturations better than continuous-flow oxygen when the respiratory rate increases (Bliss, McCoy & Adams, 1999).

Hyperbaric oxygen therapy is the administration of oxygen at pressures greater than one atmosphere. As a result, the amount of oxygen dissolved in plasma is increased, which raises oxygen levels in the tissues. It is administered through a small (single patient use) or large (multiple patient use) cylinder chamber. During therapy, the patient is placed in the chamber. Hyperbaric oxygen therapy is used to treat conditions such as air embolism, carbon monoxide poisoning, gangrene, tissue necrosis, and hemorrhage. Other uses for this therapy include treatment for multiple sclerosis, diabetic foot ulcers, closed head trauma, and acute myocardial infarction. Research continues in the area of hyperbaric oxygen use because of potential side effects, including ear trauma, central nervous system disorders, and oxygen toxicity (Takezawa, 2000; Woodrow & Roe, 2000).

### Gerontologic Considerations

The respiratory system changes throughout the aging process, and it is important for nurses to be aware of these changes when assessing patients who are receiving oxygen therapy. As the respiratory muscles weaken and the large bronchi and alveoli become enlarged, the available surface area of the lungs decreases, resulting in reduced ventilation and respiratory gas exchange. The number of functional cilia is also reduced, decreasing ciliary action and the cough reflex. As a result of osteoporosis and the calcification of the costal cartilages, chest wall compliance is decreased. Patients may display increased chest rigidity and respiratory rate and decreased PaO<sub>2</sub> and lung expansion. Nurses should be aware that the older adult is at risk for aspiration and infection related to these changes. In addition, patient education regarding adequate nutrition is essential, because appropriate dietary intake can help

**FIGURE 25-2** T-pieces and tracheostomy collars are devices used when weaning patients from mechanical ventilation.

to diminish the excess build-up of carbon dioxide and to maintain optimal respiratory functioning (Abraham, Bottrell, Fulmer & Mezey, 1999; Eliopoulos, 2001).

## Nursing Management

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** At times oxygen must be administered to the patient at home. The nurse instructs the patient or family in the methods for administering oxygen and informs the patient and family that oxygen is available in gas, liquid, and concentrated forms. The gas and liquid forms come in portable de-

vices so that the patient can leave home while receiving oxygen therapy. Humidity must be provided while oxygen is used (except with portable devices) to counteract the dry, irritating effects of compressed oxygen on the airway (Chart 25-2).

**Continuing Care.** Home visits by a home health nurse or respiratory therapist may be arranged based on the patient's status and needs. It is important to assess the patient's home environment, the patient's physical and psychological status, and the need for further teaching. The nurse reinforces the teaching points on how to use oxygen safely and effectively, including fire safety tips because oxygen is flammable. To maintain a consistent quality of care and to maximize the patient's financial reimbursement for

Chart 25-2

### Home Care Checklist • Oxygen Therapy

*At the completion of the home care instruction, the patient or caregiver will be able to:*

	Patient	Caregiver
• State proper care of and administration of oxygen to patient		
State physician's prescription for oxygen and the manner in which it is to be used	✓	✓
Indicate when a humidifier should be used	✓	✓
Identify signs and symptoms indicating the need for change in oxygen therapy	✓	✓
Describe precautions and safety measures to be used when oxygen is in use	✓	✓
State how and when to place an order for more oxygen	✓	✓
Describe a diet that meets energy demands	✓	✓
• Maintain equipment properly		
Demonstrate correct adjustment of prescribed flow rate	✓	✓
Describe how to clean and when to replace oxygen tubing	✓	✓
Identify when a portable oxygen delivery device should be used	✓	✓
Demonstrate safe and appropriate use of portable oxygen delivery device	✓	✓
Identify causes of malfunction of equipment and when to call for replacement of equipment	✓	✓
Describe the importance of determining that all electrical outlets are working properly	✓	✓

home oxygen therapy, the nurse ensures that the physician's prescription includes the diagnosis, the prescribed oxygen flow, and conditions for use (eg, continuous use, nighttime use only). Because oxygen is a medication, the nurse reminds the patient receiving long-term oxygen therapy and family about the importance of keeping follow-up appointments with the physician. The patient is instructed to see the physician every 6 months or more often, if indicated. Blood gas measurements and laboratory tests are repeated annually, or more often if the patient's condition changes (Smith & Matti, 1999).

## INTERMITTENT POSITIVE-PRESSURE BREATHING

Intermittent positive-pressure breathing (IPPB) is a form of assisted or controlled respiration produced by a ventilatory apparatus in which compressed gas is delivered under positive pressure into a person's airways until a preset pressure is reached. Passive exhalation is allowed through a valve. The specific pressure and volume amounts, along with the use of any nebulizing medications, are prescribed individually for patients. The nurse should encourage patients to relax and reassure them that the machine will automatically shut off airflow at the end of inspiration. The IPPB machine may be powered by electricity or gas and may be connected with a mouthpiece, mask, or tracheostomy adapter.

### Indications

General indications for IPPB include difficulty in raising respiratory secretions, reduced vital capacity with ineffective deep breathing and coughing, or unsuccessful trials of simpler and less costly methods for loosening secretions, delivering aerosol, or expanding the lungs.

### Complications

IPPB therapy is used rarely today because of its inherent hazards, which may include pneumothorax, mucosal drying, increased intracranial pressure, hemoptysis, gastric distention, vomiting with possible aspiration, psychological dependency (especially with long-term use, as in COPD patients), hyperventilation, excessive oxygen administration, and cardiovascular problems.

## MINI-NEBULIZER THERAPY

The mini-nebulizer is a hand-held apparatus that disperses a moisturizing agent or medication, such as a bronchodilator or mucolytic agent, into microscopic particles and delivers it to the lungs as the patient inhales. The mini-nebulizer is usually air-driven by means of a compressor through connecting tubing. In some instances, the nebulizer is oxygen-driven rather than air-driven. To be effective, a visible mist must be available for the patient to inhale.

### Indications

The indications for use of a mini-nebulizer are similar to the indications for IPPB, except that the patient must be able to generate a deep breath without the aid of the positive-pressure machine. Diaphragmatic breathing (Chart 25-3) is a helpful technique to prepare for proper use of the mini-nebulizer. Frequently,

### Chart 25-3 • PATIENT EDUCATION Breathing Exercises

#### General Instructions

- Breathe slowly and rhythmically to exhale completely and empty the lungs completely.
- Inhale through the nose to filter, humidify, and warm the air before it enters the lungs.
- If you feel out of breath, breathe more slowly by prolonging the exhalation time.
- Keep the air moist with a humidifier.

#### Diaphragmatic Breathing

Goal: To use and strengthen the diaphragm during breathing

- Place one hand on the abdomen (just below the ribs) and the other hand on the middle of the chest to increase the awareness of the position of the diaphragm and its function in breathing.
- Breathe in slowly and deeply through the nose, letting the abdomen protrude as far as possible.
- Breathe out through pursed lips while tightening (contracting) the abdominal muscles.
- Press firmly inward and upward on the abdomen while breathing out.
- Repeat for 1 minute; follow with a rest period of 2 minutes.
- Gradually increase duration up to 5 minutes, several times a day (before meals and at bedtime).

#### Pursed-Lip Breathing

Goal: To prolong exhalation and increase airway pressure during expiration, thus reducing the amount of trapped air and the amount of airway resistance.

- Inhale through the nose while counting to 3—the amount of time needed to say “Smell a rose.”
- Exhale slowly and evenly against pursed lips while tightening the abdominal muscles. (Pursing the lips increases intratracheal pressure; exhaling through the mouth offers less resistance to expired air.)
- Count to 7 while prolonging expiration through pursed lips—the length of time to say “Blow out the candle.”
- While sitting in a chair:  
Fold arms over the abdomen.  
Inhale through the nose while counting to 3.  
Bend forward and exhale slowly through pursed lips while counting to 7.
- While walking:  
Inhale while walking two steps.  
Exhale through pursed lips while walking four or five steps.

mini-nebulizers are used for patients with COPD to dispense inhaled medications and are commonly used at home on a long-term basis.

## Nursing Management

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** The nurse instructs the patient to breathe through the mouth, taking slow, deep breaths, and then to hold the breath for a few seconds at the end of inspiration to increase intrapleural pressure and reopen collapsed alveoli, thereby increasing functional residual capacity. The nurse encourages the patient to cough and to monitor the effectiveness of the therapy. The nurse instructs the patient and family about the purpose of the treatment, equipment set-up, medication additive, and proper cleaning and storage of the equipment.

## INCENTIVE SPIROMETRY (SUSTAINED MAXIMAL INSPIRATION)

**Incentive spirometry** is a method of deep breathing that provides visual feedback to help the patient inhale slowly and deeply to maximize lung inflation and prevent or reduce atelectasis. Ideally, the patient assumes a sitting or semi-Fowler's position to enhance diaphragmatic excursion (Chart 25-4). However, this procedure may be performed with the patient in any position.

Incentive spirometers may be one of two types: volume or flow. In the volume type, the tidal volume of the spirometer is set according to the manufacturer's instructions. The purpose of the device is to ensure that the volume of air inhaled is increased gradually as the patient takes deeper and deeper breaths. The patient takes a deep breath through the mouthpiece, pauses at peak lung inflation, and then relaxes and exhales. Taking several normal breaths before attempting another with the incentive spirometer helps avoid fatigue. The volume is periodically increased as tolerated.

A flow spirometer has the same purpose as a volume spirometer, but the volume is not preset. The spirometer contains a number of movable balls that are pushed up by the force of the breath and held suspended in the air while the patient inhales. The amount of air inhaled and the flow of the air are estimated by how long and how high the balls are suspended.

### Indications

Incentive spirometry is used after surgery, especially thoracic and abdominal surgery, to promote the expansion of the alveoli and to prevent or treat atelectasis. As a preventive measure, incentive spirometry may be more effective than IPPB because it maximizes the amount of air inhaled while maintaining relatively low airway pressures.

## Nursing Management

Nursing management of the patient using incentive spirometry includes placing the patient in the proper position, teaching the technique for using the incentive spirometer, setting realistic goals for the patient, and recording the results of the therapy.

## CHEST PHYSIOTHERAPY

**Chest physiotherapy (CPT)** includes **postural drainage, chest percussion and vibration**, and breathing exercises/breathing retraining. In addition, teaching the patient effective coughing technique is an important part of chest physiotherapy. The goals of chest physiotherapy are to remove bronchial secretions, improve ventilation, and increase the efficiency of the respiratory muscles.

### Postural Drainage (Segmented Bronchial Drainage)

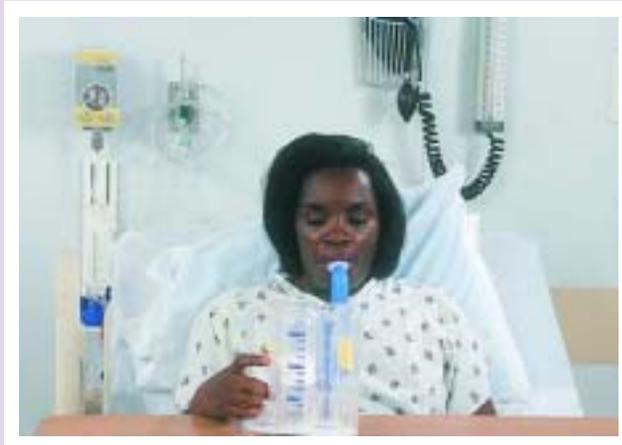

Postural drainage uses specific positions that allow the force of gravity to assist in the removal of bronchial secretions. The secretions drain from the affected bronchioles into the bronchi and trachea and are removed by coughing or suctioning. Postural drainage is used to prevent or relieve bronchial obstruction caused by accumulation of secretions.

Because the patient usually sits in an upright position, secretions are likely to accumulate in the lower parts of the lungs. With postural drainage, different positions (Fig. 25-3) are used so that the force of gravity helps to move secretions from the smaller bronchial airways to the main bronchi and trachea. The secretions then are removed by coughing. The nurse should instruct the patient to inhale bronchodilators and mucolytic agents, if prescribed, before postural drainage because these medications improve bronchial tree drainage.

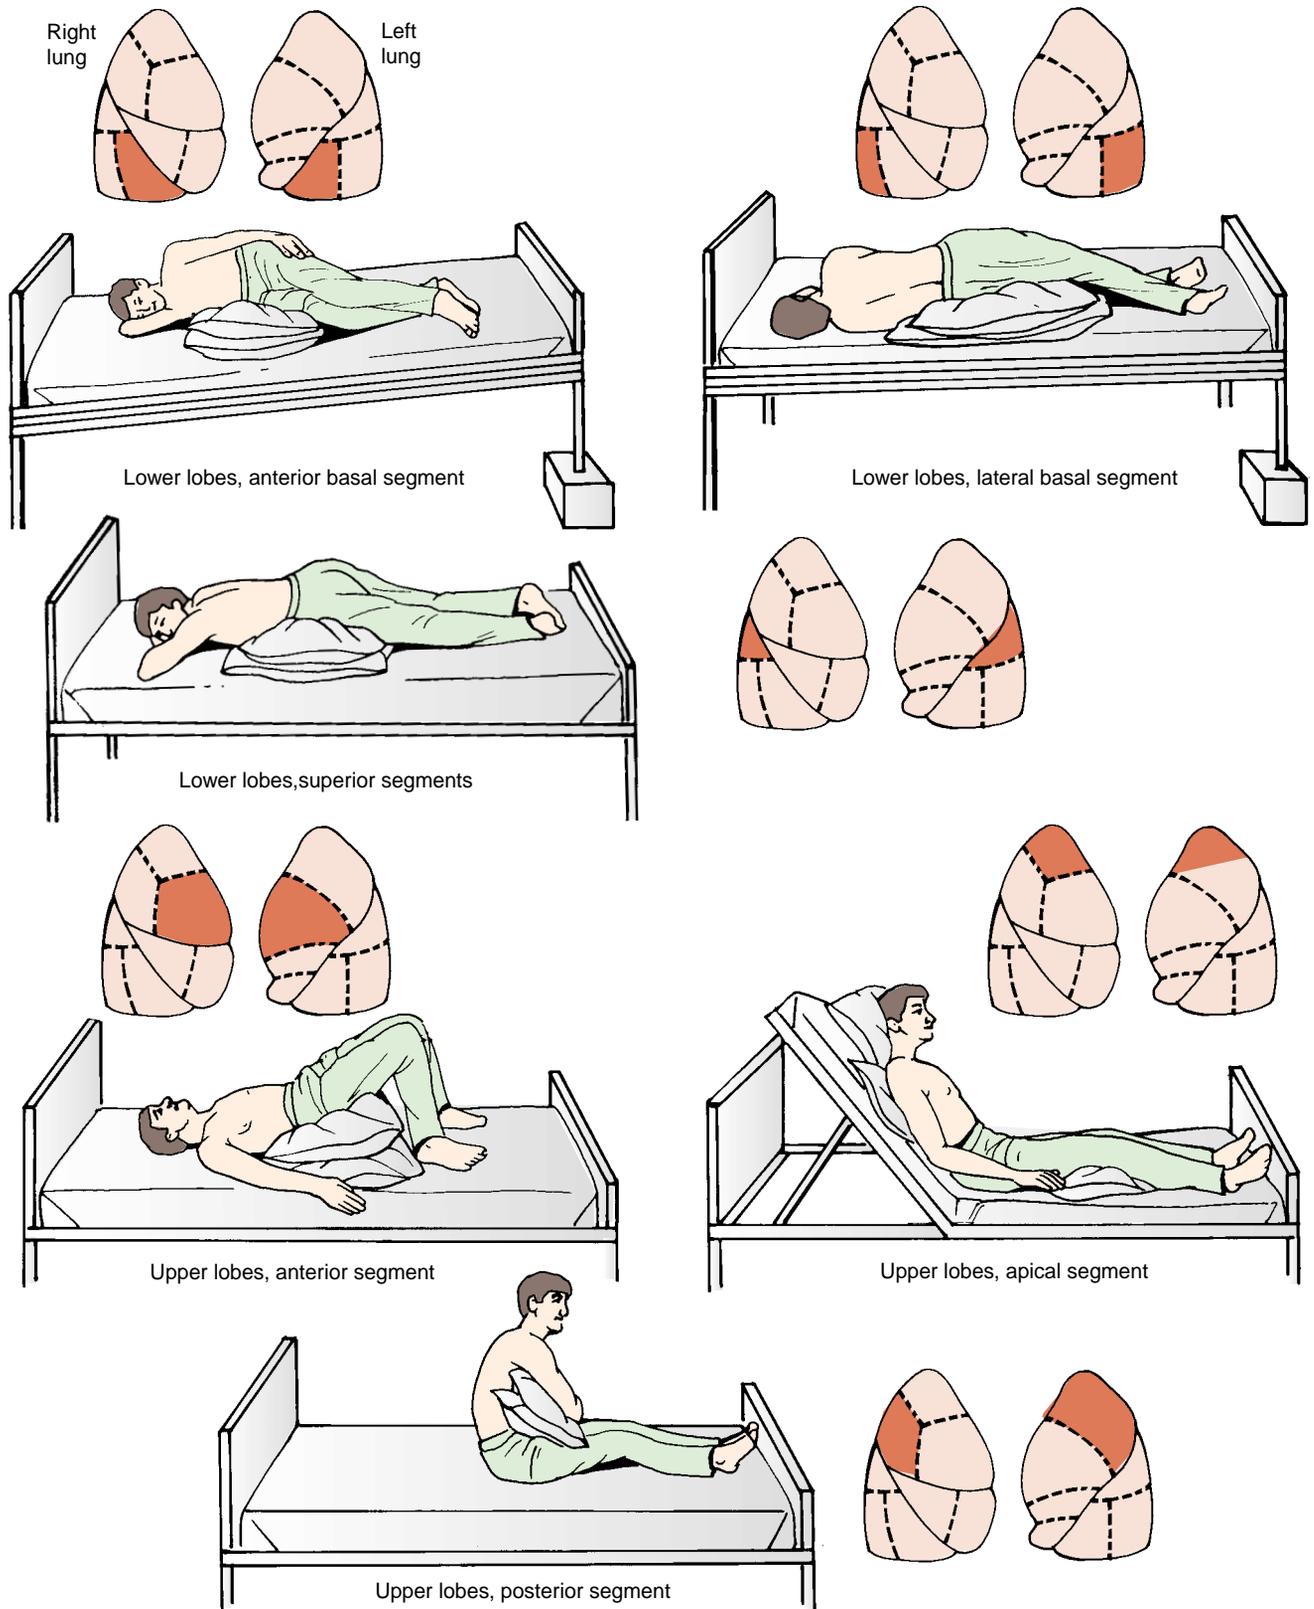

### Chart 25-4 • PATIENT EDUCATION Assisting the Patient to Perform Incentive Spirometry

- Explain the reason and objective for the therapy: the inspired air helps to inflate the lungs. The ball or weight in the spirometer will rise in response to the intensity of the intake of air. The higher the ball rises, the deeper the breath.
- Assess the patient's level of pain and administer pain medication if prescribed.
- Position the patient in semi-Fowler's position or in an upright position (although any position is acceptable).
- Demonstrate how to use diaphragmatic breathing.
- Instruct the patient to place the mouthpiece of the spirometer firmly in the mouth, to breathe air in (inspire), and to hold the breath at the end of inspiration for about 3 seconds. The patient then exhales slowly.
- Encourage approximately 10 breaths per hour with the spirometer during waking hours.
- Set a reasonable volume and repetition goal (to provide encouragement and give the patient a sense of accomplishment).
- Encourage coughing during and after each session.
- Assist the patient to splint the incision when coughing postoperatively.
- Place the spirometer within easy reach of the patient.
- For the postoperative patient, begin the therapy immediately. (If the patient begins to hypoventilate, atelectasis can start to occur within an hour.)

© B. Proud.

- Record how effectively the patient performs the therapy and the number of breaths achieved with the spirometer every 2 hours.

**FIGURE 25-3** Postural drainage positions and the areas of lung drained by each position.

Postural drainage exercises can be directed at any of the segments of the lungs. The lower and middle lobe bronchi drain more effectively when the head is down; the upper lobe bronchi drain more effectively when the head is up. Frequently, five positions are used, one for drainage of each lobe: head down, prone, right and left lateral, and sitting upright.

## Nursing Management

The nurse should be aware of the patient's diagnosis as well as the lung lobes or segments involved, the cardiac status, and any structural deformities of the chest wall and spine. Auscultating the chest before and after the procedure helps to identify the areas needing drainage and to assess the effectiveness of treatment. The nurse teaches family members who will be assisting the patient at home to evaluate breath sounds before and after treatment. The nurse explores strategies that will enable the patient to assume the indicated positions at home. This may require the creative use of objects readily available at home, such as pillows, cushions, or cardboard boxes.

Postural drainage is usually performed two to four times daily, before meals (to prevent nausea, vomiting, and aspiration) and at bedtime. Prescribed bronchodilators, water, or saline may be nebulized and inhaled before postural drainage to dilate the bronchioles, reduce bronchospasm, decrease the thickness of mucus and sputum, and combat edema of the bronchial walls. The recommended sequence of positioning is as follows: positions to drain the lower lobes first, then positions to drain the upper lobes.

The nurse makes the patient as comfortable as possible in each position and provides an emesis basin, sputum cup, and paper tissues. The nurse instructs the patient to remain in each position for 10 to 15 minutes and to breathe in slowly through the nose and then breathe out slowly through pursed lips to help keep the airways open so that secretions can drain while in each position. If a position cannot be tolerated, the nurse helps the patient to assume a modified position. When the patient changes position, the nurse explains how to cough and remove secretions (Chart 25-5).

If the patient cannot cough, the nurse may need to suction the secretions mechanically. It also may be necessary to use chest percussion and vibration to loosen bronchial secretions and mucus plugs that adhere to the bronchioles and bronchi and to propel sputum in the direction of gravity drainage (see "Chest Percussion and Vibration," below). If suctioning is required at home, the nurse instructs caregivers in safe suctioning technique and care of the suctioning equipment.

Chart  
25-5

### Effective Coughing Technique

1. The patient assumes a sitting position and bends slightly forward. This upright position permits a stronger cough.
2. The patient's knees and hips are flexed to promote relaxation and reduce the strain on the abdominal muscles while coughing.
3. The patient inhales slowly through the nose and exhales through pursed lips several times.
4. The patient should cough twice during each exhalation while contracting (pulling in) the abdomen sharply with each cough.
5. The patient splints the incisional area, if any, with firm hand pressure or supports it with a pillow or rolled blanket while coughing (see Fig. 25-8). (The nurse can initially demonstrate this by using the patient's hands.)

After the procedure, the nurse notes the amount, color, viscosity, and character of the expelled sputum. It is important to evaluate the patient's skin color and pulse the first few times the procedure is performed. It may be necessary to administer oxygen during postural drainage.

If the sputum is foul-smelling, it is important to perform postural drainage in a room away from other patients and/or family members and to use deodorizers unless contraindicated. Deodorizers delivered in aerosol sprays can cause bronchospasm and irritation to the patient with a respiratory disorder and should be used cautiously (Zang & Allender, 1999). After the procedure, the patient may find it refreshing to brush the teeth and use a mouthwash before resting.

## Chest Percussion and Vibration

Thick secretions that are difficult to cough up may be loosened by tapping (percussing) and vibrating the chest. Chest percussion and vibration help to dislodge mucus adhering to the bronchioles and bronchi.

Percussion is carried out by cupping the hands and lightly striking the chest wall in a rhythmic fashion over the lung segment to be drained. The wrists are alternately flexed and extended so that the chest is cupped or clapped in a painless manner (Fig. 25-4). A soft cloth or towel may be placed over the segment of the chest that is being cupped to prevent skin irritation and redness from direct contact. Percussion, alternating with vibration, is performed for 3 to 5 minutes for each position. The patient uses diaphragmatic breathing during this procedure to promote relaxation (see "Breathing Retraining," below). As a precaution, percussion over chest drainage tubes, the sternum, spine, liver, kidneys, spleen, or breasts (in women) is avoided. Percussion is performed cautiously in the elderly because of their increased incidence of osteoporosis and risk of rib fracture.

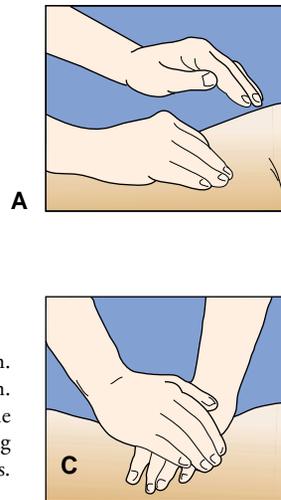

Vibration is the technique of applying manual compression and tremor to the chest wall during the exhalation phase of respiration (see Fig. 25-4). This helps to increase the velocity of the air expired from the small airways, thus freeing the mucus. After three or four vibrations, the patient is encouraged to cough, using the abdominal muscles. (Contracting the abdominal muscles increases the effectiveness of the cough.)

A scheduled program of coughing and clearing sputum, together with hydration, reduces the amount of sputum in most patients. The number of times the percussion and vibration cycle is repeated depends on the patient's tolerance and clinical response. It is important to evaluate breath sounds before and after the procedures.

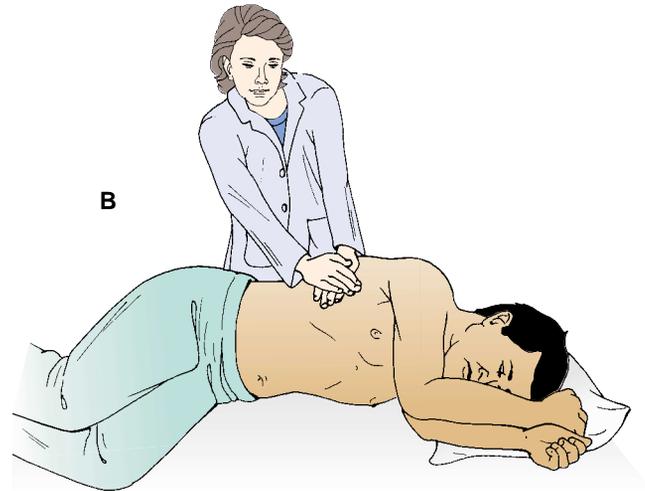

## Nursing Management

When performing chest physiotherapy, the nurse ensures that the patient is comfortable, is not wearing restrictive clothing, and has not just eaten. The uppermost areas of the lung are treated first. The nurse gives medication for pain, as prescribed, before percussion and vibration and splints any incision and provides pillows for support as needed. The positions are varied, but focus is placed on the affected areas. On completion of the treatment, the nurse assists the patient to assume a comfortable position.

The nurse must stop treatment if any of the following occur: increased pain, increased shortness of breath, weakness, lightheadedness, or hemoptysis. Therapy is indicated until the patient has normal respirations, can mobilize secretions, and has normal breath sounds, and when the chest x-ray findings are normal.

**FIGURE 25-4** Percussion and vibration. (A) Proper hand position for percussion. (B) Proper technique for vibration. The wrists and elbows remain stiff; the vibrating motion is produced by the shoulder muscles. (C) Proper hand position for vibration.

## PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** Chest physiotherapy is frequently indicated at home for patients with COPD, bronchiectasis, and cystic fibrosis. The techniques are the same as described above, but gravity drainage is achieved by placing the hips over a box, a stack of magazines, or pillows (unless a hospital bed is available). The nurse instructs the patient and family in the positions and techniques of percussion and vibration so that therapy can be continued in the home. In addition, the nurse instructs the patient to maintain an adequate fluid intake and air humidity to prevent secretions from becoming thick and tenacious. It also is important to teach the patient to recognize early signs of infection, such as fever and a change in the color or character of sputum. Resting 5 to 10 minutes in each postural drainage position before chest physiotherapy maximizes the amount of secretions obtained.

**Continuing Care.** Chest physical therapy may be carried out during visits by a home care nurse. The nurse also assesses the patient's physical status, understanding of the treatment plan, and compliance with recommended therapy, as well as the effectiveness of therapy. It is important to reinforce patient and family teaching during these visits. The nurse reports to the patient's physician any deterioration in the patient's physical status and inability to clear secretions.

## Breathing Retraining

Breathing retraining consists of exercises and breathing practices designed to achieve more efficient and controlled ventilation and to decrease the work of breathing. Breathing retraining is especially indicated in patients with COPD and dyspnea. These exercises promote maximal alveolar inflation and muscle relaxation, relieve anxiety, eliminate ineffective, uncoordinated patterns of respiratory muscle activity, slow the respiratory rate, and decrease the work of breathing. Slow, relaxed, and rhythmic breathing also helps to control the anxiety that occurs with dyspnea. Specific breathing exercises include diaphragmatic and pursed-lip breathing (see Chart 25-3).

The goal of diaphragmatic breathing is to use and strengthen the diaphragm during breathing. Diaphragmatic breathing can become automatic with sufficient practice and concentration. Pursed-lip breathing, which improves oxygen transport, helps to

induce a slow, deep breathing pattern and assists the patient to control breathing, even during periods of stress. This type of breathing helps prevent airway collapse secondary to loss of lung elasticity in emphysema. The goal of pursed-lip breathing is to train the muscles of expiration to prolong exhalation and increase airway pressure during expiration, thus lessening the amount of airway trapping and resistance. The nurse instructs the patient in diaphragmatic breathing and pursed-lip breathing, as described earlier in Chart 25-3. Breathing exercises may be practiced in several positions because air distribution and pulmonary circulation vary with the position of the chest. Many patients require additional oxygen, using a low-flow method, while performing breathing exercises. Emphysema-like changes in the lung occur as part of the natural aging process of the lung; therefore, breathing exercises are appropriate for all elderly patients who are hospitalized and elderly patients in any setting who are sedentary, even without primary lung disease.

## Nursing Management

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** The nurse instructs the patient to breathe slowly and rhythmically in a relaxed manner and to exhale completely to empty the lungs. The patient is instructed always to inhale through the nose because this filters, humidifies, and warms the air. If short of breath, the patient should concentrate on breathing slowly and rhythmically. To avoid initiating a cycle of increasing shortness of breath and panic, it is often helpful to instruct the patient to concentrate on prolonging the length of exhalation rather than merely slowing the rate of breathing. Minimizing the amount of dust or particles in the air and providing adequate humidification may also make it easier for the patient to breathe. Strategies to decrease dust or particles in the air include removing drapes or upholstered furniture, using air filters, and washing floors and dusting and vacuuming frequently.

The nurse instructs the patient that an adequate dietary intake promotes gas exchange and increases energy levels. It is important to provide adequate nutrition without overfeeding patients. Nurses should teach patients to consume small, frequent meals and snacks. Having ready-prepared meals and favorite foods available helps encourage nutrient consumption. Gas-producing foods such as beans, legumes, broccoli, cabbage, and Brussels sprouts should be avoided to prevent gastric distress. Because many of these patients

lack the energy to eat, they should be taught to rest before and after meals to conserve energy (Lutz & Przytulski, 2001).

## Airway Management

Adequate ventilation is dependent on free movement of air through the upper and lower airways. In many disorders, the airway becomes narrowed or blocked as a result of disease, bronchoconstriction (narrowing of airway by contraction of muscle fibers), a foreign body, or secretions. Maintaining a patent (open) airway is achieved through meticulous airway management, whether in an emergency situation such as airway obstruction or in long-term management, as in caring for a patient with an endotracheal or a tracheostomy tube.

### EMERGENCY MANAGEMENT OF UPPER AIRWAY OBSTRUCTION

Upper airway obstruction has a variety of causes. Acute upper airway obstruction may be caused by food particles, vomitus, blood clots, or any other particle that enters and obstructs the larynx or trachea. It also may occur from enlargement of tissue in the wall of the airway, as in epiglottitis, laryngeal edema, laryngeal carcinoma, or peritonsillar abscess, or from thick secretions. Pressure on the walls of the airway, as occurs in retrosternal goiter, enlarged mediastinal lymph nodes, hematoma around the upper airway, and thoracic aneurysm, also may result in upper airway obstruction.

The patient with an altered level of consciousness from any cause is at risk for upper airway obstruction because of loss of the protective reflexes (cough and swallowing) and the tone of the pharyngeal muscles, causing the tongue to fall back and block the airway.

The nurse makes the following rapid observations to assess for signs and symptoms of upper airway obstruction:

- **Inspection**—Is the patient conscious? Is there any inspiratory effort? Does the chest rise symmetrically? Is there use or retraction of accessory muscles? What is the skin color? Are there any obvious signs of deformity or obstruction (trauma, food, teeth, vomitus)? Is the trachea midline?
- **Palpation**—Do both sides of the chest rise equally with inspiration? Are there any specific areas of tenderness, fracture, or subcutaneous emphysema (crepitus)?
- **Auscultation**—Is there any audible air movement, stridor (inspiratory sound), or wheezing (expiratory sound)? Are breath sounds present bilaterally in all lobes?

As soon as an upper airway obstruction is identified, the nurse takes emergency measures (Chart 25-6). (See “Guidelines for Managing a Foreign Body Airway Obstruction” in Chap. 71 for more details, or see Chap. 22.)

### ENDOTRACHEAL INTUBATION

**Endotracheal intubation** involves passing an endotracheal tube through the mouth or nose into the trachea (Fig. 25-5). Intubation provides a patent airway when the patient is having respiratory distress that cannot be treated with simpler methods. It is the method of choice in emergency care. Endotracheal intubation is a means of providing an airway for patients who cannot maintain an adequate airway on their own (eg, comatose patients or pa-

tients with upper airway obstruction), for mechanical ventilation, and for suctioning secretions from the pulmonary tree.

An endotracheal tube usually is passed with the aid of a laryngoscope by specifically trained medical, nursing, or respiratory therapy personnel. (See “Guidelines for Inserting an Oropharyngeal Airway” in Chap. 71 for more details.) Once the tube is inserted, a cuff around the tube is inflated to prevent air from leaking around the outer part of the tube, to minimize the possibility of subsequent aspiration, and to prevent movement of the tube.

Nurses should be aware that complications could occur from pressure in the cuff on the tracheal wall. Cuff pressures should be checked with a calibrated aneroid manometer device every 8 to 12 hours to maintain cuff pressure between 20 and 25 mm Hg. High cuff pressure can cause tracheal bleeding, ischemia, and pressure necrosis, while low cuff pressure can increase the risk of aspiration pneumonia. Routine deflation of the cuff is not recommended due to the increased risk of aspiration and hypoxia. The cuff is deflated prior to removing the endotracheal tube (St. John, 1999b).

Tracheobronchial secretions are suctioned through the tube. Warmed, humidified oxygen should always be introduced through the tube, whether the patient is breathing spontaneously or is receiving ventilatory support. Endotracheal intubation may be used for no more than 3 weeks, by which time a tracheostomy must be considered to decrease irritation of and trauma to the tracheal lining, to reduce the incidence of vocal cord paralysis (secondary to laryngeal nerve damage), and to decrease the work of breathing. Chart 25-7 discusses the nursing care of the patient with an endotracheal tube.

There are several disadvantages of endotracheal and tracheostomy tubes. First, the tube causes discomfort. In addition, the cough reflex is depressed because closure of the glottis is hindered. Secretions tend to become thicker because the warming and humidifying effect of the upper respiratory tract has been bypassed. The swallowing reflexes, composed of the glottic, pharyngeal, and laryngeal reflexes, are depressed because of prolonged disuse and the mechanical trauma of the endotracheal or tracheostomy tube, which puts the patient at increased risk for aspiration. In addition, ulceration and stricture of the larynx or trachea may develop. Of great concern to the patient is the inability to talk and to communicate needs.

Unintentional or premature removal of the tube is a potentially life-threatening complication of endotracheal intubation. Removal of the tube is a frequent problem in intensive care units and occurs mainly during nursing care or by the patient. It is important for nurses to instruct patients and family members about the purpose of the tube and the dangers of removing it. Baseline and ongoing assessment of the patient and equipment ensures effective care. Providing comfort measures, including opioid analgesia and sedation, can improve the patient’s tolerance of the endotracheal tube.

**NURSING ALERT** Inadvertent removal of an endotracheal tube can cause laryngeal swelling, hypoxemia, bradycardia, hypotension, and even death. Measures must be taken to prevent premature or inadvertent removal.

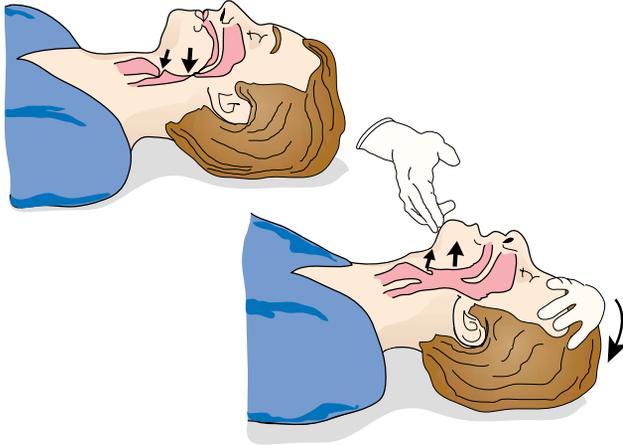

To prevent tube removal by the patient, the nurse can use the following strategies: explain to the patient and family the purpose of the tube, distract the patient through one-to-one interaction with the nurse and family or with television, and maintain comfort measures. As a last resort, soft wrist restraints may be used, according to agency policy.

Chart  
25-6

## Clearing an Upper Airway Obstruction

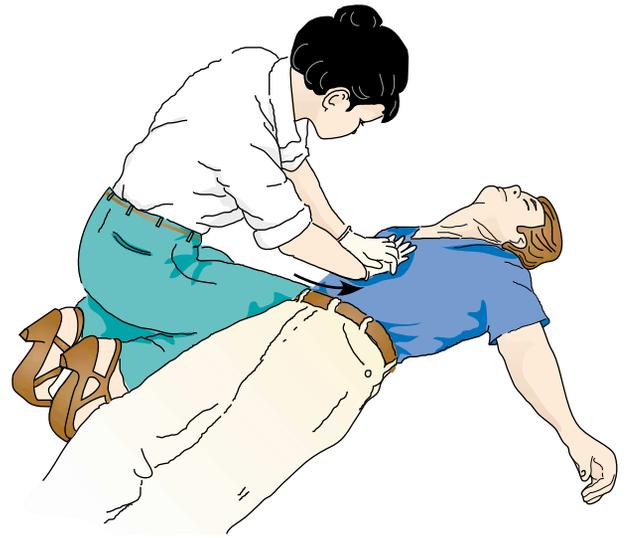

## Clearing the Airway

- Hyperextend the patient's neck by placing one hand on the forehead and placing the fingers of the other hand underneath the jaw and lifting upward and forward. This action pulls the tongue away from the back of the pharynx.

Opening the airway.

- Assess the patient by observing the chest and listening and feeling for the movement of air.
- Use a cross-finger technique to open the mouth and observe for obvious obstructions such as secretions, blood clots, or food particles.
- If no passage of air is detected, apply five quick sharp abdominal thrusts just below the xiphoid process to expel the obstruction (Heimlich maneuver). Repeat this procedure until the obstruction is expelled.
- After the obstruction is expelled, roll the patient as a unit onto the side for recovery.
- When the obstruction is relieved and the patient can breathe spontaneously but not cough, swallow, or gag, insert an oral or nasopharyngeal airway.

Abdominal thrust (Heimlich) maneuver administered to unconscious patient.

## Bag and Mask Resuscitation

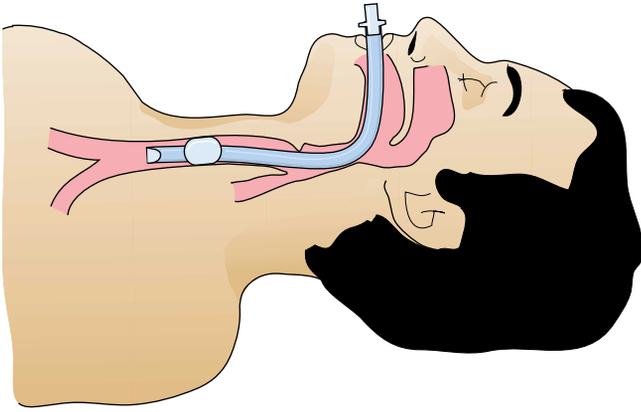

- Use a resuscitation bag and mask if assisted ventilation is required.
- Apply the mask to the patient's face and create a seal by pressing the thumb of the nondominant hand on the bridge of the nose and the index finger on the chin. Use the rest of the fingers on the hand and pull on the chin and the angle of the mandible to maintain the head in extension. Use the dominant hand to inflate the lungs by squeezing the bag to its full volume.

Resuscitation via bag and mask apparatus.

Studies have shown that the most effective way to prevent tube removal by the patient is through the use of soft wrist restraints (Happ, 2000). However, discretion and caution must always be used before applying any restraint. If the patient cannot move the arms and hands to the endotracheal tube, restraints would not be needed. If the patient is alert, oriented, able to follow directions, and

cooperative to the point that it is highly unlikely that he or she will remove the endotracheal tube, restraints are not needed. On the other hand, if the nurse determines there is a risk that the patient may try to remove the tube, soft wrist restraints are appropriate with a physician's order (check agency policy). Close monitoring of the patient remains essential to ensure safety and prevent harm.

**FIGURE 25-5** Endotracheal tube in place. Tube has been inserted using the oral route. The cuff has been inflated to maintain the tube's position and minimize the risk for aspiration.

## TRACHEOSTOMY

A **tracheotomy** is a surgical procedure in which an opening is made into the trachea. The indwelling tube inserted into the trachea is called a **tracheostomy tube**. A tracheostomy may be either temporary or permanent.

A tracheostomy is used to bypass an upper airway obstruction, to allow removal of tracheobronchial secretions, to permit the long-term use of mechanical ventilation, to prevent aspiration of oral or gastric secretions in the unconscious or paralyzed patient (by closing off the trachea from the esophagus), and to replace an endotracheal tube. There are many disease processes and emergency conditions that make a tracheostomy necessary.

### Procedure

The surgical procedure is usually performed in the operating room or in an intensive care unit, where the patient's ventilation can be well controlled and optimal aseptic technique can be maintained.

A surgical opening is made in the second and third tracheal rings. After the trachea is exposed, a cuffed tracheostomy tube of an appropriate size is inserted. The cuff is an inflatable attachment to the tracheostomy tube that is designed to occlude the space between the trachea walls and the tube to permit effective mechanical ventilation and to minimize the risk of aspiration.

The tracheostomy tube is held in place by tapes fastened around the patient's neck. Usually a square of sterile gauze is placed between the tube and the skin to absorb drainage and prevent infection.

## Complications

Complications may occur early or late in the course of tracheostomy tube management. They may even occur years after the tube has been removed. Early complications include bleeding, pneumothorax, air embolism, aspiration, subcutaneous or mediastinal emphysema, recurrent laryngeal nerve damage, and posterior tracheal wall penetration. Long-term complications include airway obstruction from accumulation of secretions or protrusion of the cuff over the opening of the tube, infection, rupture of the innominate artery, dysphagia, tracheoesophageal fistula, tracheal dilation, and tracheal ischemia and necrosis. Tracheal stenosis may develop after the tube is removed. Chart 25-8 outlines measures nurses can take to prevent complications.

## Postoperative Nursing Management

The patient requires continuous monitoring and assessment. The newly made opening must be kept patent by proper suctioning of secretions. After the vital signs are stable, the patient is placed in a semi-Fowler's position to facilitate ventilation, promote drainage, minimize edema, and prevent strain on the suture lines. Analgesia and sedative agents must be administered with caution because of the risk of suppressing the cough reflex.

Major objectives of nursing care are to alleviate the patient's apprehension and to provide an effective means of communica-

Chart  
25-7

### Care of the Patient with an Endotracheal Tube

#### Immediately After Intubation

1. Check symmetry of chest expansion.
  - Auscultate breath sounds of anterior and lateral chest bilaterally.
  - Obtain order for chest x-ray to verify proper tube placement.
  - Check cuff pressure every 8–12 hours.
  - Monitor for signs and symptoms of aspiration.
2. Ensure high humidity; a visible mist should appear in the T-piece or ventilator tubing.
3. Administer oxygen concentration as prescribed by physician.
4. Secure the tube to the patient's face with tape, and mark the proximal end for position maintenance.
  - Cut proximal end of tube if it is longer than 7.5 cm (3 inches) to prevent kinking.
  - Insert an oral airway or mouth device to prevent the patient from biting and obstructing the tube.
5. Use sterile suction technique and airway care to prevent iatrogenic contamination and infection.
6. Continue to reposition patient every 2 hours and as needed to prevent atelectasis and to optimize lung expansion.
7. Provide oral hygiene and suction the oropharynx whenever necessary.

#### Extubation (Removal of Endotracheal Tube)

1. Explain procedure.
  2. Have self-inflating bag and mask ready in case ventilatory assistance is required immediately after extubation.
  3. Suction the tracheobronchial tree and oropharynx, remove tape, and then deflate the cuff.
  4. Give oxygen for a few breaths, then insert a new, sterile suction catheter inside tube.
  5. Have the patient inhale. At peak inspiration remove the tube, suctioning the airway through the tube as it is pulled out.
- Note:* In some hospitals this procedure can be performed by respiratory therapists; in others, by nurses. Check hospital policy.

#### Care of Patient Following Extubation

1. Give heated humidity and oxygen by face mask.
2. Monitor respiratory rate and quality of chest excursions. Note stridor, color change, and change in mental alertness or behavior.
3. Monitor the patient's oxygen level using a pulse oximeter.
4. Keep NPO or give only ice chips for next few hours.
5. Provide mouth care.
6. Teach patient how to perform coughing and deep-breathing exercises.

Chart  
25-8

### Preventing Complications Associated With Endotracheal and Tracheostomy Tubes

- Administer adequate warmed humidity.
- Maintain cuff around tube.
- Suction as needed per assessment findings.
- Maintain skin integrity. Change tape and dressing as needed or per protocol.
- Auscultate lung sounds.
- Monitor for signs and symptoms of infection, including temperature and white blood cell count.
- Administer prescribed oxygen and monitor oxygen saturation.
- Monitor for cyanosis.
- Maintain adequate hydration of the patient.
- Use sterile technique when suctioning and performing tracheostomy care.

tion. The nurse keeps paper and pencil or a Magic Slate and the call light within the patient's reach to ensure a means of communication. The care of the patient with a tracheostomy tube is summarized in Chart 25-9.

#### SUCTIONING THE TRACHEAL TUBE (TRACHEOSTOMY OR ENDOTRACHEAL TUBE)

When a tracheostomy or endotracheal tube is in place, it is usually necessary to suction the patient's secretions because of the decreased effectiveness of the cough mechanism. Tracheal suctioning is performed when adventitious breath sounds are detected or whenever secretions are obviously present. Unnecessary suctioning can initiate bronchospasm and cause mechanical trauma to the tracheal mucosa.

All equipment that comes into direct contact with the patient's lower airway must be sterile to prevent overwhelming pulmonary and systemic infections. The procedure for suctioning a tracheostomy is presented in Chart 25-10. In mechanically ventilated patients, an in-line suction catheter may be used to allow rapid suction when needed and to minimize cross-contamination of airborne pathogens. An in-line suction device allows the patient to be suctioned without being disconnected from the ventilator circuit.

#### MANAGING THE CUFF

As a general rule, the cuff on an endotracheal or tracheostomy tube should be inflated. The pressure within the cuff should be the lowest possible that allows delivery of adequate tidal volumes and prevents pulmonary aspiration. Usually the pressure is maintained at less than 25 cm H<sub>2</sub>O to prevent injury and at more than 20 cm H<sub>2</sub>O to prevent aspiration. Cuff pressure must be monitored at least every 8 hours by attaching a hand-held pressure gauge to the pilot balloon of the tube or by using the minimal leak volume or minimal occlusion volume technique. With long-term intubation, higher pressures may be needed to maintain an adequate seal.

#### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** If the patient is at home with a tracheostomy, the nurse instructs the patient and family about its daily care as well as measures to take in an emergency. The nurse also makes sure the patient and family are aware of community contacts for education and support needs. It is important for the

nurse to teach the patient and family strategies to prevent infection when performing tracheostomy care (McConnell, 2000).

## Mechanical Ventilation

Mechanical ventilation may be required for a variety of reasons, including the need to control the patient's respirations during surgery or during treatment of severe head injury, to oxygenate the blood when the patient's ventilatory efforts are inadequate, and to rest the respiratory muscles. Many patients placed on a ventilator can breathe spontaneously, but the effort needed to do so may be exhausting.

A mechanical ventilator is a positive- or negative-pressure breathing device that can maintain ventilation and oxygen delivery for a prolonged period. Caring for a patient on mechanical ventilation has become an integral part of nursing care in critical care or general medical-surgical units, extended care facilities, and the home. Nurses, physicians, and respiratory therapists must understand each patient's specific pulmonary needs and work together to set realistic goals. Positive patient outcomes depend on an understanding of the principles of mechanical ventilation and the patient's care needs as well as open communication among members of the health care team about the goals of therapy, weaning plans, and the patient's tolerance of changes in ventilator settings.

### INDICATIONS FOR MECHANICAL VENTILATION

If a patient has a continuous decrease in oxygenation (PaO<sub>2</sub>), an increase in arterial carbon dioxide levels (PaCO<sub>2</sub>), and a persistent acidosis (decreased pH), mechanical ventilation may be necessary. Conditions such as thoracic or abdominal surgery, drug overdose, neuromuscular disorders, inhalation injury, COPD, multiple trauma, shock, multisystem failure, and coma all may lead to respiratory failure and the need for mechanical ventilation. The criteria for mechanical ventilation (Chart 25-11) guide the decision to place a patient on a ventilator. A patient with apnea that is not readily reversible also is a candidate for mechanical ventilation.

### CLASSIFICATION OF VENTILATORS

Several types of mechanical ventilators exist; they are classified according to the manner in which they support ventilation. The two general categories are negative-pressure and positive-pressure ventilators. The most common category in use today is the positive-pressure ventilator.

#### Negative-Pressure Ventilators

Negative-pressure ventilators exert a negative pressure on the external chest. Decreasing the intrathoracic pressure during inspiration allows air to flow into the lung, filling its volume. Physiologically, this type of assisted ventilation is similar to spontaneous ventilation. It is used mainly in chronic respiratory failure associated with neuromuscular conditions, such as poliomyelitis, muscular dystrophy, amyotrophic lateral sclerosis, and myasthenia gravis. It is inappropriate for the unstable or complex patient or the patient whose condition requires frequent ventilatory changes. Negative-pressure ventilators are simple to use and do not require intubation of the airway; consequently, they are especially adaptable for home use.

Chart  
25-9

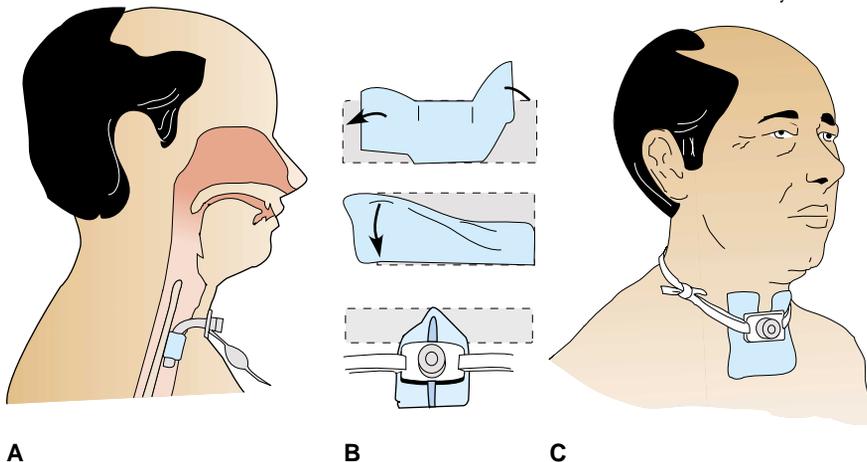

## Care of the Patient With a Tracheostomy Tube

## Nursing Intervention

- Gather the needed equipment, including sterile gloves, hydrogen peroxide, normal saline solution or sterile water, cotton-tipped applicators, dressing and twill tape (and the type of tube prescribed, if the tube is to be changed).  
A cuffed tube (air injected into cuff) is required during mechanical ventilation. A low-pressure cuff is most commonly used.  
Patients requiring long-term use of a tracheostomy tube and who can breathe spontaneously commonly use an uncuffed, metal tube.
- Provide patient and family instruction on the key points for tracheostomy care, beginning with how to inspect the tracheostomy dressing for moisture or drainage.
- Perform hand hygiene.
- Explain procedure to patient and family as appropriate.
- Put on clean gloves; remove and discard the soiled dressing in a biohazard container.
- Prepare sterile supplies, including hydrogen peroxide, normal saline solution or sterile water, cotton-tipped applicators, dressing, and tape.
- Put on sterile gloves. (Some physicians approve clean technique for long-term tracheostomy patients in the home.)
- Cleanse the wound and the plate of the tracheostomy tube with sterile cotton-tipped applicators moistened with hydrogen peroxide. Rinse with sterile saline solution.
- Soak inner cannula in peroxide and rinse with saline solution or replace with a new disposable inner cannula.
- Remove soiled twill tape with clean tape, after the new tape is in place. Place clean twill tape in position to secure the tracheostomy tube by inserting one end of the tape through the side opening of the outer cannula. Take the tape around the back of the patient's neck and thread it through the opposite opening of the outer cannula. Bring both ends around so that they meet on one side of the neck. Tighten the tape until only two fingers can be comfortably inserted under it. Secure with a knot. For a new tracheostomy, two people should assist with tape changes.
- Remove old tapes and discard in a biohazard container.
- Although some long-term tracheostomies with healed stomas may not require a dressing, other tracheostomies do. In such cases, use a sterile tracheostomy dressing, fitting it securely under the twill tapes and flange of tracheostomy tube so that the incision is covered, as shown below.

## Rationale

- Everything needed to care for a tracheostomy should be readily on hand for the most effective care.
- A cuffed tube prevents air from leaking during positive-pressure ventilation and also prevents tracheal aspiration of gastric contents. An adequate seal is indicated by the disappearance of any air leakage from the mouth or tracheostomy or by the disappearance of the harsh, gurgling sound of air coming from the throat. Low-pressure cuffs exert minimal pressure on the tracheal mucosa and thus reduce the danger of tracheal ulceration and stricture. The tracheostomy dressing is changed as needed to keep the skin clean and dry. To prevent potential breakdown, moist or soiled dressings should not remain on the skin. Hand hygiene reduces bacteria on hands. A patient with a tracheostomy is apprehensive and requires ongoing assurance and support. Observing body substance isolation reduces cross-contamination from soiled dressings. Having necessary supplies and equipment readily available allows the procedure to be completed efficiently.
- Sterile equipment minimizes transmission of surface flora to the sterile respiratory tract. Clean technique may be used in the home because of decreased exposure to potential pathogens. Hydrogen peroxide is effective in loosening crusted secretions. Rinsing prevents skin residue.
- Soaking loosens and removes secretions from the inner lumen of the tracheostomy tube. This taping technique provides a double thickness of tape around the neck, which is needed because the tracheostomy tube can be dislodged by movement or by a forceful cough if left unsecured. A dislodged tracheostomy tube is difficult to reinsert, and respiratory distress may occur. Dislodgement of a new tracheostomy is a medical emergency.
- Tapes with old secretions may harbor bacteria. Healed tracheostomies with minimal secretions do not need a dressing. Dressings that will shred are not used around a tracheostomy because of the risk that pieces of material, lint, or thread may get into the tube, and eventually into the trachea, causing obstruction or abscess formation. Special dressings that do not have a tendency to shred are used.

(A) The cuff of the tracheostomy tube fits smoothly and snugly in the trachea in a way that promotes circulation but seals off the escape of secretions and air surrounding the tube. (B) For a dressing change, a 4 × 4-inch gauze pad may be folded (cutting would promote shredding, placing the patient at risk for aspiration) around the tracheostomy tube and (C) stabilized by slipping the neck tape ties through the neck plate slots of the tracheostomy tube. The ties may be fastened to the side of the neck to eliminate the discomfort of lying on the knot.

Chart  
25-10

## Performing Tracheal Suction

**Equipment**

- Suction catheters
- Gloves
- Goggles for eye protection
- Basin for sterile normal saline solution for irrigation
- Manual resuscitation bag with supplemental oxygen
- Suction source

**Procedure**

1. Explain the procedure to the patient before beginning and offer reassurance during suctioning; the patient may be apprehensive about choking and about an inability to communicate.
2. Begin by carrying out hand hygiene.
3. Turn on suction source (pressure should not exceed 120 mm Hg).
4. Open suction catheter kit.
5. Fill basin with sterile normal saline solution.
6. Ventilate the patient with manual resuscitation bag and high-flow oxygen.
7. Put sterile glove on dominant hand.
8. Pick up suction catheter in gloved hand and connect to suction.
9. Hyperoxygenate the patient's lungs for several deep breaths. Instill normal saline solution into airway *only* if there are thick, tenacious secretions.
10. Insert suction catheter at least as far as the end of the tube without applying suction, just far enough to stimulate the cough reflex.
11. Apply suction while withdrawing and gently rotating the catheter 360° (no longer than 10 to 15 seconds, because hypoxia and dysrhythmias may develop, leading to cardiac arrest).
12. Reoxygenate and inflate the patient's lungs for several breaths.
13. Repeat previous three steps until the airway is clear.
14. Rinse catheter in basin with sterile normal saline solution between suction attempts if necessary.
15. Suction oropharyngeal cavity after completing tracheal suctioning.
16. Rinse suction tubing.
17. Discard catheter, gloves, and basin appropriately.

There are several types of negative-pressure ventilators: iron lung, body wrap, and chest cuirass.

**IRON LUNG (DRINKER RESPIRATOR TANK)**

The iron lung is a negative-pressure chamber used for ventilation. It was used extensively during polio epidemics in the past and currently is used by polio survivors and patients with other neuromuscular disorders.

**BODY WRAP (PNEUMOWRAP) AND CHEST CUIRASS (TORTOISE SHELL)**

Both of these portable devices require a rigid cage or shell to create a negative-pressure chamber around the thorax and abdomen.

Because of problems with proper fit and system leaks, these types of ventilators are used only with carefully selected patients.

**Positive-Pressure Ventilators**

Positive-pressure ventilators inflate the lungs by exerting positive pressure on the airway, similar to a bellows mechanism, forcing the alveoli to expand during inspiration. Expiration occurs passively. Endotracheal intubation or tracheostomy is necessary in most cases. These ventilators are widely used in the hospital setting and are increasingly used in the home for patients with primary lung disease. There are three types of positive-pressure ventilators, which are classified by the method of ending the inspiratory phase of respiration: pressure-cycled, time-cycled, and

**NURSING RESEARCH PROFILE 25-1***The Effect of Normal Saline Instillation Before Suctioning on Oxygenation Status*

Kinloch, D. (1999). Instillation of normal saline during endotracheal suctioning: effects on mixed venous oxygen saturation. *American Journal of Critical Care*, 8(4), 231–240.

**Purpose**

Although it has been suggested that instilling normal saline into an endotracheal tube before suctioning facilitates the removal of secretions, few studies have addressed this issue using in vivo measures of patients' oxygenation status. The purpose of this study was to determine if instillation of normal saline before endotracheal suctioning improves patients' oxygenation status.

**Study Sample and Design**

A descriptive, observational study design was used to investigate the effect of normal saline instillation (NSI) before endotracheal suctioning on mixed venous oxygen saturations. Thirty-five patients recovering from coronary artery bypass grafting were included in the study. The decision to instill normal saline into the endotracheal tube was made by the clinician caring for the patient. Patients were divided into NSI ( $n = 15$ ) and non-NSI groups ( $n = 20$ ). Patients in the NSI group received 5 mL of normal saline before endotracheal suctioning, and patients in the non-NSI group did not. A standardized suctioning protocol was used; other than NSI, suctioning procedures for both groups were identical. Baseline levels of mixed venous oxygenated

blood saturation ( $S\bar{V}O_2$ ) levels were obtained through the use of a pulmonary artery catheter at 1-minute intervals for 5 minutes before the start of suctioning; the mean of these levels was considered the patient's baseline value. After suctioning,  $S\bar{V}O_2$  levels were measured at 1-minute intervals until they returned to baseline levels.

**Findings**

The mean post-suctioning  $S\bar{V}O_2$  level of the NSI group was significantly lower ( $p = .007$ ) than that of the non-NSI group. Further, the NSI group took an average of 3.8 minutes longer to return to baseline  $S\bar{V}O_2$  than the non-NSI group; this difference was statistically significant ( $p = .05$ ).

**Nursing Implications**

The current standard of practice for nurses is to instill normal saline before suctioning, especially if the secretions are thick and tenacious. Although the findings of this study suggest that this practice should no longer be used, the issue needs further study with a larger sample and with randomization of patients to groups. The findings of this study are relevant to nurses caring for patients requiring endotracheal suctioning.

Chart  
25-11**Indications for Mechanical Ventilation**

$\text{PaO}_2 < 50$  mm Hg with  $\text{FiO}_2 > 0.60$   
 $\text{PaO}_2 > 50$  mm Hg with  $\text{pH} < 7.25$   
 Vital capacity  $< 2$  times tidal volume  
 Negative inspiratory force  $< 25$  cm  $\text{H}_2\text{O}$   
 Respiratory rate  $> 35/\text{min}$

volume-cycled. Another type of positive-pressure ventilator used for selected patients is noninvasive positive-pressure ventilation.

**PRESSURE-CYCLED VENTILATORS**

The pressure-cycled ventilator ends inspiration when a preset pressure has been reached. In other words, the ventilator cycles on, delivers a flow of air until it reaches a predetermined pressure, then cycles off. Its major limitation is that the volume of air or oxygen can vary as the patient's airway resistance or compliance changes. As a result, the tidal volume delivered may be inconsistent, possibly compromising ventilation. Consequently, in adults, pressure-cycled ventilators are intended only for short-term use. The most common type is the IPPB machine (see previous discussion of IPPB).

**TIME-CYCLED VENTILATORS**

Time-cycled ventilators terminate or control inspiration after a preset time. The volume of air the patient receives is regulated by the length of inspiration and the flow rate of the air. Most ventilators have a rate control that determines the respiratory rate, but pure time-cycling is rarely used for adults. These ventilators are used in newborns and infants.

**VOLUME-CYCLED VENTILATORS**

Volume-cycled ventilators are by far the most commonly used positive-pressure ventilators today (Fig. 25-6). With this type of ventilator, the volume of air to be delivered with each inspiration is preset. Once this preset volume is delivered to the patient, the ventilator cycles off and exhalation occurs passively. From breath to breath, the volume of air delivered by the ventilator is relatively constant, ensuring consistent, adequate breaths despite varying airway pressures.

**NONINVASIVE POSITIVE-PRESSURE VENTILATION**

Positive-pressure ventilation can be given via facemasks that cover the nose and mouth, nasal masks, or other nasal devices. This eliminates the need for endotracheal intubation or tracheostomy and decreases the risk for nosocomial infections such as pneumonia. The most comfortable mode for the patient is pressure-controlled ventilation with pressure support. This eases the work of breathing and enhances gas exchange. The ventilator can be set with a minimum backup rate for patients with periods of apnea.

Patients are considered candidates for noninvasive ventilation if they have acute or chronic respiratory failure, acute pulmonary edema, COPD, or chronic heart failure with a sleep-related breathing disorder. The device also may be used at home to improve tissue oxygenation and to rest the respiratory muscles while the patient sleeps at night. It is contraindicated for those who have experienced respiratory arrest, serious dysrhythmias, cognitive impairment, or head or facial trauma. Noninvasive ventilation may also be used for patients at the end of life and those who do not want endotracheal intubation but may need short- or long-term ventilatory support (Scanlan, Wilkins & Stoller, 1999).

Bilevel positive airway pressure (bi-PAP) ventilation offers independent control of inspiratory and expiratory pressures while providing pressure support ventilation. It delivers two levels of

**A****B**

**FIGURE 25-6** Control panels of positive pressure ventilators in current use illustrate functions made possible by technologic advances. **(A)** Bear 1000 ventilator. positive airway pressure provided via a nasal or oral mask, nasal pillow, or mouthpiece with a tight seal and a portable ventilator. Each inspiration can be initiated either by the patient or by the machine if it is programmed with a backup rate. The backup rate ensures that the patient will receive a set number of breaths per minute (Perkins & Shortall, 2000). Bi-PAP is most often used for patients who require ventilatory assistance at night, such as those with severe COPD or sleep apnea. Tolerance is variable; bi-PAP is usually most successful with highly motivated patients.

### ADJUSTING THE VENTILATOR

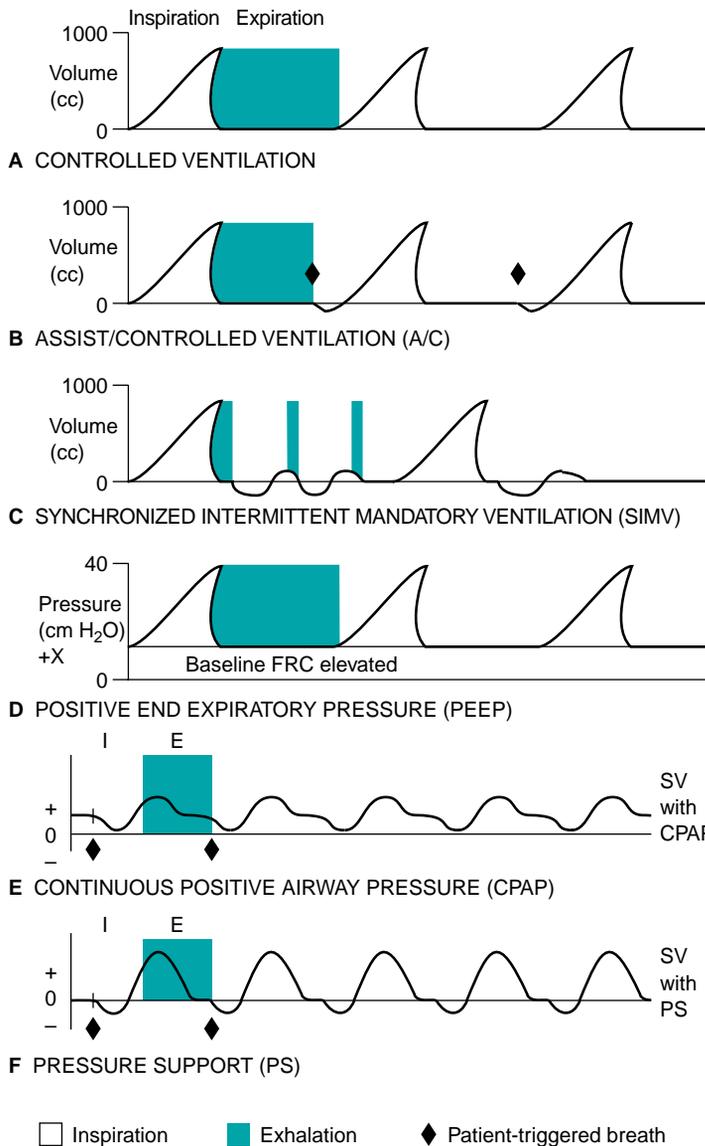

The ventilator is adjusted so that the patient is comfortable and breathes “in sync” with the machine. Minimal alteration of the normal cardiovascular and pulmonary dynamics is desired. Modes of mechanical ventilation are described in Figure 25-7. If the volume ventilator is adjusted appropriately, the patient’s arterial blood gas values will be satisfactory and there will be little or no cardiovascular compromise. Chart 25-12 discusses how to achieve adequate mechanical ventilation for each patient.

### ASSESSING THE EQUIPMENT

The ventilator needs to be assessed to make sure that it is functioning properly and that the settings are appropriate. Even though the nurse is not primarily responsible for adjusting the settings on the ventilator or measuring ventilator parameters (usually the responsibility of the respiratory therapist), the nurse is responsible for the patient and therefore needs to evaluate how the ventilator affects the patient’s overall status.

In monitoring the ventilator, the nurse should note the following:

- Type of ventilator (such as volume-cycled, pressure-cycled, negative-pressure)
- Controlling mode (such as **controlled ventilation, assist-control ventilation, synchronized intermittent mandatory ventilation**)
- Tidal volume and rate settings (tidal volume is usually 10 to 15 mL/kg; rate is usually 12 to 16/min)
- FiO<sub>2</sub> (**fraction of inspired oxygen**) setting

**A** Flow in the controlled ventilation mode. A preset volume of gas is delivered to the patient under positive pressure while spontaneous patient respiratory effort is “locked out.”

**B** Gas flow in the assist/control ventilation mode. In this mode, a preset volume of gas is delivered to the patient at a preset rate, but the patient may trigger a ventilator breath with negative inspiratory effort.

**C** Gas flow in the synchronized intermittent mandatory ventilation (SIMV) mode. A preset minimum number of breaths are synchronously delivered to the patient but the patient may also take spontaneous breaths of varying volumes. Note how inspiratory and expiratory pressures differ between spontaneous and ventilator breaths.

**D** Airway pressure with varying levels of positive end-expiratory pressure (PEEP). Note that at end expiration, the airway is not allowed to return to zero. (FRC: functional residual capacity.)

**E** Spontaneous ventilation with continuous positive airway pressure (CPAP). This ventilatory adjunct is used only with spontaneous ventilation; the patient breathes spontaneously through the ventilator at an elevated baseline pressure throughout the breathing cycle.

**F** Spontaneous ventilation with pressure support (PS). The patient breathes spontaneously with pressure assistance to each spontaneous inspiration.

FIGURE 25-7 Modes of mechanical ventilation with air flow waveforms.

Chart  
25-12**Initial Ventilator Settings**

The following guide is an example of the steps involved in operating a mechanical ventilator. The nurse, in collaboration with the respiratory therapist, always reviews the manufacturer's instructions, which vary according to the equipment, before beginning mechanical ventilation.

1. Set the machine to deliver the tidal volume required (10 to 15 mL/kg).
2. Adjust the machine to deliver the lowest concentration of oxygen to maintain normal PaO<sub>2</sub> (80 to 100 mm Hg). This setting may be high initially but will gradually be reduced based on arterial blood gas results.
3. Record peak inspiratory pressure.
4. Set mode (assist-control or synchronized intermittent mandatory ventilation) and rate according to physician order. (See the glossary for definitions of modes of mechanical ventilation.) Set PEEP and pressure support if ordered.
5. Adjust sensitivity so that the patient can trigger the ventilator with a minimal effort (usually 2 mm Hg negative inspiratory force).
6. Record minute volume and measure carbon dioxide partial pressure (PCO<sub>2</sub>), pH, and PO<sub>2</sub> after 20 minutes of continuous mechanical ventilation.
7. Adjust setting (FiO<sub>2</sub> and rate) according to results of arterial blood gas analysis to provide normal values or those set by the physician.
8. If the patient suddenly becomes confused or agitated or begins bucking the ventilator for some unexplained reason, assess for hypoxia and manually ventilate on 100% oxygen with a resuscitation bag.

- Inspiratory pressure reached and pressure limit (normal is 15 to 20 cm H<sub>2</sub>O; this increases if there is increased airway resistance or decreased compliance)
- Sensitivity (a 2-cm H<sub>2</sub>O inspiratory force should trigger the ventilator)
- Inspiratory-to-expiratory ratio (usually 1:3 [1 second of inspiration to 3 seconds of expiration] or 1:2)
- Minute volume (tidal volume × respiratory rate, usually 6 to 8 L/min)
- Sigh settings (usually 1.5 times the tidal volume and ranging from 1 to 3 per hour), if applicable
- Water in the tubing, disconnection or kinking of the tubing
- Humidification (humidifier filled with water) and temperature
- Alarms (turned on and functioning properly)
- PEEP and/or pressure support level, if applicable. PEEP is usually 5 to 15 cm H<sub>2</sub>O

**NURSING ALERT** If the ventilator system malfunctions and the problem cannot be identified and corrected immediately, the nurse must ventilate the patient with a manual resuscitation bag until the problem is resolved.

## PROBLEMS WITH MECHANICAL VENTILATION

Because of the seriousness of the patient's condition and the highly complex and technical nature of mechanical ventilation, a number of problems or complications can occur. Such situations fall

into two categories: ventilator problems and patient problems. In either case, the patient must be supported while the problem is identified and corrected. Ventilator complications include cardiovascular compromise, pneumothorax, and pulmonary infection. These problems, their probable causes, and solutions are listed in Table 25-2.

### BUCKING THE VENTILATOR

The patient is "in sync" with the ventilator when thoracic expansion coincides with the inspiratory phase of the machine and exhalation occurs passively. The patient is said to fight or buck the ventilator when out of phase with the machine. This is manifested when the patient attempts to breathe out during the ventilator's mechanical inspiratory phase or when there is jerky and increased abdominal muscle effort. The following factors contribute to this problem: anxiety, hypoxia, increased secretions, hypercapnia, inadequate minute volume, and pulmonary edema. These problems must be corrected before resorting to the use of paralyzing agents to reduce bucking; otherwise, the underlying problem is simply masked and the patient's condition will continue to deteriorate.

Muscle relaxants, tranquilizers, analgesic agents, and paralyzing agents are sometimes administered to patients receiving mechanical ventilation. Their purpose is ultimately to increase the patient-machine synchrony by decreasing the patient's anxiety, hyperventilation, or excessive muscle activity. The selection and dose of the appropriate medication are determined carefully and are based on the patient's requirements and the cause of his or her restlessness. Paralyzing agents are always used as a last resort, and always in conjunction with a sedative medication.

## Nursing Management

### PROMOTING HOME AND COMMUNITY-BASED CARE

Increasingly, patients are being cared for in extended care facilities or at home while on mechanical ventilators, with tracheostomy tubes, or on oxygen therapy. Patients receiving home ventilator care usually have chronic neuromuscular conditions or COPD.

**Teaching Patients Self-Care.** Caring for the patient with mechanical ventilator support at home can be accomplished successfully, but the family must be emotionally, educationally, and physically able to assume the role of primary caregiver. A home care team consisting of the nurse, physician, respiratory therapist, social service or home care agency, and equipment supplier is needed. The home is evaluated to determine if the electrical equipment needed can be operated safely. A summary of the basic assessment criteria needed for successful home care is presented in Chart 25-13.

Once the decision is made to initiate mechanical ventilation at home, the nurse prepares the patient and family for home care. It is important to teach them about the ventilator, suctioning, tracheostomy care, signs of pulmonary infection, cuff inflation and deflation, and assessment of vital signs. Teaching often begins in the hospital and continues at home. Nursing responsibilities include evaluating the patient's and family's understanding of the information presented.

The nurse teaches the family cardiopulmonary resuscitation, including mouth-to-tracheostomy tube (instead of mouth-to-mouth) breathing. The nurse also explains how to handle a power failure, which usually involves converting the ventilator from an electrical power source to a battery power source. Conversion is

Table 25-2 • Troubleshooting Ventilator Problems

PROBLEM	CAUSE	SOLUTION
<b>Ventilator</b>		
Increase in peak airway pressure	Coughing or plugged airway tube	Suction airway for secretions, empty condensation fluid from circuit.
	Patient “bucking” ventilator Decreasing lung compliance	Adjust sensitivity. Manually ventilate patient. Assess for hypoxia or bronchospasm. Check arterial blood gas values. Sedate only if necessary.
Decrease in pressure or loss of volume	Tubing kinked	Check tubing; reposition patient; insert oral airway if necessary.
	Pneumothorax Atelectasis or bronchospasm	Manually ventilate patient; notify physician. Clear secretions.
Decrease in pressure or loss of volume	Increase in compliance	None
	Leak in ventilator or tubing; cuff on tube/ humidifier not tight	Check entire ventilator circuit for patency. Correct leak.
<b>Patient</b>		
Cardiovascular compromise	Decrease in venous return due to application of positive pressure to lungs	Assess for adequate volume status by measuring heart rate, blood pressure, central venous pressure, pulmonary capillary wedge pressure, and urine output. Notify physician if values are abnormal.
Barotrauma/pneumothorax	Application of positive pressure to lungs; high mean airway pressures lead to alveolar rupture	Notify physician. Prepare patient for chest tube insertion. Avoid high pressure settings for patients with COPD, ARDS, or history of pneumothorax.
Pulmonary infection	Bypass of normal defense mechanisms; frequent breaks in ventilator circuit; decreased mobility; impaired cough reflex	Use meticulous aseptic technique. Provide frequent mouth care. Optimize nutritional status.

### Chart 25-13 • ASSESSMENT

#### Criteria for Successful Home Ventilator Care

The decision to proceed with home ventilation therapy is usually based on the following parameters.

##### Patient Criteria

- The patient has chronic underlying pulmonary abnormalities.
- The patient's clinical pulmonary status is stable.
- The patient is willing to go home on mechanical ventilation.

##### Home Criteria

- The home environment is conducive to care of the patient.
- The electrical facilities are adequate to operate all equipment safely.
- The home environment is controlled, without drafts in cold weather and with proper ventilation in warm weather.
- Space is available for cleaning and storing ventilator equipment.

##### Family Criteria

- Family members are competent, dependable, and willing to spend the time required for proper training with available professional support.
- Family members understand the diagnosis and prognosis.
- Family has sufficient financial and supportive resources.

automatic in most types of home ventilators and lasts approximately 1 hour. The nurse instructs the family on using a manual self-inflation bag should it be necessary. Some of the patient's and family's responsibilities are listed in Chart 25-14.

**Continuing Care.** A home care nurse monitors and evaluates how well the patient and family are adapting to providing care in the home. The nurse also assesses the adequacy of ventilation and oxygenation as well as airway patency. The nurse addresses any unique adaptation problems the patient may have and listens to the patient's and family's anxieties and frustrations, offering support and encouragement where possible. The home care nurse helps identify and contact community resources that may assist in home management of the patient with mechanical ventilation.

The technical aspects of the ventilator are managed by vendor follow-up. A respiratory therapist usually is assigned to the patient and makes frequent home visits to evaluate the patient and perform a maintenance check of the ventilator.

Transportation services are identified should the patient require transportation in an emergency. These arrangements must be made before an emergency arises.

Providing the opportunity for ventilator-dependent patients to return home to live with their families in familiar surroundings can be a positive experience. The ultimate goal of home ventilator therapy is to enhance the patient's quality of life, not simply to support or prolong life.

Chart 25-14

## Home Care Checklist • Ventilator Care

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver
• State proper care of patient on ventilator		
Observe physical signs such as color, secretions, breathing pattern, and state of consciousness.		✓
Perform physical care such as suctioning, postural drainage, and ambulation.		✓
Observe the tidal volume and pressure manometer regularly. Intervene when they are abnormal (ie, suction if airway pressure increases).		✓
Provide a communication method for the patient (eg, pad and pencil, electric larynx, talking tracheostomy).		✓
Monitor vital signs as directed.		✓
Indicate when feeling short of breath or in distress by a predetermined signal.	✓	
• Care for and maintain equipment properly		
Check the ventilator settings twice each day and whenever the patient is removed from the ventilator.		✓
Adjust the volume and pressure alarms if needed.		✓
Fill humidifier as needed and check its level three times a day.		✓
Empty water in tubing as needed.	✓	✓
Use a clean humidifier when circuitry is changed.		✓
Keep exterior of ventilator clean and free of any objects.		✓
Change external circuitry once a week or more often as indicated.		✓
Report malfunction or strange noises immediately	✓	✓

## NURSING PROCESS: THE PATIENT ON A VENTILATOR

### Assessment

The nurse has a vital role in assessing the patient's status and the functioning of the ventilator.

In assessing the patient, the nurse evaluates the patient's physiologic status and how he or she is coping with mechanical ventilation. Physical assessment includes systematic assessment of all body systems, with an in-depth focus on the respiratory system. Respiratory assessment includes vital signs, respiratory rate and pattern, breath sounds, evaluation of spontaneous ventilatory effort, and potential evidence of hypoxia. Increased adventitious breath sounds may indicate a need for suctioning. The nurse also evaluates the settings and functioning of the mechanical ventilator, as described previously.

Assessment also addresses the patient's neurologic status and effectiveness of coping with the need for assisted ventilation and the changes that accompany it. The nurse should assess the patient's comfort level and ability to communicate as well. Finally, weaning from mechanical ventilation requires adequate nutrition. Therefore, it is important to assess the function of the gastrointestinal system and nutritional status.

### Diagnosis

#### NURSING DIAGNOSES

Based on the assessment data, the patient's major nursing diagnoses may include:

- Impaired gas exchange related to underlying illness, or ventilator setting adjustment during stabilization or weaning.
- Ineffective airway clearance related to increased mucus production associated with continuous positive-pressure mechanical ventilation
- Risk for trauma and infection related to endotracheal intubation or tracheostomy
- Impaired physical mobility related to ventilator dependency

- Impaired verbal communication related to endotracheal tube and attachment to ventilator
- Defensive coping and powerlessness related to ventilator dependency

#### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on assessment data, potential complications may include:

- Alterations in cardiac function
- Barotrauma (trauma to the alveoli) and pneumothorax
- Pulmonary infection
- Sepsis

### Planning and Goals

The major goals for the patient may include achievement of optimal gas exchange, maintenance of a patent airway, absence of trauma or infection, attainment of optimal mobility, adjustment to nonverbal methods of communication, acquisition of successful coping measures, and absence of complications.

### Nursing Interventions

Nursing care of the mechanically ventilated patient requires expert technical and interpersonal skills. Nursing interventions are similar regardless of the setting; however, the frequency of interventions and the stability of the patient vary from setting to setting. Nursing interventions for the mechanically ventilated patient are not uniquely different from other pulmonary patients, but astute nursing assessment and a therapeutic nurse-patient relationship are critical. The specific interventions used by the nurse are determined by the underlying disease process and the patient's response.

Two general nursing interventions important in the care of the mechanically ventilated patient are pulmonary auscultation and interpretation of arterial blood gas measurements. The nurse is often the first to note changes in physical assessment findings or significant trends in blood gases that signal the development of a

serious problem (eg, pneumothorax, tube displacement, pulmonary embolus).

### ENHANCING GAS EXCHANGE

The purpose of mechanical ventilation is to optimize gas exchange by maintaining alveolar ventilation and oxygen delivery. The alteration in gas exchange may be due to the underlying illness or to mechanical factors related to the adjustment of the machine to the patient. The health care team, including the nurse, physician, and respiratory therapist, continually assesses the patient for adequate gas exchange, signs and symptoms of hypoxia, and response to treatment. Thus, the nursing diagnosis impaired gas exchange is, by its complex nature, multidisciplinary and collaborative. The team members must share goals and information freely. All other goals directly or indirectly relate to this primary goal.

Nursing interventions to promote optimal gas exchange include judicious administration of analgesic agents to relieve pain without suppressing the respiratory drive and frequent repositioning to diminish the pulmonary effects of immobility. The nurse also monitors for adequate fluid balance by assessing for the presence of peripheral edema, calculating daily intake and output, and monitoring daily weights. The nurse administers medications prescribed to control the primary disease and monitors for their side effects.

### PROMOTING EFFECTIVE AIRWAY CLEARANCE

Continuous positive-pressure ventilation increases the production of secretions regardless of the patient's underlying condition. The nurse assesses for the presence of secretions by lung auscultation at least every 2 to 4 hours. Measures to clear the airway of secretions include suctioning, chest physiotherapy, frequent position changes, and increased mobility as soon as possible. Frequency of suctioning should be determined by patient assessment. If excessive secretions are identified by inspection or auscultation techniques, suctioning should be performed. Sputum is not produced continuously or every 1 to 2 hours but as a response to a pathologic condition. Therefore, there is no rationale for routine suctioning of all patients every 1 to 2 hours. Although suctioning is used to aid in the clearance of secretions, it can damage the airway mucosa and impair cilia action (Scanlan, Wilkins & Stoller, 1999).

The sigh mechanism on the ventilator may be adjusted to deliver at least one to three sighs per hour at 1.5 times the tidal volume if the patient is on assist-control. Because of the risk of hyperventilation and trauma to pulmonary tissue from excess ventilator pressure (barotrauma, pneumothorax), this feature is not being used as frequently today. If the patient is on the synchronized intermittent mandatory ventilation (SIMV) mode, the mandatory ventilations act as sighs because they are of greater volume than the patient's spontaneous breaths. Periodic sighing prevents atelectasis and the further retention of secretions.

Humidification of the airway via the ventilator is maintained to help liquefy secretions so they are more easily removed. Bronchodilators are administered to dilate the bronchioles and are classified as adrenergic or anticholinergic. Adrenergic bronchodilators are mostly inhaled and work by stimulating the beta-receptor sites, mimicking the effects of epinephrine in the body. The desired effect is smooth muscle relaxation, thus dilating the constricted bronchial tubes. Medications include albuterol (Proventil, Ventolin), isoetharine (Bronkosol), isoproterenol (Isuprel), metaproterenol (Alupent, Metaprel), pirbuterol acetate (Maxair), salmeterol (Serevent), and terbutaline (Brethine, Brethaire, Bricanyl). Tachycardia, heart palpitations, and tremors are side effects that have been reported with use of these medications (Zang & Allender, 1999). Anticholinergic bronchodilators

such as ipratropium (Atrovent) and ipratropium with albuterol (Combivent) produce airway relaxation by blocking cholinergic-induced bronchoconstriction. Patients receiving bronchodilator therapy of either type should be monitored for adverse effects including dizziness, nausea, decreased oxygen saturation, hypokalemia, increased heart rate, and urine retention. Mucolytic agents such as acetylcysteine (Mucomyst) are administered as prescribed to liquefy secretions so that they are more easily mobilized. Nursing management of patients receiving mucolytic therapy includes assessment for an adequate cough reflex, sputum characteristics, and improvement in incentive spirometry (McKenry & Salerno, 2001). Side effects include nausea, vomiting, bronchospasm, stomatitis (oral ulcers), urticaria, and runny nose (LeFever & Hayes, 2000).

### PREVENTING TRAUMA AND INFECTION

Airway management must involve maintaining the endotracheal or tracheostomy tube. The nurse positions the ventilator tubing so that there is minimal pulling or distortion of the tube in the trachea; this reduces the risk of trauma to the trachea. Cuff pressure is monitored every 8 hours to maintain the pressure at less than 25 cm H<sub>2</sub>O. The nurse evaluates for the presence of a cuff leak at the same time.

Patients with endotracheal intubation or a tracheostomy tube do not have the normal defenses of the upper airway. In addition, these patients frequently have multiple additional body system disturbances that lead to immunocompromise. Tracheostomy care is performed at least every 8 hours, and more frequently if needed, because of the increased risk of infection. The ventilator circuit and in-line suction tubing is replaced periodically, according to infection control guidelines, to decrease the risk of infection.

The nurse administers oral hygiene frequently because the oral cavity is a primary source of contamination of the lungs in the intubated and compromised patient. The presence of a nasogastric tube in the intubated patient can increase the risk for aspiration, leading to nosocomial pneumonia. The nurse positions the patient with the head elevated above the stomach as much as possible. Antiulcer medications such as sucralfate (Carafate) are given to maintain normal gastric pH; research has demonstrated a lower incidence of aspiration pneumonia when sucralfate is administered (Scanlan, Wilkins & Stoller, 1999).

### PROMOTING OPTIMAL LEVEL OF MOBILITY

The patient's mobility is limited because he or she is connected to the ventilator. The nurse should assist a patient whose condition has become stable to get out of bed and to a chair as soon as possible. Mobility and muscle activity are beneficial because they stimulate respirations and improve morale. If the patient cannot get out of bed, the nurse encourages the patient to perform active range-of-motion exercises every 6 to 8 hours. If the patient cannot perform these exercises, the nurse performs passive range-of-motion exercises every 8 hours to prevent contractures and venous stasis.

### PROMOTING OPTIMAL COMMUNICATION

It is important to develop alternative methods of communication for the patient on a ventilator. The nurse assesses the patient's communication abilities to evaluate for limitations. Questions to consider when assessing the ventilator-dependent patient's ability to communicate include the following:

- Is the patient conscious and able to communicate? Can the patient nod or shake the head?

- Is the patient's mouth unobstructed by the tube so that words can be mouthed?
- Is the patient's hand strong and available for writing? (For example, if the patient is right-handed, the intravenous line is placed in the left arm if possible so that the right hand is free.)

Once the patient's limitations are known, the nurse offers several appropriate communication approaches: lip reading (use single key words), pad and pencil or Magic Slate, communication board, gesturing, or electric larynx. Use of a "talking" or fenestrated tracheostomy tube may be suggested to the physician; this allows the patient to talk while on the ventilator. If indicated, the nurse should make sure that the patient's eyeglasses and hearing aid and a translator are available to enhance the patient's ability to communicate.

The patient must be assisted to find the most suitable communication method. Some methods may be frustrating to the patient, family, and nurse; these need to be identified and minimized. A speech therapist can assist in determining the most appropriate method.

### PROMOTING COPING ABILITY

Dependence on a ventilator is frightening to both the patient and family and disrupts even the most stable families. Encouraging the family to verbalize their feelings about the ventilator, the patient's condition, and the environment in general is beneficial. Explaining procedures every time they are performed helps to reduce anxiety and familiarizes the patient with ventilator procedures. To restore a sense of control, the nurse encourages the patient to participate in decisions about care, schedules, and treatment when possible. The patient may become withdrawn or depressed while on mechanical ventilation, especially if its use is prolonged. To promote effective coping, the nurse informs the patient about progress when appropriate. It is important to provide diversions such as watching television, playing music, or taking a walk (if appropriate and possible). Stress reduction techniques (eg, a backrub, relaxation measures) help relieve tension and help the patient to deal with anxieties and fears about both the condition and the dependence on the ventilator.

### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

#### Alterations in Cardiac Function

Alterations in cardiac output may occur as a result of positive-pressure ventilation. The positive intrathoracic pressure during inspiration compresses the heart and great vessels, thereby reducing venous return and cardiac output. This is usually corrected during exhalation when the positive pressure is off. Patients may have decreased cardiac output and resultant decreased tissue perfusion and oxygenation.

To evaluate cardiac function, the nurse first looks for signs and symptoms of hypoxia (restlessness, apprehension, confusion, tachycardia, tachypnea, labored breathing, pallor progressing to cyanosis, diaphoresis, transient hypertension, and decreased urine output). If a pulmonary artery catheter is in place, cardiac output, cardiac index, and other hemodynamic values can be used to assess the patient's status.

#### Barotrauma and Pneumothorax

Excessive positive pressure may cause barotrauma, which results in a spontaneous pneumothorax. This may quickly develop into a tension pneumothorax, further compromising venous return,

cardiac output, and blood pressure. The nurse should consider any sudden onset of changes in oxygen saturation or respiratory distress to be a life-threatening emergency requiring immediate action.

### Pulmonary Infection

The patient is at high risk for infection, as described above. The nurse should report fever or a change in the color or odor of sputum to the physician for follow-up.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Exhibits adequate gas exchange, as evidenced by normal breath sounds, acceptable arterial blood gas levels, and vital signs
2. Demonstrates adequate ventilation with minimal mucus accumulation
3. Is free of injury or infection, as evidenced by normal temperature and white blood count
4. Is mobile within limits of ability
  - a. Gets out of bed to chair, bears weight, or ambulates as soon as possible
  - b. Performs range-of-motion exercises every 6 to 8 hours
5. Communicates effectively through written messages, gestures, or other communication strategies
6. Copes effectively
  - a. Verbalizes fears and concerns about condition and equipment
  - b. Participates in decision making when possible
  - c. Uses stress reduction techniques when necessary
7. Absence of complications
  - a. Absence of cardiac compromise, as evidenced by stable vital signs and adequate urine output
  - b. Absence of pneumothorax, as evidenced by bilateral chest excursion, normal chest x-ray, and adequate oxygenation
  - c. Absence of pulmonary infection, as evidenced by normal temperature, clear pulmonary secretions, and negative sputum cultures

## WEANING THE PATIENT FROM THE VENTILATOR

**Respiratory weaning**, the process of withdrawing the patient from dependence on the ventilator, takes place in three stages: the patient is gradually removed from the ventilator, then from the tube, and finally from oxygen. Weaning from mechanical ventilation is performed at the earliest possible time consistent with patient safety. The decision must be made from a physiologic rather than from a mechanical viewpoint. A thorough understanding of the patient's clinical status is required in making this decision. Weaning is started when the patient is recovering from the acute stage of medical and surgical problems and when the cause of respiratory failure is sufficiently reversed.

Successful weaning involves collaboration among the physician, respiratory therapist, and nurse. Each health care provider must understand the scope and function of other team members in relation to patient weaning to conserve the patient's strength, use resources efficiently, and maximize successful outcomes.

## NURSING RESEARCH PROFILE 25-2

### Early Versus Late Tracheostomy Decannulation

Clini, E., Vitacca, M., Bianchi, L., Porta, R., & Ambrosino, N. (1999). Long-term tracheostomy in severe COPD patients weaned from mechanical ventilation. *Respiratory Care*, 44(4), 241–244.

#### Purpose

Patients with chronic obstructive pulmonary disease (COPD) who require mechanical ventilation for management of acute respiratory failure are at risk for relapse. It is not known if patients with spontaneous respirations would benefit from retaining a tracheostomy after discharge from the intensive care unit. This study was conducted to determine the effects of maintaining a tracheal cannula in spontaneously breathing patients following discharge.

#### Study Sample and Design

Investigators studied 20 patients with severe COPD who were undergoing weaning from mechanical ventilation. The researchers used a prospective, randomized, and controlled design to measure tracheal cannula use in two groups of patients: 10 patients had the tracheal cannula removed, and 10 did not. Breathing pattern, forced lung volumes, respiratory muscle strength, and arterial blood gases were evaluated in patients at hospital discharge and at 1, 3, and 6 months after discharge. Investigators measured breathing patterns and forced lung volumes with a portable spirometer and assessed respiratory muscle strength by measuring maximal inspiratory pressure. They also recorded number

of hospital days, mortality rate, and number of new exacerbations requiring antibiotics.

#### Results

No significant differences were found between the two groups with regard to breathing patterns, forced lung volumes, respiratory strength, or arterial blood gases. In both groups, 2 of the 10 patients (20%) died due to respiratory causes. During the follow-up period, exacerbations were significantly greater in the patients with tracheostomies than in those whose tracheostomies had been removed ( $p < .005$ ).

#### Nursing Implications

The findings of this study suggest that retaining a chronic tracheostomy following weaning from mechanical ventilation in patients with COPD is associated with a higher frequency of adverse events, including exacerbations requiring treatment with antibiotics. Although there were no significant findings with regard to breathing pattern, forced lung volumes, respiratory muscle strength, and arterial blood gases, the patient population was small, thus necessitating further study. The results suggest that clinics should consider early decannulation in COPD patients weaned from mechanical ventilation.

## Criteria for Weaning

Careful assessment is required to determine whether the patient is ready to be removed from mechanical ventilation. If the patient is stable and showing signs of improvement or reversal of the disease or condition that caused the need for mechanical ventilation, weaning indices should be assessed. These indices include:

- Vital capacity: the amount of air expired after maximum inspiration. Used to assess the patient's ability to take deep breaths. Vital capacity should be 10 to 15 mL/kg to meet the criteria for weaning.
- Maximum inspiratory pressure (MIP): used to assess the patient's respiratory muscle strength. It is also known as negative inspiratory pressure and should be at least  $-20$  cm H<sub>2</sub>O.
- Tidal volume: volume of air that is inhaled or exhaled from the lungs during an effortless breath. It is normally 7 to 9 mL/kg.
- Minute ventilation: equal to the respiratory rate multiplied by tidal volume. Normal is about 6 L/min.
- Rapid/shallow breathing index: used to assess the breathing pattern and is calculated by dividing the respiratory rate by tidal volume. Patients with indices below 100 breaths/min/L are more likely to be successful at weaning.

Other measurements used to assess readiness for weaning include a PaO<sub>2</sub> of greater than 60 mm Hg with an FiO<sub>2</sub> of less than 40%. Stable vital signs and arterial blood gases are also important predictors of successful weaning. Once readiness has been determined, the nurse records baseline measurements of weaning indices to monitor progress (Cull & Inwood, 1999).

## Patient Preparation

To maximize the chances of success of weaning, the nurse must consider the patient as a whole, taking into account factors that impair the delivery of oxygen and elimination of carbon dioxide

as well as those that increase oxygen demand (sepsis, seizures, thyroid imbalances) or decrease the patient's overall strength (nutrition, neuromuscular disease). Adequate psychological preparation is necessary before and during the weaning process. Patients need to know what is expected of them during the procedure. They are often frightened by having to breathe on their own again and need reassurance that they are improving and are well enough to handle spontaneous breathing. The nurse explains what will happen during weaning and what role the patient will play in the procedure. The nurse emphasizes that someone will be with or near the patient at all times, and answers any questions simply and concisely. Proper preparation of the patient can reduce the weaning time.

## Methods of Weaning

Considerable effort has been devoted to finding the best method of weaning from mechanical ventilation, but research has not established which method is best (Tasota & Dobbin, 2000). Success depends on the combination of adequate patient preparation, available equipment, and an interdisciplinary approach to solving patient problems (Chart 25-15). The most common weaning methods in use today are described below.

Assist-control may be used as the resting mode for patients undergoing weaning trials. This mode provides full ventilatory support by delivering a preset tidal volume and respiratory rate; if the patient takes a breath, the ventilator delivers the preset volume. The cycle does not adapt to the patient's spontaneous efforts. The nurse assesses patients being weaned on this mode for the following signs of distress: rapid shallow breathing, use of accessory muscles, reduced level of consciousness, increase in carbon dioxide levels, decrease in oxygen saturations, and tachycardia.

The patient on intermittent mandatory ventilation (IMV) can increase the respiratory rate, but each spontaneous breath receives only the tidal volume the patient generates. Mechanical breaths

Chart 25-15

## GUIDELINES FOR Care of the Patient Being Weaned From Mechanical Ventilation

### NURSING INTERVENTIONS

1. Assess patient for weaning criteria: Vital capacity—10 to 15 mL/kg  
Maximum inspiratory pressure (MIP) at least  $-20$  cm H<sub>2</sub>O  
Tidal volume—7 to 9 mL/kg  
Minute ventilation—6 L/min  
Rapid/shallow breathing index—below 100 breaths/minute/L  
PaO<sub>2</sub> greater than 60 mm Hg with FiO<sub>2</sub> less than 40%
2. Monitor activity level, assess dietary intake, and monitor results of laboratory tests of nutritional status.
3. Assess the patient's and family's understanding of the weaning process and address any concerns about the process. Explain that the patient may feel short of breath initially and provide encouragement as needed. Reassure the patient that he or she will be attended closely and that if the weaning attempt is not successful, it can be tried again later.
4. Implement the weaning method prescribed: A/C, IMV, SIMV, PSV, PAV, CPAP, or T-piece.
5. Monitor vital signs, pulse oximetry, ECG, and respiratory pattern constantly for the first 20 to 30 minutes and every 5 minutes after that until weaning is complete.
6. Maintain a patent airway; monitor arterial blood gas levels and pulmonary function tests. Suction the airway as needed.
7. In collaboration with the physician, terminate the weaning process if adverse reactions occur. These include a heart rate increase of 20 beats/min, systolic blood pressure increase of 20 mm Hg, a decrease in oxygen saturation to less than 90%, respiratory rate less than 8 or greater than 20 breaths/minute, ventricular dysrhythmias, fatigue, panic, cyanosis, erratic or labored breathing, paradoxical chest movement.
8. If the weaning process continues, measure tidal volume and minute ventilation every 20 to 30 minutes; compare with the patient's desired values, which have been determined in collaboration with the physician.
9. Assess for psychological dependence if the physiologic parameters indicate weaning is feasible and the patient still resists.

### RATIONALE

1. Careful assessment of multiple weaning indices helps to determine readiness for weaning. When the criteria have been met, the patient's likelihood of successful weaning increases.
2. Reestablishing independent spontaneous ventilation can be physically exhausting. It is crucial that the patient have enough energy reserves to succeed. Providing periods of rest and recommended nutritional intake can increase the likelihood of successful weaning.
3. The weaning process can be psychologically tiring; emotional support can help promote a sense of security. Explaining that weaning will be attempted again later helps reduce the sense of failure if the first attempts are unsuccessful.
4. The prescribed weaning method should reflect the patient's individualized criteria for weaning and weaning history. By having different methods to choose from, the physician can select the one that best fits the patient.
5. Monitoring the patient closely provides ongoing indications of success or failure.
6. These values can be compared to baseline measurements to evaluate weaning. Suctioning helps to reduce the risk of aspiration and maintain the airway.
7. These signs and symptoms indicate an unstable patient at risk for hypoxia and ventricular dysrhythmias. Continuing the weaning process can lead to cardiopulmonary arrest.
8. These values help to determine if weaning is successful and should be continued.
9. Psychological dependence is a common problem after mechanical ventilation. Possible causes include fear of dying and depression from chronic illness. It is important to address this issue before the next weaning attempt.

are delivered at preset intervals and a preselected tidal volume, regardless of the patient's efforts. IMV allows patients to use their own muscles of ventilation to help prevent muscle atrophy. IMV lowers mean airway pressure, which can assist in preventing barotrauma.

Synchronized intermittent mandatory ventilation (SIMV) delivers a preset tidal volume and number of breaths per minute. Between ventilator-delivered breaths, the patient can breathe spontaneously with no assistance from the ventilator on those extra breaths. As the patient's ability to breathe spontaneously increases, the preset number of ventilator breaths is decreased and the patient does more of the work of breathing. SIMV is indicated if the patient satisfies all the criteria for weaning but cannot sustain adequate spontaneous ventilation for long periods.

IMV and SIMV can be used to provide full or partial ventilatory support. Nursing interventions for both of these include

monitoring progress by recording respiratory rate, minute volume, spontaneous and machine-generated tidal volume, FiO<sub>2</sub>, and arterial blood gas levels.

The **pressure support ventilation (PSV)** mode assists SIMV by applying a pressure plateau to the airway throughout the patient-triggered inspiration to decrease resistance by the tracheal tube and ventilator tubing. Pressure support is reduced gradually as the patient's strength increases. A SIMV backup rate may be added for extra support. The nurse must closely observe the patient's respiratory rate and tidal volumes on initiation of PSV. It may be necessary to adjust the pressure support to avoid tachypnea or large tidal volumes.

The proportional assist ventilation (PAV) mode of partial ventilatory support allows the ventilator to generate pressure in proportion to the patient's efforts. With every breath, the ventilator synchronizes with the patient's ventilatory efforts (Giannouli,

Webster, Roberts & Younes, 1999). Nursing assessment should include careful monitoring of the patient's respiratory rate, arterial blood gases, tidal volume, minute ventilation, and breathing pattern.

The continuous positive airway pressure (CPAP) mode allows the patient to breathe spontaneously, while applying positive pressure throughout the respiratory cycle to keep the alveoli open and promote oxygenation. Providing CPAP during spontaneous breathing also offers the advantage of an alarm system and may reduce patient anxiety if the patient has been taught that the machine is keeping track of breathing. It also maintains lung volumes and improves the patient's oxygenation status. CPAP is often used in conjunction with PSV. Nurses should carefully assess for tachypnea, tachycardia, reduced tidal volumes, decreasing oxygen saturations, and increasing carbon dioxide levels.

Weaning trials using a T-piece or tracheostomy mask (see Fig. 25-2) are normally conducted with the patient disconnected from the ventilator, receiving humidified oxygen only, and performing all work of breathing. Patients who do not have to overcome the resistance of the ventilator may find this mode more comfortable, or they may become anxious as they breathe with no support from the ventilator. During T-piece trials, the nurse monitors the patient closely and provides encouragement. This method of weaning is usually used when the patient is awake and alert, is breathing without difficulty, has good gag and cough reflexes, and is hemodynamically stable. During the weaning process, the patient is maintained on the same or a higher oxygen concentration than when on the ventilator. While on the T-piece, the patient should be observed for signs and symptoms of hypoxia, increasing respiratory muscle fatigue, or systemic fatigue. These include restlessness, increased respiratory rate greater than 35 breaths/min, use of accessory muscles, tachycardia with premature ventricular contractions, and paradoxical chest movement (asynchronous breathing, chest contraction during inspiration and expansion during expiration). Fatigue or exhaustion is initially manifested by an increased respiratory rate associated with a gradual reduction in tidal volume; later there is a slowing of the respiratory rate.

If the patient appears to be tolerating the T-piece trial, a second set of arterial blood gas measurements is drawn 20 minutes after the patient has been on spontaneous ventilation at a constant  $\text{FiO}_2$  pressure support ventilation. (Alveolar-arterial equilibrium takes 15 to 20 minutes to occur.)

Signs of exhaustion and hypoxia correlated with deterioration in the blood gas measurements indicate the need for ventilatory support. The patient is placed back on the ventilator each time signs of fatigue or deterioration develop.

If clinically stable, the patient usually can be extubated within 2 or 3 hours of weaning and allowed spontaneous ventilation by means of a mask with humidified oxygen. Patients who have had prolonged ventilatory assistance usually require more gradual weaning; it may take days or even weeks. They are weaned primarily during the day and placed back on the ventilator at night to rest.

Because patients respond in different manners to the various weaning methods, there is no definitive way to assess which method is best. With all of the methods, ongoing assessment of respiratory status is essential to monitor patient progress (Woodruff, 1999).

Successful weaning from the ventilator is supplemented by intensive pulmonary care. The following are continued:

- Oxygen therapy
- Arterial blood gas evaluation

- Pulse oximetry
- Bronchodilator therapy
- Chest physiotherapy
- Adequate nutrition, hydration, and humidification
- Incentive spirometry

These patients still have borderline pulmonary function and need vigorous supportive therapy before their respiratory status returns to a level that supports activities of daily living.

## Weaning From the Tube

Weaning from the tube is considered when the patient can breathe spontaneously, maintain an adequate airway by effectively coughing up secretions, swallow, and move the jaw. If frequent suctioning is needed to clear secretions, tube weaning may be unsuccessful (Ecklund, 1999). Secretion clearance and aspiration risks are assessed to determine if active pharyngeal and laryngeal reflexes are intact.

Once the patient can clear secretions adequately, a trial period of mouth breathing or nose breathing is conducted. This can be accomplished by several methods. The first method requires changing to a smaller size tube to increase the resistance to airflow and simultaneously plugging the tracheostomy tube (deflating the cuff). The smaller tube is sometimes replaced by a cuffless tracheostomy tube, which allows the tube to be plugged at lengthening intervals to monitor patient progress. A second method involves changing to a fenestrated tube (a tube with an opening or window in its bend). This permits air to flow around and through the tube to the upper airway and enables talking. A third method involves switching to a smaller tracheostomy button (stoma button). A tracheostomy button is a plastic tube approximately 1 inch long that helps to keep the windpipe open after the larger tracheostomy tube has been removed. Finally, when the patient demonstrates the ability to maintain a patent airway without a tracheostomy tube, the tube can be removed. An occlusive dressing is placed over the stoma, which usually heals anywhere from several days to many weeks (Ecklund, 1999).

## Weaning From Oxygen

The patient who has been successfully weaned from the ventilator, cuff, and tube and has adequate respiratory function is then weaned from oxygen. The  $\text{FiO}_2$  is gradually reduced until the  $\text{PaO}_2$  is in the range of 70 to 100 mm Hg while the patient is breathing room air. If the  $\text{PaO}_2$  is less than 70 mm Hg on room air, supplemental oxygen is recommended. The Centers for Medicare and Medicaid Services, formerly the Health Care Financing Administration (HCFA), requires that the patient's  $\text{PaO}_2$  on room air be less than 55 mm Hg for the patient to be eligible for financial reimbursement for in-home oxygen.

## Nutrition

Success in weaning the long-term ventilator-dependent patient requires early and aggressive but judicious nutritional support. The respiratory muscles (diaphragm and especially intercostals) become weak or atrophied after just a few days of mechanical ventilation, especially if nutrition is inadequate. Fat kilocalories produce less carbon dioxide than carbohydrate kilocalories. For this reason, a high-fat diet may assist patients with respiratory failure who are being weaned from mechanical ventilation. Research is being conducted on the role of fatty acids in lung disease (Schwartz,

2000). A high-fat diet may provide as much as 50% of the total daily kilocalories. Adequate protein intake is important in increasing respiratory muscle strength. Protein intake should be approximately 25% of total daily kilocalories, or 1.2 to 1.5 g/kg/day. Because a high-carbohydrate diet can lead to increased carbon dioxide production and retention, total carbohydrate intake should not exceed 25% of total daily kilocalories, or 2 g/kg/day in patients being weaned from mechanical ventilation. Care must be taken not to overfeed patients because excessive intake can raise the demand for oxygen and the production of carbon dioxide. Total daily kilocalories should be closely monitored (Lutz & Prytulski, 2001).

Soon after the patient is admitted, a consultation with a dietitian or nutrition support team should be arranged to plan the best form of nutritional replacement. Adequate nutrition may decrease the duration of mechanical ventilation and prevent other complications, especially sepsis. Sepsis can occur if bacteria enter the bloodstream and release toxins that, in turn, cause vasodilation and hypotension, fever, tachycardia, increased respiratory rate, and coma. Aggressive treatment of sepsis is essential to reverse this threat to survival and to promote weaning from the ventilator when the patient's condition improves. Optimal nutritional intake is an essential part of the treatment of sepsis.

## The Patient Undergoing Thoracic Surgery

Assessment and management are particularly important in the patient undergoing thoracic surgery. Frequently, patients undergoing such surgery also have obstructive pulmonary disease with compromised breathing. Preoperative preparation and careful postoperative management are crucial for successful patient outcomes because these patients may have a narrow range between their physical tolerance for certain activities and their limitations, which, if exceeded, can lead to distress. Various types of thoracic surgical procedures are performed to relieve disease conditions such as lung abscesses, lung cancer, cysts, and benign tumors (Chart 25-16). An exploratory **thoracotomy** (creation of a surgical opening into the thoracic cavity) may be performed to diagnose lung or chest disease. A biopsy may be performed in this procedure with a small amount of lung tissue removed for analysis; the chest incision is then closed.

The objectives of preoperative care for the patient undergoing thoracic surgery are to ascertain the patient's functional reserve to determine if the patient can survive the surgery and to ensure that the patient is in optimal condition for surgery.

## PREOPERATIVE MANAGEMENT

### Assessment and Diagnostic Findings

The nurse performs chest auscultation to assess breath sounds in the different regions of the lungs (see Chap. 21). It is important to note if breath sounds are normal, indicating a free flow of air in and out of the lungs. (In the patient with emphysema, the breath sounds may be markedly decreased or even absent on auscultation.) The nurse notes crackles and wheezes and assesses for hyperresonance and decreased diaphragmatic motion. Unilateral diminished breath sounds and rhonchi can be the result of occlusion of the bronchi by mucus plugs. The nurse assesses for retained secretions during auscultation by asking the patient to cough. It is important to note any signs of rhonchi or wheezing.

The patient history and assessment should include the following questions:

- What signs and symptoms are present (cough, sputum expectorated [amount and color], hemoptysis, chest pain, dyspnea)?
- If there is a smoking history, how long has the patient smoked? Does the patient smoke currently? How many packs a day?
- What is the patient's cardiopulmonary tolerance while resting, eating, bathing, and walking?
- What is the patient's breathing pattern? How much exertion is required to produce dyspnea?
- Does the patient need to sleep in an upright position or with more than two pillows?
- What is the patient's physiologic status (eg, general appearance, mental alertness, behavior, nutritional status)?
- What other medical conditions exist (eg, allergies, cardiac disorders, diabetes)?

A number of tests are performed to determine the patient's preoperative status and to assess the patient's physical assets and limitations. Many patients are seen by their surgeons in the office, and many tests and examinations are performed on an outpatient basis. The decision to perform any pulmonary resection is based on the patient's cardiovascular status and pulmonary reserve. Pulmonary function studies (especially lung volume and vital capacity) are performed to determine whether the planned resection will leave sufficient functioning lung tissue. Arterial blood gas values are assessed to provide a more complete picture of the functional capacity of the lung. Exercise tolerance tests are useful to determine if the patient who is a candidate for pneumonectomy can tolerate removal of one of the lungs.

Preoperative studies are performed to provide a baseline for comparison during the postoperative period and to detect any unsuspected abnormalities. These studies may include a bronchoscopic examination (a lighted scope is inserted into the airways to examine the bronchi), chest x-ray, electrocardiogram (for arteriosclerotic heart disease, conduction defects), nutritional assessment, determination of blood urea nitrogen and serum creatinine (renal function), glucose tolerance or blood glucose (diabetes), assessment of serum electrolytes and protein levels, blood volume determinations, and complete blood cell count.

## PREOPERATIVE NURSING MANAGEMENT

### Improving Airway Clearance

The underlying lung condition often is associated with increased respiratory secretions. Before surgery, the airway is cleared of secretions to reduce the possibility of postoperative atelectasis or infection. Risk factors for postoperative atelectasis and pneumonia are listed in Chart 25-17. Strategies to reduce the risk for atelectasis and infection include humidification, postural drainage, and chest percussion after bronchodilators are administered, if prescribed. The nurse estimates the volume of sputum if the patient expectorates large amounts of secretions. Such measurements are carried out to determine if and when the amount decreases. Antibiotics are administered as prescribed for infection, which may be causing the excessive secretions.

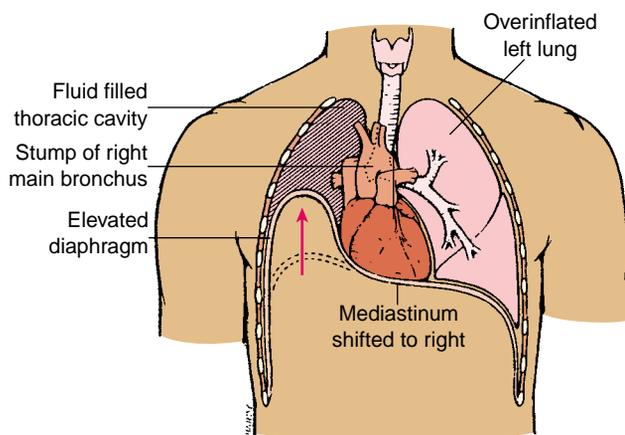

Chart  
25-16

## Thoracic Surgeries and Procedures

**Pneumonectomy**

The removal of an entire lung (pneumonectomy) is performed chiefly for cancer when the lesion cannot be removed by a less extensive procedure. It also may be performed for lung abscesses, bronchiectasis, or extensive unilateral tuberculosis. The removal of the right lung is more dangerous than the removal of the left, because the right lung has a larger vascular bed and its removal imposes a greater physiologic burden.

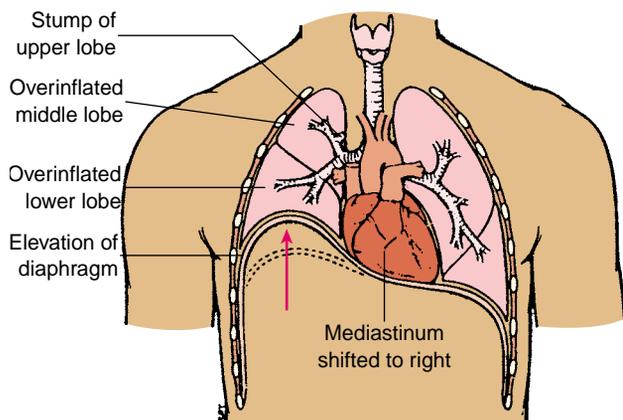

A posterolateral or anterolateral thoracotomy incision is made, sometimes with resection of a rib. The pulmonary artery and the pulmonary veins are ligated and severed. The main bronchus is divided and the lung removed. The bronchial stump is stapled, and usually no drains are used because the accumulation of fluid in the empty hemithorax prevents mediastinal shift.

Pneumonectomy

**Lobectomy**

When the pathology is limited to one area of a lung, a lobectomy (removal of a lobe of a lung) is performed. Lobectomy, which is more common than pneumonectomy, may be carried out for bronchogenic carcinoma, giant emphysematous blebs or bullae, benign tumors, metastatic malignant tumors, bronchiectasis, and fungus infections.

Lobectomy

The surgeon makes a thoracotomy incision: its exact location depends on the lobe to be resected. When the pleural space is entered, the involved lung collapses and the lobar vessels and the bronchus are ligated and divided. After the lobe is removed, the remaining lobes of the lung are reexpanded. Usually, two chest catheters are inserted for drainage. The upper tube is for air removal; the lower one is for fluid drainage. Sometimes, only one catheter is needed. The chest tube is connected to a chest drainage apparatus for several days.

**Segmentectomy (Segmental Resection)**

Some lesions are located in only one segment of the lung. Bronchopulmonary segments are subdivisions of the lung that function as individual units. They are held together by delicate connective tissue. Disease processes may be limited to a single segment. Care is used to preserve as much healthy and functional lung tissue as possible, especially in patients who already have limited cardiopulmonary reserve. Single segments can be removed from any lobe; the right middle lobe, which has only two small segments, invariably is removed entirely. On the left side, corresponding to a middle lobe, is a "lingular" segment of the upper lobe. This can be removed as a single segment or by lingulectomy. This segment frequently is involved in bronchiectasis.

**Wedge Resection**

A wedge resection of a small, well-circumscribed lesion may be performed without regard for the location of the intersegmental planes. The pleural cavity usually is drained because of the possibility of an air or blood leak. This procedure is performed for diagnostic lung biopsy and for the excision of small peripheral nodules.

**Bronchoplastic or Sleeve Resection**

Bronchoplastic resection is a procedure in which only one lobar bronchus, together with a part of the right or left bronchus, is excised. The distal bronchus is reanastomosed to the proximal bronchus or trachea.

**Lung Volume Reduction**

Lung volume reduction is a surgical procedure involving the removal of 20% to 30% of a patient's lung through a midsternal incision or video thoracoscopy. The diseased lung tissue is identified on a lung perfusion scan. Although some patients with chronic obstructive pulmonary disease have reported an improvement in the quality of their lives for at least 6 months to 1 year after the surgery, results have generally been disappointing. Research is ongoing to examine the benefits of lung volume reduction surgery using video thoracoscopy (Baker & Flynn, 1999; National Institutes of Health, 2001).

**Video Thoracoscopy**

A video thoracoscopy is an endoscopic procedure that allows the surgeon to look into the thorax without making a large incision. The procedure is performed to obtain specimens of tissue for biopsy, to treat recurrent spontaneous pneumothorax, and to diagnose either pleural effusions or pleural masses. Thoracoscopy has also been found to be an effective diagnostic and therapeutic alternative for the treatment of mediastinal disorders (Cirino et al., 2000). Some advantages of video thoracoscopy include rapid diagnosis and treatment of some conditions, a decrease in postoperative complications, and a shortened hospital stay (see Chap. 21).

Chart 25-17

### Risk Factors for Surgery-Related Atelectasis and Pneumonia

#### Preoperative Risk Factors

Increased age  
Obesity  
Poor nutritional status  
Smoking history  
Abnormal pulmonary function tests  
Preexisting lung disease  
Emergency surgery  
History of aspiration  
Comorbid states  
Preexisting disability

#### Intraoperative Risk Factors

Thoracic incision  
Prolonged anesthesia

#### Postoperative Risk Factors

Immobilization  
Supine position  
Decreased level of consciousness  
Inadequate pain management  
Prolonged intubation/mechanical ventilation  
Presence of nasogastric tube  
Inadequate preoperative education

- Take a deep diaphragmatic breath and exhale forcefully against your hand in a quick, distinct pant, or huff.
- Practice doing small huffs and progress to one strong huff during exhalation.

Patients should be informed preoperatively that blood and other fluids may be administered, oxygen will be administered, and vital signs will be checked often for several hours after surgery. If a chest tube is needed, the patient should be informed that it will drain the fluid and air that normally accumulate after chest surgery. The patient and family are informed that the patient may be admitted to the intensive care unit for 1 to 2 days after surgery, that the patient may experience pain at the incision site, and that medication is available to relieve pain and discomfort (Finkelmeier, 2000).

### Relieving Anxiety

The nurse listens to the patient to evaluate his or her feelings about the illness and proposed treatment. The nurse also determines the patient's motivation to return to normal or baseline function. The patient may reveal significant concerns: fear of hemorrhage because of bloody sputum, fear of discomfort from a chronic cough and chest pain, fear of ventilator dependence, or fear of death because of dyspnea and the underlying disease (eg, tumor).

The nurse helps the patient to overcome these fears and to cope with the stress of surgery by correcting any misconceptions, supporting the patient's decision to undergo surgery, reassuring the patient that the incision will "hold," and dealing honestly with questions about pain and discomfort and their treatment. The management and control of pain begin before surgery, when the nurse informs the patient that many postoperative problems can be overcome by following certain routines related to deep breathing, coughing, turning, and moving. If patient-controlled analgesia or epidural analgesia is to be used after surgery, the nurse instructs the patient in its use.

### Teaching the Patient

Increasingly, patients are admitted on the day of surgery, which does not provide much time for the acute care nurse to talk with the patient. Nurses in all settings must take an active role in educating the patient and relieving anxiety. The nurse informs the patient what to expect, from administration of anesthesia to thoracotomy and the likely use of chest tubes and a drainage system in the postoperative period. The patient is also informed about the usual postoperative administration of oxygen to facilitate breathing, and the possible use of a ventilator. It is essential to explain the importance of frequent turning to promote drainage of lung secretions. Instruction in the use of incentive spirometry begins before surgery to familiarize the patient with its correct use. The nurse should teach diaphragmatic and pursed-lip breathing, and the patient should begin practicing these techniques (see Chart 25-3, "Breathing Exercises," and Chart 25-4, "Assisting the Patient to Perform Incentive Spirometry").

Because a coughing schedule will be necessary in the postoperative period to promote the clearance or removal of secretions, the nurse instructs the patient in the technique of coughing and warns the patient that the coughing routine may be uncomfortable. The nurse teaches the patient to splint the incision with the hands, a pillow, or a folded towel (see Chart 25-5).

Another technique, "huffing," may be helpful for the patient with diminished expiratory flow rates or for the patient who refuses to cough because of severe pain. Huffing is the expulsion of air through an open glottis. This type of forced expiration technique (FET) stimulates pulmonary expansion and assists in alveolar inflation. The nurse instructs the patient as follows:

### POSTOPERATIVE MANAGEMENT

After surgery the vital signs are checked frequently. Oxygen is administered by a mechanical ventilator, nasal cannula, or mask for as long as necessary. A reduction in lung capacity requires a period of physiologic adjustment, and fluids may be given at a low hourly rate to prevent fluid overload and pulmonary edema. When the patient is conscious and the vital signs have stabilized, the head of the bed may be elevated 30 to 45 degrees. Careful positioning of the patient is important. Following pneumonectomy, a patient is usually turned every hour from the back to the operative side and should not be completely turned to the unoperated side. This allows the fluid left in the space to consolidate and prevents the remaining lung and the heart from shifting (mediastinal shift) toward the operative side. The patient with a lobectomy may be turned to either side, and a patient with a segmental resection usually is not turned onto the operative side unless the surgeon prescribes this position (Finkelmeier, 2000).

Medication for pain is needed for several days after surgery. Because coughing can be painful, patients should be taught to splint the chest. Exercises are resumed early in the postoperative

period to facilitate lung ventilation. The nurse assesses for signs of complications, including cyanosis, dyspnea, and acute chest pain. These may indicate atelectasis and should be reported immediately. Increased temperature or white blood cell count may indicate an infection, and pallor and increased pulse may indicate internal hemorrhage. Dressings should be assessed for fresh bleeding.

## Mechanical Ventilation

Depending on the nature of the surgery, the patient's underlying condition, the intraoperative course, and the depth of anesthesia, the patient may require mechanical ventilation after surgery. The physician is responsible for determining the ventilator settings and modes, as well as determining the overall method and pace of weaning. However, the physician, nurse, and respiratory therapist work together closely to assess the patient's tolerance and weaning progress. Early extubation from mechanical ventilation can also lead to earlier removal of arterial lines (Zevola & Maier, 1999).

## Chest Drainage

A crucial intervention for improving gas exchange and breathing in the postoperative period is the proper management of chest drainage and the **chest drainage system**. After thoracic surgery, chest tubes and a closed drainage system are used to re-expand the involved lung and to remove excess air, fluid, and blood. Chest

drainage systems also are used in treatment of spontaneous pneumothorax and trauma resulting in pneumothorax. Table 25-3 describes and compares the main features of these systems. Management of chest drainage systems is explained in Chart 25-18. Prevention of cardiopulmonary complications following thoracic surgery is discussed in Chart 25-19.

The normal breathing mechanism operates on the principle of negative pressure; that is, the pressure in the chest cavity normally is lower than the pressure of the atmosphere, causing air to move into the lungs during inspiration. Whenever the chest is opened, there is a loss of negative pressure, which can result in the collapse of the lung. The collection of air, fluid, or other substances in the chest can compromise cardiopulmonary function and can also cause the lung to collapse. Pathologic substances that collect in the pleural space include fibrin, or clotted blood; liquids (serous fluids, blood, pus, chyle); and gases (air from the lung, tracheobronchial tree, or esophagus).

Chest tubes may be inserted to drain fluid or air from any of the three compartments of the thorax (the right and left pleural spaces and the mediastinum). The pleural space, located between the visceral and parietal pleura, normally contains 20 mL or less of fluid, which helps to lubricate the visceral and parietal pleura. Surgical incision of the chest wall almost always causes some degree of pneumothorax (air accumulating in the pleural space) or hemothorax (build-up of serous fluid or blood in the pleural space). Air and fluid collect in the pleural space, restricting lung expansion and reducing gas exchange. Placement of a chest tube in the pleural space restores the negative intrathoracic pressure needed for lung re-expansion following surgery or trauma.

**Table 25-3 • Comparison of Chest Drainage Systems**

TYPES OF CHEST DRAINAGE SYSTEMS	DESCRIPTION	COMMENTS
<b>Traditional Water Seal</b> Also referred to as wet suction	Has 3 chambers: a collection chamber, water seal chamber (middle chamber), and wet suction control chamber	Requires that sterile fluid be instilled into water seal and suction chambers Has positive- and negative-pressure release valves Intermittent bubbling indicates that the system is functioning properly Additional suction can be added by connecting system to a suction source
<b>Dry Suction Water Seal</b> Also referred to as dry suction	Has 3 chambers: a collection chamber, water seal chamber (middle chamber), and wet suction control chamber	Requires that sterile fluid be instilled in water seal chamber at 2-cm level No need to fill suction chamber with fluid Suction pressure is set with a regulator Has positive- and negative-pressure release valves Has an indicator to signify that the suction pressure is adequate Quieter than traditional water seal systems
<b>Dry Suction</b> Also referred to as one-way valve system	Has a one-way mechanical valve that allows air to leave the chest and prevents air from moving back into the chest	No need to fill suction chamber with fluid; thus, can be set up quickly in an emergency Works even if knocked over, making it ideal for patients who are ambulatory

**NURSING INTERVENTIONS**

1. If using a chest drainage system with a water seal, fill the water seal chamber with sterile water to the level specified by the manufacturer.
2. When using suction in chest drainage systems with a water seal, fill the suction control chamber with sterile water to the 20-cm level or as prescribed. In systems without a water seal, set the regulator dial at the appropriate suction level.
3. Attach the drainage catheter exiting the thoracic cavity to the tubing coming from the collection chamber. Tape securely with adhesive tape.
4. If suction is used, connect the suction control chamber tubing to the suction unit. If using a wet suction system, turn on the suction unit and increase pressure until slow but steady bubbling appears in the suction control chamber. If using a chest drainage system with a dry suction control chamber, turn the regulator dial to 20 cm H<sub>2</sub>O.

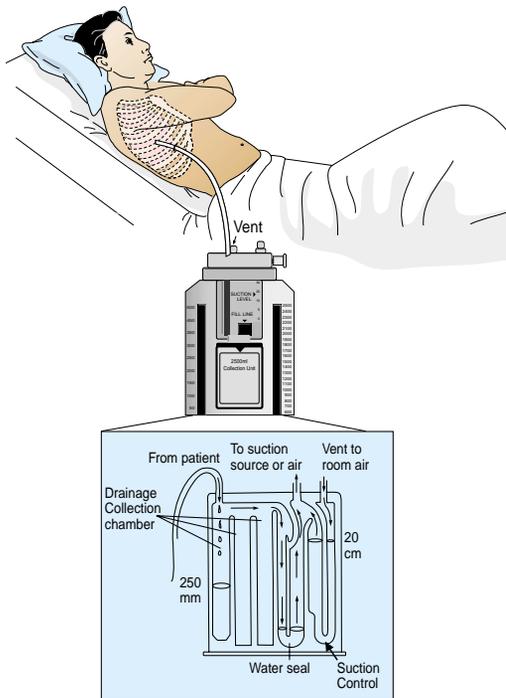

**RATIONALE**

Water seal drainage allows air and fluid to escape into a drainage chamber. The water acts as a seal and keeps the air from being drawn back into the pleural space. The water level regulator dial setting determines the degree of suction applied.

In chest drainage units, the system is closed. The only connection is the one to the patient's catheter.

With a wet suction system, the degree of suction is determined by the amount of water in the suction control chamber and is not dependent on the rate of bubbling or the pressure gauge setting on the suction unit.

With a dry suction control chamber, the regulator dial replaces the water.

Example of a disposable chest drainage system.

5. Mark the drainage from the collection chamber with tape on the outside of the drainage unit. Mark hourly/daily increments (date and time) at the drainage level.
6. Ensure that the drainage tubing does not kink, loop, or interfere with the patient's movements.
7. Encourage the patient to assume a comfortable position with good body alignment. With the lateral position, make sure that the patient's body does not compress the tubing. The patient should be turned and repositioned every 1.5 to 2 hours. Provide adequate analgesia.

This marking shows the amount of fluid loss and how fast fluid is collecting in the drainage chamber. It serves as a basis for determining the need for blood replacement, if the fluid is blood. Visibly bloody drainage will appear in the chamber in the immediate postoperative period but should gradually become serous. If the patient is bleeding as heavily as 100 mL every 15 minutes, check the drainage every few minutes. A reoperation or autotransfusion may be needed. The transfusion of blood collected in the drainage chamber must be reinfused within 4 to 6 hours. Usually, however, drainage decreases progressively in the first 24 hours.

Kinking, looping, or pressure on the drainage tubing can produce back-pressure, which may force fluid back into the pleural space or impede its drainage.

Frequent position changes promote drainage, and good body alignment helps prevent postural deformities and contractures. Proper positioning also helps breathing and promotes better air exchange. Analgesics may be needed to promote comfort.

*(continued)*

Chart 25-18

## GUIDELINES FOR Managing Chest Drainage Systems (Continued)

### NURSING INTERVENTIONS

8. Assist the patient with range-of-motion exercises for the affected arm and shoulder several times daily. Provide adequate analgesia.
9. Gently “milk” the tubing in the direction of the drainage chamber as needed.
10. Make sure there is fluctuation (“tidaling”) of the fluid level in the water seal chamber (in wet systems), or check the air leak indicator for leaks (in dry systems with a one-way valve). *Note:* Fluid fluctuations in the water seal chamber or air leak indicator area will stop when:
  - The lung has reexpanded
  - The tubing is obstructed by blood clots, fibrin, or kinks
  - A loop of tubing hangs below the rest of the tubing
  - Suction motor or wall suction is not working properly
11. With a dry system, assess for the presence of the indicator (bellows or float device) when setting the regulator dial to the desired level of suction.
12. Observe for air leaks in the drainage system; they are indicated by constant bubbling in the water seal chamber, or by the air leak indicator in dry systems with a one-way valve. Also assess the chest tube system for correctable external leaks. Notify the physician immediately of excessive bubbling in the water seal chamber not due to external leaks.
13. When turning down the dry suction, depress the manual high-negativity vent, and assess for a rise in the water level of the water seal chamber.
14. Observe and immediately report rapid and shallow breathing, cyanosis, pressure in the chest, subcutaneous emphysema, symptoms of hemorrhage, or significant changes in vital signs.
15. Encourage the patient to breathe deeply and cough at frequent intervals. Provide adequate analgesia. If needed, request an order for patient-controlled analgesia. Also teach the patient how to perform incentive spirometry.
16. If the patient is lying on a stretcher and must be transported to another area, place the drainage system below the chest level. If the tubing disconnects, cut off the contaminated tips of the chest tube and tubing, insert a sterile connector in the cut ends, and reattach to the drainage system. Do *not* clamp the chest tube during transport.
17. When assisting in the chest tube’s removal, instruct the patient to perform a gentle Valsalva maneuver or to breathe quietly. The chest tube is then clamped and quickly removed. Simultaneously, a small bandage is applied and made airtight with petrolatum gauze covered by a 4 × 4-inch gauze pad and thoroughly covered and sealed with nonporous tape.

### RATIONALE

- Exercise helps to prevent ankylosis of the shoulder and to reduce postoperative pain and discomfort. Analgesics may be needed to relieve pain.
- “Milking” prevents the tubing from becoming obstructed by clots and fibrin. Constant attention to maintaining the patency of the tube facilitates prompt expansion of the lung and minimizes complications.
- Fluctuation of the water level in the water seal shows effective connection between the pleural cavity and the drainage chamber and indicates that the drainage system remains patent. Fluctuation is also a gauge of intrapleural pressure in systems with a water seal (wet and dry, but not with the one-way valve).
- An air leak indicator shows changes in intrathoracic pressure in dry systems with a one-way valve. Bubbles will appear if a leak is present. The air leak indicator takes the place of fluid fluctuations in the water seal chamber.
- The indicator shows that the vacuum is adequate to maintain the desired level of suction.
- Leaking and trapping of air in the pleural space can result in tension pneumothorax.
- A rise in the water level of the water seal chamber indicates high negative pressure in the system that could lead to increased intrathoracic pressure.
- Many clinical conditions can cause these signs and symptoms, including tension pneumothorax, mediastinal shift, hemorrhage, severe incisional pain, pulmonary embolus, and cardiac tamponade. Surgical intervention may be necessary.
- Deep breathing and coughing help to raise the intrapleural pressure, which promotes drainage of accumulated fluid in the pleural space. Deep breathing and coughing also promote removal of secretions from the tracheobronchial tree, which in turn promotes lung expansion and prevents atelectasis (alveolar collapse).
- The drainage apparatus must be kept at a level lower than the patient’s chest to prevent fluid from flowing backward into the pleural space. Clamping can result in a tension pneumothorax.
- The chest tube is removed as directed when the lung is reexpanded (usually 24 hours to several days), depending on the cause of the pneumothorax. During tube removal, the chief priorities are preventing air from entering the pleural cavity as the tube is withdrawn and preventing infection.

The mediastinal space is an extrapleural space that lies between the right and left thoracic cavities. Mediastinal chest tubes promote the removal of blood or other fluid from around the heart (Finkelmeier, 2000). Accumulating fluid can stop the heart from beating if it is not drained. A mediastinal tube can be inserted either anteriorly or posteriorly to the heart to drain blood after surgery or trauma. Without a tube, compression of the heart could occur, leading to death (Carroll, 2000).

There are two types of chest tubes: small-bore and large-bore catheters. Small-bore catheters (7F to 12F) have a one-way valve apparatus to prevent air from moving back into the patient. They can be inserted through a small skin incision. Large-bore catheters,

which range in size up to 40F, are usually connected to a chest drainage system to collect any pleural fluid and monitor for air leaks (Scanlan, Wilkins & Stoller, 1999). After the chest tube is positioned, it is sutured to the skin and connected to a drainage apparatus to remove the residual air and fluid from the pleural or mediastinal space. This results in the re-expansion of remaining lung tissue.

### CHEST DRAINAGE SYSTEMS

Chest drainage systems have a suction source, a collection chamber for pleural drainage, and a mechanism to prevent air from reentering the chest with inhalation. Various types of

Chart  
25-19

## Preventing Postoperative Cardiopulmonary Complications After Thoracic Surgery

### Patient Management

- Auscultate lung sounds and assess for rate, rhythm, and depth.
- Monitor oxygenation with pulse oximetry.
- Monitor electrocardiogram for rate and rhythm changes.
- Assess capillary refill, skin color, and status of the surgical dressing.
- Encourage and assist the patient to turn, cough, and take deep breaths.

### Chest Drainage Management

- Verify that all connection tubes are patent and connected securely.
- Assess that the water seal is intact when using a wet suction system and assess the regulator dial in dry suction systems.
- Monitor characteristics of drainage including color, amount, and consistency. Assess for significant increases or decreases in drainage output.
- Note fluctuations in the water seal chamber for wet suction systems and the air leak indicator for dry suction systems.
- Keep system below the patient's chest level.
- Assess suction control chamber for bubbling in wet suction systems.
- Keep suction at level ordered.
- Maintain appropriate fluid in water seal for wet suction systems.
- Keep air vent open when suction is off.

chest drainage systems are available for use in removal of air and fluid from the pleural space and re-expansion of the lungs. Chest drainage systems come with either wet (water seal) or dry suction control. In wet suction systems, the amount of suction is determined by the amount of water instilled in the suction chamber. The amount of bubbling in the suction chamber indicates how strong the suction is. Wet systems use a water seal to prevent air from moving back into the chest on inspiration. Dry systems use a one-way valve and a suction control dial in place of the water needed with wet or water seal system. Both systems can operate by gravity drainage, without a suction source.

**Water Seal Chest Drainage Systems.** The traditional water seal chest drainage system (or wet suction) has three chambers: a collection chamber, a water seal chamber, and a wet suction control chamber. The collection chamber acts as a reservoir for fluid draining from the chest tube. It is graduated to permit easy measurement of drainage. Suction may be added to create negative pressure and promote drainage of fluid and removal of air. The suction control chamber regulates the amount of negative pressure applied to the chest. The amount of suction is determined by the water level. It is generally set at 20-cm water; adding more fluid results in more suction. After the suction is turned on, bubbling appears in the suction chamber. A positive-pressure valve is located at the top of the suction chamber that automatically opens with increases in positive pressure within the system. Air will automatically be released through a positive-pressure relief valve if the suction tubing is inadvertently clamped or kinked.

The water seal chamber has a one-way valve or water seal that prevents air from moving back into the chest when the patient in-

hales. There will be an increase in the water level with inspiration and a return to the baseline level during exhalation; this is referred to as tidaling. Intermittent bubbling in the water seal chamber is normal, but continuous bubbling can indicate an air leak. Bubbling and tidaling do not occur when the tube is placed in the mediastinal space; however, fluid may pulsate with the patient's heartbeat. If the chest tube is connected to gravity drainage only, suction is not used. The pressure is equal to the water seal only. Two-chamber chest drainage systems (water seal chamber and collection chamber) are available for use with patients who need only gravity drainage.

The water level in the water seal chamber reflects the negative pressure present in the intrathoracic cavity. A rise in the water level indicates negative pressure in the pleural or mediastinal space. Excessive negative pressure can cause trauma to tissue (Bar-El, Ross, Kablawi & Egenburg, 2001). Most chest drainage systems have an automatic means to prevent excessive negative pressure. By pressing and holding a manual high-negativity vent (usually located on the top of the chest drainage system) until the water level in the water seal chamber returns to the 2-cm mark, excessive negative pressure is avoided, preventing damage to tissue.

**NURSING ALERT** When the wall vacuum is turned off, the drainage system must be open to the atmosphere so that intrapleural air can escape from the system. This can be done by detaching the tubing from the suction port to provide a vent.

**NURSING ALERT** If the chest tube and drainage system become disconnected, air can enter the pleural space, producing a pneumothorax. To prevent pneumothorax if the chest tube is inadvertently disconnected from the drainage system, a temporary water seal can be established by immersing the chest tube's open end in a bottle of sterile water.

**Dry Suction Water Seal Systems.** Dry suction water seal systems, also referred to as dry suction, have a collection chamber for drainage, a water seal chamber, and a dry suction control chamber. The water seal chamber is filled with water to the 2-cm level. Bubbling in this area can indicate an air leak. The dry suction control chamber contains a regulator dial that conveniently regulates vacuum to the chest drain. Water is not needed for suction as it is in the wet system. Without the bubbling in the suction chamber, the machine is quieter.

Once the tube is connected to the suction source, the regulator dial allows the desired level of suction to be dialed in; the suction is increased until an indicator appears. The indicator has the same function as the bubbling in the traditional water seal system; that is, it indicates that the vacuum is adequate to maintain the desired level of suction. Some drainage systems use a bellows (a chamber that can be expanded or contracted) or an orange-colored float device as an indicator of when the suction control regulator is set.

When the water in the water seal rises above the 2-cm level, intrathoracic pressure increases. Dry suction water seal systems have a manual high-negativity vent located on top of the drain. Pressing the manual high-negativity vent until the indicator appears (either a float device or bellows) and the water level in the water seal returns to the desired level, intrathoracic pressure is decreased.

**NURSING ALERT** The manual vent should not be used to lower the water level in the water seal when the patient is on gravity drainage (no suction) because intrathoracic pressure is equal to the pressure in the water seal.

**Dry Suction with a One-Way Valve System.** A third type of chest drainage system is dry suction with a one-way mechanical valve. This system has a collection chamber, a one-way mechanical valve, and a dry suction control chamber. The valve acts in the same way as a water seal and permits air to leave the chest but prevents it from moving back into the pleural space. This model lacks a water seal chamber and therefore has the advantage of a system that operates without water. For example, it can be set up quickly in emergency situations, and the dry control drain will still work even if it is knocked over. If the wet suction drain is knocked over, the water seal could be lost. This makes the dry suction systems useful for the patient who is ambulating or being transported. However, without the water seal chamber, there is no way to tell by inspection if the pressure in the chest has changed. An air leak indicator is present so that the system can be checked for air leaks. If an air leak is suspected, 30 mL of water are injected into the air leak indicator. Bubbles will appear if a leak is present (Carroll, 2000).

## NURSING PROCESS: THE PATIENT UNDERGOING THORACIC SURGERY

### Postoperative Assessment

The nurse monitors the heart rate and rhythm by auscultation and electrocardiography because episodes of major dysrhythmias are common after thoracic and cardiac surgery. In the immediate postoperative period, an arterial line may be maintained to allow frequent monitoring of arterial blood gases, serum electrolytes, hemoglobin and hematocrit values, and arterial pressure. Central venous pressure may be monitored to detect early signs of fluid volume disturbances. Central venous pressure monitoring devices are being used less frequently and for shorter periods of time than in the past. Early extubation from mechanical ventilation can also lead to earlier removal of arterial lines (Zevola & Maier, 1999). Another important component of postoperative assessment is to note the results of the preoperative evaluation of the patient's lung reserve by pulmonary function testing. A preoperative FEV<sub>1</sub> of more than 2 L or more than 70% of predicted value indicates a good lung reserve. Patients who have a postoperative predicted FEV<sub>1</sub> of less than 40% of predicted value have a higher incidence of morbidity and mortality (Scanlan, Wilkins & Stoller, 1999). This results in decreased tidal volumes, placing the patient at risk for respiratory failure.

### Diagnosis

#### NURSING DIAGNOSES

Based on the assessment data, the patient's major postoperative nursing diagnoses may include:

- Impaired gas exchange related to lung impairment and surgery
- Ineffective airway clearance related to lung impairment, anesthesia, and pain
- Acute pain related to incision, drainage tubes, and the surgical procedure

- Impaired physical mobility of the upper extremities related to thoracic surgery
- Risk for imbalanced fluid volume related to the surgical procedure
- Imbalanced nutrition, less than body requirements related to dyspnea and anorexia
- Deficient knowledge about self-care procedures at home

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on assessment data, potential complications may include:

- Respiratory distress
- Dysrhythmias
- Atelectasis, pneumothorax, and bronchopleural fistula
- Blood loss and hemorrhage
- Pulmonary edema

### Planning and Goals

The major goals for the patient may include improvement of gas exchange and breathing, improvement of airway clearance, relief of pain and discomfort, increased arm and shoulder mobility, maintenance of adequate fluid volume and nutritional status, understanding of self-care procedures, and absence of complications.

### Nursing Interventions

#### IMPROVING GAS EXCHANGE AND BREATHING

Gas exchange is determined by evaluating oxygenation and ventilation. In the immediate postoperative period, this is achieved by measuring vital signs (blood pressure, pulse, and respirations) at least every 15 minutes for the first 1 to 2 hours, then less frequently as the patient's condition stabilizes.

Pulse oximetry is used for continuous monitoring of the adequacy of oxygenation. It is important to draw blood for arterial blood gas measurements early in the postoperative period to establish a baseline to assess the adequacy of oxygenation and ventilation and the possible retention of CO<sub>2</sub>. The frequency with which postoperative arterial blood gases are measured depends on whether the patient is mechanically ventilated or exhibits signs of respiratory distress; these measurements can help determine appropriate therapy. It also is common practice for patients to have an arterial line in place to obtain blood for blood gas measurements and to monitor blood pressure closely. Hemodynamic monitoring may be used to assess hemodynamic stability.

Breathing techniques, such as diaphragmatic and pursed-lip breathing, that were taught before surgery should be performed by the patient every 2 hours to expand the alveoli and prevent atelectasis. Another technique to improve ventilation is sustained maximal inspiration therapy or incentive spirometry. This technique promotes lung inflation, improves the cough mechanism, and allows early assessment of acute pulmonary changes. (See Charts 25-3 and 25-4 for more information.)

Positioning also improves breathing. When the patient is oriented and blood pressure is stabilized, the head of the bed is elevated 30 to 40 degrees during the immediate postoperative period. This facilitates ventilation, promotes chest drainage from the lower chest tube, and helps residual air to rise in the upper portion of the pleural space, where it can be removed through the upper chest tube.

The nurse should consult with the surgeon about patient positioning. There is controversy regarding the best side-lying position. In general, the patient should be positioned from back to

side frequently and moved from horizontal to semi-upright position as soon as tolerated. Most commonly, the patient is instructed to lie on the operative side. However, the patient with unilateral lung pathology may not be able to turn well onto that side because of pain. In addition, positioning the patient with the “good lung” (the nonoperated lung) down allows a better match of ventilation and perfusion and therefore may actually improve oxygenation. The patient’s position is changed from horizontal to semi-upright as soon as possible, because remaining in one position tends to promote the retention of secretions in the dependent portion of the lungs. After a pneumonectomy, the operated side should be dependent so that fluid in the pleural space remains below the level of the bronchial stump, and the other lung can fully expand.

The procedure for turning the patient is as follows:

- Instruct the patient to bend the knees and use the feet to push.
- Have the patient shift hips and shoulders to the opposite side of the bed while pushing with the feet.
- Bring the patient’s arm over the chest, pointing it in the direction toward which the patient is being turned. Have the patient grasp the side rail with the hand.
- Turn the patient in log-roll fashion to prevent twisting at the waist and pain from possible pulling on the incision.

### IMPROVING AIRWAY CLEARANCE

Retained secretions are a threat to the thoracotomy patient after surgery. Trauma to the tracheobronchial tree during surgery, diminished lung ventilation, and diminished cough reflex all result in the accumulation of excessive secretions. If the secretions are retained, airway obstruction occurs. This, in turn, causes the air in the alveoli distal to the obstruction to become absorbed and the affected portion of the lung to collapse. Atelectasis, pneumonia, and respiratory failure may result.

Several techniques are used to maintain a patent airway. First, secretions are suctioned from the tracheobronchial tree before the endotracheal tube is discontinued. Secretions continue to be removed by suctioning until the patient can cough up secretions effectively. Nasotracheal suctioning may be needed to stimulate a deep cough and aspirate secretions that the patient cannot cough up. However, it should be used only after other methods to raise secretions have been unsuccessful (Chart 25-20).

Coughing technique is another measure used in maintaining a patent airway. The patient is encouraged to cough effectively; ineffective coughing results in exhaustion and retention of secretions (see Chart 25-5). To be effective, the cough must be low-pitched, deep, and controlled. Because it is difficult to cough in a supine position, the patient is helped to a sitting position on the edge of the bed, with the feet resting on a chair. The patient should cough at least every hour during the first 24 hours and when necessary thereafter. If audible crackles are present, it may be necessary to use chest percussion with the cough routine until the lungs are clear. Aerosol therapy is helpful in humidifying and mobilizing secretions so that they can easily be cleared with coughing. To minimize incisional pain during coughing, the nurse supports the incision or encourages the patient to do so (Fig. 25-8).

After helping the patient to cough, the nurse should listen to both lungs, anteriorly and posteriorly, to determine whether there are any changes in breath sounds. Diminished breath sounds may indicate collapsed or hypoventilated alveoli.

Chart  
25-20

## Performing Nasotracheal Suction

### Sterile Technique to Be Used

1. Explain procedure to the patient.
2. Medicate patient for pain if necessary.
3. Place the patient in a sitting or semi-Fowler’s position. Make sure the patient’s head is not flexed forward. Remove excess pillows if necessary.
4. Oxygenate the patient several minutes before initiating the suctioning procedure. Have oxygen source ready nearby during procedure.
5. Put on sterile gloves.
6. Lubricate catheter with water-soluble gel.
7. Gently pass catheter through the patient’s nose to the pharynx. If it is difficult to pass the catheter, and repeated suctioning is expected, a soft rubber nasal trumpet may be placed nasopharyngeally to provide easier catheter passage. Check the position of the tip of the catheter by asking the patient to open the mouth and inspecting it; the tip of the catheter should be in the lower pharynx.
8. Instruct the patient to take a deep breath or stick out the tongue. This action opens the epiglottis and promotes downward movement of the catheter.
9. Advance the catheter into the trachea only during inspiration. Listen for cough or for passage of air through the catheter.
10. Attach the catheter to suction apparatus. Apply intermittent suction while slowly withdrawing the catheter. Do not let suction exceed 120 mm Hg.
11. Do not suction for longer than 10 to 15 seconds, as dysrhythmias, bradycardia, or cardiac arrest may occur in patients with borderline oxygenation.
12. If additional suctioning is needed, withdraw the catheter to the back of the pharynx. Reassure patient and oxygenate for several minutes before resuming suctioning.

Chest physiotherapy is the final technique for maintaining a patent airway. If a patient is identified as being at high risk for developing postoperative pulmonary complications, then chest physiotherapy is started immediately (perhaps even before surgery). The techniques of postural drainage, vibration, and percussion help to loosen and mobilize the secretions so that they can be coughed up or suctioned.

### RELIEVING PAIN AND DISCOMFORT

Pain after a thoracotomy may be severe, depending on the type of incision and the patient’s reaction to and ability to cope with pain. Deep inspiration is very painful after thoracotomy. Pain can lead to postoperative complications if it reduces the patient’s ability to breathe deeply and cough, and if it further limits chest excursions so that ventilation becomes ineffective.

Immediately after the surgical procedure and before the incision is closed, the surgeon may perform a nerve block with a long-acting local anesthetic such as bupivacaine (Marcaine, Sensorcaine). Bupivacaine is titrated to relieve postoperative pain while allowing the patient to cooperate in deep breathing, coughing, and mobilization. However, it is important to avoid depressing the respiratory system with excessive analgesia: the patient should not be so sedated as to be unable to cough. There is controversy about the effectiveness of injections of local anesthetic for pain relief after thoracotomy surgery. Research has shown that bupivacaine was no

A The nurse's hands should support the chest incision anteriorly and posteriorly. The patient is instructed to take several deep breaths, inhale, and then cough forcibly.

B With one hand, the nurse exerts downward pressure on the shoulder of the affected side while firmly supporting the area beneath the wound with the other hand. The patient is instructed to take several deep breaths, inhale, and then cough forcibly.

C The nurse can wrap a towel or sheet around the patient's chest and hold the ends together, pulling slightly as the patient coughs, and releasing during deep breaths.

D The patient can be taught to hold a pillow firmly against the incision while coughing. This can be done while lying down or sitting in an upright position.

**FIGURE 25-8** Techniques for supporting incision while a patient recovering from thoracic surgery coughs.

more effective than saline injections in treating postoperative thoracotomy pain (Silomon et al., 2000).

Lidocaine and prilocaine are local anesthetic agents used to treat pain at the site of the chest tube insertion. These medications are administered as topical transdermal analgesics that penetrate the skin. Lidocaine and prilocaine have also been found to be effective when used together. EMLA cream, which is a mixture of the two medications, has been found to be effective in treating pain from chest tube removal, and recent studies found it to be more effective than intravenous morphine (Valenzuela & Rosen, 1999).

Because of the need to maximize patient comfort without depressing the respiratory drive, patient-controlled analgesia (PCA) is often used. Opioid analgesic agents such as morphine are commonly used. PCA, administered through an intravenous pump or an epidural catheter, allows the patient to control the frequency and total dosage. Preset limits on the pump avoid overdose. With proper instruction, these methods are well tolerated and allow earlier mobilization and cooperation with the treatment regimen. (See Chap. 13 for a more extensive discussion of PCA and pain management.)

**NURSING ALERT** It is important not to confuse the restlessness of hypoxia with the restlessness caused by pain. Dyspnea, restlessness, increasing respiratory rate, increasing blood pressure, and tachycardia are warning signs of impending respiratory insufficiency. Pulse oximetry is used to monitor oxygenation and to differentiate causes of restlessness.

## PROMOTING MOBILITY AND SHOULDER EXERCISES

Because large shoulder girdle muscles are transected during a thoracotomy, the arm and shoulder must be mobilized by full range of motion of the shoulder. As soon as physiologically possible, usually within 8 to 12 hours, the patient is helped to get out of bed. Although this may be painful initially, the earlier the patient moves, the sooner the pain will subside. In addition to getting out of bed, the patient begins arm and shoulder exercises to restore movement and prevent painful stiffening of the affected arm and shoulder (Chart 25-21).

## MAINTAINING FLUID VOLUME AND NUTRITION

### Intravenous Therapy

During the surgical procedure or immediately after, the patient may receive a transfusion of blood products, followed by a continuous intravenous infusion. Because a reduction in lung capacity often occurs following thoracic surgery, a period of physiologic adjustment is needed. Fluids should be administered at a low hourly rate and titrated (as prescribed) to prevent overloading the vascular system and precipitating pulmonary edema. The nurse performs careful respiratory and cardiovascular assessments, as well as intake and output, vital signs, and assessment of jugular vein distention. The nurse should also monitor the infusion site for signs of infiltration, including swelling, tenderness, and redness.

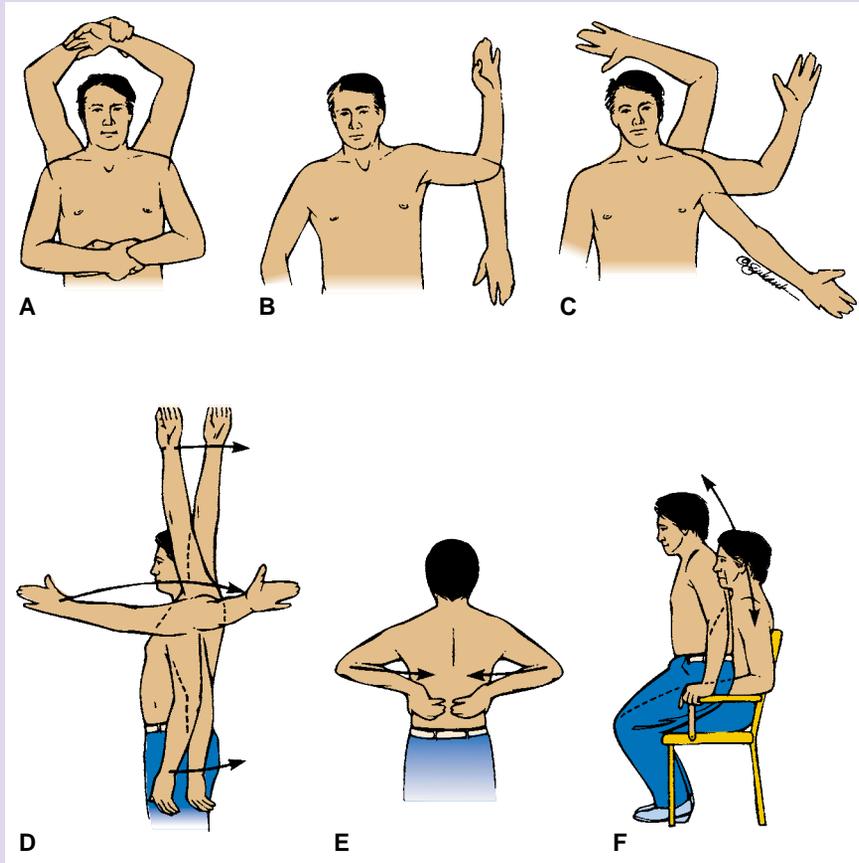

### Diet

It is not unusual for patients undergoing thoracotomy to have poor nutritional status before surgery because of dyspnea, sputum production, and poor appetite. Therefore, it is especially important

### Chart 25-21 • PATIENT EDUCATION Performing Arm and Shoulder Exercises

Arm and shoulder exercises are performed after thoracic surgery to restore movement, prevent painful stiffening of the shoulder, and improve muscle power.

(A) Hold hand of the affected side with the other hand, palms facing in. Raise the arms forward, upward, and then overhead, while taking a deep breath. Exhale while lowering the arms. Repeat five times. (B) Raise arm sideward, upward, and downward in a waving motion. (C) Place arm at side. Raise arm sideward, upward, and over the head. Repeat five times. These exercises can also be performed while lying in bed. (D) Extend the arm up and back, out to the side and back, down at the side and back. (E) Place hands in small of back. Push elbows as far back as possible. (F) Sit erect in an armchair; place the hands on the arms of the chair directly opposite the sides of the body. Press down on hands, consciously pulling the abdomen in and stretching up from the waist. Inhale while raising the body until the elbows are extended completely. Hold this position a moment, and begin exhaling while lowering the body slowly to the original position.

that adequate nutrition be provided. A liquid diet is provided as soon as bowel sounds return; the patient is progressed to a full diet as soon as possible. Small, frequent meals are better tolerated and are crucial to the recovery and maintenance of lung function.

#### MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Complications after thoracic surgery are always a possibility and must be identified and managed early. In addition, the nurse monitors the patient at regular intervals for signs of respiratory distress or developing respiratory failure, dysrhythmias, bronchopleural fistula, hemorrhage and shock, atelectasis, and pulmonary infection.

Respiratory distress is treated by identifying and eliminating its cause while providing supplemental oxygen. If the patient progresses to respiratory failure, intubation and mechanical ventilation are necessary, eventually requiring weaning.

Dysrhythmias are often related to the effects of hypoxia or the surgical procedure. They are treated with antiarrhythmic medication and supportive therapy (see Chap. 27). Pulmonary infec-

tions or effusion, often preceded by atelectasis, may occur a few days into the postoperative course.

Pneumothorax may occur following thoracic surgery if there is an air leak from the surgical site to the pleural cavity or from the pleural cavity to the environment. Failure of the chest drainage system will prevent return of negative pressure in the pleural cavity and result in pneumothorax. In the postoperative patient pneumothorax is often accompanied by hemothorax. The nurse maintains the chest drainage system and monitors the patient for signs and symptoms of pneumothorax: increasing shortness of breath, tachycardia, increased respiratory rate, and increasing respiratory distress.

Bronchopleural fistula is a serious but rare complication preventing the return of negative intrathoracic pressure and lung re-expansion. Depending on its severity, it is treated with closed chest drainage, mechanical ventilation, and possibly talc pleurodesis (described in Chap. 23).

Hemorrhage and shock are managed by treating the underlying cause, whether by reoperation or by administration of blood products or fluids. Pulmonary edema from overinfusion of intravenous fluids is a significant danger. The early symptoms are dys-

plea, crackles, bubbling sounds in the chest, tachycardia, and pink, frothy sputum. This constitutes an emergency and must be reported and treated immediately.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

The nurse instructs the patient and family about postoperative care that will be continued at home. The nurse explains signs and symptoms that should be reported to the physician. These include:

- Change in respiratory status: increasing shortness of breath, fever, increased restlessness or other changes in mental or cognitive status, increased respiratory rate, change in respiratory pattern, change in amount or color of sputum
- Bleeding or other drainage from the surgical incision or chest tube exit sites
- Increased chest pain

In addition, respiratory care and other treatment modalities (oxygen, incentive spirometer, chest physiotherapy, and oral, inhaled, or intravenous medications) may be continued at home. Therefore, the nurse needs to instruct the patient and family in their correct and safe use.

The nurse emphasizes the importance of progressively increased activity. The nurse instructs the patient to ambulate within limits and explains that return of strength is likely to be very gradual. Another important aspect of patient teaching addresses shoulder exercises. It is important to instruct the patient to do these exercises five times daily. Additional patient teaching is described in Chart 25-22.

### Continuing Care

Depending on the patient's physical status and the availability of family assistance, a home care referral may be indicated. The home care nurse assesses the patient's recovery from surgery, with special attention to respiratory status, the surgical incision, chest drainage, pain control, ambulation, and nutritional status. The patient's use of respiratory modalities should be assessed to ensure they are being used correctly and safely. In addition, the nurse assesses the patient's compliance with the

postoperative treatment plan and identifies acute or late postoperative complications.

The recovery process may be longer than the patient had expected, and providing support to the patient is an important task for the home care nurse. Because of shorter hospital stays, attending follow-up physician appointments is essential. The nurse teaches the patient about the importance of keeping follow-up appointments and completing laboratory tests as prescribed to assist the physician in evaluating recovery. The home care nurse provides continuous encouragement and education to the patient and family during the process. As recovery progresses, the nurse also reminds the patient and family about the importance of participating in health promotion activities and recommended health screening.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Demonstrates improved gas exchange, as reflected in arterial blood gas measurements, breathing exercises, and use of incentive spirometry
2. Shows improved airway clearance, as evidenced by deep, controlled coughing and clear breath sounds or decreased presence of adventitious sounds
3. Has decreased pain and discomfort by splinting incision during coughing and increasing activity level
4. Shows improved mobility of shoulder and arm; demonstrates arm and shoulder exercises to relieve stiffening
5. Maintains adequate fluid intake and maintains nutrition for healing
6. Exhibits less anxiety by using appropriate coping skills, and demonstrates a basic understanding of technology used in care
7. Adheres to therapeutic program and home care
8. Is free of complications, as evidenced by normal vital signs and temperature, improved arterial blood gas measurements, clear lung sounds, and adequate respiratory function

For a detailed plan of nursing care for the patient who has had a thoracotomy, see the Plan of Nursing Care.

Chart 25-22

### Home Care Checklist • The Patient With a Thoracotomy

*At the completion of the home care instruction, the patient or caregiver will be able to:*

	Patient	Caregiver
• Use local heat and oral analgesia to relieve intercostal pain.	✓	✓
• Alternate walking and other activities with frequent rest periods, expecting weakness and fatigue for the first 3 weeks.	✓	✓
• Perform breathing exercises several times daily for the first few weeks at home.	✓	
• Avoid lifting more than 20 pounds until complete healing has taken place; the chest muscles and incision may be weaker than normal for 3 to 6 months after surgery.	✓	
• Walk at a moderate pace, gradually and persistently extending walking time and distance.	✓	
• Immediately stop any activity that causes undue fatigue, increased shortness of breath, or chest pain.	✓	
• Avoid bronchial irritants (smoke, fumes, air pollution, aerosol sprays).	✓	✓
• Avoid others with known colds or lung infections.	✓	✓
• Obtain an annual influenza vaccine and discuss vaccination against pneumonia with the physician.	✓	
• Report for follow-up care by the surgeon or clinic as necessary.	✓	✓
• Stop smoking, if applicable.	✓	✓

## Plan of Nursing Care

### Care of the Patient After Thoracotomy

#### Nursing Interventions

#### Rationale

#### Expected Patient Outcomes

**Nursing Diagnosis:** Impaired gas exchange related to lung impairment and surgery

**Goal:** Improvement of gas exchange and breathing

<ol style="list-style-type: none"> <li>1. Monitor pulmonary status as directed and as needed:               <ol style="list-style-type: none"> <li>a. Auscultate breath sounds.</li> <li>b. Check rate, depth, and pattern of respirations.</li> <li>c. Assess blood gases for signs of hypoxemia or CO<sub>2</sub> retention.</li> <li>d. Evaluate patient's color for cyanosis.</li> </ol> </li> <li>2. Monitor and record blood pressure, apical pulse, and temperature every 2–4 hours, central venous pressure (if indicated) every 2 hours.</li> <li>3. Monitor continuous electrocardiogram for pattern and dysrhythmias.</li> <li>4. Elevate head of bed 30–40 degrees when patient is oriented and hemodynamic status is stable.</li> <li>5. Encourage deep-breathing exercises (see section on Breathing Retraining) and effective use of incentive spirometer (sustained maximal inspiration).</li> <li>6. Encourage and promote an effective cough routine to be performed every 1–2 hours during first 24 hours.</li> <li>7. Assess and monitor the chest drainage system:*               <ol style="list-style-type: none"> <li>a. Assess for leaks and patency as needed.</li> <li>b. Monitor amount and character of drainage and document every 2 hours. Notify physician if drainage is 150 mL/h or greater.</li> <li>c. See Chart 25-18 for summary of nurse's role in management of chest drainage systems.</li> </ol> </li> </ol>	<ol style="list-style-type: none"> <li>1. Changes in pulmonary status indicate improvement or onset of complications.</li> <li>2. Aid in evaluating effect of surgery on cardiac status.</li> <li>3. Dysrhythmias (especially atrial fibrillation and atrial flutter) are more frequently seen after thoracic surgery. A patient with total pneumonectomy is especially prone to cardiac irregularity.</li> <li>4. Maximum lung excursion is achieved when patient is as close to upright as possible.</li> <li>5. Helps to achieve maximal lung inflation and to open closed airways.</li> <li>6. Coughing is necessary to remove retained secretions.</li> <li>7. System is used to eliminate any residual air or fluid after thoracotomy.</li> </ol>	<ul style="list-style-type: none"> <li>• Lungs are clear on auscultation</li> <li>• Respiratory rate is within acceptable range with no episodes of dyspnea</li> <li>• Vital signs are stable</li> <li>• Dysrhythmias are not present or are under control</li> <li>• Demonstrates deep, controlled, effective breathing to allow maximal lung expansion</li> <li>• Uses incentive spirometer every 2 hours while awake</li> <li>• Demonstrates deep, effective coughing technique</li> <li>• Lungs are expanded to capacity (evidenced by chest x-ray)</li> </ul>
--	---	--

**Nursing Diagnosis:** Ineffective airway clearance related to lung impairment, anesthesia, and pain

**Goal:** Improvement of airway clearance and achievement of a patent airway

<ol style="list-style-type: none"> <li>1. Maintain an open airway.</li> <li>2. Perform endotracheal suctioning until patient can raise secretions effectively.</li> <li>3. Assess and medicate for pain. Encourage deep-breathing and coughing exercises. Help splint incision during coughing.</li> </ol>	<ol style="list-style-type: none"> <li>1. Provides for adequate ventilation and gas exchange</li> <li>2. Endotracheal secretions are present in excessive amounts in post-thoracotomy patients due to trauma to the tracheo-bronchial tree during surgery, diminished lung ventilation, and cough reflex.</li> <li>3. Helps to achieve maximal lung inflation and to open closed airways. Coughing is painful; incision needs to be supported.</li> </ol>	<ul style="list-style-type: none"> <li>• Airway is patent</li> <li>• Coughs effectively</li> <li>• Splints incision while coughing</li> <li>• Sputum is clear or colorless</li> <li>• Lungs are clear on auscultation</li> </ul>
--	---	--

\*A patient with a pneumonectomy usually does not have water seal chest drainage because it is desirable that the pleural space fill with an effusion, which eventually obliterates this space. Some surgeons do use a modified water seal system.

(continued)

## Plan of Nursing Care

### Care of the Patient After Thoracotomy (Continued)

Nursing Interventions	Rationale	Expected Patient Outcomes
4. Monitor amount, viscosity, color, and odor of sputum. Notify physician if sputum is excessive or contains bright-red blood.	4. Changes in sputum suggest presence of infection or change in pulmonary status. Colorless sputum is not unusual; opacification or coloring of sputum may indicate dehydration or infection.	
5. Administer humidification and mini-nebulizer therapy as prescribed.	5. Secretions must be moistened and thinned if they are to be raised from the chest with the least amount of effort.	
6. Perform postural drainage, percussion, and vibration as prescribed. Do not percuss or vibrate directly over operative site.	6. Chest physiotherapy uses gravity to help remove secretions from the lung.	
7. Auscultate both sides of chest to determine changes in breath sounds.	7. Indications for tracheal suctioning are determined by chest auscultation.	

**Nursing Diagnosis:** Acute pain related to incision, drainage tubes, and the surgical procedure

**Goal:** Relief of pain and discomfort

1. Evaluate location, character, quality, and severity of pain. Administer analgesic medication as prescribed and as needed. Observe for respiratory effect of opioid. Is patient too somnolent to cough? Are respirations depressed?	1. Pain limits chest excursions and thereby decreases ventilation.	<ul style="list-style-type: none"> <li>Asks for pain medication, but verbalizes that he or she expects some discomfort while deep breathing and coughing</li> <li>Verbalizes that he or she is comfortable and not in acute distress</li> <li>No signs of incisional infection evident</li> </ul>
2. Maintain care postoperatively in positioning the thoracotomy patient: <ol style="list-style-type: none"> <li>Place patient in semi-Fowler's position.</li> <li>Patients with limited respiratory reserve may not be able to turn on unoperated side.</li> <li>Assist or turn patient every 2 hours.</li> </ol>	2. The patient who is comfortable and free of pain will be less likely to splint the chest while breathing. A semi-Fowler's position permits residual air in the pleural space to rise to upper portion of pleural space and be removed via the upper chest catheter.	
3. Assess incision area every 8 hours for redness, heat, induration, swelling, separation, and drainage.	3. These signs indicate possible infection.	
4. Request order for patient-controlled analgesia pump if appropriate for patient.	4. Allowing patient control over frequency and dose improves comfort and compliance with treatment regimen.	

**Nursing Diagnosis:** Anxiety related to outcomes of surgery, pain, technology

**Goal:** Reduction of anxiety to a manageable level

1. Explain all procedures in understandable language.	1. Explaining what can be expected in understandable terms decreases anxiety and increases cooperation.	<ul style="list-style-type: none"> <li>States that anxiety is at a manageable level</li> <li>Participates with health care team in treatment regimen</li> </ul>
2. Assess for pain and medicate, especially before potentially painful procedures.	2. Premedication before painful procedures or activities improves comfort and minimizes undue anxiety.	<ul style="list-style-type: none"> <li>Uses appropriate coping skills (verbalization, pain relief strategies, use of support systems such as family, clergy)</li> </ul>
3. Silence all <i>unnecessary</i> alarms on technology (monitors, ventilators).	3. <i>Unnecessary</i> alarms increase the risk of sensory overload and may increase anxiety.	<ul style="list-style-type: none"> <li>Demonstrates basic understanding of technology used in care</li> </ul>
4. Encourage and support patient while increasing activity level.	4. Positive reinforcement improves patient motivation and independence.	
5. Mobilize resources (family, clergy, social worker) to help patient cope with outcomes of surgery (diagnosis, change in functional abilities).	5. A multidisciplinary approach promotes the patient's strengths and coping mechanisms.	

(continued)

### Nursing Interventions

### Rationale

### Expected Patient Outcomes

**Nursing Diagnosis:** Impaired physical mobility of the upper extremities related to thoracic surgery

**Goal:** Increased mobility of the affected shoulder and arm

- |   |   |  |
|---|---|--|
| <ol style="list-style-type: none"> <li>1. Assist patient with normal range of motion and function of shoulder and trunk:               <ol style="list-style-type: none"> <li>a. Teach breathing exercises to mobilize thorax.</li> <li>b. Encourage skeletal exercises to promote abduction and mobilization of shoulder (see Chart 25-21).</li> <li>c. Assist out of bed to chair as soon as pulmonary and circulatory systems are stable (usually by evening of surgery).</li> </ol> </li> <li>2. Encourage progressive activities according to level of fatigue.</li> </ol> | <ol style="list-style-type: none"> <li>1. Necessary to regain normal mobility of arm and shoulder and to speed recovery and minimize discomfort</li> <li>2. Increases patient's use of affected shoulder and arm</li> </ol> | <ul style="list-style-type: none"> <li>• Demonstrates arm and shoulder exercises and verbalizes intent to perform them on discharge</li> <li>• Regains previous range of motion in shoulder and arm</li> </ul> |
|---|---|--|

**Nursing Diagnosis:** Risk for imbalanced fluid volume related to the surgical procedure

**Goal:** Maintenance of adequate fluid volume

- |  |  |  |
|--|--|--|
| <ol style="list-style-type: none"> <li>1. Monitor and record hourly intake and output. Urine output should be at least 30 mL/h after surgery.</li> <li>2. Administer blood component therapy and parenteral fluids and/or diuretics as prescribed to restore and maintain fluid volume.</li> </ol> | <ol style="list-style-type: none"> <li>1. Fluid management may be altered before, during, and after surgery, and patient's response to and need for fluid management must be assessed.</li> <li>2. Pulmonary edema due to transfusion or fluid overload is an ever-present threat; after pneumonectomy, the pulmonary vascular system has been greatly reduced.</li> </ol> | <ul style="list-style-type: none"> <li>• Patient is adequately hydrated, as evidenced by:               <ul style="list-style-type: none"> <li>• Urine output greater than 30 mL/h</li> <li>• Vital signs stable, heart rate, and central venous pressure approaching normal</li> <li>• No excessive peripheral edema</li> </ul> </li> </ul> |
|--|--|--|

**Nursing Diagnosis:** Deficient knowledge of home care procedures

**Goal:** Increased ability to carry out care procedures at home

- |   |   |   |
|---|---|---|
| <ol style="list-style-type: none"> <li>1. Encourage patient to practice arm and shoulder exercises five times daily at home.</li> <li>2. Instruct patient to practice assuming a functionally erect position in front of a full-length mirror.</li> <li>3. Instruct patient in following aspects of home care:               <ol style="list-style-type: none"> <li>a. Relieve intercostal pain by local heat or oral analgesia.</li> <li>b. Alternate activities with frequent rest periods.</li> <li>c. Practice breathing exercises at home.</li> <li>d. Avoid heavy lifting until complete healing has occurred.</li> <li>e. Avoid undue fatigue, increased shortness of breath, or chest pain.</li> <li>f. Avoid bronchial irritants.</li> <li>g. Prevent colds or lung infection.</li> <li>h. Get annual influenza vaccine.</li> <li>i. Keep follow-up appointment with physician.</li> <li>j. Stop smoking.</li> </ol> </li> </ol> | <ol style="list-style-type: none"> <li>1. Exercise accelerates recovery of muscle function and reduces long-term pain and discomfort.</li> <li>2. Practice will help restore normal posture.</li> <li>3. Knowing what to expect facilitates recovery.               <ol style="list-style-type: none"> <li>a. Some soreness may persist for several weeks.</li> <li>b. Weakness and fatigue are common for the first 3 weeks or longer.</li> <li>c. Effective breathing is necessary to prevent splinting of affected side, which may lead to atelectasis.</li> <li>d. Chest muscles and incision may be weaker than normal for 3–6 months.</li> <li>e. Undue stress may prolong the healing process.</li> <li>f. The lung is more susceptible to irritants.</li> <li>g. The lung is more susceptible to infection during the recovery phase.</li> <li>h. Vaccination helps prevent flu.</li> <li>i. This allows timely follow-up assessment.</li> <li>j. Smoking will slow healing process by decreasing oxygen delivery to tissues and make lung susceptible to infection and other complications.</li> </ol> </li> </ol> | <ul style="list-style-type: none"> <li>• Demonstrates arm and shoulder exercises</li> <li>• Verbalizes need to try to assume an erect posture</li> <li>• Verbalizes the importance of relieving discomfort, alternating walking and rest, performing breathing exercises, avoiding heavy lifting, avoiding undue fatigue, avoiding bronchial irritants, preventing colds or lung infections, getting flu vaccine, keeping follow-up visits, and stopping smoking</li> </ul> |
|---|---|---|

## Critical Thinking Exercises

- Oxygen therapy is required for the following patients: a 45-year-old patient who has undergone a right lower lobe lobectomy and needs short-term, low-flow oxygen; a 62-year-old patient with severe COPD admitted to the hospital for the fourth time in the past year; and a 74-year-old patient with dyspnea secondary to advanced lung cancer. Describe the explanations and safety precautions indicated for each of these patients and their families.
- Your patient has just returned from the operating room after chest surgery with an endotracheal tube, a chest tube, and two intravenous lines and cardiac monitoring in place. Identify the priorities of assessment and interventions for this patient.
- Your patient, who underwent a thoracotomy less than 24 hours ago, has a chest tube in place on the right side. Identify the actions that are indicated for each of the following situations and state the rationale for your actions:
  - Output in chest drainage chamber of 500 mL of serous drainage in the last 8 hours
  - Continuous bubbling in the water seal chamber
  - Patient reports chest pain and dyspnea; absence of breath sounds on the right side of the thorax
- A patient is being discharged home on oxygen therapy for the first time. The physician's prescription is for 2 L of oxygen via nasal cannula. Write a teaching plan for home oxygen therapy to be discussed with the patient before discharge from the hospital.
- A patient who had a chest tube inserted 8 hours ago becomes confused and disconnects the chest tube from the drainage system. What immediate actions are indicated in this situation? What nursing assessments and interventions are needed once the immediate situation has been corrected?

# ● Assessment of Cardiovascular Function

## **LEARNING OBJECTIVES**

*On completion of this chapter, the learner will be able to:*

1. Explain cardiac physiology in relation to cardiac anatomy and the conduction system of the heart.
2. Incorporate assessment of functional health patterns and cardiac risk factors into the health history and physical assessment of the patient with cardiac conditions.
3. Identify the clinical significance and related nursing implications of the various tests and procedures used for diagnostic assessment of cardiac function.
4. Compare central venous pressure monitoring, pulmonary artery pressure monitoring, and systemic intra-arterial monitoring with regard to clinical usefulness and significance, possible complications, and nursing responsibilities.

Throughout the continuum of care, whether in a home, hospital, or rehabilitation setting, all patients with cardiovascular disease (disorders of the heart and major blood vessels; CVD) require similar assessments. Key components of the cardiovascular assessment include obtaining a health history, performing a physical assessment, and monitoring a variety of laboratory and diagnostic test results. An accurate and timely assessment of cardiovascular function provides the data necessary to identify nursing diagnoses, formulate a plan of care, and evaluate the response of the patient to the care provided. Essential to the development of these assessment skills is an understanding of the structure and function of the heart in health and in disease.

## Anatomic and Physiologic Overview

The heart is a hollow, muscular organ located in the center of the thorax, where it occupies the space between the lungs (mediastinum) and rests on the diaphragm. It weighs approximately 300 g (10.6 oz), although heart weight and size are influenced by age, gender, body weight, extent of physical exercise and conditioning, and heart disease. The heart pumps blood to the tissues, supplying them with oxygen and other nutrients.

The pumping action of the heart is accomplished by the rhythmic contraction and relaxation of its muscular wall. During **systole** (contraction of the muscle), the chambers of the heart become smaller as the blood is ejected. During **diastole** (relaxation of the muscle), the heart chambers fill with blood in preparation for the subsequent ejection. A normal resting adult heart beats approximately 60 to 80 times per minute. Each ventricle ejects approxi-

mately 70 mL of blood per beat and has an output of approximately 5 L per minute.

## ANATOMY OF THE HEART

The heart is composed of three layers (Fig. 26-1). The inner layer, or endocardium, consists of endothelial tissue and lines the inside of the heart and valves. The middle layer, or myocardium, is made up of muscle fibers and is responsible for the pumping action. The exterior layer of the heart is called the epicardium.

The heart is encased in a thin, fibrous sac called the pericardium, which is composed of two layers. Adhering to the epicardium is the visceral pericardium. Enveloping the visceral pericardium is the parietal pericardium, a tough fibrous tissue that attaches to the great vessels, diaphragm, sternum, and vertebral column and supports the heart in the mediastinum. The space between these two layers (pericardial space) is filled with about 30 mL of fluid, which lubricates the surface of the heart and reduces friction during systole.

## Heart Chambers

The four chambers of the heart constitute the right- and left-sided pumping systems. The right side of the heart, made up of the right atrium and right ventricle, distributes venous blood (deoxygenated blood) to the lungs via the pulmonary artery (pulmonary circulation) for oxygenation. The right atrium receives blood returning from the superior vena cava (head, neck, and upper extremities), inferior vena cava (trunk and lower extremities), and coronary sinus (coronary circulation). The left

## Glossary

**afterload:** the amount of resistance to ejection of blood from the ventricle

**apical impulse** (also called point of maximum impulse [PMI]): impulse normally palpated at the fifth intercostal space, left midclavicular line; caused by contraction of the left ventricle

**baroreceptors:** nerve fibers located in the aortic arch and carotid arteries that are responsible for reflex control of the blood pressure

**cardiac catheterization:** an invasive procedure used to measure cardiac chamber pressures and assess patency of the coronary arteries

**cardiac conduction system:** specialized heart cells strategically located throughout the heart that are responsible for methodically generating and coordinating the transmission of electrical impulses to the myocardial cells

**cardiac output:** amount of blood pumped by each ventricle in liters per minute; normal cardiac output is 5 L per minute in the resting adult heart

**cardiac stress test:** a test used to evaluate the functioning of the heart during a period of increased oxygen demand

**contractility:** ability of the cardiac muscle to shorten in response to an electrical impulse

**depolarization:** electrical activation of a cell caused by the influx of sodium into the cell while potassium exits the cell

**diastole:** period of ventricular relaxation resulting in ventricular filling

**ejection fraction:** percentage of the end-diastolic blood volume ejected from the ventricle with each heartbeat

**hemodynamic monitoring:** use of monitoring devices to measure cardiovascular function

**hypertension:** blood pressure greater than 140/90 mm Hg

**hypotension:** a decrease in blood pressure to less than 100/60 mm Hg

**international normalized ratio (INR):** a standard method for reporting prothrombin levels, eliminating the variation in test results from laboratory to laboratory

**murmurs:** sounds created by abnormal, turbulent flow of blood in the heart

**myocardial ischemia:** condition in which heart muscle cells receive less oxygen than needed

**myocardium:** muscle layer of the heart responsible for the pumping action of the heart

**normal heart sounds:** sounds produced when the valves close; normal heart sounds are S<sub>1</sub> (atrioventricular valves) and S<sub>2</sub> (semilunar valves)

**postural (orthostatic) hypotension:** a significant drop in blood pressure (usually 10 mm Hg systolic or more) after an upright posture is assumed

**preload:** degree of stretch of the cardiac muscle fibers at the end of diastole

**pulmonary vascular resistance:** resistance to right ventricle ejection of blood

**radioisotopes:** unstable atoms that emit small amounts of energy in the form of gamma rays; used in cardiac nuclear medicine studies

**repolarization:** return of the cell to resting state, caused by reentry of potassium into the cell while sodium exits the cell

**sinoatrial (SA) node:** primary pacemaker of the heart, located in the right atrium

**stroke volume:** amount of blood ejected from the ventricle per heartbeat; normal stroke volume is 70 mL in the resting heart

**systemic vascular resistance:** resistance to left ventricle ejection

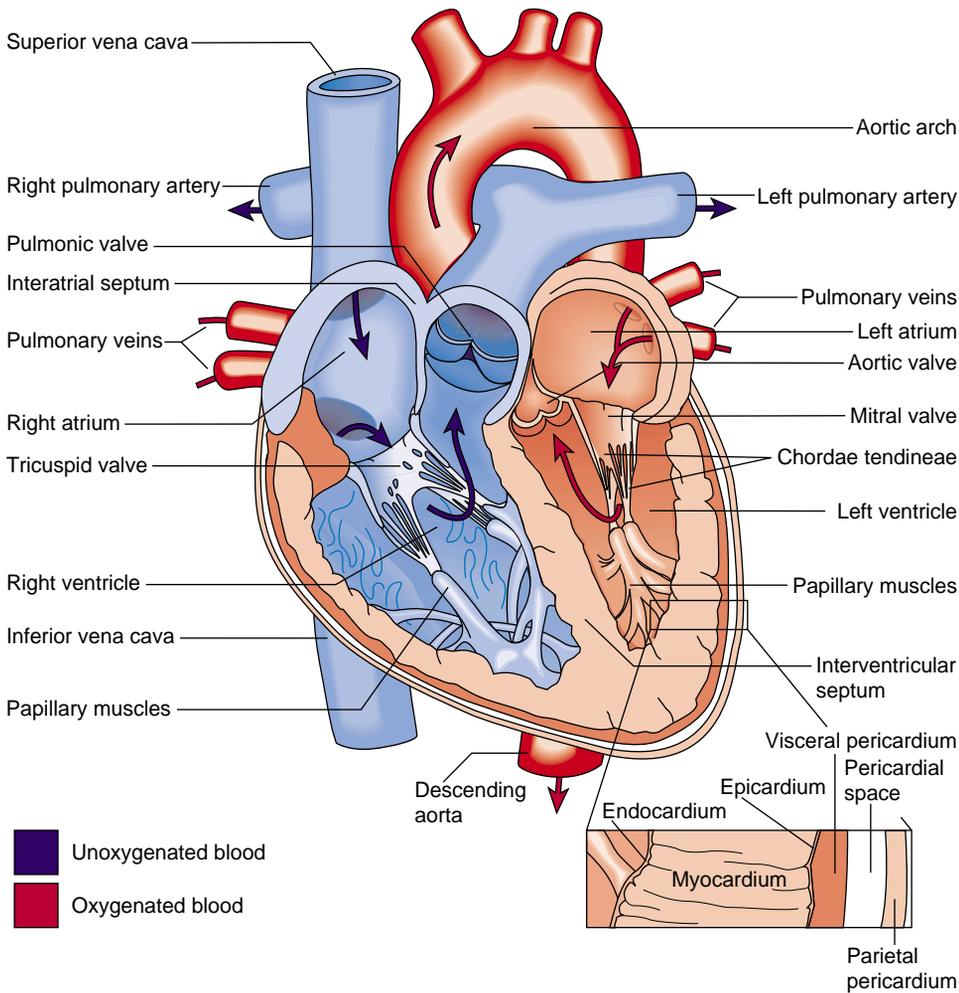

**systole:** period of ventricular contraction resulting in ejection of blood from the ventricles into the pulmonary artery and aorta

**telemetry:** the process of continuous electrocardiographic monitoring by the transmission of radiowaves from a battery-operated transmitter worn by the patient

**venodilating agent:** medication causing dilation of veins

## Physiology/Pathophysiology

**FIGURE 26-1** Structure of the heart. Arrows show course of blood flow through the heart chambers.

side of the heart, composed of the left atrium and left ventricle, distributes oxygenated blood to the remainder of the body via the aorta (systemic circulation). The left atrium receives oxygenated blood from the pulmonary circulation via the pulmonary veins. The relationships of the four heart chambers are shown in Figure 26-1.

The varying thicknesses of the atrial and ventricular walls relate to the workload required by each chamber. The atria are thin-walled because blood returning to these chambers generates low pressures. In contrast, the ventricular walls are thicker because they generate greater pressures during systole. The right ventricle contracts against low pulmonary vascular pressure and has thinner walls than the left ventricle. The left ventricle, with walls two-and-a-half times more muscular than those of the right ventricle, contracts against high systemic pressure.

Because the heart lies in a rotated position within the chest cavity, the right ventricle lies anteriorly (just beneath the sternum) and the left ventricle is situated posteriorly. The left ventricle is responsible for the apex beat or the point of maximum impulse (PMI), which is normally palpable in the left midclavicular line of the chest wall at the fifth intercostal space.

## Heart Valves

The four valves in the heart permit blood to flow in only one direction. The valves, which are composed of thin leaflets of fibrous tissue, open and close in response to the movement of blood and pressure changes within the chambers. There are two types of valves: atrioventricular and semilunar.

### ATRIOVENTRICULAR VALVES

The valves that separate the atria from the ventricles are termed atrioventricular valves. The tricuspid valve, so named because it is composed of three cusps or leaflets, separates the right atrium from the right ventricle. The mitral, or bicuspid (two cusps) valve, lies between the left atrium and the left ventricle (see Fig. 26-1).

Normally, when the ventricles contract, ventricular pressure rises, closing the atrioventricular valve leaflets. Two additional structures, the papillary muscles and the chordae tendineae, maintain valve closure. The papillary muscles, located on the sides of the ventricular walls, are connected to the valve leaflets by thin fibrous bands called chordae tendineae. During systole, contraction of the papillary muscles causes the chordae tendineae to become taut, keeping the valve leaflets approximated and closed.

## SEMILUNAR VALVES

The two semilunar valves are composed of three half-moon-like leaflets. The valve between the right ventricle and the pulmonary artery is called the pulmonic valve; the valve between the left ventricle and the aorta is called the aortic valve.

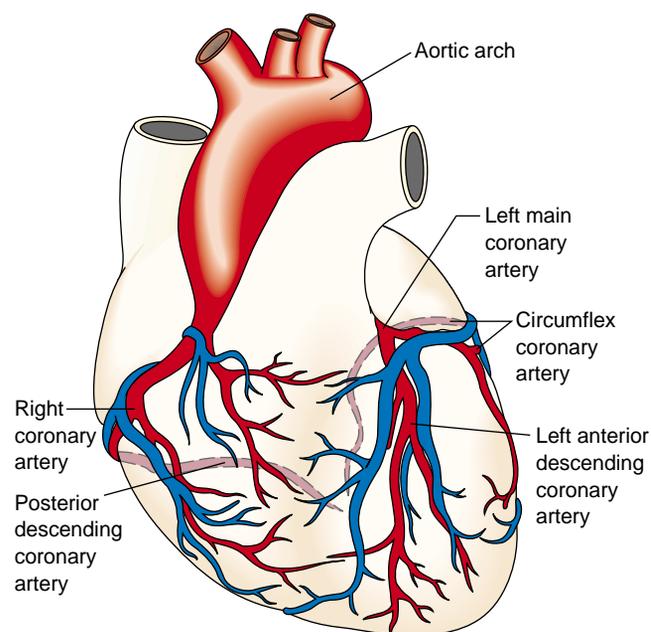

## Coronary Arteries

The left and right coronary arteries and their branches (Fig. 26-2) supply arterial blood to the heart. These arteries originate from the aorta just above the aortic valve leaflets. The heart has large metabolic requirements, extracting approximately 70% to 80% of the oxygen delivered (other organs consume, on average, 25%). Unlike other arteries, the coronary arteries are perfused during diastole. An increase in heart rate shortens diastole and can decrease myocardial perfusion. Patients, particularly those with coronary artery disease (CAD), can develop **myocardial ischemia** (inadequate oxygen supply) when the heart rate accelerates.

The left coronary artery has three branches. The artery from the point of origin to the first major branch is called the left main coronary artery. Two bifurcations arise off the left main coronary artery. These are the left anterior descending artery, which courses down the anterior wall of the heart, and the circumflex artery, which circles around to the lateral left wall of the heart.

The right side of the heart is supplied by the right coronary artery, which progresses around to the bottom or inferior wall of the heart. The posterior wall of the heart receives its blood supply by an additional branch from the right coronary artery called the posterior descending artery.

Superficial to the coronary arteries are the coronary veins. Venous blood from these veins returns to the heart primarily through the coronary sinus, which is located posteriorly in the right atrium.

**FIGURE 26-2** Coronary arteries (red vessels) arise from the aorta and encircle the heart. Coronary veins are shown in blue.

## Cardiac Muscle

The myocardium is composed of specialized muscle tissue. Microscopically, myocardial muscle resembles striated (skeletal) muscle, which is under conscious control. Functionally, however, myocardial muscle resembles smooth muscle because its contraction is involuntary. The myocardial muscle fibers are arranged in an interconnected manner (called a syncytium) that allows for coordinated myocardial contraction and relaxation. The sequential pattern of contraction and relaxation of individual muscle fibers ensures the rhythmic behavior of the myocardium as a whole and enables it to function as an effective pump.

## FUNCTION OF THE HEART: CONDUCTION SYSTEM

The specialized heart cells of the **cardiac conduction system** methodically generate and coordinate the transmission of electrical impulses to the myocardial cells. The result is sequential atrioventricular contraction, which provides for the most effective flow of blood, thereby optimizing cardiac output. Three physiologic characteristics of the cardiac conduction cells account for this coordination:

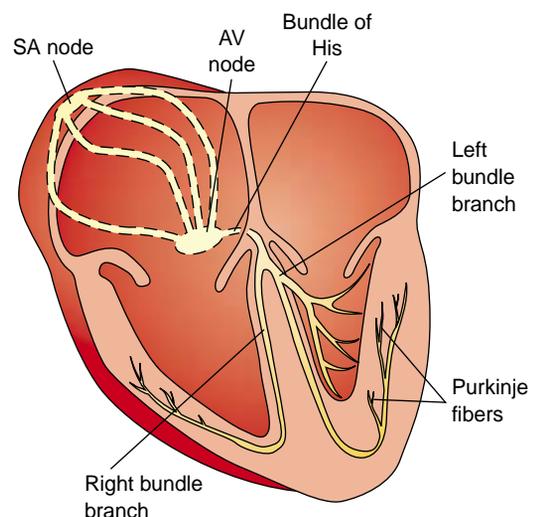

*Automaticity:* ability to initiate an electrical impulse

*Excitability:* ability to respond to an electrical impulse

*Conductivity:* ability to transmit an electrical impulse from one cell to another

The **sinoatrial (SA) node**, referred to as the primary pacemaker of the heart, is located at the junction of the superior vena cava and the right atrium (Fig. 26-3). The SA node in a normal resting heart has an inherent firing rate of 60 to 100 impulses per minute, but the rate can change in response to the metabolic demands of the body.

The electrical impulses initiated by the SA node are conducted along the myocardial cells of the atria via specialized tracts called internodal pathways. The impulses cause electrical stimulation

**FIGURE 26-3** The cardiac conduction system. AV, atrioventricular; SA, sinoatrial.

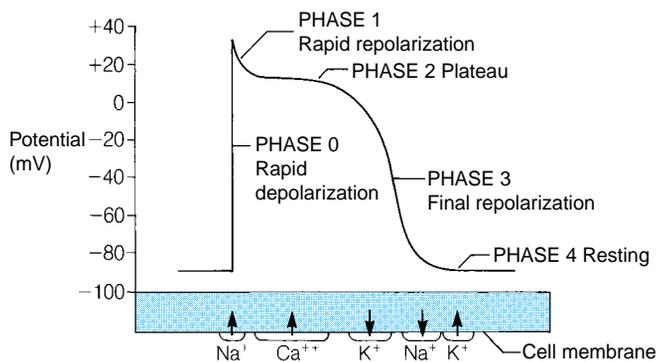

and subsequent contraction of the atria. The impulses are then conducted to the atrioventricular (AV) node. The AV node (located in the right atrial wall near the tricuspid valve) consists of another group of specialized muscle cells similar to those of the SA node. The AV node coordinates the incoming electrical impulses from the atria and, after a slight delay (allowing the atria time to contract and complete ventricular filling), relays the impulse to the ventricles. This impulse is then conducted through a bundle of specialized conduction cells (bundle of His) that travel in the septum separating the left and right ventricles. The bundle of His divides into the right bundle branch (conducting impulses to the right ventricle) and the left bundle branch (conducting impulses to the left ventricle). To transmit impulses to the largest chamber of the heart, the left bundle branch bifurcates into the left anterior and left posterior bundle branches. Impulses travel through the bundle branches to reach the terminal point in the conduction system, called the Purkinje fibers. This is the point at which the myocardial cells are stimulated, causing ventricular contraction.

The heart rate is determined by the myocardial cells with the fastest inherent firing rate. Under normal circumstances, the SA node has the highest inherent rate, the AV node has the second-highest inherent rate (40 to 60 impulses per minute), and the ventricular pacemaker sites have the lowest inherent rate (30 to 40 impulses per minute). If the SA node malfunctions, the AV node generally takes over the pacemaker function of the heart at its inherently lower rate. Should both the SA and the AV nodes fail in their pacemaker function, a pacemaker site in the ventricle will fire at its inherent bradycardic rate of 30 to 40 impulses per minute.

## Physiology of Cardiac Conduction

Cardiac electrical activity is the result of the movement of ions (charged particles such as sodium, potassium, and calcium) across the cell membrane. The electrical changes recorded within a single cell result in what is known as the cardiac action potential (Fig. 26-4).

In the resting state, cardiac muscle cells are polarized, which means an electrical difference exists between the negatively charged inside and the positively charged outside of the cell membrane.

**FIGURE 26-4** Cardiac action potential. The arrows indicate the approximate time and direction of movement of each ion influencing membrane potential. Ca<sup>2+</sup> movement out of the cell is not well defined but is thought to occur during Phase 4.

As soon as an electrical impulse is initiated, cell membrane permeability changes and sodium moves rapidly into the cell, while potassium exits the cell. This ionic exchange begins **depolarization** (electrical activation of the cell), converting the internal charge of the cell to a positive one (see Fig. 26-4). Contraction of the myocardium follows depolarization. The interaction between changes in membrane voltage and muscle contraction is called electromechanical coupling. As one cardiac muscle cell is depolarized, it acts as a stimulus to its neighboring cell, causing it to depolarize. Sufficient depolarization of a single specialized conduction system cell results in depolarization and contraction of the entire myocardium. **Repolarization** (return of the cell to its resting state) occurs as the cell returns to its baseline or resting state; this corresponds to relaxation of myocardial muscle.

After the rapid influx of sodium into the cell during depolarization, the permeability of the cell membrane to calcium is changed. Calcium enters the cell and is released from intracellular calcium stores. The increase in calcium, which occurs during the plateau phase of repolarization, is much slower than that of sodium and continues for a longer period.

Cardiac muscle, unlike skeletal or smooth muscle, has a prolonged refractory period during which it cannot be restimulated to contract. There are two phases of the refractory period, referred to as the absolute refractory period and the relative refractory period. The absolute refractory period is the time during which the heart cannot be restimulated to contract regardless of the strength of the electrical stimulus. This period corresponds with depolarization and the early part of repolarization. During the latter part of repolarization, however, if the electrical stimulus is stronger than normal, the myocardium can be stimulated to contract. This short period at the end of repolarization is called the relative refractory period.

Refractoriness protects the heart from sustained contraction (tetany), which would result in sudden cardiac death. Normal electromechanical coupling and contraction of the heart depend on the composition of the interstitial fluid surrounding the heart muscle cells. In turn, the composition of this fluid is influenced by the composition of the blood. A change in serum calcium concentration may alter the contraction of the heart muscle fibers. A change in serum potassium concentration is also important, because potassium affects the normal electrical voltage of the cell.

## Cardiac Hemodynamics

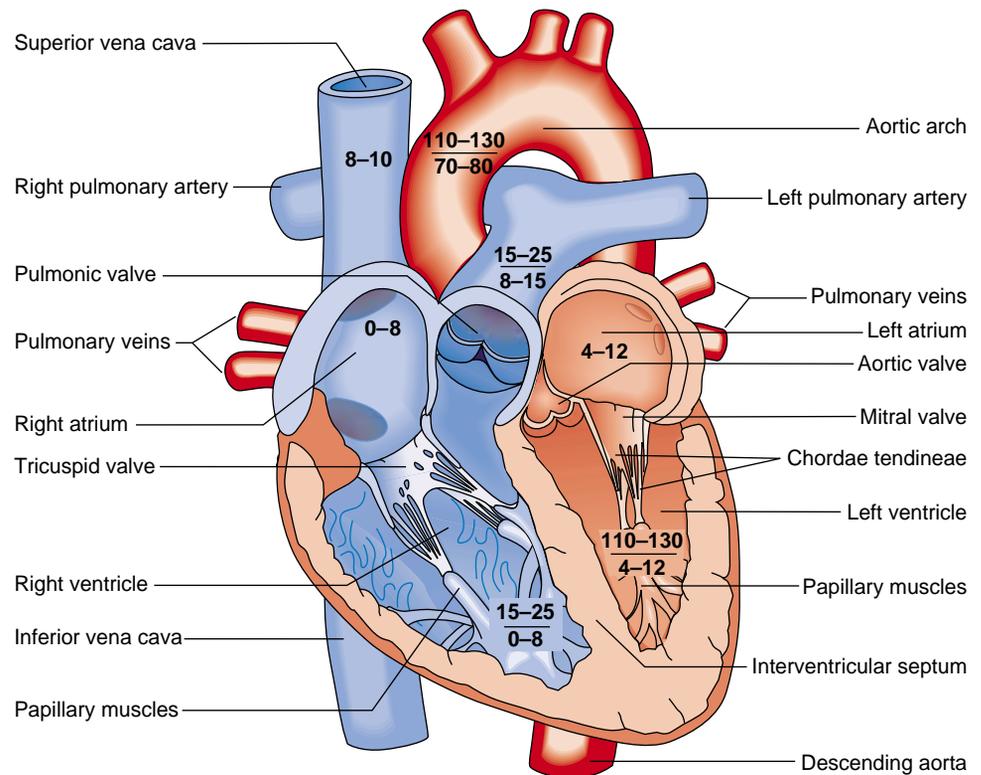

An important determinant of blood flow in the cardiovascular system is the principle that fluid flows from a region of higher pressure to one of lower pressure. The pressures responsible for blood flow in the normal circulation are generated during systole and diastole. Figure 26-5 depicts the pressure differences in the great vessels and in the four chambers of the heart during systole and diastole.

## CARDIAC CYCLE

Beginning with systole, the pressure inside the ventricles rapidly rises, forcing the atrioventricular valves to close. As a result, blood ceases to flow from the atria into the ventricles and regurgitation (backflow) of blood into the atria is prevented. The rapid rise of pressure inside the right and left ventricles forces the pulmonic and aortic valves to open, and blood is ejected into the pulmonary artery and aorta, respectively. The exit of blood is at first rapid;

## Physiology/Pathophysiology

**FIGURE 26-5** Great vessel and chamber pressures. Pressures are identified in millimeters of mercury (mm Hg) as mean pressure or systolic over diastolic pressure.

then, as the pressure in each ventricle and its corresponding artery equalizes, the flow of blood gradually decreases. At the end of systole, pressure within the right and left ventricles rapidly decreases. This lowers pulmonary artery and aortic pressure, causing closure of the semilunar valves. These events mark the onset of diastole.

During diastole, when the ventricles are relaxed and the atrioventricular valves are open, blood returning from the veins flows into the atria and then into the ventricles. Toward the end of this diastolic period, the atrial muscles contract in response to an electrical impulse initiated by the SA node (atrial systole). The resultant contraction raises the pressure inside the atria, ejecting blood into the ventricles. Atrial systole augments ventricular blood volume by 15% to 25% and is sometimes referred to as the “atrial kick.” At this point, ventricular systole begins in response to propagation of the electrical impulse that began in the SA node some milliseconds previously. The following section reviews the chamber pressures generated during systole and diastole.

**Chamber Pressures.** In the right side of the heart, the pressure generated during ventricular systole (15 to 25 mm Hg) exceeds the pulmonary artery diastolic pressure (8 to 15 mm Hg), and blood is ejected into the pulmonary circulation. During diastole, venous blood flows into the atrium because pressure in the superior and inferior vena cava (8 to 10 mm Hg) is higher than that in the atrium. Blood flows through the open tricuspid valve and

into the right ventricle until the two right chamber pressures equalize (0 to 8 mm Hg).

In the left side of the heart, similar events occur, although higher pressures are generated. As pressure mounts in the left ventricle during systole (110 to 130 mm Hg), resting aortic pressure (80 mm Hg) is exceeded and blood is ejected into the aorta. During left ventricular ejection, the resultant aortic pressure (110 to 130 mm Hg) forces blood progressively through the arteries. Forward blood flow into the aorta ceases as the ventricle relaxes and pressure drops. During diastole, oxygenated blood returning from the pulmonary circulation via the four pulmonary veins flows into the atrium, where pressure remains low. Blood readily flows into the left ventricle because ventricular pressure is also low. At the end of diastole, pressure in the atrium and ventricle equilibrates (4 to 12 mm Hg). Figure 26-5 depicts the systolic and diastolic pressures in the four chambers of the heart.

**Pressure Measurement.** Chamber pressures are measured with the use of special monitoring catheters and equipment. This technique is called hemodynamic monitoring. Nurses caring for critically ill patients must have a sophisticated working knowledge of normal chamber pressures and the hemodynamic changes that occur during serious illnesses. The data obtained from hemodynamic monitoring assist with the diagnosis and management of pathophysiologic conditions affecting critically ill patients. Hemodynamic monitoring is covered in more detail at the end of this chapter.

## Cardiac Output

**Cardiac output** is the amount of blood pumped by each ventricle during a given period. The cardiac output in a resting adult is about 5 L per minute but varies greatly depending on the metabolic needs of the body. Cardiac output is computed by multiplying the stroke volume by the heart rate. **Stroke volume** is the amount of blood ejected per heartbeat. The average resting stroke volume is about 70 mL, and the heart rate is 60 to 80 beats per minute (bpm). Cardiac output can be affected by changes in either stroke volume or heart rate.

### CONTROL OF HEART RATE

Cardiac output must be responsive to changes in the metabolic demands of the tissues. For example, during exercise the total cardiac output may increase fourfold, to 20 L per minute. This increase is normally accomplished by approximate doubling of both the heart rate and the stroke volume. Changes in heart rate are accomplished by reflex controls mediated by the autonomic nervous system, including its sympathetic and parasympathetic divisions. The parasympathetic impulses, which travel to the heart through the vagus nerve, can slow the cardiac rate, whereas sympathetic impulses increase it. These effects on heart rate result from action on the SA node, to either decrease or increase its inherent rate. The balance between these two reflex control systems normally determines the heart rate. The heart rate is stimulated also by an increased level of circulating catecholamines (secreted by the adrenal gland) and by excess thyroid hormone, which produces a catecholamine-like effect.

Heart rate is also affected by central nervous system and baroreceptor activity. **Baroreceptors** are specialized nerve cells located in the aortic arch and in both right and left internal carotid arteries (at the point of bifurcation from the common carotid arteries). The baroreceptors are sensitive to changes in blood pressure (BP). During elevations in BP (**hypertension**), these cells increase their rate of discharge, transmitting impulses to the medulla. This initiates parasympathetic activity and inhibits sympathetic response, lowering the heart rate and the BP. The opposite is true during **hypotension** (low BP). Hypotension results in less baroreceptor stimulation, which prompts a decrease in parasympathetic inhibitory activity in the SA node, allowing for enhanced sympathetic activity. The resultant vasoconstriction and increased heart rate elevate the BP.

### CONTROL OF STROKE VOLUME

Stroke volume is primarily determined by three factors: preload, afterload, and contractility.

**Preload** is the term used to describe the degree of stretch of the cardiac muscle fibers at the end of diastole. The end of diastole is the period when filling volume in the ventricles is the highest and the degree of stretch on the muscle fibers is the greatest. The volume of blood within the ventricle at the end of diastole determines preload. Preload has a direct effect on stroke volume. As the volume of blood returning to the heart increases, muscle fiber stretch also increases (increased preload), resulting in stronger contraction and a greater stroke volume. This relationship, called the Frank-Starling law of the heart (or sometimes the Starling law of the heart), is maintained until the physiologic limit of the muscle is reached.

The Frank-Starling law is based on the fact that, within limits, the greater the initial length or stretch of the cardiac muscle cells (sarcomeres), the greater the degree of shortening that occurs. This result is caused by increased interaction between the

thick and thin filaments within the cardiac muscle cells. Preload is decreased by a reduction in the volume of blood returning to the ventricles. Diuresis, **venodilating agents** (eg, nitrates), and loss of blood or body fluids from excessive diaphoresis, vomiting, or diarrhea reduce preload. Preload is increased by increasing the return of circulating blood volume to the ventricles. Controlling the loss of blood or body fluids and replacing fluids (ie, blood transfusions and intravenous fluid administration) are examples of ways to increase preload.

The second determinant of stroke volume is **afterload**, the amount of resistance to ejection of blood from the ventricle. The resistance of the systemic BP to left ventricular ejection is called **systemic vascular resistance**. The resistance of the pulmonary BP to right ventricular ejection is called **pulmonary vascular resistance**. There is an inverse relationship between afterload and stroke volume. For example, afterload is increased by arterial vasoconstriction, which leads to decreased stroke volume. The opposite is true with arterial vasodilation: afterload is reduced because there is less resistance to ejection, and stroke volume increases.

**Contractility** is a term used to denote the force generated by the contracting myocardium under any given condition. Contractility is enhanced by circulating catecholamines, sympathetic neuronal activity, and certain medications (eg, digoxin, intravenous dopamine or dobutamine). Increased contractility results in increased stroke volume. Contractility is depressed by hypoxemia, acidosis, and certain medications (eg, beta-adrenergic blocking agents such as atenolol [Tenormin]).

The heart can achieve a greatly increased stroke volume (eg, during exercise) by increasing preload (through increased venous return), increasing contractility (through sympathetic nervous system discharge), and decreasing afterload (through peripheral vasodilation with decreased aortic pressure).

The percentage of the end-diastolic volume that is ejected with each stroke is called the **ejection fraction**. With each stroke, about 42% (right ventricle) to 50% (left ventricle) or more of the end-diastolic volume is ejected by the normal heart. The ejection fraction can be used as an index of myocardial contractility: the ejection fraction decreases if contractility is depressed.

### Gerontologic Considerations

Changes in cardiac structure and function are clearly observable in the older heart. To understand the changes specifically related to aging, it is helpful to distinguish the normal aging process from changes related to CVD. The anatomic and functional changes in the aging heart are listed in Table 26-1.

Studies show that the normal aging heart can produce adequate cardiac output under ordinary circumstances but may have a limited ability to respond to situations that cause physical or emotional stress. In an elderly person who is less active, the left ventricle may become smaller (atrophy) as a consequence of physical deconditioning. Aging also results in decreased elasticity and widening of the aorta, thickening and rigidity of the cardiac valves, and increased connective tissue in the SA and AV nodes and bundle branches.

These changes lead to decreased myocardial contractility, increased left ventricular ejection time (prolonged systole), and delayed conduction. Therefore, stressful physical and emotional conditions, especially those that occur suddenly, may have adverse effects on the aged person. The heart cannot respond to such conditions with an adequate rate increase and needs more time to return to a normal resting rate after even a minimal increase in heart rate. In some patients, the added stress may precipitate heart failure (HF).

**Table 26-1 • Age-Related Changes of the Cardiac System**

CARDIOVASCULAR SYSTEM	STRUCTURAL CHANGES	FUNCTIONAL CHANGES	HISTORY AND PHYSICAL FINDINGS
Atria	↑ Size of left atrium Thickening of the endocardium	↑ Atrial irritability	Irregular heart rhythm from atrial dysrhythmias
Left ventricle	Endocardial fibrosis Myocardial thickening (hypertrophy) Infiltration of fat into myocardium	Left ventricle stiff and less compliant Progressive decline in cardiac output ↑ Risk for ventricular dysrhythmias Prolonged systole	Fatigue ↓ Exercise tolerance Signs and symptoms of HF or ventricular dysrhythmias Point of maximal impulse palpated lateral to the midclavicular line ↓ Intensity S <sub>1</sub> , S <sub>2</sub> ; split S <sub>2</sub> S <sub>4</sub> may be present
Valves	Thickening and rigidity of AV valves Calcification of aortic valve	Abnormal blood flow across valves during cardiac cycle	Murmurs may be present Thrill may be palpated if significant murmur is present
Conduction system	Connective tissue collects in SA node, AV node, and bundle branches ↓ Number SA node cells ↓ Number AV, bundle of His, right and left bundle branch cells	Slower SA node rate of impulse discharge Slowed conduction across AV node and ventricular conduction system	Bradycardia Heart block ECG changes consistent with slowed conduction (↑ PR interval, widened QRS complex)
Sympathetic nervous system	↓ Response to beta-adrenergic stimulation	↓ Adaptive response to exercise: contractility and heart rate slower to respond to exercise demands Heart rate takes more time to return to baseline	Fatigue Diminished exercise tolerance ↓ Ability to respond to stress
Aorta and arteries	Stiffening of vasculature ↓ Elasticity and widening of aorta Elongation of aorta, displacing the brachiocephalic artery upward	Left ventricular hypertrophy	Progressive increase in systolic BP; slight ↑ in diastolic BP Widening pulse pressure Pulsation visible above right clavicle
Baroreceptor response	↓ Sensitivity of baroreceptors in the carotid artery and aorta to transient episodes of hypertension and hypotension	Baroreceptors unable to regulate heart rate and vascular tone, causing slow response to postural changes in body position	Postural blood pressure changes and reports feeling dizzy, fainting when moving from lying to sitting or standing position

AV, atrioventricular; BP, blood pressure; CHF, congestive heart failure; ECG, electrocardiographic; SA, sinoatrial.

## GENDER DIFFERENCES IN CARDIAC STRUCTURE AND FUNCTION

Compared with a man's heart, a woman's heart tends to be smaller. It weighs less and has smaller coronary arteries. These structural differences have significant implications. Because the coronary arteries of a woman are smaller, they occlude from atherosclerosis more easily, making procedures such as cardiac catheterization and angioplasty technically more difficult, with a higher incidence of postprocedure complications. In addition, the resting rate, stroke volume, and ejection fraction of a woman's heart are higher than those of a man's, and the conduction time of an electrical impulse coursing from the SA node through the AV node to the Purkinje fibers is briefer.

Another significant difference between the genders is the physiologic effects of estrogen on the cardiovascular system. Two important effects of estrogen, regulation of vasomotor tone and of response to vascular injury, may be the mechanisms that protect women against the development of atherosclerosis. An additional, potentially beneficial effect of estrogen is its action on the

liver, which results in improved lipid profiles. On the other hand, less favorable effects of estrogen include an increase in coagulation proteins and a decrease in fibrinolytic protein, which enhance the risk of thrombus formation. Progesterone also has vascular effects, but its role in the development of CVD is unclear at this time. Beneficial effects of estrogen disappear after menopause, as evidenced by the increased incidence of CVD in this population. However, because of health risks associated with hormone replacement therapy, the American Heart Association does not recommend its use as a primary or secondary prevention intervention for CVD (Mosca et al., 2001; Roussouw et al., 2002).

## Assessment

The severity of the patient's symptoms, the practice setting of the nurse, and the purpose of the assessment are factors that need to be considered when determining the frequency and extent of nursing assessment required. The assessment of the acutely ill cardiac patient will be different from that of a patient with stable or chronic cardiac conditions. For example, the assessment per-

formed by an emergency department nurse caring for a patient who is experiencing an acute myocardial infarction (MI) must be very focused and must be performed rapidly. The nurse must assess the patient for complications associated with the MI, screen the patient for contraindications to coronary artery reperfusion strategies including thrombolytic therapy or primary percutaneous transluminal coronary angioplasty (PTCA), and evaluate the patient's response to medical and nursing interventions. For this patient, the health history, physical assessment, and important nursing interventions (eg, cardiac monitoring, administration of intravenous medications) are performed simultaneously.

## HEALTH HISTORY AND CLINICAL MANIFESTATIONS

For the patient experiencing an acute MI, the nurse obtains the health history using a few specific questions about the onset and severity of chest discomfort, associated symptoms, current medications, and allergies. At the same time, the nurse observes the

patient's general appearance and evaluates hemodynamic status (heart rate and rhythm, BP). Once the condition of the patient stabilizes, a more extensive history can be obtained.

With stable patients, a complete health history is obtained during the initial contact. Often, it is helpful to have the patient's spouse or partner available during the health history interview. Initially, demographic information regarding age, gender, and ethnic origin is obtained. The family history, as well as the physical examination, should include assessment for genetic abnormalities associated with cardiovascular disorders (see Genetics in Nursing Practice box). Height, current weight, and usual weight (if there has been a recent weight loss or gain) are established. During the interview, the nurse conveys sensitivity to the cultural background and religious practices of the patient. This removes barriers to communication that may result if the interview is based only on the nurse's personal frame of reference. Patients from different cultural and ethnic groups may have different ways of describing symptoms such as pain and may engage in different health practices before seeking formal medical attention.

### NURSING RESEARCH PROFILE 26-1

#### *Racial Differences in Coronary Artery Disease: Symptoms and Seeking Care*

Richards, S. B., Funk, M., & Milner, K. A. (2000). Differences between blacks and whites with coronary heart disease in initial symptoms and delay in seeking care. *American Journal of Critical Care, 9*, 237–244.

#### Purpose

Mortality rates due to coronary artery disease (CAD) are higher in African American men (7%) and African American women (35%) than in their Caucasian counterparts. Recent findings suggest that African Americans may delay longer than Caucasians in seeking emergency care and commonly have atypical symptom presentation. The purpose of this study was to explore differences between African Americans and Caucasians in both manifestations of symptoms of CAD and delay in seeking treatment by answering the following research questions:

- Do African Americans and Caucasians differ in their manifestation of symptoms of CAD?
- Among patients with confirmed CAD, do African Americans and Caucasians differ in the elapsed time between the onset of symptoms and arrival at the emergency department?

#### Study Sample and Design

This study, part of a larger study investigating aspects of CAD presentation, is the first of its kind to use a prospective, observational design. One member of the team of nurse researchers unobtrusively observed patients in the emergency department as they described their symptoms to the clinician.

The sample consisted of African Americans and Caucasians drawn from a total of 545 patients who were recruited from the emergency department of an 810-bed university teaching hospital. Patients with one or more typical or atypical symptoms of CAD, who met age-specific inclusion criteria based on the Framingham Heart Study, were enrolled. Electrocardiographic and cardiac enzyme criteria were used to confirm the diagnosis of angina or myocardial infarction.

#### Findings

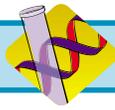

Of the 231 patients with CAD, 40 (17%) were African American and 191 (82.7%) were Caucasian. The majority of the patients were male (58%). Ages ranged from 31 to 91 years. There were statistically sig-

nificant differences in age and cardiac risk factors between the groups of African Americans and Caucasians. The mean age was significantly younger in African Americans than in Caucasians. Caucasians were more likely than African Americans to have hyperlipidemia, and African Americans were more likely than Caucasians to have hypertension.

Among all patients, shortness of breath, not chest pain, was the most common symptom (39.8%). Next, in descending order, were substernal chest pain (34%) and arm pain (27.2%). Both research questions were answered affirmatively. African Americans were more likely than Caucasians to have atypical presentation of acute CAD symptoms. These patients, the majority of whom were female (62.5%), were about three times more likely than Caucasians to experience shortness of breath as the predominant symptom and two times more likely to complain of left-sided chest pain. African Americans were found to have a median delay time of 11 hours, while Caucasians delayed 5 hours. This difference was significant ( $p = .05$ ), demonstrating a trend toward longer delays by African Americans compared with Caucasians. Nineteen people in this study delayed 72 hours or longer before seeking treatment.

#### Nursing Implications

Studies such as this one contribute to the growing body of evidence showing that there are racial differences in the presentation of acute CAD. Nurses and other health care professionals need to be aware that "atypical" symptoms of angina and myocardial infarction, such as shortness of breath or left-sided chest pain, are common, especially among African Americans. Any patient with shortness of breath or left-sided chest pain should be assessed for other symptoms of CAD. Nurses should consult with nurse practitioners or physicians regarding diagnostic studies for CAD for any patient experiencing one or both of these symptoms. Nurses can teach colleagues and the lay public about shortness of breath, left-sided chest pain, and other symptoms of CAD and instruct them on how to access the emergency medical system if any of these symptoms are experienced.

## GENETICS IN NURSING PRACTICE—Cardiovascular Disorders

Several cardiovascular disorders are associated with genetic abnormalities. Some examples are:

- Familial hypercholesterolemia
- Hypertrophic cardiomyopathy
- Long QT syndrome (LQTS)
- Hereditary hemochromatosis
- Elevated homocystine levels

### NURSING ASSESSMENTS

#### FAMILY HISTORY ASSESSMENT

- Assess all patients with cardiovascular symptoms for coronary artery disease, regardless of age (early-onset CAD occurs).
- Assess family history of sudden death in persons who may or may not have been diagnosed with coronary disease (especially of early onset).
- Ask about sudden death in a previously asymptomatic child, adolescent, or adult.
- Ask about other family members with biochemical or neuromuscular conditions (eg, hemochromatosis or muscular dystrophy).
- Assess whether DNA mutation or other genetic testing has been performed on an affected family member

#### ASSESSMENT

- Assess for signs and symptoms of hyperlipidemias (xanthomas, corneal arcus, abdominal pain of unexplained origin).
- Assess for muscular weakness.

The baseline information derived from the history assists in identifying pertinent issues related to the patient's condition and educational and self-care needs. Once these problems are clearly identified, a plan of care is instituted. During subsequent contacts or visits with the patient, a more focused health history is performed to determine whether goals have been met, whether the plan needs to be modified, and whether new problems have developed. During the interview, the nurse asks questions to evaluate cardiac symptoms and health status.

### Cardiac Signs and Symptoms

Patients with cardiovascular disorders commonly have one or more of the following signs and symptoms:

- Chest pain or discomfort (angina pectoris, MI, valvular heart disease)
- Shortness of breath or dyspnea (MI, left ventricular failure, HF)
- Edema and weight gain (right ventricular failure, HF)
- Palpitations (dysrhythmias resulting from myocardial ischemia, valvular heart disease, ventricular aneurysm, stress, electrolyte imbalance)
- Fatigue (earliest symptom associated with several cardiovascular disorders)

### MANAGEMENT ISSUES SPECIFIC TO GENETICS

- If indicated, refer for further genetic counseling and evaluation so that the family can discuss inheritance, risk to other family members, availability of genetic testing, and gene-based interventions
- Offer appropriate genetic information and resources (eg, Genetic Alliance website, American Heart Association, Muscular Dystrophy Association)
- Provide support to families newly diagnosed with genetic-related cardiovascular disease

### GENETICS RESOURCES

Genetic Alliance—a directory of support groups for patients and families with genetic conditions;

<http://www.geneticalliance.org>.

Gene Clinics—a listing of common genetic disorders with up-to-date clinical summaries, genetic counseling, and testing information; <http://www.geneclinics.org>.

National Organization of Rare Disorders—a directory of support groups and information for patients and families with rare genetic disorders; <http://www.rarediseases.org>.

OMIM: Online Mendelian Inheritance in Man—a complete listing of inherited genetic conditions; <http://www.ncbi.nlm.nih.gov/omim/stats/html>.

- Dizziness and syncope or loss of consciousness (postural hypotension, dysrhythmias, vasovagal effect, cerebrovascular disorders)

Not all chest discomfort is related to myocardial ischemia. When a patient has chest discomfort, questions should focus on differentiating a serious, life-threatening condition such as MI from conditions that are less serious or that would be treated differently (see Table 26-2).

The following points should be remembered when assessing patients with cardiac symptoms:

- Women are more likely to present with atypical symptoms of MI than are men.
- There is little correlation between the severity of the chest discomfort and the gravity of its cause. Elderly people and those with diabetes may not have pain with angina or MI because of neuropathies. Fatigue and shortness of breath may be the predominant symptoms in these patients.
- There is poor correlation between the location of chest discomfort and its source.
- The patient may have more than one clinical condition occurring simultaneously.
- In a patient with a history of CAD, the chest discomfort should be assumed to be secondary to ischemia until proven otherwise.

**NURSING ALERT** People experiencing myocardial ischemia can have a variety of symptoms. The typical symptom is angina presenting as pressure, fullness, squeezing pain, or discomfort in the center of the chest. This pain may radiate to the shoulders, neck, jaw, or arms. Angina can also have an atypical or uncommon presentation, referred to as anginal equivalent. It is characterized by shortness of breath, fatigue, weakness, or pain in other parts of the upper body, including the neck, shoulder, jaw, arm, back, or stomach. Angina patterns are usually predictable (eg, with activity). Rest or sublingual nitroglycerin relieves symptoms within a few minutes. A patient in the midst of an MI, however, can present with angina or its equivalent symptoms, which last longer than 15 minutes. Signs and symptoms associated with an MI include lightheadedness, fainting, diaphoresis, unexplained anxiety, nausea, and shortness of breath. Symptoms are unrelieved by rest or nitroglycerin.

## HEALTH PERCEPTION AND MANAGEMENT

In an effort to determine how patients perceive their current health status. The nurse might ask some of the following questions:

- Do you have any health problems? If so, what do you think caused them?
- How has your health been recently? Have you noticed any changes from last year? from 5 years ago?
- Do you have a cardiologist or primary health care provider? How often do you go for checkups?
- Do you use tobacco or consume alcohol?
- What are your risk factors for heart disease? What do you do to stay healthy and take care of your heart?
- What prescription and over-the-counter medications are you taking? Do you take vitamins or herbal supplements?

Some patients may not be aware of their own medical diagnosis. For example, patients may not realize that their heart attack was caused by CAD. Patients who do not understand that their behaviors or diagnoses pose a threat to their health may be less motivated to make lifestyle changes or to manage their illness effectively. On the other hand, patients who perceive that their modifiable cardiovascular risk factors have contributed to their health conditions may be more likely to change these behaviors (Chart 26-1).

The patient's ability to recognize cardiac symptoms and to know what to do when they occur is essential for effective self-care

Chart 26-1

### Risk Factors for Heart Disease

#### Nonmodifiable risk factors include the following:

Positive family history for premature coronary artery disease  
Increasing age  
Gender (men and postmenopausal women)  
Race (higher incidence in African Americans than in Caucasians)

#### Modifiable risk factors include the following:

Hyperlipidemia  
Hypertension  
Cigarette smoking  
Elevated blood glucose level (ie, diabetes mellitus)  
Obesity  
Physical inactivity  
Type A personality characteristics, particularly hostility  
Use of oral contraceptives

management. All too often, patients' new symptoms or symptoms of progressing cardiac dysfunction go unrecognized. This results in prolonged delays in seeking life-saving treatment. Major barriers to seeking prompt medical care include lack of knowledge about symptoms to expect with heart disease, attribution of symptoms to a benign source, psychological factors such as denial of symptom significance, and social factors, specifically feeling embarrassed about having symptoms (Zerwic, 1999).

An additional issue to consider is the patient's medication history, dosages, and schedules. Is the patient independent in taking medications? Are the medications taken as prescribed? Does the patient understand why the medication regimen is important? Are doses ever forgotten or skipped, or does the patient ever decide to stop taking a medication? An aspirin a day is a common non-prescription medication that improves patient outcomes after an MI. However, if patients are not aware of this benefit, they may be inclined to stop taking aspirin if they think it is a trivial medication. A careful medication history will often uncover common medication errors and causes for nonadherence to the medication regimen.

Table 26-2 summarizes the characteristics and patterns of the more common cardiac and noncardiac causes of chest pain. Table 26-3 identifies typical questions nurses use to assess cardiac signs and symptoms, as well as those used to determine the patient's ability to recognize and manage them. Some of the patient's responses may require further clarification and follow-up.

## NUTRITION AND METABOLISM

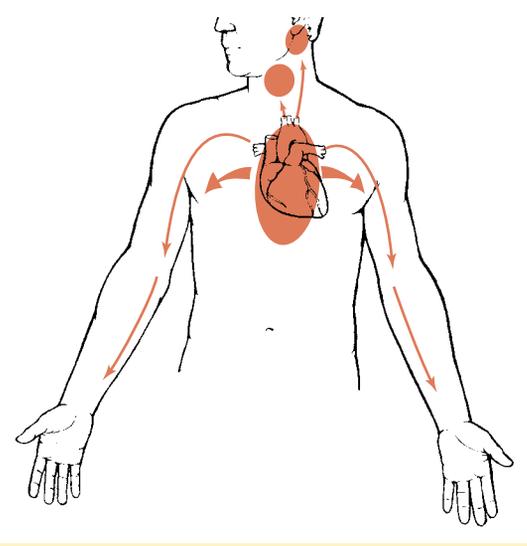

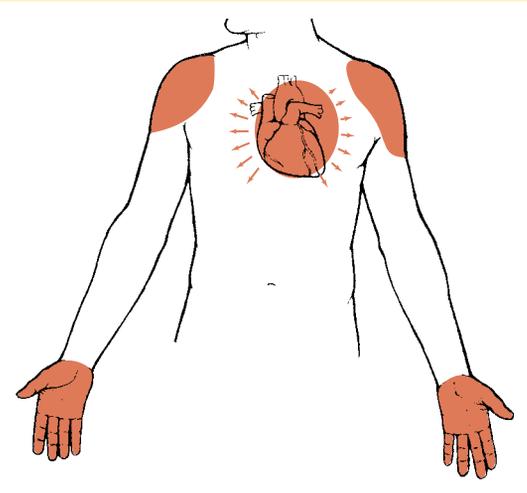

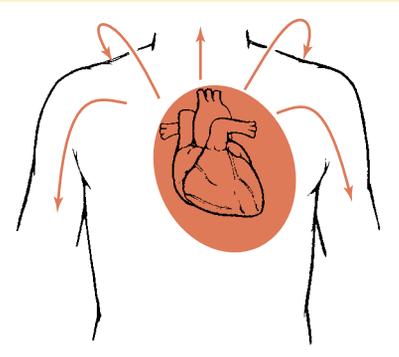

Dietary modifications, exercise, weight loss, and careful monitoring are important strategies for managing three major cardiovascular risk factors: hyperlipidemia, hypertension, and hyperglycemia (diabetes mellitus). Diets that are restricted in sodium, fat, cholesterol, and/or calories are commonly prescribed. The nurse should obtain the following information:

- The patient's current height and weight (to determine body mass index), waist measurement (assessment for obesity), BP, and any laboratory test results such as blood glucose, glycosylated hemoglobin (diabetes), total blood cholesterol, high-density and low-density lipoprotein levels, and triglyceride levels (hyperlipidemia).
- How often the patient self-monitors BP, blood glucose, and weight as appropriate to the medical diagnoses.
- The patient's level of awareness regarding his or her target goals for each of the risk factors and any problems achieving or maintaining these goals.
- What the patient normally eats and drinks in a typical day and any food preferences (including cultural or ethnic preferences).
- Eating habits (canned or commercially prepared foods versus fresh foods, restaurant cooking versus home cooking, assessing for high sodium foods, dietary intake of fats).
- Who shops for groceries and prepares meals.

## ELIMINATION

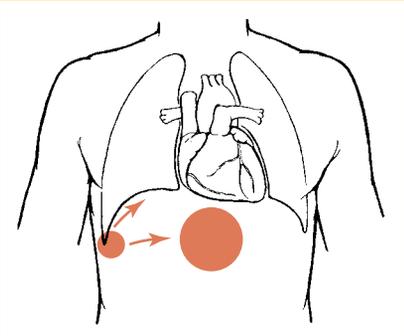

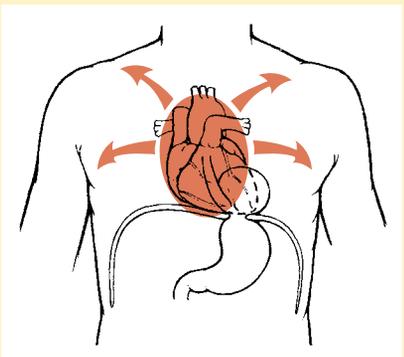

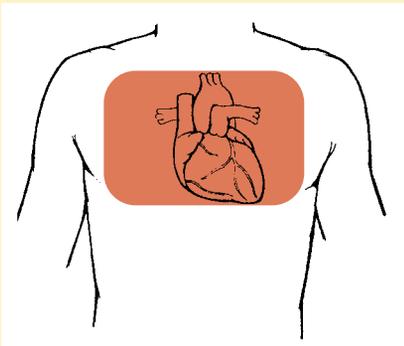

Typical bowel and bladder habits need to be identified. Nocturia (awakening at night to urinate) is common for patients with HF. Fluid collected in the dependent tissues (extremities) during the day redistributes into the circulatory system once the patient is recumbent at night. The increased circulatory volume is excreted by the kidneys (increased urine production). Patients need to be aware of their response to diuretic therapy and any changes in urination. This is vitally important for patients with HF. Patients may be taught to modify (titrate) their dose of diuretics based on urinary pattern, daily weight, and symptoms of dyspnea.

Table 26-2 • Assessing Chest Pain

	CHARACTER, LOCATION, AND RADIATION	DURATION	PRECIPITATING EVENTS	RELIEVING MEASURES
<b>Angina Pectoris</b>	 <p>Substernal or retro-sternal pain spreading across chest; may radiate to inside of arm, neck, or jaw</p>	5–15 min	Usually related to exertion, emotion, eating, cold	Rest, nitroglycerin, oxygen
<b>Myocardial Infarction</b>	 <p>Substernal pain or pain over precordium; may spread widely throughout chest. Pain in shoulders and hands may be present.</p>	>15 min	Occurs spontaneously but may be sequela to unstable angina	Morphine sulfate, successful reperfusion of blocked coronary artery
<b>Pericarditis</b>	 <p>Sharp, severe substernal pain or pain to the left of sternum; may be felt in epigastrium and may be referred to neck, arms, and back</p>	Intermittent	Sudden onset. Pain increases with inspiration, swallowing, coughing, and rotation of trunk.	Sitting upright, analgesia, anti-inflammatory medications

(continued)

Table 26-2 • Assessing Chest Pain (Continued)

	CHARACTER, LOCATION, AND RADIATION	DURATION	PRECIPITATING EVENTS	RELIEVING MEASURES
<p><b>Pleuritic Pain</b></p> 	Pain arises from inferior portion of pleura; may be referred to costal margins or upper abdomen. Patient may be able to localize the pain.	30+ min	Often occurs spontaneously. Pain occurs or increases with inspiration.	Rest, time. Treatment of underlying cause, bronchodilators.
<p><b>Esophageal Pain</b> (Hiatal hernia, reflux esophagitis or spasm)</p> 	Substernal pain; may be projected around chest to shoulders.	5–60 min	Recumbency, cold liquids, exercise. May occur spontaneously.	Food, antacid. Nitroglycerin relieves spasm.
<p><b>Anxiety</b></p> 	Pain over chest; may be variable. Does not radiate. Patient may complain of numbness and tingling of hands and mouth.	2–3 min	Stress, emotional tachypnea	Removal of stimulus, relaxation

To avoid straining, patients who become easily constipated need to establish a regular bowel regimen. When straining, the patient tends to bear down (the Valsalva maneuver), which momentarily increases pressure on the baroreceptors. This triggers a vagal response, causing the heart rate to slow down and resulting in syncope in some patients. For the same reason, straining during urination should be avoided. Because many cardiac medications can cause gastrointestinal side effects or bleeding, the nurse asks about bloating, diarrhea, constipation, stomach upset, heartburn, loss of appetite, nausea, and vomiting. Patients taking platelet-inhibiting medications such as aspirin and clopidogrel (Plavix); intravenous GP IIb/IIIa platelet aggregation inhibitors such as abciximab (ReoPro), eptifibatid (Integrilin), and tirofiban (Aggrastat); and anticoagulants such as low-molecular-weight

heparin (ie, dalteparin [Fragmin]), enoxaparin (Lovenox), heparin, or warfarin (Coumadin) are screened for bloody urine or stools.

### ACTIVITY AND EXERCISE

As the nurse assesses the patient's activity and exercise history, it is important to note that decreases in activity tolerance are typically gradual and may go unnoticed by the patient. Therefore, the nurse needs to determine whether there has been a change in the activity pattern during the last 6 to 12 months. The patient's subjective response to activity is an essential assessment parameter. New symptoms or a change in the usual angina or angina equivalent during activity is a significant finding. Fatigue, associated with low ejection fraction and certain medications (eg, beta-blockers), can result in activity intolerance. Patients with fatigue may benefit

**Table 26-3 • Asking Questions to Evaluate Cardiac Problems**

SYMPTOMS	ASSESSMENT QUESTIONS	ASSESSING PATIENT'S CAPACITY FOR SELF-MANAGEMENT
Chest pain, chest discomfort, angina pain	<ul style="list-style-type: none"> <li>• Where is your pain (ask patient to point to location on chest)</li> <li>• What does the pain feel like? (pressure, heaviness, burning)</li> <li>• How severe is it on a scale of 0 to 10?</li> <li>• What causes the pain? (exertion, stress)</li> <li>• Does anything relieve it? (rest, nitroglycerin)</li> <li>• Does it spread to your arms, neck, jaw, shoulders, or back?</li> <li>• How long does the pain last?</li> <li>• Do you have any additional symptoms? (shortness of breath, palpitations, dizziness, sweating)</li> </ul>	<p><i>Symptom Recognition</i></p> <ul style="list-style-type: none"> <li>• If you have angina, what does it usually feel like?</li> <li>• If you have angina, how do your angina symptoms differ from the discomfort caused by your other medical conditions? (indigestion, GI disorders)</li> <li>• How do you think you would tell the difference between the symptoms of angina and a heart attack?</li> <li>• What were you doing when the pain started?</li> </ul> <p><i>Symptom Management</i></p> <ul style="list-style-type: none"> <li>• What did you do when the pain started?</li> <li>• How long did you wait before seeking medical attention (calling the doctor, coming to the emergency department, or calling the ambulance)</li> </ul> <p><i>Use of Nitroglycerin</i></p> <ul style="list-style-type: none"> <li>• Do you have a prescription for nitroglycerin (NTG) tablets or spray?</li> <li>• At the time of your chest pain, did you use your NTG?</li> <li>• How many tablets or sprays did you use and how frequently?</li> <li>• If you have NTG and did not take it with this angina episode, why do you think you did not take it?</li> <li>• When did you first open your NTG container? Where is it stored?</li> </ul>
Shortness of breath, edema, weight gain	<ul style="list-style-type: none"> <li>• When did you first notice feeling short of breath?</li> <li>• Do you have a cough? If yes, what do you cough up?</li> <li>• What makes you short of breath? Does anything make your breathing better or worse?</li> <li>• What activities are you no longer able to do because you are short of breath?</li> <li>• Do you ever wake up at night feeling short of breath?</li> <li>• What is your normal weight?</li> <li>• Have you had a recent weight gain?</li> <li>• Do you get up at night to urinate? Have you noticed an increase or decrease in the amount you usually urinate?</li> <li>• Have you noticed any weight gain or swelling in your feet, ankles, legs, or abdomen (sacrum if bedridden)? Do your shoes feel tight or clothes feel tight around your waist?</li> <li>• On how many pillows do you sleep, and has this changed recently?</li> <li>• Do you sleep in your bed, or do you breathe easier sleeping in a chair?</li> </ul>	<ul style="list-style-type: none"> <li>• Has anyone ever told you that you have heart failure? What does this mean to you?</li> <li>• Do you ever forget to take your diuretic medication (water pill) or other heart medicines or decide not to take them? If so, why do you think this happens?</li> <li>• What do you typically eat or drink? Who does the food shopping and meal preparation?</li> <li>• Are you on a sodium- or fluid-restricted diet? Have you been able to follow your special diet?</li> <li>• Do you have a scale to weigh yourself? How often do you weigh yourself?</li> <li>• What are important signs or symptoms to report to your doctor?</li> </ul>
Palpitations	<ul style="list-style-type: none"> <li>• Do you ever feel your heart racing, skipping beats, or pounding?</li> <li>• Do you ever feel lightheaded or dizzy?</li> <li>• Are there any other symptoms that occur at the same time?</li> <li>• How much caffeine do you consume?</li> <li>• Do you use tobacco (cigarettes, cigars, chew)?</li> <li>• Do you use any other stimulants, recreational drugs?</li> <li>• Do you use any nutritional supplements or herbs?</li> <li>• Have there been any changes in the amount of stress you experience?</li> </ul>	<ul style="list-style-type: none"> <li>• What did you do when your symptoms first occurred?</li> <li>• Is your primary health care provider aware of these symptoms?</li> <li>• Are you taking medication for this condition, and have you been taking it as directed?</li> </ul>
Fatigue	<ul style="list-style-type: none"> <li>• How would you describe your usual activity level?</li> <li>• What is your current activity level?</li> <li>• What were you able to do 1 month and 6 months ago?</li> <li>• What activities can you no longer do because of fatigue?</li> <li>• Do you feel rested when you wake up in the morning?</li> <li>• Can you rest during the day?</li> <li>• How often do you awaken at night, and for what reason?</li> </ul>	<ul style="list-style-type: none"> <li>• Have you spoken with your primary health care provider about decreases in your activity level?</li> <li>• Has anyone ever taught you energy conservation techniques? If so, are you able to use them?</li> </ul>

(continued)

**Table 26-3 • Asking Questions to Evaluate Cardiac Problems (Continued)**

SYMPTOMS	ASSESSMENT QUESTIONS	ASSESSING PATIENT'S CAPACITY FOR SELF-MANAGEMENT
Dizziness, syncope (loss of consciousness)	<ul style="list-style-type: none"> <li>• Do you ever feel dizzy or lightheaded?</li> <li>• Do you ever pass out or have fainting spells?</li> <li>• Does this happen when you move from a lying to a sitting or standing position?</li> <li>• Do you strain while having a bowel movement or when urinating?</li> <li>• Have you been urinating more than usual?</li> <li>• Have you decreased the amount of fluids you normally drink?</li> <li>• Do you have headaches?</li> </ul>	<ul style="list-style-type: none"> <li>• Have you ever been told you have high or low blood pressure? Has it been checked recently?</li> <li>• Are you taking any medications that can lower your blood pressure?</li> <li>• Before standing from a lying position, do you sit for a few minutes? Does that relieve the dizziness?</li> <li>• What are you using to prevent constipation?</li> </ul>

from having their medications adjusted and learning energy conservation techniques.

Additional areas to ask about include possible architectural barriers and challenges in the home, and what the patient does for exercise. If the patient exercises, the nurse asks additional questions: What is the intensity, and how long and how often is exercise performed? Has the patient ever participated in a cardiac rehabilitation program? Functional levels are known to improve for almost all patients who participate in a cardiac rehabilitation program, and attendance is highly recommended (Smith et al., 2001). Patients with disabilities may require an individually tailored exercise program.

### SLEEP AND REST

Clues to worsening cardiac disease, especially HF, can be revealed by sleep-related events. Determining where the patient sleeps or rests is important. Recent changes, such as sleeping upright in a chair instead of in bed, increasing the number of pillows used, awakening short of breath at night (paroxysmal nocturnal dyspnea [PND]), or awakening with angina (nocturnal angina), are all indicative of worsening HF.

### COGNITION AND PERCEPTION

Evaluating cognitive ability helps to determine whether the patient has the mental capacity to manage safe and effective self-care. Is the patient's short-term memory intact? Is there any history of dementia? Is there evidence of depression or anxiety? Can the patient read? Can the patient read English? What is the patient's reading level? What is the patient's preferred learning style? What information does the patient perceive as important?

Providing the patient with written information can be a valuable part of patient education, but only if the patient can read and comprehend the information. Related assessments include possible hearing or visual impairments. If vision is impaired, patients with HF may not be able to weigh themselves independently nor keep records of weight, BP, pulse, or other data requested by the health care team.

### SELF-PERCEPTION AND SELF-CONCEPT

Personality factors are associated with the development of and recovery from CAD. Most commonly cited is "type A behavior," which is characterized by competitive, hard-driving behaviors and a sense of time urgency. Although this behavior is not an independent risk factor for CAD, anger and hostility (personality traits common in people with "type A behavior") do affect the heart. People with these traits react to frustrating situations with an increase in BP, heart rate, and neuroendocrine responses. This

physiologic activation, called cardiac reactivity, is thought to trigger acute cardiovascular events (Woods et al., 1999).

During the health history, the nurse discovers how patients feel about themselves by asking questions such as: How would you describe yourself? Have you changed the way you feel about yourself since your heart attack or surgery? Do you find that you are easily angered or hostile? How do you feel right now? What helps to manage these feelings? To fully evaluate this health pattern, assistance from a psychiatric clinical nurse specialist, psychologist, or psychiatrist may be necessary.

### ROLES AND RELATIONSHIPS

Determining the patient's social support systems is vitally important in today's health care environment. Hospital stays for cardiac illnesses have shortened. Many invasive diagnostic cardiac procedures, such as cardiac catheterization and percutaneous transluminal coronary angioplasty (PTCA) are performed as outpatient procedures. Patients are discharged back into the community with activity limitations, such as driving restrictions, and with greater nursing care and educational needs. These needs have significant implications for people who are independent under normal circumstances, and for people who are at higher risk for problems, such as older adults.

To assess support systems, the nurse needs to ask: Who is the primary caregiver? With whom does the patient live? Are there adequate services in place to provide a safe home environment? The nurse also assesses for any significant effects the cardiac illness has had on the patient's role in the family. Are there adequate finances and health insurance? The answers to these questions will assist the nurse in developing a plan to meet the patient's home care needs.

### SEXUALITY AND REPRODUCTION

Although people recovering from cardiac illnesses or procedures are concerned about sexual activity, they are less likely to ask their nurse or other health care provider for information to help them resume their normal sex life. Lack of correct information and fear lead to reduced frequency and satisfaction with sexual activity. Therefore, nurses need to initiate this discussion with patients and not wait for them to bring it up in conversation. At first, inform the patient that it is common for people with similar heart problems to worry about resuming sexual activity. Then ask the patient to talk about his or her concerns.

The most commonly cited reasons for changes in sexual activity are fear of another heart attack or sudden death; untoward symptoms such as angina, dyspnea, or palpitations; and problems

with impotence or depression. In men, impotence may develop as a side effect of cardiac medications (beta-adrenergic blocking agents) and may prompt patients to stop taking them. Other medications can be substituted, so patients should be encouraged to discuss this problem with their health care provider. Often, patients and their partners do not have adequate information about the physical demands related to sexual activity and ways in which these demands can be modified. The physiologic demands are greatest during orgasm, reaching 5 or 6 metabolic equivalents (METs). This level of activity is equivalent to walking 3 to 4 miles per hour on a treadmill. The METs expended before and after orgasm are considerably less, at 3.7 METs (Steinke, 2000). Having this information may make patients and their partners more comfortable with resuming sexual activity.

A reproductive history is necessary for women of childbearing age, particularly those with seriously compromised cardiac function. These women may be advised by their physicians not to become pregnant. The reproductive history includes information about previous pregnancies, plans for future pregnancies, oral contraceptive use (especially in women older than 35 years of age who are smokers), and use of hormone replacement therapy.

### COPING AND STRESS TOLERANCE

It is important to determine the presence of psychosocial factors that adversely affect cardiac health. Anxiety, depression, and stress are known to influence both the development of and recovery from CAD. High levels of anxiety are associated with an increased incidence of CAD and increased in-hospital complication rates after MI. People with depression have an increased risk of MI and heart disease–related death, compared to people without depression. It is postulated that people who are depressed feel hopeless and are less motivated to make lifestyle changes and follow treatment plans, explaining the association between mortality and depression (Buselli & Stuart, 1999).

Stress initiates a variety of physiologic responses, including increases in the circulation of catecholamines and cortisol, and has been strongly linked to cardiovascular events. Therefore, patients need to be assessed for presence of negative and positive emotions, as well as sources of stress. This is achieved by asking questions about recent or ongoing stressors, previous coping styles and effectiveness, and the patient's perception of his or her current mood and coping ability. To adequately evaluate this health pattern, consultation with a psychiatric clinical nurse specialist, psychologist, or psychiatrist may be indicated.

### PREVENTION STRATEGIES

Additional features of the health history include identification of risk factors and measures taken by the patient to prevent disease. The nurse's questions need to focus on the patient's health promotion practices. Epidemiologic studies show that certain conditions or behaviors (ie, risk factors) are associated with a greater incidence of coronary artery, peripheral vascular, and cerebrovascular disease. Risk factors are classified by the extent to which they can be modified by changing one's lifestyle or modifying personal behaviors.

Once a patient's risk factors are determined, the nurse assesses whether the patient has a plan for making necessary behavioral changes and whether assistance is needed to support these lifestyle changes. For example, tobacco use is the most common avoidable cause of CAD. The first step in treating this health risk is to identify patients who use tobacco products and those who have recently quit. Because 70% of smokers visit a health care facility each

year, nurses have ample opportunities to assess patients for tobacco use. For those who use tobacco, it is imperative to ask whether they are willing to quit. Provide cessation advice, motivation to quit, and relapse prevention strategies, as outlined in a U.S. Public Health Service report (The Tobacco Use and Dependence Clinical Practice Guideline Update Panel, Staff, and Consortium Representatives, 2000), can be delivered. For patients who have obesity, hyperlipidemia, hypertension, and diabetes, the nurse determines any problems the patient may be having following the prescribed management plan (ie, diet, exercise, and medications). It may be necessary to clarify the patient's responsibilities, assist with finding additional resources, or make alternative plans for risk factor modification.

Comprehensive secondary prevention strategies (early diagnosis and prompt intervention to halt or slow the disease process and its consequences) aimed at reducing cardiovascular risk factors improve overall survival, improve quality of life, reduce the need for revascularization procedures (coronary artery bypass surgery and PTCA), and reduce the incidence of subsequent MIs. The overall benefits of secondary prevention also apply to other patient groups with atherosclerotic vascular disease, including patients with transient ischemic attacks, stroke, and peripheral vascular disease (the leading cause of disability and death in these patients being CAD). Despite these findings, only one third of eligible patients, over the long term, adhere to risk factor interventions. Patient compliance increases significantly with a team approach that includes long-term follow-up with office or clinic visits and telephone contact (Smith et al., 2001).

## PHYSICAL ASSESSMENT

A physical examination is performed to confirm the data obtained in the health history. In addition to observing the patient's general appearance, a cardiac physical examination should include an evaluation of the following:

- Effectiveness of the heart as a pump
- Filling volumes and pressures
- Cardiac output
- Compensatory mechanisms

Indications that the heart is not contracting sufficiently or functioning effectively as a pump include reduced pulse pressure, cardiac enlargement, and murmurs and gallop rhythms (abnormal heart sounds).

The amount of blood filling the atria and ventricles and the resulting pressures (called filling volumes and pressures) are estimated by the degree of jugular vein distention and the presence or absence of congestion in the lungs, peripheral edema, and postural changes in BP that occur when the individual sits up or stands.

Cardiac output is reflected by cognition, heart rate, pulse pressure, color and texture of the skin, and urine output. Examples of compensatory mechanisms that help maintain cardiac output are increased filling volumes and elevated heart rate. Note that the findings on the physical examination are correlated with data obtained from diagnostic procedures, such as hemodynamic monitoring (discussed later).

The examination, which proceeds logically from head to toe, can be performed in about 10 minutes with practice and covers the following areas: (1) general appearance, (2) cognition, (3) skin, (4) BP, (5) arterial pulses, (6) jugular venous pulsations and pressures, (7) heart, (8) extremities, (9) lungs, and (10) abdomen.

## General Appearance and Cognition

The nurse observes the patient's level of distress, level of consciousness, and thought processes as an indication of the heart's ability to propel oxygen to the brain (cerebral perfusion). The nurse also observes for evidence of anxiety, along with any effects emotional factors may have on cardiovascular status. The nurse attempts to put the anxious patient at ease throughout the examination.

## Inspection of the Skin

Examination of the skin begins during the evaluation of the general appearance of the patient and continues throughout the assessment. It includes all body surfaces, starting with the head and finishing with the lower extremities. Skin color, temperature, and texture are assessed. The more common findings associated with cardiovascular disease are as follows.

- **Pallor**—a decrease in the color of the skin—is caused by lack of oxyhemoglobin. It is a result of anemia or decreased arterial perfusion. Pallor is best observed around the fingernails, lips, and oral mucosa. In patients with dark skin, the nurse observes the palms of the hands and soles of the feet.
- **Peripheral cyanosis**—a bluish tinge, most often of the nails and skin of the nose, lips, earlobes, and extremities—suggests decreased flow rate of blood to a particular area, which allows more time for the hemoglobin molecule to become desaturated. This may occur normally in peripheral vasoconstriction associated with a cold environment, in patients with anxiety, or in disease states such as HF.
- **Central cyanosis**—a bluish tinge observed in the tongue and buccal mucosa—denotes serious cardiac disorders (pulmonary edema and congenital heart disease) in which venous blood passes through the pulmonary circulation without being oxygenated.
- **Xanthelasma**—yellowish, slightly raised plaques in the skin—may be observed along the nasal portion of one or both eyelids and may indicate elevated cholesterol levels (hypercholesterolemia).
- **Reduced skin turgor** occurs with dehydration and aging.
- **Temperature and moistness** are controlled by the autonomic nervous system. Normally the skin is warm and dry. Under stress, the hands may become cool and moist. In cardiogenic shock, sympathetic nervous system stimulation causes vasoconstriction, and the skin becomes cold and clammy. During an acute MI, diaphoresis is common.
- **Ecchymosis (bruise)**—a purplish-blue color fading to green, yellow, or brown over time—is associated with blood outside of the blood vessels and is usually caused by trauma. Patients who are receiving anticoagulant therapy should be carefully observed for unexplained ecchymosis. In these patients, excessive bruising indicates prolonged clotting times (prothrombin or partial thromboplastin time) caused by an anticoagulant dosage that is too high.
- **Wounds, scars, and tissue surrounding implanted devices** should also be examined. Wounds are assessed for adequate healing, and any scars from previous surgeries are noted. The skin surrounding a pacemaker or implantable cardioverter defibrillator generator is examined for thinning, which could indicate erosion of the device through the skin.

## Blood Pressure

Systemic arterial BP is the pressure exerted on the walls of the arteries during ventricular systole and diastole. It is affected by factors such as cardiac output, distention of the arteries, and the volume, velocity, and viscosity of the blood. BP usually is expressed as the ratio of the systolic pressure over the diastolic pressure, with normal adult values ranging from 100/60 to 140/90 mm Hg. The average normal BP usually cited is 120/80 mm Hg. An increase in BP above the upper normal range is called hypertension (see Chap. 32 for further definitions and management), whereas a decrease below the lower range is called hypotension.

### BLOOD PRESSURE MEASUREMENT

BP can be measured with the use of invasive arterial monitoring systems (discussed later) or noninvasively by a sphygmomanometer and stethoscope or by an automated BP monitoring device. A detailed description of the procedure for obtaining BP can be found in nursing skills textbooks, and specific manufacturer's instructions review the proper use of the automated monitoring devices. Several important details must be observed to ensure that BP measurements are accurate; these are highlighted in Chart 26-2.

### PULSE PRESSURE

The difference between the systolic and the diastolic pressures is called the pulse pressure. It is a reflection of stroke volume, ejection velocity, and systemic vascular resistance. Pulse pressure, which normally is 30 to 40 mm Hg, indicates how well the patient maintains cardiac output. The pulse pressure increases in conditions that elevate the stroke volume (anxiety, exercise, bradycardia), reduce systemic vascular resistance (fever), or reduce distensibility of the arteries (atherosclerosis, aging, hypertension). Decreased pulse pressure is an abnormal condition reflecting reduced stroke volume and ejection velocity (shock, HF, hypovolemia, mitral regurgitation) or obstruction to blood flow during systole (mitral or aortic

Chart  
26-2

### Ensuring Accurate Blood Pressure Measurement

- Cuff size must be appropriate for the patient. (The cuff size should have a bladder width at least 40% and length at least 80% of limb circumference.) The average adult cuff is 12 to 14 cm wide and 30 cm long. Using a cuff that is too small will give a high reading, whereas, too large a cuff results in a falsely low reading.
- Calibration of the sphygmomanometer should be performed routinely to ensure accuracy of blood pressure reading.
- Cuff is firmly wrapped around the arm, and cuff bladder is centered over the brachial artery.
- Patient's arm should be at heart level.
- Initial recordings are made on both arms, and subsequent measurements are taken on the arm with the higher pressure. Normally, in the absence of disease of the vasculature, there is a difference of no more than 5 mm Hg between arm pressures.
- Position of the patient and site of blood pressure measurement (eg, RA for right arm) are recorded.
- Palpation of the systolic pressure before auscultation helps to detect an auscultatory gap more readily.
- The patient is asked not to talk during blood pressure measurements. A significant increase in blood pressure and heart rate occurs when subjects are talking.

stenosis). A pulse pressure of less than 30 mm Hg signifies a serious reduction in cardiac output and requires further cardiovascular assessment.

### POSTURAL BLOOD PRESSURE CHANGES

**Postural (orthostatic) hypotension** occurs when the BP drops significantly after the patient assumes an upright posture. It is usually accompanied by dizziness, lightheadedness, or syncope.

Although there are many causes of postural hypotension, the three most common causes in patients with cardiac problems are a reduced volume of fluid or blood in the circulatory system (intravascular volume depletion, dehydration), inadequate vasoconstrictor mechanisms, and insufficient autonomic effect on vascular constriction. Postural changes in BP and an appropriate history help health care providers differentiate among these causes. The following recommendations are important when assessing postural BP changes:

- Position the patient supine and flat (as symptoms permit) for 10 minutes before taking the initial BP and heart rate measurements.
- Check supine measurements before checking upright measurements.
- Do not remove the BP cuff between position changes, but check to see that it is still correctly placed.
- Assess postural BP changes with the patient sitting on the edge of the bed with feet dangling and, if appropriate, with the patient standing at the side of the bed.
- Wait 1 to 3 minutes after each postural change before measuring BP and heart rate.
- Be alert for any signs or symptoms of patient distress. If necessary, return the patient to a lying position before completing the test.
- Record both heart rate and BP and indicate the corresponding position (e.g., lying, sitting, standing) and any signs or symptoms that accompany the postural change.

Normal postural responses that occur when a person stands up or goes from a lying to a sitting position include (1) a heart rate increase of 5 to 20 bpm above the resting rate (to offset reduced stroke volume and maintain cardiac output); (2) an unchanged systolic pressure, or a slight decrease of up to 10 mm Hg; and (3) a slight increase of 5 mm Hg in diastolic pressure.

A decrease in the amount of blood or fluid in the circulatory system should be suspected after diuretic therapy or bleeding, when a postural change results in an increased heart rate and either a decrease in systolic pressure by 15 mm Hg or a drop in the diastolic pressure by 10 mm Hg. Vital signs alone do not differentiate between a decrease in intravascular volume and inadequate constriction of the blood vessels as a cause of postural hypotension. With intravascular volume depletion, the reflexes that maintain cardiac output (increased heart rate and peripheral vasoconstriction) function correctly; the heart rate increases, and the peripheral vessels constrict. However, because of lost volume, the BP falls. With inadequate vasoconstrictor mechanisms, the heart rate again responds appropriately, but because of diminished peripheral vasoconstriction the BP drops. The following is an example of a postural BP recording showing either intravascular volume depletion or inadequate vasoconstrictor mechanisms:

Lying down, BP 120/70, heart rate 70  
Sitting, BP 100/55, heart rate 90  
Standing, BP 98/52, heart rate 94

In autonomic insufficiency, the heart rate is unable to increase to completely compensate for the gravitational effects of an upright posture. Peripheral vasoconstriction may be absent or diminished. Autonomic insufficiency does not rule out a concurrent decrease in intravascular volume. The following is an example of autonomic insufficiency as demonstrated by postural BP changes:

Lying down, BP 150/90, heart rate 60  
Sitting, BP 100/60, heart rate 60

### Arterial Pulses

Factors to be evaluated in examining the pulse are rate, rhythm, quality, configuration of the pulse wave, and quality of the arterial vessel.

#### PULSE RATE

The normal pulse rate varies from a low of 50 bpm in healthy, athletic young adults to rates well in excess of 100 bpm after exercise or during times of excitement. Anxiety frequently raises the pulse rate during the physical examination. If the rate is higher than expected, it is appropriate to reassess it near the end of the physical examination, when the patient may be more relaxed.

#### PULSE RHYTHM

The rhythm of the pulse is as important to assess as the rate. Minor variations in regularity of the pulse are normal. The pulse rate, particularly in young people, increases during inhalation and slows during exhalation. This is called sinus arrhythmia.

For the initial cardiac examination, or if the pulse rhythm is irregular, the heart rate should be counted by auscultating the apical pulse for a full minute while simultaneously palpating the radial pulse.

Any discrepancy between contractions heard and pulses felt is noted. Disturbances of rhythm (dysrhythmias) often result in a pulse deficit, a difference between the apical rate (the heart rate heard at the apex of the heart) and the peripheral rate. Pulse deficits commonly occur with atrial fibrillation, atrial flutter, premature ventricular contractions, and varying degrees of heart block. See Chapter 27 for a detailed discussion of these dysrhythmias.

To understand the complexity of dysrhythmias that may be encountered during the examination, the nurse needs to have a sophisticated knowledge of cardiac electrophysiology, obtained through advanced education and training.

#### PULSE QUALITY

The quality, or amplitude, of the pulse can be described as absent, diminished, normal, or bounding. It should be assessed bilaterally. Scales can be used to rate the strength of the pulse. The following is an example of a 0-to-4 scale:

0	pulse not palpable or absent
+1	weak, thready pulse; difficult to palpate; obliterated with pressure
+2	diminished pulse; cannot be obliterated
+3	easy to palpate, full pulse; cannot be obliterated
+4	strong, bounding pulse; may be abnormal

The numerical classification is quite subjective; therefore, when documenting the pulse quality, it helps to specify a scale range (eg, “left radial +3/+4”).

#### PULSE CONFIGURATION

The configuration (contour) of the pulse conveys important information. In patients with stenosis of the aortic valve, the valve

opening is narrowed, reducing the amount of blood ejected into the aorta. The pulse pressure is narrow, and the pulse feels feeble. In aortic insufficiency, the aortic valve does not close completely, allowing blood to flow back or leak from the aorta into the left ventricle. The rise of the pulse wave is abrupt and strong, and its fall is precipitous—a “collapsing” or “water hammer” pulse. The true configuration of the pulse is best appreciated by palpating over the carotid artery rather than the distal radial artery, because the dramatic characteristics of the pulse wave may be distorted when the pulse is transmitted to smaller vessels.

### EFFECT OF VESSEL QUALITY ON PULSE

The condition of the vessel wall also influences the pulse and is of concern, especially in older patients. Once rate and rhythm have been determined, the nurse assesses the quality of the vessel by palpating along the radial artery and comparing it with normal vessels. Does the vessel wall appear to be thickened? Is it tortuous?

To assess peripheral circulation, the nurse locates and evaluates all arterial pulses. Arterial pulses are palpated at points where the arteries are near the skin surface and are easily compressed against bones or firm musculature. Pulses are detected over the temporal, carotid, brachial, radial, femoral, popliteal, dorsalis pedis, and posterior tibial arteries. A reliable assessment of the pulses of the lower extremities depends on accurate identification of the location of the artery and careful palpation of the area. Light palpation is essential; firm finger pressure can easily obliterate the dorsalis pedis and posterior tibial pulses and confuse the examiner. In approximately 10% of patients, the dorsalis pedis pulses are not palpable. In such circumstances, both are usually absent together, and the posterior tibial arteries alone provide adequate blood supply to the feet. Arteries in the extremities are often palpated simultaneously to facilitate comparison of quality.

**NURSING ALERT** Do not palpate temporal or carotid arteries simultaneously, because it is possible to decrease the blood flow to the brain.

### Jugular Venous Pulsations

An estimate of right-sided heart function can be made by observing the pulsations of the jugular veins of the neck. This provides a means of estimating central venous pressure, which reflects right atrial or right ventricular end-diastolic pressure (the pressure immediately preceding the contraction of the right ventricle).

Pulsations of the internal jugular veins are most commonly assessed. If they are difficult to see, pulsations of the external jugular veins may be noted. These veins are more superficial and are visible just above the clavicles, adjacent to the sternocleidomastoid muscles. The external jugular veins are frequently distended while the patient lies supine on the examining table or bed. As the patient's head is elevated, the distention of the veins disappears. The veins normally are not apparent if the head of the bed or examining table is elevated more than 30 degrees.

Obvious distention of the veins with the patient's head elevated 45 degrees to 90 degrees indicates an abnormal increase in the volume of the venous system. This is associated with right-sided HF, less commonly with obstruction of blood flow in the superior vena cava, and rarely with acute massive pulmonary embolism.

### Heart Inspection and Palpation

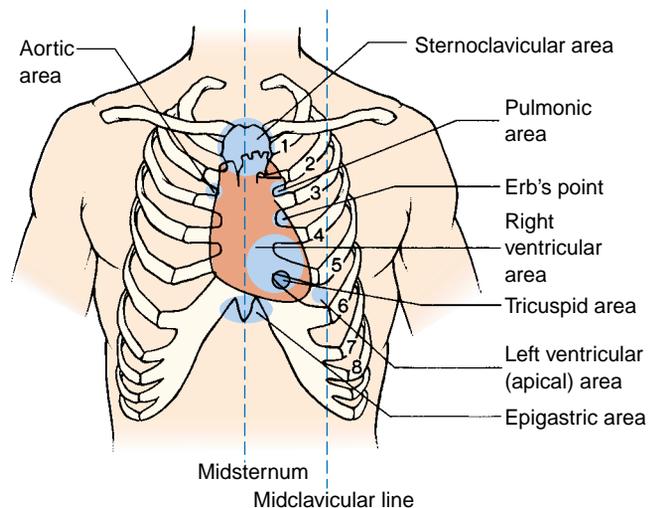

The heart is examined indirectly by inspection, palpation, percussion, and auscultation of the chest wall. A systematic approach is the cornerstone of a thorough assessment. Examination of the chest wall is performed in the following six areas (Fig. 26-6):

1. **Aortic area**—second intercostal space to the right of the sternum. To determine the correct intercostal space, start at the angle of Louis by locating the bony ridge near the top of the sternum, at the junction of the body and the manubrium. From this angle, locate the second intercostal space by sliding one finger to the left or right of the sternum. Subsequent intercostal spaces are located from this reference point by palpating down the rib cage.
2. **Pulmonic area**—second intercostal space to the left of the sternum
3. **Erb's point**—third intercostal space to the left of the sternum
4. **Right ventricular or tricuspid area**—fourth and fifth intercostal spaces to the left of the sternum
5. **Left ventricular or apical area**—the PMI, location on the chest where heart contractions can be palpated
6. **Epigastric area**—below the xiphoid process

For most of the examination, the patient lies supine, with the head slightly elevated. The right-handed examiner is positioned at the right side of the patient and the left-handed examiner at the left side.

In a systematic fashion, each area of the precordium is inspected and then palpated. Oblique lighting is used to assist the examiner in identifying subtle pulsation. A normal impulse that is distinct and located over the apex of the heart is called the **apical impulse** (PMI). It may be observed in young people and in older people who are thin. The apical impulse is normally located and auscultated in the left fifth intercostal space in the midclavicular line (Fig. 26-7).

In many cases, the apical impulse is palpable and is normally felt as a light pulsation, 1 to 2 cm in diameter. It is felt at the onset of the first heart sound and lasts for only half of systole. (See the next section for a discussion of heart sounds.) The nurse uses the palm of the hand to locate the apical impulse initially and the fingerpads to assess its size and quality. A broad and forceful apical impulse is

**FIGURE 26-6** Areas of the precordium to be assessed when evaluating heart function. (Numerals identify ribs of adjacent intercostal spaces.)

**FIGURE 26-7** Locating (A) and palpating (B) the apical impulse (also called the point of maximal impulse, PMI). The apical impulse normally is located at the fifth intercostal space to the left of the sternum at the midclavicular line. The nurse locates the impulse with the palm of the hand and palpates with the fingerpads. © B. Proud in Weber, J. W., & Kelley, J. (2003). *Health assessment in nursing* (2nd ed.). Philadelphia: Lippincott Williams & Wilkins.

known as a left ventricular heave or lift. It is so named because it appears to lift the hand from the chest wall during palpation.

An apical impulse below the fifth intercostal space or lateral to the midclavicular line usually denotes left ventricular enlargement from left ventricular failure. Normally, the apical impulse is palpable in only one intercostal space; palpability in two or more adjacent intercostal spaces indicates left ventricular enlargement. If the apical impulse can be palpated in two distinctly separate areas and the pulsation movements are paradoxical (not simultaneous), a ventricular aneurysm should be suspected.

Abnormal, turbulent blood flow within the heart may be palpated with the palm of the hand as a purring sensation. This phenomenon is called a thrill and is associated with a loud murmur. A thrill is always indicative of significant pathology within the heart. Thrills also may be palpated over vessels when blood flow is significantly and substantially obstructed and over the carotid arteries if aortic stenosis is present or if the aortic valve is narrowed.

## Chest Percussion

Normally, only the left border of the heart can be detected by percussion. It extends from the sternum to the midclavicular line in the third to fifth intercostal spaces. The right border lies under

the right margin of the sternum and is not detectable. Enlargement of the heart to either the left or right usually can be noted. In people with thick chests, obesity, or emphysema, the heart may lie so deep under the thoracic surface that not even its left border can be noted unless the heart is enlarged. In such cases, unless the nurse detects a displaced apical impulse and suspects cardiac enlargement, percussion is omitted.

## Cardiac Auscultation

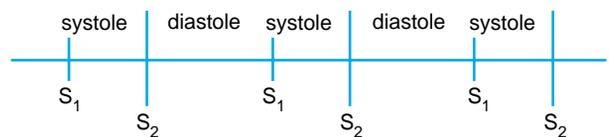

All areas identified in Figure 26-6, except the epigastric area, are auscultated. These include the aortic area, the pulmonary area, Erb's point, the tricuspid area, and the apical area. The actions of the four valves are uniquely reflected at specific locations on the chest wall. These locations do not correspond to the anatomic locations of the valves within the chest; rather, they reflect the patterns by which heart sounds radiate toward the chest wall. Sound in vessels through which blood is flowing is always reflected downstream. For example, the actions of the mitral valve are usually heard best in the fifth intercostal space at the midclavicular line. This is called the mitral valve area.

## HEART SOUNDS

The **normal heart sounds**,  $S_1$  and  $S_2$ , are produced primarily by the closing of the heart valves. The time between  $S_1$  and  $S_2$  corresponds to systole (Fig. 26-8). This is normally shorter than the time between  $S_2$  and  $S_1$  (diastole). As the heart rate increases, diastole shortens.

In normal physiology, the periods of systole and diastole are silent. Ventricular disease, however, can give rise to transient sounds in systole and diastole that are called gallops, snaps, or clicks. Significant narrowing of the valve orifices at times when they should be open, or residual gapping of valves at times when they should be closed, gives rise to prolonged sounds called murmurs.

**$S_1$ —First Heart Sound.** Closure of the mitral and tricuspid valves creates the first heart sound ( $S_1$ ), although vibration of the myocardial wall also may contribute to this sound. Although  $S_1$  is heard over the entire precordium, it is heard best at the apex of the heart (apical area). Its intensity increases when the valve leaflets are made rigid by calcium in rheumatic heart disease and in any circumstance in which ventricular contraction occurs at a time when the valve is caught wide open. The latter circumstance occurs, for example, when a premature ventricular contraction interrupts the normal cardiac cycle.  $S_1$  varies in intensity from beat to beat when atrial contraction is not synchronous with ventricular contraction. This is because the valve may be fully or partially closed on one beat and open on the subsequent one as a function of irregular atrial activity.  $S_1$  is easily identifiable and serves as the point of reference for the remainder of the cardiac cycle.

**FIGURE 26-8** Normal heart sounds. The first heart sound ( $S_1$ ) is produced by the closing of the mitral and tricuspid valves and is best heard at the apex of the heart (left ventricular or apical area). The second heart sound ( $S_2$ ) is produced by the closing of the aortic and pulmonic valves and is loudest at the base of the heart. The time between  $S_1$  and  $S_2$  corresponds to systole. The time between  $S_2$  and  $S_1$  is diastole.

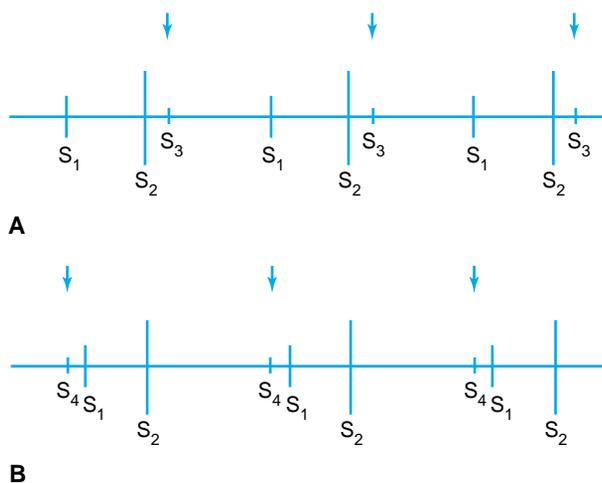

**S<sub>2</sub>—Second Heart Sound.** Closing of the aortic and pulmonic valves produces the second heart sound (S<sub>2</sub>). Although these two valves close almost simultaneously, the pulmonic valve usually lags slightly behind. Therefore, under certain circumstances, the two components of the second sound may be heard separately (split S<sub>2</sub>). The splitting is more likely to be accentuated on inspiration and to disappear on exhalation. (More blood is ejected from the right ventricle during inspiration than during exhalation.)

S<sub>2</sub> is heard loudest at the base of the heart. The aortic component of S<sub>2</sub> is heard clearly in both the aortic and pulmonic areas, and less clearly at the apex. The pulmonic component of S<sub>2</sub>, if present, may be heard only over the pulmonic area. Therefore, one may hear a “single” S<sub>2</sub> in the aortic area and a split S<sub>2</sub> in the pulmonic area.

**Gallop Sounds.** If the blood filling the ventricle is impeded during diastole, as occurs in certain disease states, then a temporary vibration may occur in diastole that is similar to, although usually softer than, S<sub>1</sub> and S<sub>2</sub>. The heart sounds then come in triplets and have the acoustic effect of a galloping horse; they are called gallops. This may occur early in diastole, during the rapid-filling phase of the cardiac cycle, or later at the time of atrial contraction.

A gallop sound occurring during rapid ventricular filling is called a third heart sound (S<sub>3</sub>); it represents a normal finding in children and young adults (Fig. 26-9A). Such a sound is heard in patients who have myocardial disease or in those who have HF and whose ventricles fail to eject all of their blood during systole. An S<sub>3</sub> gallop is heard best with the patient lying on the left side.

Gallop sounds heard during atrial contraction are called fourth heart sounds (S<sub>4</sub>) (see Fig. 26-9B). An S<sub>4</sub> is often heard when the ventricle is enlarged or hypertrophied and therefore resistant to filling. Such a circumstance may be associated with CAD, hypertension, or stenosis of the aortic valve. On rare occasions, all four heart sounds are heard within a single cardiac cycle, giving rise to what is called a quadruple rhythm.

**FIGURE 26-9** Gallops. (A) An S<sub>3</sub> gallop is heard immediately following the S<sub>2</sub> and occurs when the blood filling the ventricle is impeded during diastole, resulting in temporary vibrations. The heart sounds come in triplets and resemble the sound of a galloping horse. Myocardial disease and heart failure are associated with this sound. (B) An S<sub>4</sub> gallop is heard immediately preceding the S<sub>1</sub>. The S<sub>4</sub> sound occurs during atrial contraction and is often heard when the ventricle is enlarged or hypertrophied. Associated conditions include coronary artery disease, hypertension, and stenosis of the aortic valve.

Gallop sounds are very low-frequency sounds and may be heard only with the bell of the stethoscope placed very lightly against the chest. They are heard best at the apex, although occasionally, when emanating from the right ventricle, they may be heard to the left of the sternum.

**Snaps and Clicks.** Stenosis of the mitral valve resulting from rheumatic heart disease gives rise to an unusual sound very early in diastole that is high-pitched and is best heard along the left sternal border. The sound is caused by high pressure in the left atrium with abrupt displacement of a rigid mitral valve. The sound is called an opening snap. It occurs too long after S<sub>2</sub> to be mistaken for a split S<sub>2</sub> and too early in diastole to be mistaken for a gallop. It almost always is associated with the murmur of mitral stenosis and is specific to this disorder.

In a similar manner, stenosis of the aortic valve gives rise to a short, high-pitched sound immediately after S<sub>1</sub> that is called an ejection click. This is caused by very high pressure within the ventricle, displacing a rigid and calcified aortic valve.

**Murmurs.** Murmurs are created by the turbulent flow of blood. The causes of the turbulence may be a critically narrowed valve, a malfunctioning valve that allows regurgitant blood flow, a congenital defect of the ventricular wall, a defect between the aorta and the pulmonary artery, or an increased flow of blood through a normal structure (eg, with fever, pregnancy, hyperthyroidism). Murmurs are characterized and consequently described by several characteristics, including timing in the cardiac cycle, location on the chest wall, intensity, pitch, quality, and pattern of radiation (Chart 26-3).

**Friction Rub.** In pericarditis, a harsh, grating sound that can be heard in both systole and diastole is called a friction rub. It is caused by abrasion of the pericardial surfaces during the cardiac cycle. Because a friction rub may be confused with a murmur, care should be taken to identify the sound and to distinguish it from murmurs that may be heard in both systole and diastole. A pericardial friction rub can be heard best using the diaphragm of the stethoscope, with the patient sitting up and leaning forward.

## AUSCULTATION PROCEDURE

During auscultation, the patient remains supine and the examining room is as quiet as possible. A stethoscope with a diaphragm and a bell is necessary for accurate auscultation of the heart.

Using the diaphragm of the stethoscope, the examiner starts at the apical area and progresses upward along the left sternal border to the pulmonic and aortic areas. If desired, the examiner may choose to begin the examination at the aortic and pulmonic areas and progress downward to the apex of the heart. Initially, S<sub>1</sub> is identified and evaluated with respect to its intensity and splitting. Next, S<sub>2</sub> is identified, and its intensity and any splitting are noted. After concentrating on S<sub>1</sub> and S<sub>2</sub>, the examiner listens for extra sounds in systole and then in diastole.

Sometimes it helps to ask the following questions: Do I hear snapping or clicking sounds? Do I hear any high-pitched blowing sounds? Is this sound in systole, or diastole, or both? The examiner again proceeds to move the stethoscope to all of the designated areas of the precordium, listening carefully for these sounds. Finally, the patient is turned on the left side and the stethoscope is placed on the apical area, where an S<sub>3</sub>, an S<sub>4</sub>, and a mitral murmur are more readily detected.

Once an abnormality is heard, the entire chest surface is re-examined to determine the exact location of the sound and its

Chart  
26-3**Characteristics of Heart Murmurs**

Heart murmurs are described in terms of location, timing, intensity, pitch, quality, and radiation. These characteristics provide data about the location and nature of the cardiac abnormality.

**Location**

The location of the murmur (where it is detected on the chest wall) is crucial. Depending on the type of valvular disorder, a murmur can be heard only at the apex or more widely over the chest wall, or along the left sternal border between the third and fourth interspaces.

**Timing**

Timing of the murmur in the cardiac cycle is vital. The examiner first determines whether the murmur is occurring in systole or in diastole. Then, does it begin simultaneously with a heart sound, or is there some delay between the sound and the beginning of the murmur? Does the murmur continue to (or through) the second heart sound, or is there a delay between the end of the murmur and the second heart sound? Are diastolic murmurs (between the second and first heart sounds) continuous, or do they subside in mid- or late diastole?

**Intensity**

The intensity of murmurs is conventionally graded from I through VI. Sometimes, grade I murmurs are difficult to hear. However, a grade II cardiac murmur can be easily perceived by the experienced examiner. Murmurs of grades IV or louder are usually associated with thrills that may be palpated on the surface of the chest wall. A grade VI murmur can be heard with the stethoscope off the chest. A murmur may vary in intensity from its beginning to its conclusion. This is very characteristic of certain valvular disorders.

**Pitch**

The next important characteristic of a murmur is its pitch, which may be low, often heard only with the bell of the stethoscope placed lightly on the chest wall, or a very high-pitched murmur, heard best with the stethoscope's diaphragm. Other murmurs contain the full spectrum of sound frequency.

**Quality**

In addition to the intensity and pitch, the character of the sound. A murmur may be described as rumbling, blowing, whistling, harsh, or musical.

**Radiation**

The last feature of concern is radiation of the murmur. A murmur can radiate into the axilla, the carotid arteries in the neck, the left shoulder, or the back.

radiation. Also, the patient, who may be concerned about the prolonged examination, must be supported and reassured. The auscultatory findings, particularly murmurs, are documented by identifying the following characteristics:

- Location on chest wall.
- Timing of sound as either during systole or during diastole; described as early, middle, or late. (If heard throughout the systole, the sound is often referred to as pansystolic or holosystolic.)
- Intensity of the sound (I, very faint; II, quiet; III, moderately loud; IV, loud; V, very loud; or VI, heard with stethoscope removed from the chest).
- Pitch, described as high, medium, or low.
- Quality of the sound, commonly described as blowing, harsh, or musical.

- Location of radiation of the sound away from where it is heard the loudest.

**INTERPRETATION OF CARDIAC SOUNDS**

Interpreting cardiac sounds requires detailed knowledge of cardiac physiology and the pathophysiology of cardiac diseases. There are different levels of performance at which the nurse may be expected to function. The first level is simply recognizing that what one is hearing is not normal—such as a third heart sound, a murmur in systole or diastole, a pericardial friction rub over the midsternum, or a second heart sound that is widely split. These findings are reported to the physician and acted on accordingly. This level of function is useful in screening. It is the kind of activity involved in performing physical examinations in schools on normal children or in performing routine physical examinations or screening examinations.

The second level involves recognizing patterns. The nurse correctly observes the findings and can recognize the constellation of sounds and the diagnostic significance of common ones.

At its most sophisticated level, cardiac diagnosis can be interpretive. Highly skilled nurses can differentiate among dysrhythmias and respond accordingly. They can determine the significance of the appearance and disappearance of gallops during the treatment of patients who have had MIs or who have HF. This is the role that the coronary care nurse and the cardiovascular advanced practice nurse assume. They function with a team of other health care professionals who have highly tuned skills of cardiovascular assessment and diagnosis.

**Inspection of the Extremities**

The hands, arms, legs, and feet are observed for skin and vascular changes. The most noteworthy changes include the following:

- Decreased capillary refill time indicates a slower peripheral flow rate from sluggish reperfusion and is often observed in patients with hypotension or HF. Capillary refill time provides the basis for estimating the rate of peripheral blood flow. To test capillary refill, briefly compress the nailbed so that it blanches, and then release the pressure. Normally, reperfusion occurs within 3 seconds, as evidenced by the return of color.
- Vascular changes from decreased arterial circulation include decrease in quality or loss of pulse, discomfort or pain, paresthesia, numbness, decrease in temperature, pallor, and loss of movement. During the first few hours after invasive cardiac procedures (eg, cardiac catheterization), affected extremities should be assessed for vascular changes frequently.
- Hematoma, or a localized collection of clotted blood in the tissue, may be observed in patients who have undergone invasive cardiac procedures such as cardiac catheterization, PTCA, or cardiac electrophysiology testing. Major blood vessels of the arms and legs are selected for catheter insertion. During these procedures, systemic anticoagulation with heparin is necessary, and minor or small hematomas may occur at the catheter puncture site. However, large hematomas are a serious complication that can compromise circulating blood volume and cardiac output, requiring blood transfusions. All patients who have undergone these procedures must have their puncture sites frequently observed until hemostasis is adequately achieved.
- Peripheral edema is fluid accumulation in dependent areas of the body (feet and legs, sacrum in the bedridden patient). Assess for pitting edema (a depression over an area of pres-

sure) by pressing firmly for 5 seconds with the thumb over the dorsum of each foot, behind each medial malleolus, and over the shins. Pitting edema is graded as absent or as present on a scale from slight (1+ = 0 to 2 mm) to very marked (4+ = more than 8 mm). Peripheral edema is observed in patients with HF and in those with peripheral vascular diseases such as deep vein thrombosis or chronic venous insufficiency.

- Clubbing of the fingers and toes implies chronic hemoglobin desaturation, as in congenital heart disease.
- Lower extremity ulcers are observed in patients with arterial or venous insufficiency. Chapter 31 provides a complete description of differentiating characteristics.

## Other Systems

### LUNGS

The details of respiratory assessment are described in Chapter 21. Findings frequently exhibited by cardiac patients include the following:

*Tachypnea:* Rapid, shallow breathing may be noted in patients who have HF or pain, and in those who are extremely anxious.

*Cheyne-Stokes respirations:* Patients with severe left ventricular failure may exhibit Cheyne-Stokes breathing, a pattern of rapid respirations alternating with apnea. It is important to note the duration of the apnea.

*Hemoptysis:* Pink, frothy sputum is indicative of acute pulmonary edema.

*Cough:* A dry, hacking cough from irritation of small airways is common in patients with pulmonary congestion from HF.

*Crackles:* HF or atelectasis associated with bed rest, splinting from ischemic pain, or the effects of pain medications and sedatives often results in the development of crackles. Typically, crackles are first noted at the bases (because of gravity's effect on fluid accumulation and decreased ventilation of basilar tissue), but they may progress to all portions of the lung fields.

*Wheezes:* Compression of the small airways by interstitial pulmonary edema may cause wheezing. Beta-adrenergic blocking agents (beta-blockers), such as propranolol (Inderal), may precipitate airway narrowing, especially in patients with underlying pulmonary disease.

### ABDOMEN

For the cardiac patient, two components of the abdominal examination are frequently performed.

*Hepatojugular reflux:* Liver engorgement occurs because of decreased venous return secondary to right ventricular failure. The liver is enlarged, firm, nontender, and smooth. The hepatojugular reflux may be demonstrated by pressing firmly over the right upper quadrant of the abdomen for 30 to 60 seconds and noting a rise of 1 cm or more in jugular venous pressure. This rise indicates an inability of the right side of the heart to accommodate increased volume.

*Bladder distention:* Urine output is an important indicator of cardiac function, especially when urine output is reduced. This may indicate inadequate renal perfusion or a less serious problem such as one caused by urinary retention. When the urine output is decreased, the patient needs to be assessed for a distended bladder or difficulty voiding. The bladder may be assessed with an ultrasound scanner or

the suprapubic area palpated for an oval mass and percussed for dullness, indicative of a full bladder.

### Gerontologic Considerations

When performing a cardiovascular examination on an elderly patient, the nurse may note such differences as more readily palpable peripheral pulses because of increased hardness of the arteries and a loss of adjacent connective tissue. Palpation of the precordium in the elderly is affected by the changes in the shape of the chest. For example, a cardiac impulse may not be palpable in patients with chronic obstructive pulmonary disease, because these patients usually have an increased anterior-posterior chest diameter. Kyphoscoliosis, a spinal deformity that occurs frequently in elderly patients, may dislocate the cardiac apex downward so that the diagnostic significance of palpating the apical impulse is obscured.

Systolic BP increases with age, but diastolic BP usually plateaus after 50 years. Medication therapy is usually initiated for high BP when consistent systolic readings of 160 mm Hg or diastolic readings of 95 mm Hg are observed. For the elderly patient, however, many factors are considered before initiating treatment. Orthostatic hypotension may reflect a decreasing sensitivity of postural reflexes, which must be considered when medication therapy is prescribed.

An  $S_4$  is heard in about 90% of elderly patients; this is thought to be caused by decreased compliance of the left ventricle. The  $S_2$  is usually split. At least 60% of elderly patients have murmurs, the most common being a soft systolic ejection murmur resulting from sclerotic changes of the aortic leaflets (see Table 26-1).

## Diagnostic Evaluation

Diagnostic tests and procedures are used to confirm the data obtained by history and physical assessment. Some tests are easy to interpret, but others must be interpreted by expert clinicians. All tests should be explained to the patient. Some necessitate special preparation before they are performed and special monitoring by the nurse after the procedure.

## LABORATORY TESTS

Laboratory tests may be performed for the following reasons:

- To assist in diagnosing an acute MI. (Angina pectoris, chest pain resulting from an insufficient supply of blood to the heart, cannot be confirmed by either blood or urine studies.)
- To identify abnormalities in the blood that affect the prognosis of a patient with a cardiac condition
- To assess the degree of inflammation
- To screen for risk factors associated with atherosclerotic coronary artery disease
- To determine baseline values before performing therapeutic interventions
- To monitor serum levels of medications
- To assess the effects of medications (e.g., the effects of diuretics on serum potassium levels)
- To screen generally for abnormalities

Because different laboratories use different equipment and different methods of measurements, normal test values may vary depending on the laboratory and the health care institution.

## Cardiac Enzyme Analysis

Plasma cardiac enzyme analysis is part of a diagnostic profile that also includes the health history, symptoms, and electrocardiogram (ECG), associated with acute MI. Enzymes are released from injured cells when the cell membranes rupture. Most enzymes are nonspecific in relation to the particular organ that has been damaged. Certain isoenzymes, however, come only from myocardial cells and are released when the cells are damaged, such as by sustained hypoxia resulting in infarction or by trauma. The isoenzymes leak into the interstitial spaces of the myocardium and are carried into the general circulation by the lymphatic system and the coronary circulation, resulting in elevated serum enzyme concentrations.

Because different enzymes move into the blood at varying periods after MI, enzyme levels should be tested in relation to the time of onset of chest discomfort or other symptoms. Creatine kinase (CK) and its isoenzyme CK-MB are the most specific enzymes analyzed in acute MI, and they are the first enzyme levels to rise. Lactic dehydrogenase and its isoenzymes also are analyzed in patients who have delayed seeking medical attention, because these blood levels rise and peak in 2 to 3 days, much later than CK levels (see Table 28-5 in Chap. 28 for the time course of cardiac enzymes).

Myoglobin, an early marker of MI, is a heme protein with a small molecular weight. This allows it to be rapidly released from damaged myocardial tissue and accounts for its early rise, within 1 to 3 hours after the onset of an acute MI. Myoglobin peaks in 4 to 12 hours and returns to normal in 24 hours. Myoglobin is not used alone to diagnose MI, because elevations can also occur in patients with renal or musculoskeletal disease. However, negative results are helpful in ruling out an early diagnosis of MI.

Troponin I is measured in a laboratory test that has several advantages over traditional enzyme studies. Troponin I is a contractile protein found only in cardiac muscle. After myocardial injury, elevated serum troponin I concentrations can be detected within 3 to 4 hours; they peak in 4 to 24 hours and remain elevated for 1 to 3 weeks. These early and prolonged elevations make very early diagnosis of MI possible or allow for late diagnosis if the patient has delayed seeking treatment.

## Blood Chemistry

### LIPID PROFILE

Cholesterol, triglycerides, and lipoproteins are measured to evaluate a person's risk for developing atherosclerotic disease, especially if there is a family history of premature heart disease, or to diagnose a specific lipoprotein abnormality. Cholesterol and triglycerides are transported in the blood by combining with protein molecules to form lipoproteins. The lipoproteins are referred to as low-density lipoproteins (LDL) and high-density lipoproteins (HDL). The risk of CAD increases as the ratio of LDL to HDL or the ratio of total cholesterol (LDL + HDL) to HDL increases. Although cholesterol levels remain relatively constant over 24 hours, the blood specimen for the lipid profile should be obtained after a 12-hour fast.

### CHOLESTEROL LEVELS

Cholesterol (normal level, less than 200 mg/dL) is a lipid required for hormone synthesis and cell membrane formation. It is found in large quantities in brain and nerve tissue. Two major sources of cholesterol are diet (animal products) and the liver, where cholesterol is synthesized. Elevated cholesterol levels are

known to increase the risk for CAD. Factors that contribute to variations in cholesterol levels include age, gender, diet, exercise patterns, genetics, menopause, tobacco use, and stress levels.

LDLs (normal level, less than 130 mg/dL) are the primary transporters of cholesterol and triglycerides into the cell. One harmful effect of LDL is the deposition of these substances in the walls of arterial vessels. Elevated LDL levels are associated with a greater incidence of CAD. In people with known CAD or diabetes, the primary goal for lipid management is reduction of LDL levels to less than 100 mg/dL.

HDLs (normal range in men, 35 to 65 mg/dL; in women, 35 to 85 mg/dL) have a protective action. They transport cholesterol away from the tissue and cells of the arterial wall to the liver for excretion. Therefore, there is an inverse relationship between HDL levels and risk for CAD. Factors that lower HDL levels include smoking, diabetes, obesity, and physical inactivity. In patients with CAD, a secondary goal of lipid management is the increase of HDL levels to more than 40 mg/dL.

Triglycerides (normal range, 40 to 150 mg/dL), composed of free fatty acids and glycerol, are stored in the adipose tissue and are a source of energy. Triglyceride levels increase after meals and are affected by stress. Diabetes, alcohol use, and obesity can elevate triglyceride levels. These levels have a direct correlation with LDL and an inverse one with HDL.

### SERUM ELECTROLYTE LEVELS

Sodium, potassium, and calcium are ions that are vital to cellular depolarization and repolarization. In addition, the serum sodium concentration reflects relative fluid balance. Generally, hyponatremia (low sodium level) indicates fluid excess, and hypernatremia (high sodium level) indicates fluid deficit.

Serum potassium is affected by renal function and may be decreased by diuretic agents that are used to treat HF. A decrease in potassium causes cardiac irritability and predisposes the patient receiving a digitalis preparation to digitalis toxicity and dysrhythmias. The effect of an elevated serum potassium concentration is myocardial depression and ventricular irritability. Both hypokalemia and hyperkalemia can lead to ventricular fibrillation or cardiac standstill. Calcium is necessary for blood coagulability and neuromuscular activity. Hypocalcemia and hypercalcemia can cause dysrhythmias.

Magnesium is integral to the absorption of calcium and the maintenance of potassium stores. It is required in the metabolism of adenosine triphosphate, playing a major role in protein synthesis, carbohydrate metabolism, and muscular contraction. Initial symptoms of hypermagnesemia are lethargy and decreased neuromuscular activity. On the ECG, hypomagnesemia lengthens the QT interval, predisposing the patient to life-threatening dysrhythmias.

### BLOOD UREA NITROGEN LEVEL

Blood urea nitrogen (BUN) is an end product of protein metabolism and is excreted by the kidneys. In the patient with cardiac disease, an elevated BUN level may reflect reduced renal perfusion (from decreased cardiac output) or intravascular fluid volume deficit (from diuretic therapy or dehydration). The cause of elevated BUN is determined from the serum creatinine: high BUN and high creatinine reflect renal impairment, high BUN and normal creatinine reflect intravascular fluid volume deficit.

### SERUM GLUCOSE LEVEL

The serum glucose level is important to monitor, because many patients with cardiac disease also have diabetes mellitus. In addition,

tion, the serum glucose level may be mildly elevated in stressful situations, when mobilization of endogenous epinephrine results in conversion of liver glycogen to glucose. Serum glucose levels are drawn in a fasting state. Glycosylated hemoglobin is an important measure to monitor in people with diabetes, because it reflects the blood glucose levels over 2 to 3 months. Hemoglobin A<sub>1C</sub> is the common name for this test. The goal of diabetes management is to maintain the hemoglobin A<sub>1C</sub> below 7% (normal range 4%–6%), reflecting consistent near-normal blood glucose levels. This is particularly important for primary and secondary prevention of CVD (Brundy et al., 2002; Smith et al., 2001).

## Coagulation Studies

The formation of a thrombus is initiated by injury to a vessel wall or to the tissue. These events activate the coagulation cascade, a complex series of interactions among phospholipids, calcium, and various clotting factors that converts prothrombin to thrombin. The coagulation cascade has two pathways, the intrinsic pathway and the extrinsic pathway. Coagulation studies are routinely performed before invasive procedures, such as cardiac catheterization, electrophysiology testing, and coronary or cardiac surgery.

Partial thromboplastin time (PTT) and activated partial thromboplastin time (aPTT) measure the activity of the intrinsic pathway. The values of PTT and aPTT are used to assess the effects of heparin therapy. Patients receiving heparin have their PTT or aPTT levels maintained at 1.5 to 2.5 times their baseline values (reference range, 25 to 38 seconds). Prothrombin time (PT) measures the extrinsic pathway activity and is used to monitor the effects of therapeutic anticoagulation with warfarin (Coumadin). Laboratory results of PT also include the **International Normalized Ratio (INR)**. The INR provides a standard method for reporting PT levels, eliminating the variation of PT results from laboratory to laboratory. The INR, rather than the PT alone, is used to monitor patients receiving warfarin therapy. The INR is maintained between 2.0 and 3.0 for patients with deep vein thrombosis, pulmonary embolism, valvular heart disease, or atrial fibrillation, and between 2.5 and 3.5 for patients with mechanical prosthetic heart valve replacements.

## Hematologic Studies

The complete blood cell count (CBC) identifies the total number of white and red blood cells, the platelet count, and the hemoglobin and hematocrit. The CBC is carefully monitored in patients with CVD. White blood cell counts are monitored in immunocompromised patients, including patients with transplanted hearts, and in situations where there is concern for infection (eg, after invasive procedures or surgery). The red blood cells carry hemoglobin, which transports oxygen to the cells. The hematocrit is a measure of the relative proportion of red blood cells and plasma. Low hemoglobin and hematocrit levels have serious consequences for patients with CAD, such as more frequent angina episodes. Platelets are the first line of protection against bleeding. Once activated by blood vessel wall injury or rupture of atherosclerotic plaque, platelets undergo chemical changes that form a thrombus. Patients are prescribed medications to inhibit platelet function, including aspirin, clopidogrel (Plavix), and intravenous GP IIb/IIIa inhibitors (abciximab [ReoPro], eptifibatid [Integrilin], tirofiban [Aggrastat]); therefore, it is essential to monitor for thrombocytopenia (low platelet counts). Chapter 33 provides an in-depth review of these laboratory tests and normal values.

## CHEST X-RAY AND FLUOROSCOPY

A chest x-ray usually is obtained to determine the size, contour, and position of the heart. It reveals cardiac and pericardial calcifications and demonstrates physiologic alterations in the pulmonary circulation. It does not help diagnose acute MI but can help diagnose some complications (eg, HF). Correct placement of cardiac catheters, such as pacemakers and pulmonary artery catheters, is also confirmed by chest x-ray.

Fluoroscopy allows visualization of the heart on an x-ray screen. It shows cardiac and vascular pulsations and unusual cardiac contours. Fluoroscopy is useful for positioning intravenous pacing electrodes and for guiding catheter insertion during cardiac catheterization.

## ELECTROCARDIOGRAPHY

The ECG is a diagnostic tool used in assessing the cardiovascular system. It is a graphic recording of the electrical activity of the heart; an ECG can be recorded with 12, 15, or 18 leads, showing the activity from those different reference points. The ECG is obtained by placing disposable electrodes in standard positions on the skin of the chest wall and extremities. The heart's electrical impulses are recorded as a tracing on special graph paper.

The standard 12-lead ECG is the most commonly used tool to diagnose dysrhythmias, conduction abnormalities, enlarged heart chambers, myocardial ischemia or infarction, high or low calcium and potassium levels, and effects of some medications. A 15-lead ECG adds 3 additional chest leads across the right precordium and is a valuable tool for the early diagnosis of right ventricular and posterior left ventricular infarction. The 18-lead ECG adds 3 posterior leads to the 15-lead ECG and is very useful for early detection of myocardial ischemia and injury (Wung & Drew, 1999). To enhance interpretation of the ECG, the patient's age, gender, BP, height, weight, symptoms, and medications (especially digitalis and antiarrhythmic agents) should be noted on the ECG requisition. The details of electrocardiography are covered in Chapter 27.

## Continuous Electrocardiographic Monitoring

Continuous ECG monitoring is standard for patients who are at high risk for dysrhythmias. Two continuous ECG monitoring techniques are hardwire monitoring, found in critical care units and specialty step-down units, and telemetry, found in specialty step-down units and general nursing care units. Patients who are receiving continuous ECG monitoring need to be informed of its purpose and cautioned that this monitoring method will not detect symptoms such as dyspnea or chest pain. Therefore, patients need to be advised to report symptoms to the nurse whenever they occur.

### HARDWIRE CARDIAC MONITORING

The patient's ECG can be continuously observed for dysrhythmias and conduction disorders on an oscilloscope at the bedside or at a central monitoring station by a hardwire monitoring system. This system is composed of three to five electrodes positioned on the patient's chest, a lead cable, and a bedside monitor. Hardwire monitoring systems vary in sophistication but in general can do the following:

- Monitor more than one lead simultaneously
- Monitor ST segments (ST-segment depression is a marker of myocardial ischemia; ST-segment elevation provides evidence of an evolving MI)

- Provide graded visual and audible alarms (based on priority, asystole would be highest)
- Computerize rhythm monitoring (dysrhythmias are interpreted and stored in memory)
- Print a rhythm strip
- Record a 12-lead ECG

Two leads commonly used for continuous monitoring are leads II and V1 or a modification of V1 (MCL1) (Fig. 26-10). Lead II provides the best visualization of atrial depolarization (represented by the P wave). Leads V1 and MCL1 best visualize the ventricle responsible for ectopic or abnormal ventricular beats.

### TELEMETRY

In addition to hardwire monitoring systems, the ECG can be continuously observed by **telemetry**, the transmission of radio-waves from a battery-operated transmitter worn by the patient to a central bank of monitors. Although telemetry systems have the same capabilities as hardwire systems, they are wireless, allowing the patient to ambulate while being monitored. Following the guidelines for electrode placement will ensure good conduction and a clear picture of the patient's rhythm on the monitor:

- Clean the skin surface with soap and water and dry well (or as recommended by the manufacturer) before applying the electrodes. If the patient has much hair where the electrodes need to be placed, shave or clip the hair.
- Apply a small amount of benzoin to the skin if the patient is diaphoretic (sweaty) and the electrodes do not adhere well.
- Change the electrodes every 24 to 48 hours and examine the skin for irritation. Apply the electrodes to different locations each time they are changed.
- If the patient is sensitive to the electrodes, use hypoallergenic electrodes.

### SIGNAL-AVERAGED ELECTROCARDIOGRAM

For some patients who are considered to be at high risk for sudden cardiac death, a signal-averaged ECG is performed. This high-resolution ECG assists in identifying the risk for life-threatening dysrhythmias and helps to determine the need for invasive diagnostic procedures. Signal averaging works by averaging about 150 to 300 QRS waveforms (QRS waveforms represent depolarization

of the ventricle). The resulting averaged QRS complex is analyzed for certain characteristics that are likely to lead to lethal ventricular dysrhythmias. The recording is performed at the bedside and requires about 15 minutes.

### CONTINUOUS AMBULATORY MONITORING

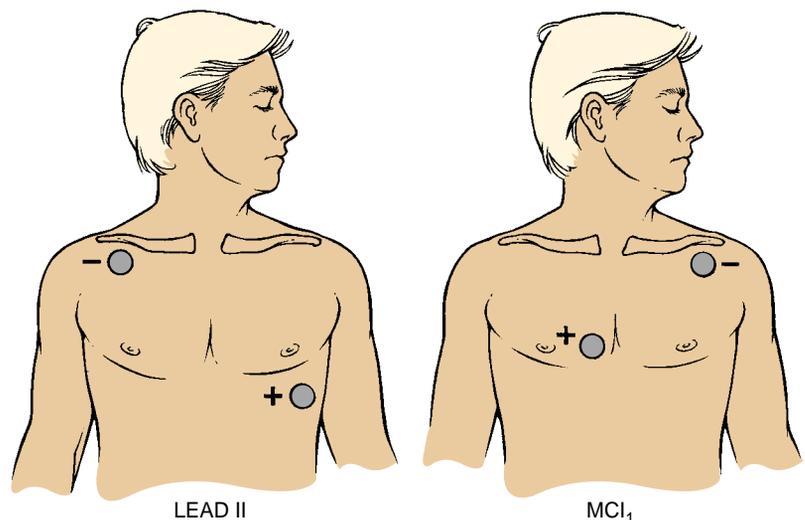

In ambulatory ECG monitoring, which may occur in the hospital but is more commonly prescribed for outpatients, one lead of the patient's ECG can be monitored by a Holter monitor. This monitor is a small tape recorder that continuously (for 10 to 24 hours) documents the heart's electrical activity on a magnetic tape. The tape recorder weighs approximately 2 pounds and can be carried over the shoulder or worn around the waist day and night to detect dysrhythmias or evidence of myocardial ischemia during activities of daily living. The patient keeps a diary of activity, noting the time of any symptoms, experiences, or unusual activities performed. The tape recording is then examined with a special scanner, analyzed, and interpreted. Evidence obtained in this way helps the physician diagnose dysrhythmias and myocardial ischemia and evaluate therapy, such as antiarrhythmic and antianginal medications or pacemaker function.

### TRANSTELEPHONIC MONITORING

Another method of evaluating the ECG of a patient at home is by transtelephonic monitoring. The patient attaches a specific lead system for transmitting the signals and places a telephone mouthpiece over the transmitter box; the ECG is recorded and evaluated at another location. This method is often used for diagnosing dysrhythmias and in follow-up evaluation of permanent cardiac pacemakers.

### CARDIAC STRESS TESTING

Normally, the coronary arteries dilate to four times their usual diameter in response to increased metabolic demands for oxygen and nutrients. Coronary arteries with atherosclerosis, however, dilate much less, compromising blood flow to the myocardium and causing ischemia. Therefore, abnormalities in cardiovascular function are more likely to be detected during times of increased demand, or "stress." The **cardiac stress test** procedures—the exercise stress test, the pharmacologic stress test, and, more recently, the mental or emotional stress test—are noninvasive ways to evaluate the response of the cardiovascular system to stress. The stress

**FIGURE 26-10** Two leads (views of the heart) commonly used for continuous monitoring. To monitor lead II, the negative electrode is placed on the right upper chest; the positive electrode is placed on the left lower chest. To monitor MCL1, the negative electrode is placed on the left upper chest; the positive electrode is placed in the V1 position. If three electrodes are used, the third electrode, which is the ground electrode, can be placed anywhere on the chest.

test helps determine the following: (1) CAD, (2) cause of chest pain, (3) functional capacity of the heart after an MI or heart surgery, (4) effectiveness of antianginal or antiarrhythmic medications, (5) dysrhythmias that occur during physical exercise, and (6) specific goals for a physical fitness program. Contraindications to stress testing include severe aortic stenosis, acute myocarditis or pericarditis, severe hypertension, suspected left main CAD, HF, and unstable angina. Because complications associated with stress testing can be life-threatening (MI, cardiac arrest, HF, and severe dysrhythmias), testing facilities must have staff and equipment ready to provide advanced cardiac life support.

Mental stress testing uses a mental arithmetic test or simulated public speech to determine whether an ischemic myocardial response occurs, similar to the response evoked by a conventional treadmill exercise test. Although its use for diagnostic purposes in patients with CAD is currently investigational, preliminary results indicate that the ischemic and hemodynamic measures obtained from mental stress testing may be useful in assessing the prognosis of patients with CHD who have had a positive exercise test (Krantz et al., 1999).

Stress testing is often combined with echocardiography or radionuclide imaging (discussed later). These techniques are performed during the resting state and immediately after stress.

## Exercise Stress Testing

In an exercise stress test, the patient walks on a treadmill (most common) or pedals a stationary bicycle or arm crank. Exercise intensity progresses according to established protocols. The Bruce protocol, for example, is a common treadmill protocol in which the speed and grade of the treadmill are increased every 3 minutes. The goal of the test is to increase the heart rate to the “target heart rate.” This is 80% to 90% of the maximum predicted heart rate and is based on the age and gender of the patient. During the test, the following are monitored: two or more ECG leads for heart rate, rhythm, and ischemic changes; BP; skin temperature; physical appearance; perceived exertion; and symptoms including chest pain, dyspnea, dizziness, leg cramping, and fatigue. The test is terminated when the target heart rate is achieved or when the patient experiences chest pain, extreme fatigue, a decrease in BP or pulse rate, serious dysrhythmias or ST segment changes on ECG, or other complications. When significant ECG abnormalities occur during the stress test (ST segment depressions), the test result is reported as positive and further diagnostic testing is required.

## NURSING INTERVENTIONS

In preparation for the exercise stress test, the patient is instructed to fast for 4 hours before the test and to avoid stimulants such as tobacco and caffeine. Medications may be taken with sips of water. The physician may instruct patients not to take certain cardiac medications, such as beta-blockers, before the test. Clothes and sneakers or rubber-soled shoes suitable for exercising are to be worn. Women are advised to wear a bra that provides adequate support. The nurse describes the equipment used and the sensations and experiences that the patient may have during the test. The nurse explains the monitoring equipment used, the need to have an intravenous line placed, and the symptoms to report. The type of exercise is reviewed, and patients are asked to put forth their best exercise effort. If the test is to be performed with echocardiography or radionuclide imaging, this information is reviewed as well. After the test, patients are monitored for 10 to 15 minutes. Once stable, they may resume their usual activities.

## Pharmacologic Stress Testing

Physically disabled or deconditioned patients will not be able to achieve their target heart rate by exercising on a treadmill or bicycle. Two vasodilating agents, dipyridamole (Persantin) and adenosine (Adenocard), administered intravenously, are used to mimic the effects of exercise by maximally dilating the coronary arteries. The effects of dipyridamole last about 15 to 30 minutes. The side effects are related to its vasodilating action and include chest discomfort, dizziness, headache, flushing, and nausea. Adenosine has similar side effects, although patients report these symptoms as more severe. A unique property of adenosine is that it has an extremely short half-life (less than 10 seconds), so any severe effects rapidly subside. Dipyridamole and adenosine are the agents of choice used in conjunction with radionuclide imaging techniques. Theophylline and other xanthines, such as caffeine, block the effects of dipyridamole and adenosine and must be avoided before either of these pharmacologic stress tests.

Dobutamine (Dobutrex) is another medication that may be used for patients who cannot exercise. Dobutamine, a synthetic sympathomimetic, increases heart rate, myocardial contractility, and BP, thereby increasing the metabolic demands of the heart. It is the agent of choice when echocardiography is used because of its effects on altering myocardial wall motion (due to enhanced contractility). In addition, dobutamine is used for patients who have bronchospasm or pulmonary disease and cannot tolerate having doses of theophylline withheld.

## NURSING INTERVENTIONS

In preparation for the pharmacologic stress test, patients are instructed not to eat or drink anything for at least 4 hours before the test. This includes chocolate, caffeine, caffeine-free coffee, tea, carbonated beverages, or medications with caffeine (eg, Anacin, Darvon). If caffeine is ingested before a dipyridamole or adenosine stress test, the test will have to be rescheduled. Patients taking aminophylline or theophylline are instructed to stop taking these medications for 24 to 48 hours before the test (if tolerated). Oral doses of dipyridamole are to be withheld as well. Patients are informed about the transient sensations they may experience during infusion of the vasodilating agent, such as flushing or nausea, which will disappear quickly. The patient is instructed to report any other symptoms occurring during the test to the cardiologist or nurse. An explanation of echocardiography or radionuclide imaging is also provided as necessary. The stress test may take about 1 hour, or up to 3 hours if imaging is performed.

## ECHOCARDIOGRAPHY

Echocardiography is a noninvasive ultrasound test that is used to examine the size, shape, and motion of cardiac structures. It is a particularly useful tool for diagnosing pericardial effusions, determining the etiology of heart murmurs, evaluating the function of prosthetic heart valves, determining chamber size, and evaluating ventricular wall motion. It involves transmission of high-frequency sound waves into the heart through the chest wall and recording of the return signals. The ultrasound is generated by a hand-held transducer applied to the front of the chest. The transducer picks up the echoes, converts them to electrical impulses, and transmits them to the echocardiography machine for display on an oscilloscope and recording on a videotape. An ECG is recorded simultaneously to assist with interpreting the echocardiogram.

M-mode (motion), the unidimensional mode that was first introduced, provides information about the cardiac structures and their motion. Two-dimensional or cross-sectional echocardiography (Fig. 26-11), an enhancement of the technique, creates a sophisticated, spatially correct image of the heart. Other techniques, such as Doppler and color flow imaging echocardiography, show the direction and velocity of the blood flow through the heart.

As previously mentioned, echocardiography may be performed with an exercise or pharmacologic stress test; resting and stress images are obtained. Myocardial ischemia from decreased perfusion during stress causes abnormalities in ventricular wall motion and is easily detected by echocardiography. A stress test using echocardiography is considered positive if abnormalities in ventricular wall motion are detected during stress but not during rest. These findings are highly suggestive of CAD and require further evaluation, such as a cardiac catheterization.

### Transesophageal Echocardiography

A significant limitation of traditional echocardiography has been the poor quality of the images produced. Ultrasound loses its clarity as it passes through tissue, lung, and bone. Another echocardiographic technique involves threading a small transducer through the mouth and into the esophagus. This technique, called transesophageal echocardiography (TEE), provides clearer images because ultrasound waves are passing through less tissue. Pharmacologic stress testing using dobutamine and TEE can also be performed. The high-quality imaging obtained during TEE makes this technique an important adjunct to the technology available for detecting and evaluating the severity of CAD. Complications are uncommon during TEE, but if they do occur they are serious. These complications are caused by sedation and impaired swallowing from topical anesthesia (respiratory depression and aspiration) and by insertion and manipulation of the transducer into the esophagus and stomach (vasovagal response or esophageal perforation). The patient must be assessed before TEE for a history of dysphagia or radiation therapy to the chest that would increase the risk for complications.

**FIGURE 26-11** Two-dimensional echocardiogram, four-chamber view in a normal patient. The ventricles and atria are the dark areas outlined by the white. LA = left atrium, LV = left ventricle, RA = right atrium, RV = right ventricle. Courtesy of V. Bowles, RCS, CCT, Inova Alexandria Hospital, Alexandria, Virginia.

### NURSING INTERVENTIONS

Before traditional echocardiography, the nurse informs the patient about the test, explaining that it is painless. Echocardiographic monitoring is performed while a transducer that emits the sound waves is moved about the chest. Gel applied to the skin helps transmit the sound waves. Periodically, the patient will have to turn onto the left side or hold a breath. The test takes about 30 to 45 minutes. If the patient is to undergo an exercise or pharmacologic stress test with echocardiography, information on stress testing is also reviewed.

In preparation for a TEE study, the following information is reviewed:

- The patient must fast for 6 hours before the study.
- An intravenous line is started for administering a sedative and any pharmacologic stress testing medications.
- The patient's throat is anesthetized before the probe is inserted.
- BP and the ECG are monitored throughout the study.
- The patient will be kept comfortable but not heavily sedated. The patient must be alert enough to follow instructions and to report symptoms such as chest pain.

After the study, monitoring continues for 30 to 60 minutes. The patient is to continue fasting for 4 hours. The patient may have a sore throat for the next 24 hours.

### RADIONUCLIDE IMAGING

Radionuclide imaging studies involve the use of radioisotopes to evaluate coronary artery perfusion noninvasively, to detect myocardial ischemia and infarction, and to assess left ventricular function. **Radioisotopes** are atoms in an unstable form. Thallium 201 ( $Tl^{201}$ ) and technetium 99m ( $Tc^{99m}$ ) are two of the most common radioisotopes used in cardiac nuclear medicine studies. As they decay, they give off small amounts of energy in the form of gamma rays. When they are injected intravenously into the bloodstream, the energy emitted by the radioisotope can be detected by a gamma scintillation camera positioned over the body. Planar imaging, used with thallium, is a technique that provides a one-dimensional view of the heart from three locations. A relatively new technique called single photon emission computed tomography (SPECT) provides three-dimensional images. With SPECT, the patient is positioned supine with arms raised above the head, while the camera moves around the patient's chest in a 180- to 360-degree arc to identify the areas of decreased myocardial perfusion more precisely.

### Myocardial Perfusion Imaging

The radioisotope  $Tl^{201}$  is used to assess myocardial perfusion. It resembles potassium and readily crosses into the cells of healthy myocardium. It is taken up more slowly and in smaller amounts by myocardial cells that are ischemic from decreased blood flow. However, thallium will not cross into the necrotic tissue that results from an MI.

Often, thallium is used with stress testing to assess changes in myocardial perfusion immediately after exercise (or after injection of one of the agents used in stress testing) and at rest. One or two minutes before the end of the stress test, a dose of  $Tl^{201}$  is injected into the intravenous line, allowing the radioisotope to be distributed into the myocardium. Images are taken immediately. Areas that do not show thallium uptake are noted as defects and indicate areas of either infarction or stress-induced myocardial

ischemia. The resting images, taken 3 hours later, help to differentiate infarction from ischemia. Infarcted tissue is unable to take up thallium regardless of when the scan is taken; the defect remains the same size. This is called a fixed defect, indicating that there is no perfusion in that area of the myocardium. Ischemic myocardium, on the other hand, recovers in a few hours. Once perfusion is restored, thallium crosses into the myocardial cells, and the area of defect on the resting images is either smaller or completely reversed. These reversible defects constitute positive stress test findings. Usually, cardiac catheterization is recommended after a positive test result to determine whether angioplasty or coronary artery bypass graft surgery is needed.

Another radioisotope used for cardiac imaging is  $Tc^{99m}$ . Technetium can be combined with various chemical compounds, giving it an affinity for different types of cells. For example,  $Tc^{99m}$  sestamibi (Cardiolite) is distributed to myocardial cells in proportion to their amount of perfusion, making this tracer excellent for assessing perfusion to the myocardium. The procedure for cardiac imaging using  $Tc^{99m}$  sestamibi with stress testing is similar to the one using thallium, with two differences. Patients receiving  $Tc^{99m}$  sestamibi can have their resting images recorded before or after the exercise images. Timing of the images is not important because the half-life of  $Tc^{99m}$  is short, and  $Tc^{99m}$  needs to be injected before each scan. Also, SPECT imaging with  $Tc^{99m}$  sestamibi provides high-quality images.

### NURSING INTERVENTIONS

The patient undergoing nuclear imaging techniques with stress testing should be prepared for the type of stressor to be used (exercise or drug) and the type of imaging technique (planar or SPECT). The patient may be concerned about receiving a radioactive substance and needs to be reassured that these tracers are safe, the radiation exposure being similar to that of other diagnostic x-ray studies. No postprocedure radiation precautions are necessary.

When providing teaching for patients undergoing SPECT, the nurse should instruct them that their arms will need to be positioned over their head for about 20 to 30 minutes. If they are physically unable to do this, thallium with planar imaging can be used.

### Test of Ventricular Function and Wall Motion

Equilibrium radionuclide angiography (ERNA), also known as multiple-gated acquisition (MUGA) scanning, is a common noninvasive technique that uses a conventional scintillation camera interfaced with a computer to record images of the heart during several hundred heartbeats. The computer processes the data and allows for sequential viewing of the functioning heart. The sequential images are analyzed to evaluate left ventricular function, wall motion, and ejection fraction. MUGA scanning can also be used to assess the differences in left ventricular function during rest and exercise.

The patient is reassured that there is no known radiation danger and is instructed to remain motionless during the scan.

### Computed Tomography

Computed tomography (CT), also called computerized axial tomographic (CAT) scanning or electron-beam computed tomography (EBCT), uses x-rays to provide cross-sectional images of the chest, including the heart and great vessels. These techniques are used to evaluate cardiac masses and diseases of the aorta and pericardium.

EBCT, also known as the Ultrafast CT, is an especially fast x-ray scanning technique that results in much faster image acquisition with a higher degree of resolution than traditional x-ray or CT scanning provides (Woods et al., 1999). It is used to evaluate bypass graft patency, congenital heart lesions, left and right ventricular muscle mass, chamber volumes, cardiac output, and ejection fraction. For people without previous MI, PTCA, or coronary artery bypass surgery, the EBCT is used to determine the amount of calcium deposits in the coronary arteries and underlying atherosclerosis. From this scan, a calcium score is derived that predicts the incidence of cardiac events, such as MI or the need for a revascularization procedure within the next 1 to 2 years.

The EBCT is not widely used, but it does show great promise for early detection of CAD that is not yet clinically significant and that would not be identified by traditional testing methods, such as the exercise stress test.

### NURSING INTERVENTIONS

Patient preparation is the primary role of the nurse for these tests. The nurse should instruct the patient that he will be positioned on a table during the scan while the scanner rotates around him. The procedure is noninvasive and painless. However, to obtain adequate images, the patient must lie perfectly still during the scanning process. An intravenous access line is necessary if contrast enhancement is to be used.

### Positron Emission Tomography

Positron emission tomography (PET) is a noninvasive scanning method that was used in the past primarily to study neurologic dysfunction. More recently, and with increasing frequency, PET has been used to diagnose cardiac dysfunction. PET provides more specific information about myocardial perfusion and viability than does TEE or thallium scanning. For cardiac patients, including those without symptoms, PET helps in planning treatment (eg, coronary artery bypass surgery, angioplasty). PET also helps evaluate the patency of native and previously grafted vessels and the collateral circulation.

During a PET scan, radioisotopes are administered by injection; one compound is used to determine blood flow in the myocardium, and another shows the metabolic function. The PET camera provides detailed three-dimensional images of the distributed compounds. The viability of the myocardium is determined by comparing the extent of glucose metabolism in the myocardium to the degree of blood flow. For example, ischemic but viable tissue would show decreased blood flow and elevated metabolism. For a patient with this finding, revascularization through surgery or angioplasty would be likely to improve heart function. Restrictions of food intake before the test vary among institutions, but, because PET evaluates glucose metabolism, the patient's blood glucose level should be in the normal range. Although PET equipment is costly, it is increasingly valued and available.

### NURSING INTERVENTIONS

Nurses involved in PET and other scanning procedures may instruct the patient to refrain from using tobacco and ingesting caffeine for 4 hours before the procedure. They should also reassure the patient that radiation exposure is at safe and acceptable levels, similar to those of other diagnostic x-ray studies.

## Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a noninvasive, painless technique that is used to examine both the physiologic and anatomic properties of the heart. MRI uses a powerful magnetic field and computer-generated pictures to image the heart and great vessels. It is valuable in diagnosing diseases of the aorta, heart muscle, and pericardium, as well as congenital heart lesions. The application of this technique to the evaluation of coronary artery anatomy, cardiac blood flow, and myocardial viability in conjunction with pharmacologic stress testing is being investigated.

### NURSING INTERVENTIONS

Because of the strong magnetic field used during MRI, diagnostic centers where these procedures are performed carefully screen patients for contraindications. Standardized questionnaires are commonly used to determine whether the patient has a pacemaker, metal plates, prosthetic joints, or other metallic implants that can become dislodged if exposed to MRI. During an MRI, the patient is positioned supine on a table that is placed into an enclosed imager or tube that contains the magnetic field. People who are claustrophobic may need to receive a mild sedative before undergoing an MRI. As the MRI is performed, there is an intermittent clanking or thumping sound from the magnetic coils that can be annoying to the patient, so patients are offered headsets to listen to music. The scanner is equipped with a microphone so that the patient can communicate with the staff. During the scanning, the patient is instructed to remain still and not move.

 **NURSING ALERT** No metal can be in the MRI room because metal objects can become dangerous projectiles; this includes such items as clipboards, paperclips, oxygen tanks, and monitors.

## CARDIAC CATHETERIZATION

**Cardiac catheterization** is an invasive diagnostic procedure in which radiopaque arterial and venous catheters are introduced into selected blood vessels of the right and left sides of the heart. Catheter advancement is guided by fluoroscopy. Most commonly, the catheters are inserted percutaneously through the blood vessels, or via a cutdown procedure if the patient has poor vascular access. Pressures and oxygen saturations in the four heart chambers are measured. Cardiac catheterization is used to diagnose CAD, assess coronary artery patency, and determine the extent of atherosclerosis based on the percentage of coronary artery obstruction. These results determine whether revascularization procedures including PTCA or coronary artery bypass surgery may be of benefit to the patient (see Chap. 28).

During cardiac catheterization, the patient has an intravenous line in place for the administration of sedatives, fluids, heparin, and other medications. Noninvasive hemodynamic monitoring that includes BP and multiple ECG tracings is necessary to continuously observe for dysrhythmias or hemodynamic instability. The myocardium can become ischemic and trigger dysrhythmias as catheters are positioned in the coronary arteries or during injection of contrast agents. Resuscitation equipment must be readily available during the procedure. Staff must be prepared to provide advanced cardiac life support measures as necessary.

Radiopaque contrast agents are used to visualize the coronary arteries; some contrast agents contain iodine. The patient is as-

essed before the procedure for previous reactions to contrast agents or allergies to iodine-containing substances (eg, seafood). If the patient has a suspected or known allergy to the substance, antihistamines or methylprednisolone (Solu-Medrol) may be administered before the procedure. In addition, the following blood tests are performed to identify abnormalities that may complicate recovery: BUN and creatinine levels, INR or PT, aPTT, hematocrit and hemoglobin values, platelet count, and electrolyte levels.

Diagnostic cardiac catheterizations are commonly performed on an outpatient basis and require 2 to 6 hours of bed rest before ambulation. For most patients, bed rest for 6 hours compared to 2 hours has no advantage with regard to groin bleeding complications (Logemann et al., 1999). However, variations in time to ambulation are most often related to the size of the catheter used during the procedure, the anticoagulation status of the patient, other patient variables (eg, advanced age, obesity, bleeding disorder), the method used for hemostasis of the arterial puncture site after the procedure, and institutional policies. The use of smaller (4 or 6 Fr) catheters, which are more amenable to shorter recovery times, is common in diagnostic cardiac catheterizations. There are several methods available to achieve arterial hemostasis after catheter removal, including manual pressure, mechanical compression devices such as the FemoStop (placed over puncture site for 30 minutes), and percutaneously deployed devices. The latter devices are positioned at the femoral arterial puncture site after completion of the procedure. They deploy collagen (VasoSeal), sutures (Perclose, Techstar), or a combination of both (AngioSeal). Major benefits of these devices include reliable, immediate hemostasis and shorter time on bed rest without a significant increase in bleeding or other complications (Baim et al., 2000). A number of factors determine which hemostatic methods are used and are based on the physician's preference, the patient's condition, cost, and institutional availability of the equipment.

Patients hospitalized for angina or acute MI may also require cardiac catheterization. After the procedure, these patients usually return to their hospital rooms for recovery. In some cardiac catheterization laboratories, an angioplasty may be performed immediately after the catheterization if indicated.

## ANGIOGRAPHY

Cardiac catheterization is usually performed with angiography, a technique of injecting a contrast agent into the vascular system to outline the heart and blood vessels. When a particular heart chamber or blood vessel is singled out for study, the procedure is known as selective angiography. Angiography makes use of cine-angiograms, a series of rapidly changing films on an intensified fluoroscopic screen that record the passage of the contrast agent through the vascular site or sites. The recorded information allows for comparison of data over time. Common sites for selective angiography are the aorta, the coronary arteries, and the right and left sides of the heart.

### Aortography

An aortogram is a form of angiography that outlines the lumen of the aorta and the major arteries arising from it. In thoracic aortography, a contrast agent is used to study the aortic arch and its major branches. The catheter may be introduced into the aorta using the translumbar or retrograde brachial or femoral artery approach.

## Coronary Arteriography

In coronary arteriography, the catheter is introduced into the right or left brachial or femoral artery, then passed into the ascending aorta and manipulated into the appropriate coronary artery. Coronary arteriography is used to evaluate the degree of atherosclerosis and to guide the selection of treatment. It is also used to study suspected congenital anomalies of the coronary arteries.

## Right Heart Catheterization

Right heart catheterization usually precedes left heart catheterization. It involves the passage of a catheter from an antecubital or femoral vein into the right atrium, right ventricle, pulmonary artery, and pulmonary arterioles. Pressures and oxygen saturations from each of these areas are obtained and recorded.

Although right heart catheterization is considered a relatively safe procedure, potential complications include cardiac dysrhythmias, venous spasm, infection of the insertion site, cardiac perforation, and, rarely, cardiac arrest.

## Left Heart Catheterization

Left heart catheterization is performed to evaluate the patency of the coronary arteries and the function of the left ventricle and the mitral and aortic valves. Potential complications include dysrhythmias, MI, perforation of the heart or great vessels, and systemic embolization. Left heart catheterization is performed by retrograde catheterization of the left ventricle. In this approach, the physician usually inserts the catheter into the right brachial artery or a femoral artery and advances it into the aorta and left ventricle.

After the procedure, the catheter is carefully withdrawn and arterial hemostasis is achieved using manual pressure or other techniques previously described. If the physician performed an arterial or venous cutdown, the site is sutured and a sterile dressing is applied.

### NURSING INTERVENTIONS

Nursing responsibilities before cardiac catheterization include the following:

- Instruct the patient to fast, usually for 8 to 12 hours, before the procedure. If catheterization is to be performed as an outpatient procedure, explain that a friend, family member, or other responsible person must transport the patient home.
- Prepare the patient for the expected duration of the procedure; indicate that it will involve lying on a hard table for less than 2 hours.
- Reassure the patient that mild sedatives or moderate sedation will be given intravenously.
- Prepare the patient to experience certain sensations during the catheterization. Knowing what to expect can help the patient cope with the experience. Explain that an occasional pounding sensation (palpitation) may be felt in the chest because of extrasystoles that almost always occur, particularly when the catheter tip touches the myocardium. The patient may be asked to cough and to breathe deeply, especially after the injection of contrast agent. Coughing may help to disrupt a dysrhythmia and to clear the contrast agent from the arteries. Breathing deeply and holding the breath helps to lower the diaphragm for better visualization of heart structures. The injection of a contrast agent into either side

of the heart may produce a flushed feeling throughout the body and a sensation similar to the need to void, which subsides in 1 minute or less.

- Encourage the patient to express fears and anxieties. Provide teaching and reassurance to reduce apprehension.

Nursing responsibilities after cardiac catheterization may include the following:

1. Observe the catheter access site for bleeding or hematoma formation, and assess the peripheral pulses in the affected extremity (dorsalis pedis and posterior tibial pulses in the lower extremity, radial pulse in the upper extremity) every 15 minutes for 1 hour, and then every 1 to 2 hours until the pulses are stable.
2. Evaluate temperature and color of the affected extremity and any patient complaints of pain, numbness, or tingling sensations to determine signs of arterial insufficiency. Report changes promptly.
3. Monitor for dysrhythmias by observing the cardiac monitor or by assessing the apical and peripheral pulses for changes in rate and rhythm. A vasovagal reaction, consisting of bradycardia, hypotension, and nausea, can be precipitated by a distended bladder or by discomfort during removal of the arterial catheter, especially if a femoral site has been used. Prompt intervention is critical; this includes raising the feet and legs above the head, administering intravenous fluids, and administering intravenous atropine.
4. Inform the patient that if the procedure is performed percutaneously through the femoral artery (and without the use of devices such as VasoSeal, Perclose, or Angio-Seal), the patient will remain on bed rest for 2 to 6 hours with the affected leg straight and the head elevated to 30 degrees (Logemann et al., 1999). For comfort, the patient may be turned from side to side with the affected extremity straight. If the cardiologist uses deployed devices, check local nursing care standards, but anticipate that the patient will have less restrictions on elevation of the head of the bed and will be allowed to ambulate in 2 hours or less (Baim et al., 2000). Analgesic medication is administered as prescribed for discomfort.
5. Instruct the patient to report chest pain and bleeding or sudden discomfort from the catheter insertion sites immediately.
6. Encourage fluids to increase urinary output and flush out the dye.
7. Ensure safety by instructing the patient to ask for help when getting out of bed the first time after the procedure, because orthostatic hypotension may occur and the patient may feel dizzy and lightheaded.

For patients being discharged from the hospital on the same day as the procedure, additional instructions are provided. They appear in Chart 26-4.

## ELECTROPHYSIOLOGIC TESTING

The electrophysiology study (EPS) is an invasive procedure that plays a major role in the diagnosis and management of serious dysrhythmias and is used (1) to distinguish atrial from ventricular tachycardias when the determination cannot be made from the 12-lead ECG, (2) to evaluate how readily a life-threatening dysrhythmia (eg, ventricular tachycardia, ventricular fibrillation)

### Chart 26-4 • PATIENT EDUCATION Self-Management After Cardiac Catheterization

After discharge from the hospital for cardiac catheterization, guidelines for self-care include the following:

- For the next 24 hours, do not bend at the waist (to lift anything), strain, or lift heavy objects.
- Avoid tub baths, but shower as desired.
- Talk with your physician about when you may return to work, drive, or resume strenuous activities.
- Call your physician if any of the following occur: bleeding, swelling, new bruising or pain from your procedure puncture site, temperature of 101.5°F (38.6°C) or more.
- If test results show that you have coronary artery disease, talk with your physician about options for treatment, including cardiac rehabilitation programs in your community.
- Talk with your physician and nurse about lifestyle changes to reduce your risk for further or future heart problems, such as quitting smoking, lowering your cholesterol level, initiating dietary changes, beginning an exercise program, or losing weight.

can be induced, (3) to evaluate AV node function, (4) to evaluate the effectiveness of antiarrhythmic medications in suppressing the dysrhythmia, and (5) to determine the need for other therapeutic interventions, such as a pacemaker, implantable cardioverter defibrillator, or radiofrequency ablation (discussed in Chap. 27). EPS is indicated for patients with syncope and/or palpitations and for survivors of cardiac arrest from ventricular fibrillation (sudden cardiac death).

The initial study can take up to 4 hours. The patient receives moderate sedation. Catheters with recording and electrical stimulating (pacing) capabilities are inserted into the heart through the femoral and right subclavian veins to record electrical activity in the right and left atrium, bundle of His, and right ventricle. Fluoroscopy guides the positioning of these catheters. Baseline intracardiac recordings are obtained; programmed electrical stimulations of the atrium or ventricle are then administered in an attempt to induce the patient's dysrhythmia. If the dysrhythmia is induced, various antiarrhythmic medications are administered intravenously. The study is repeated after each medication to evaluate which medication or combination of medications is most effective in controlling the dysrhythmia.

After the study, the patient receives an equivalent oral antiarrhythmic agent, and subsequent studies may be necessary to evaluate the effectiveness of that medication. Results of the study may indicate the need for other therapeutic interventions, such as a pacemaker or implantable cardioverter defibrillator.

During EPS, lethal dysrhythmias may be induced; therefore, the procedure must be performed in a controlled environment with resuscitation equipment (eg, defibrillator) readily available. Possible complications include bleeding and hematoma from the catheter insertion sites, pneumothorax (air in the pleural cavity that may collapse portions of the lung), deep vein thrombosis, stroke, and sudden death.

## Nursing Interventions

Patients receive nothing to eat or drink for 8 hours before the procedure. Antiarrhythmic medications are withheld for at least 24 hours before the initial study, and the patient's cardiac rate

and rhythm are carefully monitored for dysrhythmias. Other medications may be taken with sips of water.

Thorough preparation before EPS will help to minimize patient anxiety. Ensure that the patient understands the reason for the study and is able to describe the common sensations and experiences expected during and after the study. Often the EPS laboratory has relaxation interventions available for patients, such as headsets with music. Also, the patient needs to be aware that the nurses in the EPS laboratory will be monitoring carefully for signs of discomfort and will offer intravenous medications to reduce discomfort or anxiety. Patients should be reminded to request these medications if necessary. Postprocedure interventions include careful monitoring for complications. The nurse takes vital signs, reviews tracings of continuous ECG monitoring, assesses the apical pulse, auscultates for pericardial friction rub (which indicates bleeding into the pericardial sac), and inspects the catheter insertion sites for bleeding or hematoma formation.

In addition, the nurse assists the patient to maintain bed rest with the affected extremity kept straight and the head of the bed elevated to 30 degrees for 4 to 6 hours. The frequency of assessments and the duration of bed rest may vary based on institutional policy and physician preference.

## HEMODYNAMIC MONITORING

Critically ill patients require continuous assessment of their cardiovascular system to diagnose and manage their complex medical conditions. This is most commonly achieved by the use of direct pressure monitoring systems, often referred to as **hemodynamic monitoring**. Central venous pressure (CVP), pulmonary artery pressure, and intra-arterial BP monitoring are common forms of hemodynamic monitoring. Patients requiring hemodynamic monitoring are cared for in specialty critical care units. Some critical care step-down units also admit stable patients with CVP or intra-arterial BP monitoring. Noninvasive hemodynamic monitoring is used in some facilities.

To perform invasive monitoring, specialized equipment is necessary and includes the following:

- A CVP, pulmonary artery, or arterial catheter, which is introduced into the appropriate blood vessel or heart chamber
- A flush system composed of intravenous solution (which may include heparin), tubing, stopcocks, and a flush device, which provides for continuous and manual flushing of the system
- A pressure bag placed around the flush solution that is maintained at 300 mm Hg of pressure; the pressurized flush system delivers 3 to 5 mL of solution per hour through the catheter to prevent clotting and backflow of blood into the pressure monitoring system
- A transducer to convert the pressure coming from the artery or heart chamber into an electrical signal
- An amplifier or monitor, which increases the size of the electrical signal for display on an oscilloscope

## Central Venous Pressure Monitoring

The CVP, the pressure in the vena cava or right atrium, is used to assess right ventricular function and venous blood return to the right side of the heart. The CVP can be continuously measured by connecting either a catheter positioned in the vena cava or the proximal port of a pulmonary artery catheter to a pressure monitoring system. The pulmonary artery catheter, described in greater

detail later, is used for critically ill patients. Patients in general medical-surgical units who require CVP monitoring may have a single-lumen or multilumen catheter placed into the superior vena cava. Intermittent measurement of the CVP can then be obtained with the use of a water manometer.

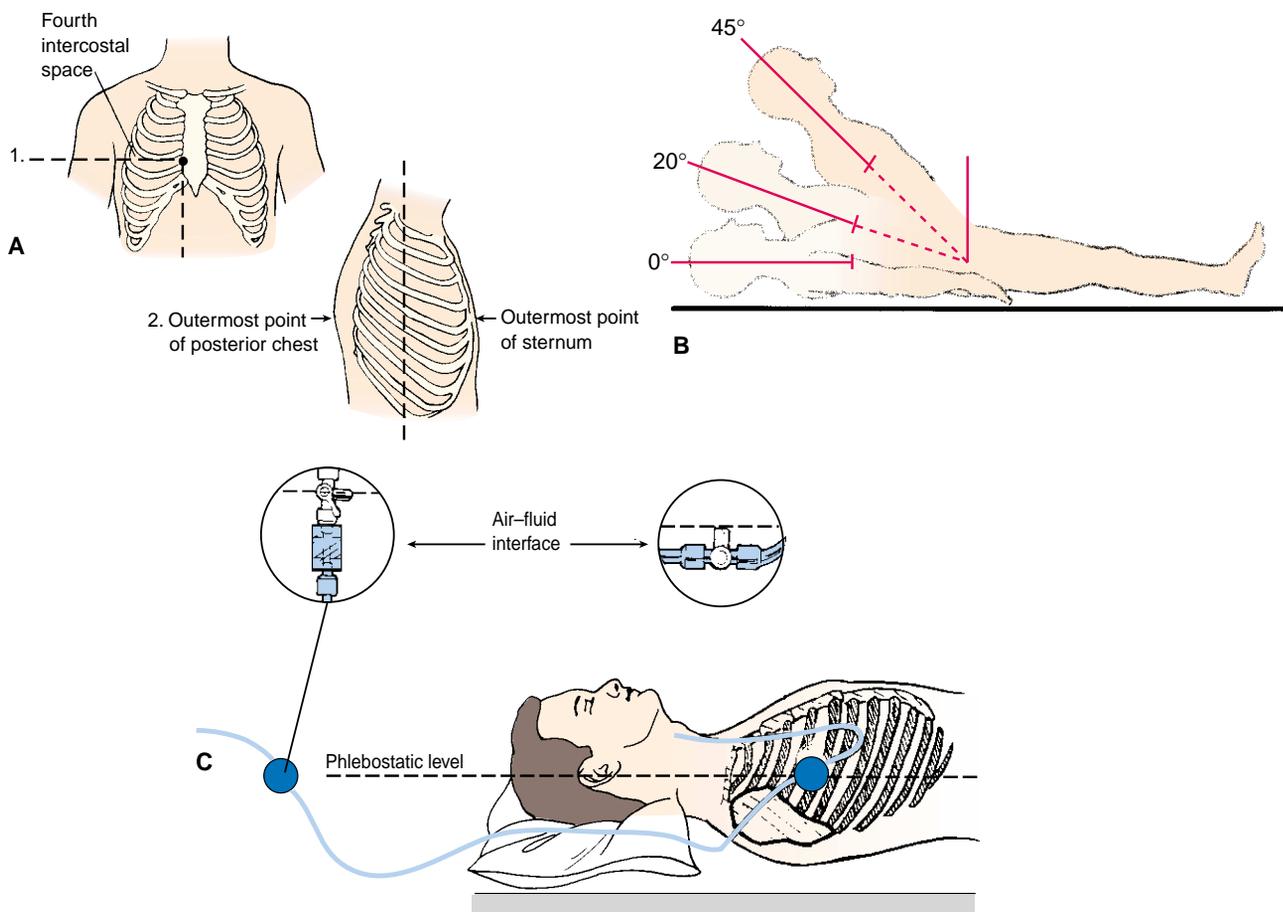

Because the pressures in the right atrium and right ventricle are equal at the end of diastole (0 to 8 mm Hg), the CVP is also an indirect method of determining right ventricular filling pressure (preload). This makes the CVP a useful hemodynamic parameter to observe when managing an unstable patient's fluid volume status. CVP monitoring is most valuable when pressures are monitored over time and are correlated with the patient's clinical status. A rising pressure may be caused by hypervolemia or by a condition, such as HF, that results in a decrease in myocardial contractility. Pulmonary artery monitoring is preferred for the patient with HF. Decreased CVP indicates reduced right ventricular preload, most often caused by hypovolemia. This diagnosis can be substantiated when a rapid intravenous infusion causes the CVP to rise. (CVP monitoring is not clinically useful in a patient with HF in whom left ventricular failure precedes right ventricular failure, because in these patients an elevated CVP is a very late sign of HF.)

Before insertion of a CVP catheter, the site is prepared by shaving if necessary and by cleansing with an antiseptic solution. A local anesthetic may be used. The physician threads a single-lumen or multilumen catheter through the external jugular, antecubital, or femoral vein into the vena cava just above or within the right atrium.

### NURSING INTERVENTIONS

Once the CVP catheter is inserted, it is secured and a dry, sterile dressing is applied. Catheter placement is confirmed by a chest x-ray, and the site is inspected daily for signs of infection. The dressing and pressure monitoring system or water manometer are changed according to hospital policy. In general, the dressing is to be kept dry and air occlusive. Dressing changes are performed with the use of sterile technique. CVP catheters can be used for infusing intravenous fluids, administering intravenous medications, and drawing blood specimens in addition to monitoring pressure.

To measure the CVP, the transducer (when a pressure monitoring system is used) or the zero mark on the manometer (when a water manometer is used) must be placed at a standard reference point, called the phlebostatic axis (Fig. 26-12). After locating this position, the nurse may make an ink mark on the

**FIGURE 26-12** The phlebostatic axis and the phlebostatic level. (A) The phlebostatic axis is the crossing of two reference lines: (1) a line from the fourth intercostal space at the point where it joins the sternum, drawn out to the side of the body beneath the axilla; and (2) a line midway between the anterior and posterior surfaces of the chest. (B) The phlebostatic level is a horizontal line through the phlebostatic axis. The air–fluid interface of the stopcock of the transducer, or the zero mark on the manometer, must be level with this axis for accurate measurements. When moving from the flat to erect positions, the patient moves the chest and therefore the reference level; the phlebostatic level stays horizontal through the same reference point. (C) Two methods for referencing the pressure system to the phlebostatic axis. The system can be referenced by placing the air–fluid interface of either the in-line stopcock or stopcock on top of the transducer at the phlebostatic level.

patient's chest to indicate the location. If the phlebostatic axis is used, CVP can be measured correctly with the patient supine at any backrest position up to 45 degrees. The range for a normal CVP is 0 to 8 mm Hg with a pressure monitoring system or 3 to 8 cm H<sub>2</sub>O with a water manometer system. The most common complications of CVP monitoring are infection and air embolism.

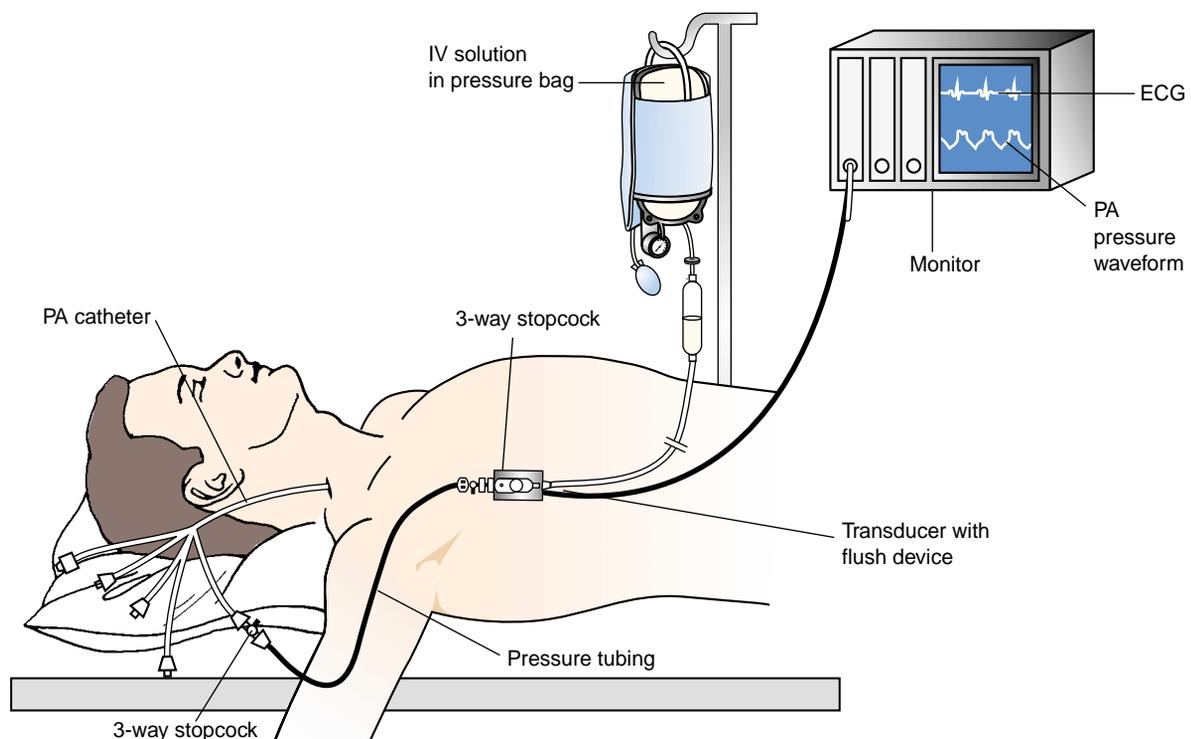

### Pulmonary Artery Pressure Monitoring

Pulmonary artery pressure monitoring is an important tool used in critical care for assessing left ventricular function, diagnosing the etiology of shock, and evaluating the patient's response to medical interventions (eg, fluid administration, vasoactive medications). Pulmonary artery pressure monitoring is achieved by using a pulmonary artery catheter and pressure monitoring system. Catheters vary in their number of lumens and their types of measurement (eg, cardiac output, oxygen saturation) or pacing capabilities. All types require that a balloon-tipped, flow-directed catheter be inserted into a large vein (usually the subclavian, jugular, or femoral vein); the catheter is then passed into the vena cava and right atrium. In the right atrium, the balloon tip is inflated, and the catheter is carried rapidly by the flow of blood through the tricuspid valve, into the right ventricle, through the pulmonic valve, and into a branch of the pulmonary artery. When the catheter reaches a small pulmonary artery, the balloon is deflated and the catheter is secured with sutures. Fluoroscopy may be used during insertion to visualize the progression of the catheter through the heart chambers to the pulmonary artery. This procedure can be performed in the operating room or cardiac catheterization laboratory or at the bedside in the critical care unit. During insertion of the pulmonary artery catheter, the bedside monitor is observed for waveform and ECG changes as the catheter is moved

through the heart chambers on the right side and into the pulmonary artery.

After the catheter is correctly positioned, the following pressures can be measured: CVP or right atrial pressure, pulmonary artery systolic and diastolic pressures, mean pulmonary artery pressure, and pulmonary artery wedge pressure (Fig. 26-13). If a thermodilution catheter is used, the cardiac output can be measured and systemic vascular resistance and pulmonary vascular resistance can be calculated.

Normal pulmonary artery pressure is 25/9 mm Hg, with a mean pressure of 15 mm Hg (see Fig. 26-5 for normal ranges). When the balloon tip is inflated, usually with 1 mL of air, the catheter floats farther out into the pulmonary artery until it becomes wedged. This is an occlusive maneuver that impedes blood flow through that segment of the pulmonary artery. A pressure measurement, called pulmonary artery wedge pressure, is taken within seconds after wedging of the pulmonary artery catheter; then the balloon is immediately deflated and blood flow is restored. The nurse who obtains the wedge reading ensures that the catheter has returned to its normal position in the pulmonary artery by evaluating the pulmonary artery pressure waveform. The pulmonary artery diastolic reading and the wedge pressure reflect the pressure in the ventricle at end-diastole and are particularly important to monitor in critically ill patients, because they are used to evaluate left ventricular filling pressures (preload). At end-diastole, when the mitral valve is open, the wedge pressure is the same as the pressure in the left atrium and the left ventricle, unless the patient has mitral valve disease or pulmonary hypertension. Pulmonary capillary wedge pressure is a mean pressure and is normally 4.5 to 13 mm Hg. Critically ill patients usually require higher left ventricular filling pressures to optimize cardiac output. These patients may need to have their wedge pressure maintained as high as 18 mm Hg.

**FIGURE 26-13** Example of a pulmonary artery (PA) pressure monitoring system. PA catheter is inserted into the internal jugular vein and advanced into the pulmonary artery.

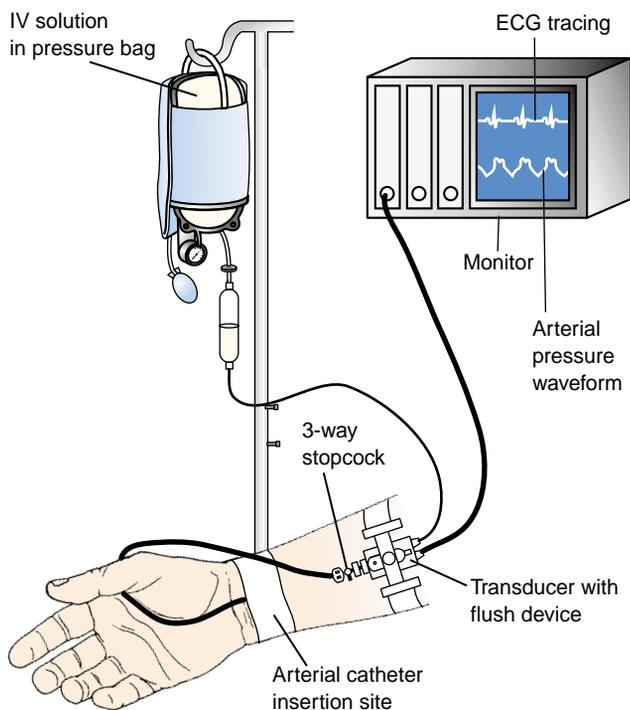

## NURSING INTERVENTIONS

Catheter site care is essentially the same as for a CVP catheter. As in measuring CVP, the transducer must be positioned at the phlebostatic axis to ensure accurate readings (see Fig. 26-12). Complications of pulmonary artery pressure monitoring include infection, pulmonary artery rupture, pulmonary thromboembolism, pulmonary infarction, catheter kinking, dysrhythmias, and air embolism.

## Intra-arterial Blood Pressure Monitoring

Intra-arterial BP monitoring is used to obtain direct and continuous BP measurements in critically ill patients who have severe hypertension or hypotension (Fig. 26-14). Arterial catheters are also useful when arterial blood gas measurements and blood samples need to be obtained frequently.

Once an arterial site is selected (radial, brachial, femoral, or dorsalis pedis), collateral circulation to the area must be confirmed before the catheter is placed. This is a safety precaution to prevent compromised arterial perfusion to the area distal to the arterial catheter insertion site. If no collateral circulation exists and the cannulated artery became occluded, ischemia and infarction of the area distal to that artery could occur. Collateral circulation to the hand can be checked by the Allen test to evaluate the radial and ulnar arteries or by an ultrasonic Doppler test for any of the arteries. With the Allen test, the nurse compresses the radial and ulnar arteries simultaneously and asks the patient to make a fist, causing the hand to blanch. After the patient opens the fist, the nurse releases the pressure on the ulnar artery while maintaining pressure on the radial artery. The patient's hand will turn pink if the ulnar artery is patent.

**FIGURE 26-14** Example of an arterial pressure monitoring system. The arterial catheter is inserted into the radial artery. A three-way stopcock is used for drawing arterial blood samples.

## NURSING INTERVENTIONS

Site preparation and care are the same as for CVP catheters. The catheter flush solution is the same as for pulmonary artery catheters. A transducer is attached, and pressures are measured in millimeters of mercury (mm Hg). Complications include local obstruction with distal ischemia, external hemorrhage, massive ecchymosis, dissection, air embolism, blood loss, pain, arteriospasm, and infection.

## Critical Thinking Exercises

1. You are caring for an elderly man who has had three hospital admissions in 6 months for HF. To plan for his discharge you need to fully understand what is causing these recurrent HF episodes. What medical and nursing history, physical examination, and laboratory data will you need to collect to help you understand the recurrent episodes of HF? What types of information are necessary to help you formulate his plan for discharge? With what other team members might you consult before completing this plan?
2. While working in a primary care clinic, you notice that many of the patients use tobacco products including cigarettes and chewing tobacco. What are the health risks of tobacco use? The clinic does not have a smoking cessation protocol. You want to help people become tobacco free but have little experience in providing cessation advice. What information and resources will you need to obtain to devise and implement a smoking cessation protocol?
3. While making a home visit, your patient, a 54-year-old African American woman with a history of hypertension, diabetes, and tobacco use, tells you she has had overwhelming fatigue and right scapular and shoulder pain going down into her arm for the last 10 hours. Describe your rapid chest pain assessment and management plan for this patient. Discuss the factors that may be contributing to her delay in seeking care for symptoms of acute MI. Compare and contrast symptoms of acute MI and factors contributing to delay in seeking care.

# ● Management of Patients With Dysrhythmias and Conduction Problems

## LEARNING OBJECTIVES ●

*On completion of this chapter, the learner will be able to:*

1. Correlate the components of the normal ECG with physiologic events of the heart.
2. Define the ECG as a waveform that represents the cardiac electrical event in relation to the lead depicted (placement of electrodes).
3. Analyze elements of an ECG rhythm strip: ventricular and atrial rate, ventricular and atrial rhythm, QRS complex and shape, QRS duration, P wave and shape, PR interval, and P:QRS ratio.
4. Identify the ECG criteria, causes, and management of several dysrhythmias, including conduction disturbances.
5. Use the nursing process as a framework for care of patients with dysrhythmias.
6. Compare the different types of pacemakers, their uses, possible complications, and nursing implications.
7. Use the nursing process as a framework for care of patients with pacemakers.
8. Describe the key points of using a defibrillator.
9. Describe the purpose of an implantable cardioverter defibrillator (ICD), the types available, and the nursing implications.
10. Describe invasive methods to diagnose and treat recurrent dysrhythmias, and discuss the nursing implications.

Without a regular rate and rhythm, the heart may not perform efficiently as a pump to circulate oxygenated blood and other life-sustaining nutrients to all the body organs (including itself) and tissues. With an irregular or erratic rhythm, the heart is considered to be dysrhythmic (sometimes called arrhythmic). This has the potential to be a dangerous condition.

## Dysrhythmias

**Dysrhythmias** are disorders of the formation or conduction (or both) of the electrical impulse within the heart. These disorders can cause disturbances of the heart rate, the heart rhythm, or both. Dysrhythmias may initially be evidenced by the hemodynamic effect they cause (eg, a change in conduction may change the pumping action of the heart and cause decreased blood pressure). Dysrhythmias are diagnosed by analyzing the electrocardiographic waveform. They are named according to the site of origin of the impulse and the mechanism of formation or conduction involved (Chart 27-1). For example, an impulse that originates in the sinoatrial (SA) node and that has a slow rate is called sinus bradycardia.

## NORMAL ELECTRICAL CONDUCTION

The electrical impulse that stimulates and paces the cardiac muscle normally originates in the sinus node (SA node), an area located near the superior vena cava in the right atrium. Usually, the electrical impulse occurs at a rate ranging between 60 and 100 times a minute in the adult. The electrical impulse quickly travels from the sinus node through the atria to the atrioventricular (AV) node (Fig. 27-1). The electrical stimulation of the muscle cells of the atria causes them to contract. The structure of the AV node slows the electrical impulse, which allows time for the atria to contract and fill the ventricles with blood before the electrical impulse

### Chart 27-1

### Identifying Dysrhythmias

#### Sites of Origin

- Sinus (SA) node
- Atria
- Atrioventricular (AV) node or junction
- Ventricles

#### Mechanisms of Formation or Conduction

- Normal (idio) rhythm
- Bradycardia
- Tachycardia
- Dysrhythmia

- Blocks

travels very quickly through the bundle of His to the right and left bundle branches and the Purkinje fibers, located in the ventricular muscle. The electrical stimulation of the muscle cells of the ventricles, in turn, causes the mechanical contraction of the ventricles (systole). The cells repolarize and the ventricles then relax (diastole). The process from sinus node electrical impulse generation through ventricular repolarization completes the electro-mechanical circuit, and the cycle begins again.

Sinus rhythm promotes cardiovascular circulation. The electrical impulse causes (and, therefore, is followed by) the mechanical contraction of the heart muscle. The electrical stimulation is called **depolarization**; the mechanical contraction is called systole. Electrical relaxation is called **repolarization** and mechanical relaxation is called diastole. See Chapter 26 for a more complete explanation of cardiac function.

## Glossary

**ablation:** purposeful destruction of heart muscle cells, usually in an attempt to control a dysrhythmia

**antiarrhythmic:** a medication that suppresses or prevents a dysrhythmia

**automaticity:** ability of the cardiac muscle to initiate an electrical impulse

**cardioversion:** electrical current administered in synchrony with the patient's own QRS to stop a dysrhythmia

**conductivity:** ability of the cardiac muscle to transmit electrical impulses

**defibrillation:** electrical current administered to stop a dysrhythmia, not synchronized with the patient's QRS complex

**depolarization:** process by which cardiac muscle cells change from a more negatively charged to a more positively charged intracellular state

**dysrhythmia (also referred to as arrhythmia):** disorder of the formation or conduction (or both) of the electrical impulse within the heart, altering the heart rate, heart rhythm, or both and potentially causing altered blood flow

**implantable cardioverter defibrillator (ICD):** a device implanted into the chest to treat dysrhythmias

**inhibited:** in reference to pacemakers, term used to describe the pacemaker withholding an impulse (not firing)

**P wave:** the part of an electrocardiogram (ECG) that reflects conduction of an electrical impulse through the atrium; atrial depolarization

**paroxysmal:** a dysrhythmia that has a sudden onset and/or termination and is usually of short duration

**PR interval:** the part of an ECG that reflects conduction of an electrical impulse from the sinoatrial (SA) node through the atrioventricular (AV) node

**proarrhythmic:** an agent (eg, a medication) that causes or exacerbates a dysrhythmia

**QRS complex:** the part of an ECG that reflects conduction of an electrical impulse through the ventricles; ventricular depolarization

**QT interval:** the part of an ECG that reflects the time from ventricular depolarization to repolarization

**repolarization:** process by which cardiac muscle cells return to a more negatively charged intracellular condition, their resting state

**sinus rhythm:** electrical activity of the heart initiated by the sinoatrial (SA) node

**ST segment:** the part of an ECG that reflects the end of ventricular depolarization (end of the QRS complex) through ventricular repolarization (end of the T wave)

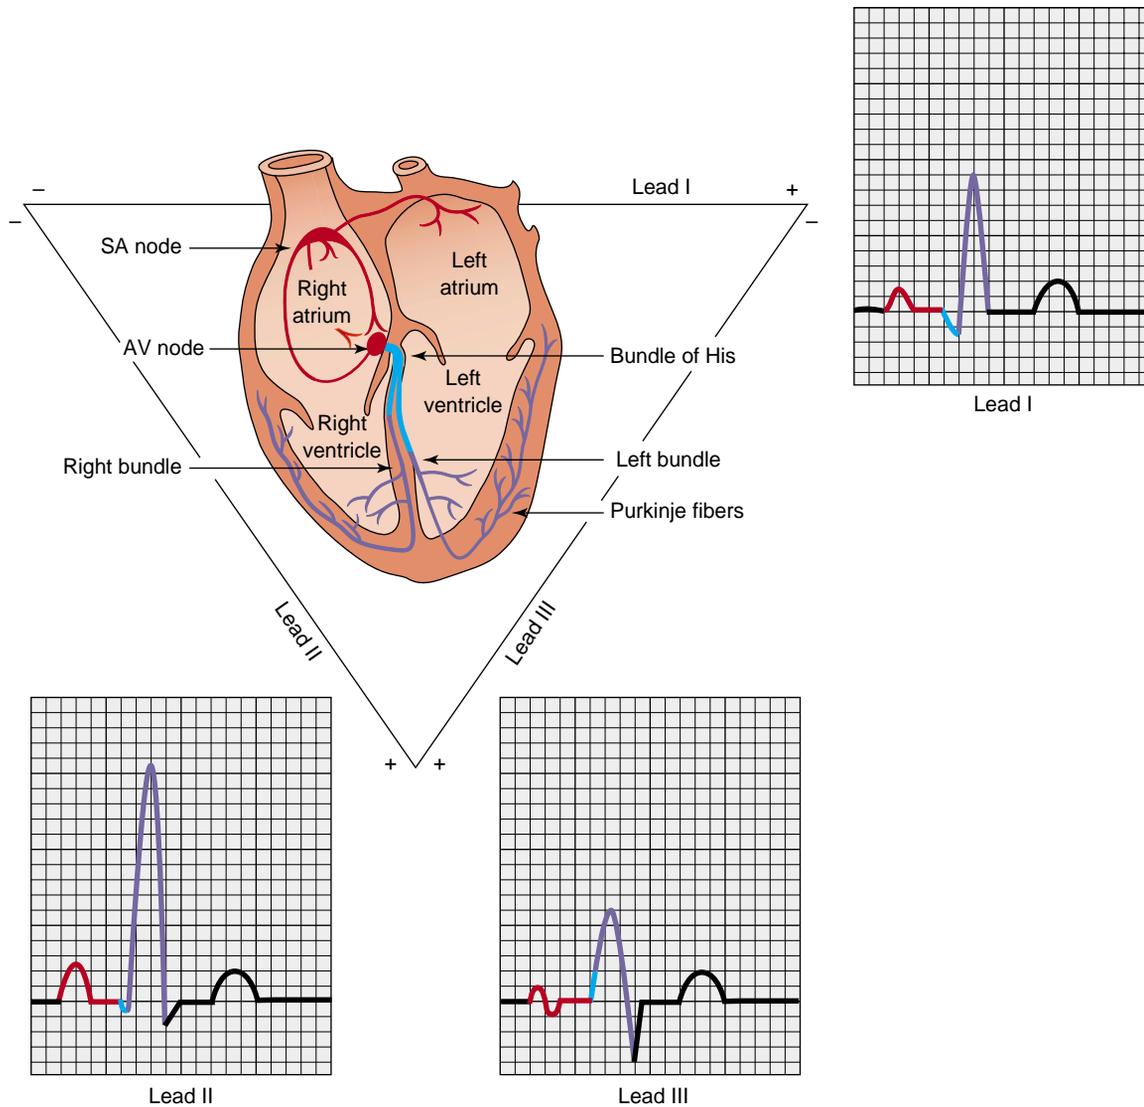

**supraventricular tachycardia (SVT):** a rhythm that originates in the conduction system above the ventricles

**T wave:** the part of an ECG that reflects repolarization of the ventricles

**triggered:** in reference to pacemakers, term used to describe the release of an impulse in response to some stimulus

**U wave:** the part of an ECG that may reflect Purkinje fiber repolarization; usually seen when a patient's serum potassium level is low

**ventricular tachycardia (VT):** a rhythm that originates in the ventricles

**FIGURE 27-1** Relationship of electrocardiogram (ECG) complex, lead system, and electrical impulse. The heart conducts electrical activity, which the ECG measures and shows. The configurations of electrical activity displayed on the ECG vary depending on the lead (or view) of the ECG and on the rhythm of the heart. Therefore, the configuration of a normal rhythm tracing from lead I will differ from the configuration of a normal rhythm tracing from lead II, lead II will differ from lead III, and so on. The same is true for abnormal rhythms and cardiac disorders. To make an accurate assessment of the heart's electrical activity or to identify where, when, and what abnormalities occur, the ECG needs to be evaluated from every lead, not just from lead II. Here the different areas of electrical activity are identified by color.

## Influences on Heart Rate and Contractility

The heart rate is influenced by the autonomic nervous system, which consists of sympathetic and parasympathetic fibers. Sympathetic nerve fibers (also referred to as adrenergic fibers) are attached to the heart and arteries as well as several other areas in the body. Stimulation of the sympathetic system increases heart rate (positive chronotropy), conduction through the AV node (positive dromotropy), and the force of myocardial contraction (positive inotropy). Sympathetic stimulation also constricts peripheral blood vessels, therefore increasing blood pressure. Parasympathetic nerve fibers are also attached to the heart and arteries. Parasympathetic stimulation reduces the heart rate (negative chronotropy), AV conduction (negative dromotropy), and the force of atrial myocardial contraction. The decreased sympathetic stimulation results in dilation of arteries, thereby lowering blood pressure.

Manipulation of the autonomic nervous system may increase or decrease the incidence of dysrhythmias. Increased sympathetic stimulation—caused, for example, by exercise, anxiety, fever, or administration of catecholamines (eg, dopamine [Intropin], aminophylline, dobutamine [Dobutrex])—may increase the incidence of dysrhythmias. Decreased sympathetic stimulation (eg, with rest, anxiety-reduction methods such as therapeutic communication or prayer, administration of beta-adrenergic blocking agents) may decrease the incidence of dysrhythmias.

## INTERPRETATION OF THE ELECTROCARDIOGRAM

The electrical impulse that travels through the heart can be viewed by means of electrocardiography, the end product of which is an electrocardiogram (ECG). Each phase of the cardiac cycle is re-

flected by specific waveforms on the screen of a cardiac monitor or on a strip of ECG graph paper.

An ECG is obtained by slightly abrading the skin with a clean dry gauze pad and placing electrodes on the body at specific areas. Electrodes come in various shapes and sizes, but all have two components: (1) an adhesive substance that attaches to the skin to secure the electrode in place and (2) a substance that reduces the skin's electrical impedance and promotes detection of the electrical current.

The number and placement of the electrodes depend on the type of ECG needed. Most continuous monitors use two to five electrodes, usually placed on the limbs and the chest. These electrodes create an imaginary line, called a lead, that serves as a reference point from which the electrical activity is viewed. A lead is like an eye of a camera; it has a narrow peripheral field of vision, looking only at the electrical activity directly in front of it. Therefore, the ECG waveforms that appear on the paper or cardiac monitor represent the electrical current in relation to the lead (see Fig. 27-1). A change in the waveform can be caused by a change in the electrical current (where it originates or how it is conducted) or by a change in the lead.

### Obtaining an Electrocardiogram

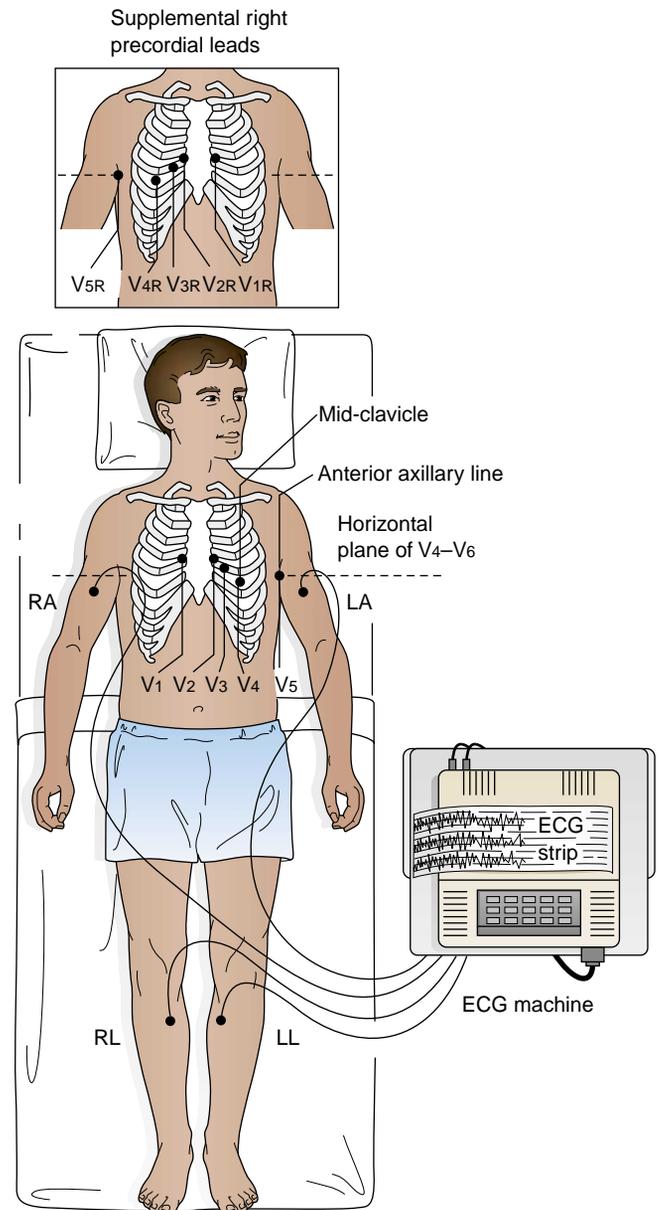

Electrodes are attached to cable wires, which are connected to one of the following:

- An ECG machine placed at the patient's side for an immediate recording (standard 12-lead ECG)
- A cardiac monitor at the patient's bedside for continuous reading; this kind of monitoring, usually called hardwire monitoring, is associated with intensive care units
- A small box that the patient carries and that continuously transmits the ECG information by radio waves to a central monitor located elsewhere (called telemetry)
- A small, lightweight tape recorder-like machine (called a Holter monitor) that the patient wears and that continuously records the ECG on a tape, which is later viewed and analyzed with a scanner

The placement of electrodes for continuous monitoring, telemetry, or Holter monitoring varies with the type of technology that is appropriate and available, the purpose of monitoring, and the standards of the institution. For a standard 12-lead ECG, 10 electrodes (six on the chest and four on the limbs) are placed on the body (Fig. 27-2). To prevent interference from the electrical activity of skeletal muscle, the limb electrodes are usually placed on areas that are not bony and that do not have significant movement. These limb electrodes provide the first six leads: leads I, II, III, aVR, aVL, and aVF. The six chest electrodes are attached to the chest at very specific areas. The chest electrodes provide the V or precordial leads, V<sub>1</sub> through V<sub>6</sub>. To locate the fourth intercostal space and the placement of V<sub>1</sub>, locate the sternal angle and then the sternal notch, which is about 1 or 2 inches below the sternal angle. When the fingers are moved to the patient's immediate right, the second rib can be palpated. The second intercostal space is the indentation felt just below the second rib.

Locating the specific intercostal space is critical for correct chest electrode placement. Errors in diagnosis can occur if electrodes are incorrectly placed. Sometimes, when the patient is in the hospital and needs to be monitored closely for ECG changes, the chest electrodes are left in place to ensure the same placement for follow-up ECGs.

A standard 12-lead ECG reflects the electrical activity primarily in the left ventricle. Placement of additional electrodes for

**FIGURE 27-2** ECG electrode placement. The standard left precordial leads are V<sub>1</sub>—4th intercostal space, right sternal border; V<sub>2</sub>—4th intercostal space, left sternal border; V<sub>3</sub>—diagonally between V<sub>2</sub> and V<sub>4</sub>; V<sub>4</sub>—5th intercostal space, left midclavicular line; V<sub>5</sub>—same level as V<sub>4</sub>, anterior axillary line; V<sub>6</sub> (not illustrated)—same level as V<sub>4</sub> and V<sub>5</sub>, midaxillary line. The right precordial leads, placed across the right side of the chest, are the mirror opposite of the left leads. Adapted from Hosley, J. B., & Molle-Matthews, E. (1999). *Lippincott's pocket guide to medical assisting*. Philadelphia: Lippincott Williams & Wilkins.

other leads may be needed to obtain more complete information. For example, in patients with suspected right-sided heart damage, right-sided precordial leads are required to evaluate the right ventricle (see Fig. 27-2).

### Analysis of the Electrocardiogram

The ECG waveform represents the function of the heart's conduction system, which normally initiates and conducts the electrical activity, in relation to the lead. When analyzed accurately, the ECG offers important information about the electrical activity

of the heart. ECG waveforms are printed on graph paper that is divided by light and dark vertical and horizontal lines at standard intervals (Fig. 27-3). Time and rate are measured on the horizontal axis of the graph, and amplitude or voltage is measured on the vertical axis. When an ECG waveform moves toward the top of the paper, it is called a positive deflection. When it moves toward the bottom of the paper, it is called a negative deflection. When reviewing an ECG, each waveform should be examined and compared with the others.

### WAVES, COMPLEXES, AND INTERVALS

The ECG is composed of waveforms (including the P wave, the QRS complex, the T wave, and possibly a U wave) and of segments or intervals (including the PR interval, the ST segment, and the QT interval) (see Fig. 27-3).

The **P wave** represents the electrical impulse starting in the sinus node and spreading through the atria. Therefore, the P wave represents atrial muscle depolarization. It is normally 2.5 mm or less in height and 0.11 second or less in duration.

The **QRS complex** represents ventricular muscle depolarization. Not all QRS complexes have all three waveforms. The first negative deflection after the P wave is the Q wave, which is normally less than 0.04 second in duration and less than 25% of the R wave amplitude; the first positive deflection after the P wave is the R wave; and the S wave is the first negative deflection after the R wave. When a wave is less than 5 mm in height, small letters (q, r, s) are used; when a wave is taller than 5 mm, capital letters (Q, R, S) are used. The QRS complex is normally less than 0.12 seconds in duration.

The **T wave** represents ventricular muscle repolarization (when the cells regain a negative charge; also called the resting state). It follows the QRS complex and is usually the same direction as the QRS complex.

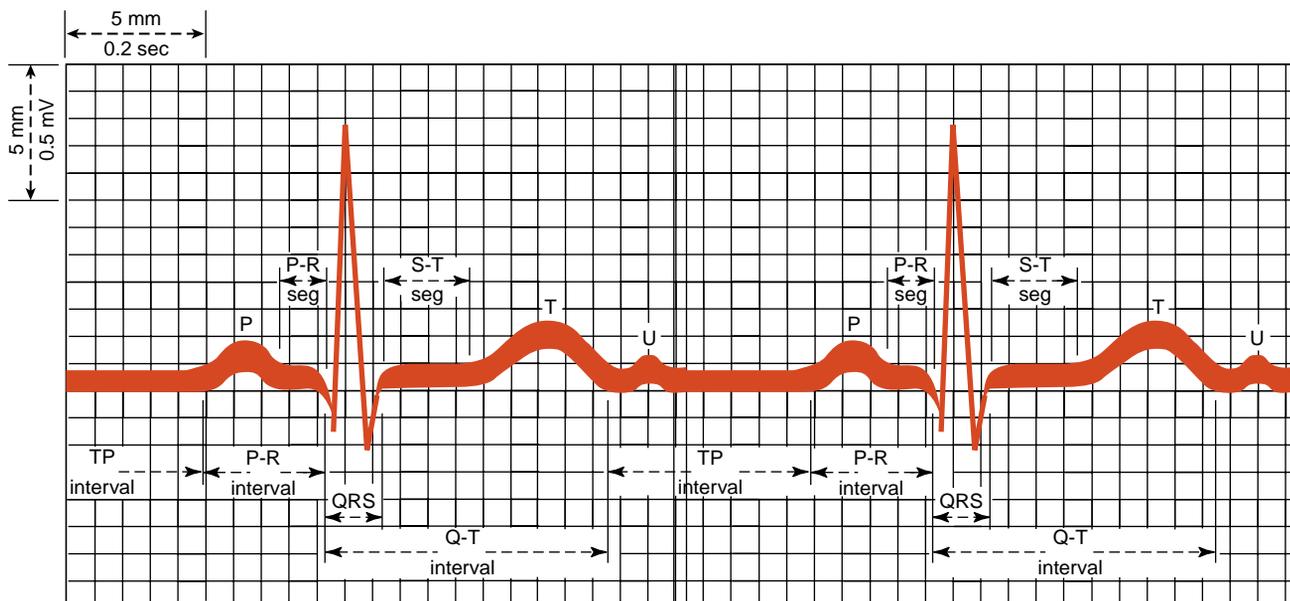

The **U wave** is thought to represent repolarization of the Purkinje fibers, but it sometimes is seen in patients with hypokalemia (low potassium levels), hypertension, or heart disease. If present, the U wave follows the T wave and is usually smaller than the P wave. If tall, it may be mistaken for an extra P wave.

The **PR interval** is measured from the beginning of the P wave to the beginning of the QRS complex and represents the time needed for sinus node stimulation, atrial depolarization, and conduction through the AV node before ventricular depolarization. In adults, the PR interval normally ranges from 0.12 to 0.20 seconds in duration.

The **ST segment**, which represents early ventricular repolarization, lasts from the end of the QRS complex to the beginning of the T wave. The beginning of the ST segment is usually identified by a change in the thickness or angle of the terminal portion of the QRS complex. The end of the ST segment may be more difficult to identify because it merges into the T wave. The ST segment is normally isoelectric (see discussion of TP interval). It is analyzed to identify whether it is above or below the isoelectric line, which may be, among other signs and symptoms, a sign of cardiac ischemia (see Chap. 28).

The **QT interval**, which represents the total time for ventricular depolarization and repolarization, is measured from the beginning of the QRS complex to the end of the T wave. The QT interval varies with heart rate, gender, and age, and the measured interval needs to be corrected for these variables through a specific calculation. Several ECG interpretation books contain charts of these calculations. The QT interval is usually 0.32 to 0.40 seconds in duration if the heart rate is 65 to 95 beats per minute. If the QT interval becomes prolonged, the patient may be at risk for a lethal ventricular dysrhythmia called torsades de pointes.

The **TP interval** is measured from the end of the T wave to the beginning of the next P wave, an isoelectric period (see Fig 27-3).

**FIGURE 27-3** ECG graph and commonly measured components. Each small box represents 0.04 seconds on the horizontal axis and 1 mm or 0.1 millivolt on the vertical axis. The PR interval is measured from the beginning of the P wave to the beginning of the QRS complex; the QRS complex is measured from the beginning of the Q wave to the end of the S wave; the QT interval is measured from the beginning of the Q wave to the end of the T wave; and the TP interval is measured from the end of the T wave to the beginning of the next P wave.

When no electrical activity is detected, the line on the graph remains flat; this is called the isoelectric line. The ST segment is compared with the TP interval to detect changes from the line on the graph during the isoelectric period.

The **PP interval** is measured from the beginning of one P wave to the beginning of the next. The PP interval is used to determine atrial rhythm and atrial rate. The RR interval is measured from one QRS complex to the next QRS complex. The RR interval is used to determine ventricular rate and rhythm (Fig. 27-4).

### DETERMINING VENTRICULAR HEART RATE FROM THE ELECTROCARDIOGRAM

Heart rate can be obtained from the ECG strip by several methods. A 1-minute strip contains 300 large boxes and 1500 small boxes. Therefore, an easy and accurate method of determining heart rate with a regular rhythm is to count the number of small boxes within an RR interval and divide 1500 by that number. If, for example, there are 10 small boxes between two R waves, the heart rate is  $1500 \div 10$ , or 150; if there are 25 small boxes, the heart rate is  $1500 \div 25$ , or 60 (see Fig. 27-4A).

An alternative but less accurate method for estimating heart rate, which is usually used when the rhythm is irregular, is to count the number of RR intervals in 6 seconds and multiply that number by 10. The top of the ECG paper is usually marked at 3-second intervals, which is 15 large boxes horizontally (see Fig. 27-4B). The RR intervals are counted, rather than QRS complexes, because a computed heart rate based on the latter might be inaccurately high.

The same methods may be used for determining atrial rate, using the PP interval instead of the RR interval.

### DETERMINING HEART RHYTHM FROM THE ELECTROCARDIOGRAM

The rhythm is often identified at the same time the rate is determined. The RR interval is used to determine ventricular rhythm and the PP interval to determine atrial rhythm. If the intervals are the same or nearly the same throughout the strip, the rhythm is

called regular. If the intervals are different, the rhythm is called irregular.

## ANALYZING THE ELECTROCARDIOGRAM RHYTHM STRIP

The ECG must be analyzed in a systematic manner to determine the patient's cardiac rhythm and to detect dysrhythmias and conduction disorders, as well as evidence of myocardial ischemia, injury, and infarction. Chart 27-2 is an example of a method that can be used to analyze the patient's rhythm.

Once the rhythm has been analyzed, the findings are compared with and matched to the ECG criteria for dysrhythmias to determine a diagnosis. It is important for the nurse to assess the patient to determine the physiologic effect of the dysrhythmia and to identify possible causes. Treatment of dysrhythmias is based on the etiology and the effect of the dysrhythmia, not on its presence alone.

### Normal Sinus Rhythm

**Normal sinus rhythm** occurs when the electrical impulse starts at a regular rate and rhythm in the sinus node and travels through the normal conduction pathway. The following are the ECG criteria for normal sinus rhythm (Fig. 27-5):

*Ventricular and atrial rate:* 60 to 100 in the adult

*Ventricular and atrial rhythm:* Regular

*QRS shape and duration:* Usually normal, but may be regularly abnormal

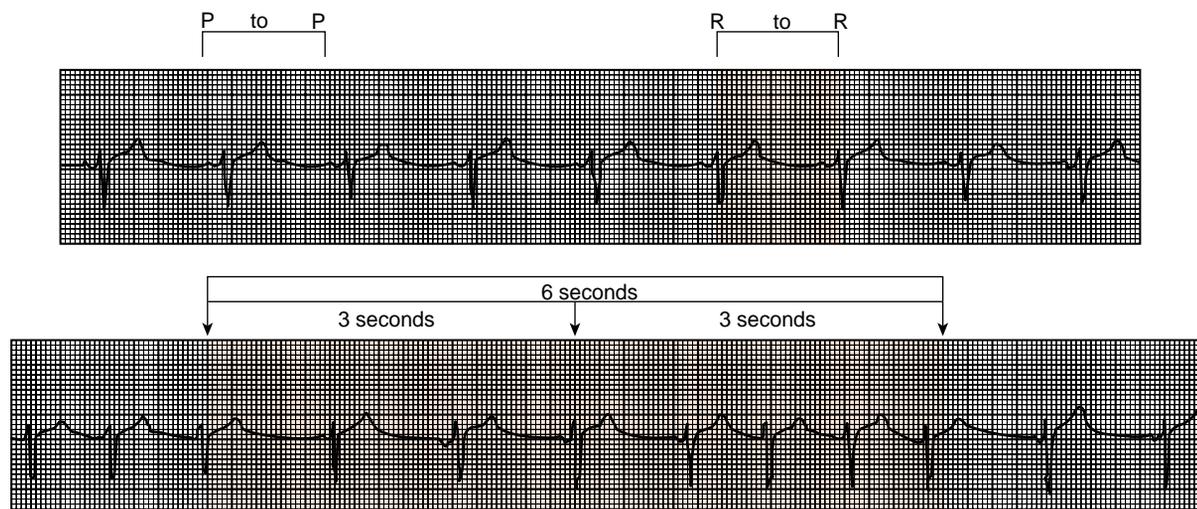

*P wave:* Normal and consistent shape; always in front of the QRS

*PR interval:* Consistent interval between 0.12 and 0.20 seconds

*P: QRS ratio:* 1 : 1

### Types of Dysrhythmias

Dysrhythmias include sinus node, atrial, junctional, and ventricular dysrhythmias and their various subcategories.

**FIGURE 27-4** (A) Heart rate determination for a regular rhythm: 1500 divided by the number of small boxes between two R waves (there are 25 in this example) equals the ventricular heart rate. The heart rate in this example is 60. (B) Heart rate determination if the rhythm is irregular. There are approximately seven RR intervals in 6 seconds. Seven times 10 equals 70. The heart rate is 70.

Chart  
27-2

### Interpreting Dysrhythmias: Systematic Analysis of the Electrocardiogram

When examining an ECG rhythm strip to learn more about a patient's dysrhythmia, the nurse conducts the following assessment:

1. Determine the ventricular rate.
  2. Determine the ventricular rhythm.
  3. Determine QRS duration.
  4. Determine whether the QRS duration is consistent throughout the strip. If not, identify other duration.
  5. Identify QRS shape; if not consistent, then identify other shapes.
  6. Identify P waves; is there a P in front of every QRS?
  7. Identify P-wave shape; identify whether it is consistent or not.
  8. Determine the atrial rate.
  9. Determine the atrial rhythm.
  10. Determine each PR interval.
  11. Determine if the PR intervals are consistent, irregular but with a pattern to the irregularity, or just irregular.
  12. Determine how many P waves for each QRS (P:QRS ratio).
- In many cases, the nurse may use a checklist and document the findings next to the appropriate ECG criterion.

## SINUS NODE DYSRHYTHMIAS

**Sinus Bradycardia.** Sinus bradycardia occurs when the sinus node creates an impulse at a slower-than-normal rate. Causes include lower metabolic needs (eg, sleep, athletic training, hypothermia, hypothyroidism), vagal stimulation (eg, from vomiting, suctioning, severe pain, extreme emotions), medications (eg, calcium channel blockers, amiodarone, beta-blockers), increased intracranial pressure, and myocardial infarction (MI), especially of the inferior wall. The following are characteristics of sinus bradycardia (Fig. 27-6):

*Ventricular and atrial rate:* Less than 60 in the adult

*Ventricular and atrial rhythm:* Regular

*QRS shape and duration:* Usually normal, but may be regularly abnormal

*P wave:* Normal and consistent shape; always in front of the QRS

*PR interval:* Consistent interval between 0.12 and 0.20 seconds

*P: QRS ratio:* 1:1

All characteristics of sinus bradycardia are the same as those of normal sinus rhythm, except for the rate. The patient is assessed to determine the hemodynamic effect and the possible cause of the dysrhythmia. If the decrease in heart rate results from stimulation of the vagus nerve, such as with bearing down during defecation or vomiting, attempts are made to prevent further vagal

stimulation. If the bradycardia is from a medication such as a beta-blocker, the medication may be withheld. If the slow heart rate causes significant hemodynamic changes, resulting in shortness of breath, decreased level of consciousness, angina, hypotension, ST-segment changes, or premature ventricular complexes, treatment is directed toward increasing the heart rate.

Atropine, 0.5 to 1.0 mg given rapidly as an intravenous (IV) bolus, is the medication of choice in treating sinus bradycardia. It blocks vagal stimulation, thus allowing a normal rate to occur. Rarely, catecholamines and emergency transcutaneous pacing also may be implemented.

**Sinus Tachycardia.** Sinus tachycardia occurs when the sinus node creates an impulse at a faster-than-normal rate. It may be caused by acute blood loss, anemia, shock, hypervolemia, hypovolemia, congestive heart failure, pain, hypermetabolic states, fever, exercise, anxiety, or sympathomimetic medications. The ECG criteria for sinus tachycardia follow (Fig. 27-7):

*Ventricular and atrial rate:* Greater than 100 in the adult

*Ventricular and atrial rhythm:* Regular

*QRS shape and duration:* Usually normal, but may be regularly abnormal

*P wave:* Normal and consistent shape; always in front of the QRS, but may be buried in the preceding T wave

*PR interval:* Consistent interval between 0.12 and 0.20 seconds

*P: QRS ratio:* 1:1

All aspects of sinus tachycardia are the same as those of normal sinus rhythm, except for the rate. As the heart rate increases, the diastolic filling time decreases, possibly resulting in reduced cardiac output and subsequent symptoms of syncope and low blood pressure. If the rapid rate persists and the heart cannot compensate for the decreased ventricular filling, the patient may develop acute pulmonary edema.

Treatment of sinus tachycardia is usually directed at abolishing its cause. Calcium channel blockers and beta-blockers (Table 27-1) may be used to reduce the heart rate quickly.

**Sinus Arrhythmia.** Sinus arrhythmia occurs when the sinus node creates an impulse at an irregular rhythm; the rate usually increases with inspiration and decreases with expiration. Nonrespiratory causes include heart disease and valvular disease, but these are rarely seen. The ECG criteria for sinus arrhythmia follow (Fig. 27-8):

*Ventricular and atrial rate:* 60 to 100 in the adult

*Ventricular and atrial rhythm:* Irregular

*QRS shape and duration:* Usually normal, but may be regularly abnormal

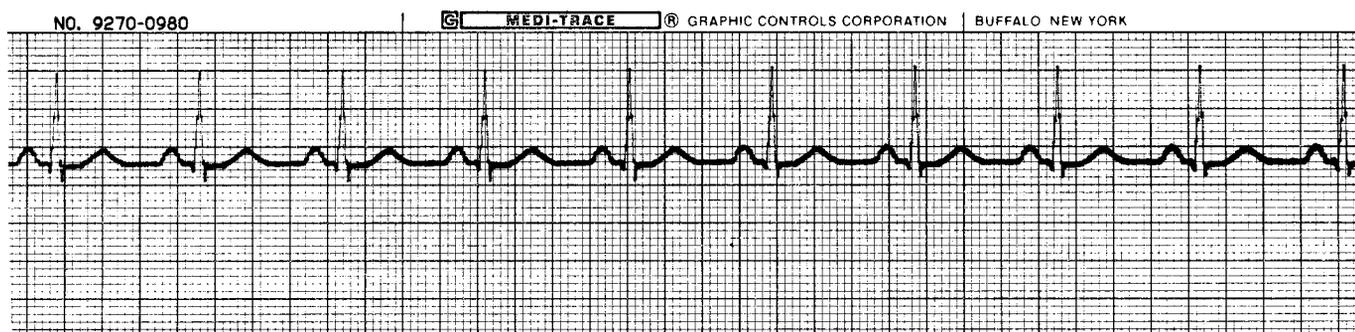

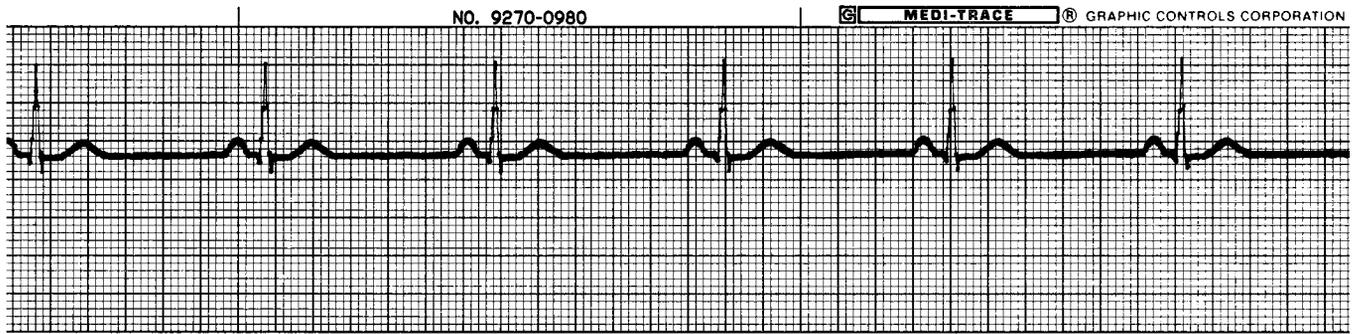

FIGURE 27-5 Normal sinus rhythm in lead II.

**FIGURE 27-6** Sinus bradycardia in lead II.

*P wave:* Normal and consistent shape; always in front of the QRS

*PR interval:* Consistent interval between 0.12 and 0.20 seconds

*P: QRS ratio:* 1 : 1

Sinus arrhythmia does not cause any significant hemodynamic effect and usually is not treated.

## ATRIAL DYSRHYTHMIAS

**Premature Atrial Complex.** A premature atrial complex (PAC) is a single ECG complex that occurs when an electrical impulse starts in the atrium before the next normal impulse of the sinus node. The PAC may be caused by caffeine, alcohol, nicotine, stretched atrial myocardium (as in hypervolemia), anxiety, hypokalemia (low potassium level), hypermetabolic states, or atrial ischemia, injury, or infarction. PACs are often seen with sinus tachycardia. PACs have the following characteristics (Fig. 27-9):

*Ventricular and atrial rate:* Depends on the underlying rhythm (eg, sinus tachycardia)

*Ventricular and atrial rhythm:* Irregular due to early P waves, creating a PP interval that is shorter than the others. This is sometimes followed by a longer-than-normal PP interval, but one that is less than twice the normal PP interval. This type of interval is called a noncompensatory pause.

*QRS shape and duration:* The QRS that follows the early P wave is usually normal, but it may be abnormal (aberrantly conducted PAC). It may even be absent (blocked PAC).

*P wave:* An early and different P wave may be seen or may be hidden in the T wave; other P waves in the strip are consistent.

*PR interval:* The early P wave has a shorter-than-normal PR interval, but still between 0.12 and 0.20 seconds.

*P: QRS ratio:* usually 1 : 1

PACs are common in normal hearts. The patient may say, “My heart skipped a beat.” A pulse deficit (a difference between the apical and radial pulse rate) may exist.

If PACs are infrequent, no treatment is necessary. If they are frequent (more than 6 per minute), this may herald a worsening disease state or the onset of more serious dysrhythmias, such as atrial fibrillation. Treatment is directed toward the cause.

**Atrial Flutter.** Atrial flutter occurs in the atrium and creates impulses at an atrial rate between 250 and 400 times per minute. Because the atrial rate is faster than the AV node can conduct, not all atrial impulses are conducted into the ventricle, causing a therapeutic block at the AV node. This is an important feature of this dysrhythmia. If all atrial impulses were conducted to the ventricle, the ventricular rate would also be 250 to 400, which would result in ventricular fibrillation, a life-threatening dysrhythmia. Causes are similar to that of atrial fibrillation. Atrial flutter is characterized by the following (Fig. 27-10):

*Ventricular and atrial rate:* Atrial rate ranges between 250 and 400; ventricular rate usually ranges between 75 and 150.

*Ventricular and atrial rhythm:* The atrial rhythm is regular; the ventricular rhythm is usually regular but may be irregular because of a change in the AV conduction.

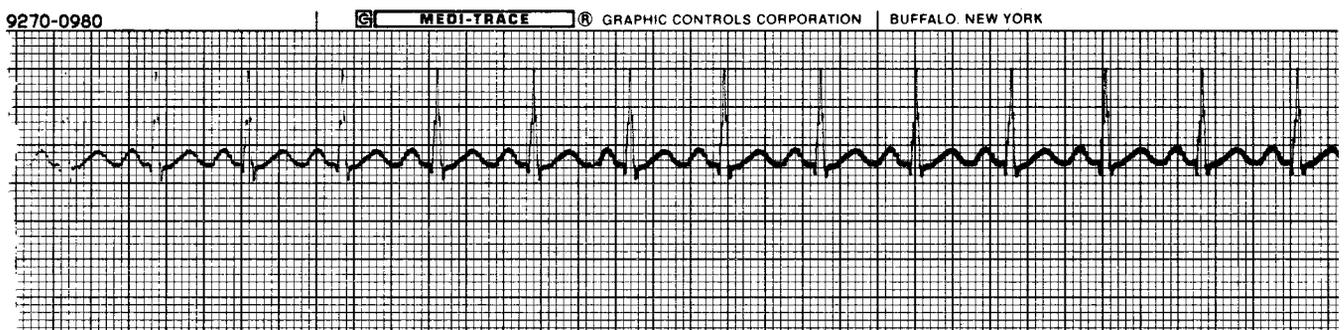

*QRS shape and duration:* Usually normal, but may be abnormal or may be absent

*P wave:* Saw-toothed shape. These waves are referred to as F waves.

*PR interval:* Multiple F waves may make it difficult to determine the PR interval.

*P: QRS ratio:* 2 : 1, 3 : 1, or 4 : 1

Atrial flutter can cause serious signs and symptoms, such as chest pain, shortness of breath, and low blood pressure. If the

**FIGURE 27-7** Sinus tachycardia in lead II.

Table 27-1 • Summary of Antiarrhythmic Medications\*

CLASS	ACTION	DRUGS: GENERIC (TRADE) NAMES	SIDE EFFECTS	NURSING INTERVENTIONS
1A	Moderate depression of depolarization; prolongs repolarization Treats and prevents atrial and ventricular dysrhythmias	quinidine (Quinaglute, Quinalan, Quinora, Quinidex, Cardioquin) procainamide (Pronestyl) disopyramide (Norpace)	Decreased cardiac contractility Prolonged QRS, QT Proarrhythmic Hypotension with IV administration Lupus-like syndrome with Pronestyl Anticholinergic effects: dry mouth, decreased urine output	Observe for HF Monitor BP with IV administration Monitor QRS duration for increase >50% from baseline Monitor for prolonged QT Monitor <i>N</i> -acetyl procainamide (NAPA) laboratory values during procainamide therapy
1B	Minimal depression of depolarization; shortened repolarization Treats ventricular dysrhythmias	lidocaine (Xylocaine) mexiletine (Mexitil) tocainide (Tonocard)	CNS changes (eg, confusion, lethargy)	Discuss with physician decreasing the dose in elderly patients and patients with cardiac/liver dysfunction
1C	Marked depression of depolarization; little effect on repolarization Treats atrial and ventricular dysrhythmias	flecainide (Tambocor) propafenone (Rhythmol)	Proarrhythmic HF Bradycardia AV blocks	Discuss patient's left ventricular function with physician
II	Decreases automaticity and conduction Treats atrial and ventricular dysrhythmias	acebutolol (Sectral) atenolol (Tenormin) esmolol (Brevibloc) labetalol (Normodyne) metoprolol (Lopressor, Toprol) nadolol (Corgard) propranolol (Betachron E-R, Inderal) sotalol (Betapace; also has class III actions)	Bradycardia, AV block Decreased contractility Bronchospasm Hypotension with IV administration Masks hypoglycemia and thyrotoxicosis CNS disturbances	Monitor heart rate, PR interval, signs and symptoms of HF Monitor blood glucose level in patients with type 2 diabetes mellitus
III	Prolongs repolarization Primarily treats and prevents ventricular dysrhythmias; may also be used to treat atrial dysrhythmias	amiodarone (Cordarone, Pacerone) dofetilide (Tikosyn) ibutilide (Corvert)	Pulmonary toxicity (amiodarone) Corneal microdeposits (amiodarone) Photosensitivity (amiodarone) Hypotension with IV administration Polymorphic ventricular dysrhythmias Nausea and vomiting See beta-blockers (sotalol)	Make sure patient is sent for baseline pulmonary function tests (amiodarone) Closely monitor patient
IV	Blocks calcium channel Treats atrial dysrhythmias	verapamil (Calan, Isoptin, Verlan) diltiazem (Cardizem, Dilacor, Tiazac)	Bradycardia, AV blocks Hypotension with IV administration HF, peripheral edema	Monitor heart rate, PR interval Monitor blood pressure closely with IV administration Monitor for signs and symptoms of HF

\*Based on Vaughn-Williams classification.

AV, atrioventricular; BP, blood pressure; CNS, central nervous system; HF, heart failure; IV, intravenous.

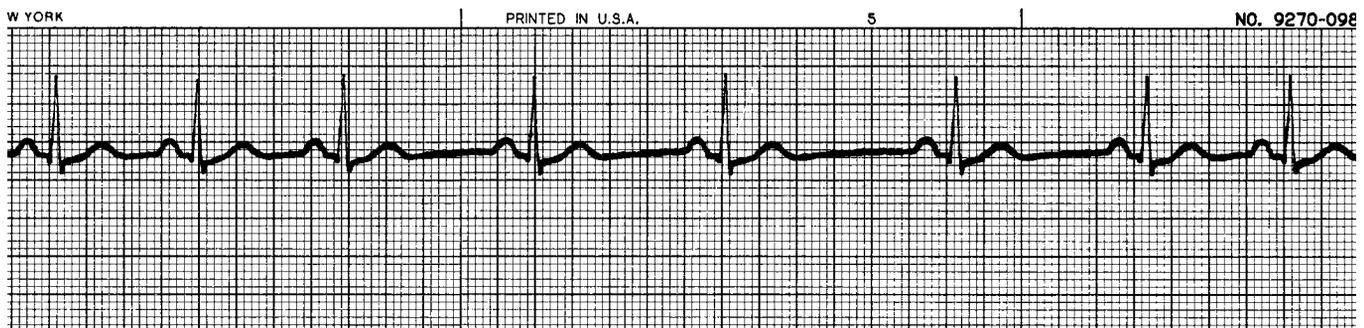

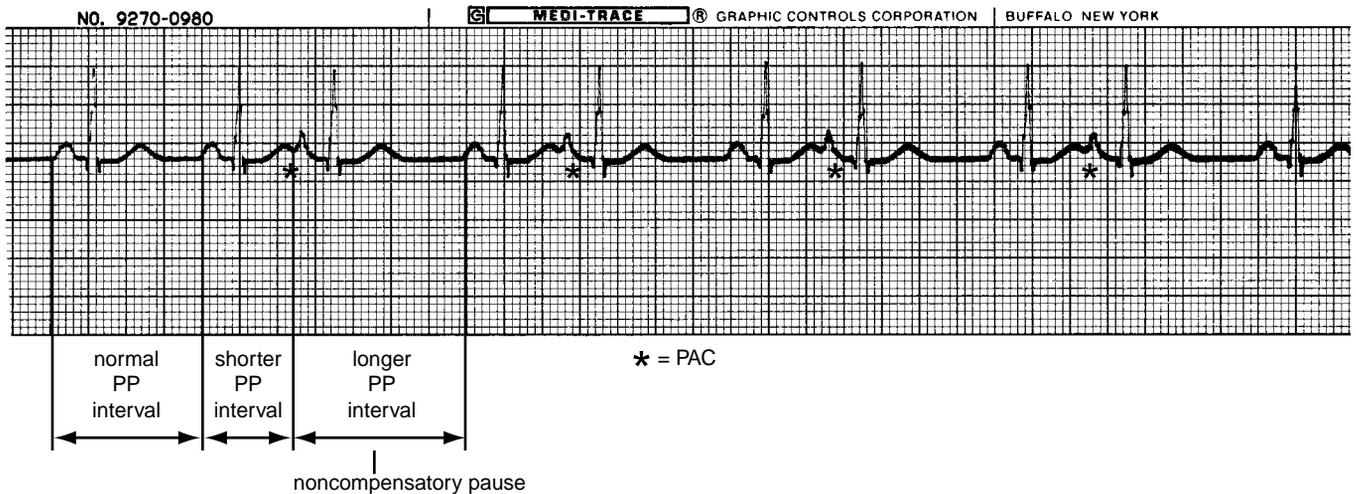

FIGURE 27-8 Sinus arrhythmia in lead II.

**FIGURE 27-9** Premature atrial complexes (PACs) in lead II. Note pause following PAC that is longer than the normal PP interval, but shorter than twice the normal PP interval.

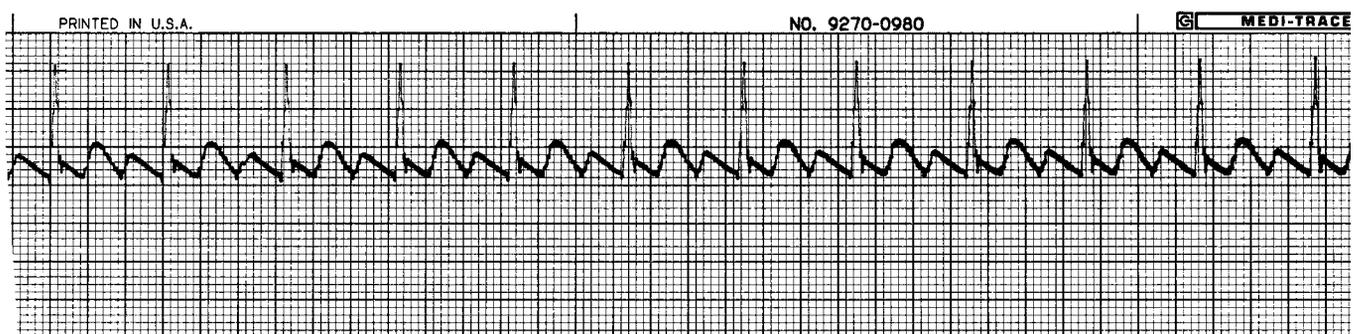

patient is unstable, electrical cardioversion (discussed later) is usually indicated. If the patient is stable, diltiazem (eg, Cardizem), verapamil (eg, Calan, Isoptin), beta-blockers, or digitalis may be administered intravenously to slow the ventricular rate. These medications can slow conduction through the AV node. Flecainide (Tambocor), ibutilide (Corvert), dofetilide (Tikosyn), quinidine (eg, Cardioquin, Quinaglute), disopyramide (Norpace), or amiodarone (Cordarone, Pacerone) may be given to promote conversion to sinus rhythm (see Table 27-1). If medication therapy is unsuccessful, electrical cardioversion is often successful. Once conversion has occurred, quinidine, disopyramide, flecainide, propafenone (Rhythmol), amiodarone, or sotalol (Betapace) may be given to maintain sinus rhythm (see Table 27-1).

**Atrial Fibrillation.** Atrial fibrillation causes a rapid, disorganized, and uncoordinated twitching of atrial musculature. It is the most common dysrhythmia that causes patients to seek medical attention. It may start and stop suddenly. Atrial fibrillation may occur for a very short time (**paroxysmal**), or it may be chronic. Atrial fibrillation is usually associated with advanced age, valvular heart disease, coronary artery disease, hypertension, cardiomyopathy, hyperthyroidism, pulmonary disease, acute moderate to heavy ingestion of alcohol (“holiday heart” syndrome), or the aftermath of open heart surgery. Sometimes it occurs in people without any underlying pathophysiology (termed lone atrial fibrillation). Atrial fibrillation is characterized by the following (Fig. 27-11):

*Ventricular and atrial rate:* Atrial rate is 300 to 600. Ventricular rate is usually 120 to 200 in untreated atrial fibrillation  
*Ventricular and atrial rhythm:* Highly irregular  
*QRS shape and duration:* Usually normal, but may be abnormal  
*P wave:* No discernible P waves; irregular undulating waves are seen and are referred to as fibrillatory or f waves  
*PR interval:* Cannot be measured  
*P: QRS ratio:* many: 1

A rapid ventricular response reduces the time for ventricular filling, resulting in a smaller stroke volume. Because this rhythm causes the atria and ventricles to contract at different times, the atrial kick (the last part of diastole and ventricular filling, which accounts for 25% to 30% of the cardiac output) is also lost. This leads to symptoms of irregular palpitations, fatigue, and malaise. There is usually a pulse deficit, a numerical difference between apical and radial pulse rates. The shorter time in diastole reduces the time available for coronary artery perfusion, thereby increasing the risk for myocardial ischemia. The erratic atrial contraction promotes the formation of a thrombus within the atria, increasing the risk for an embolic event. There is a two- to five-fold increase in the risk of stroke (brain attack).

Treatment of atrial fibrillation depends on its cause and duration and the patient’s symptoms, age, and comorbidities. In many patients, atrial fibrillation converts to sinus rhythm within 24 hours and without treatment. Both stable and unstable atrial fibrillation

**FIGURE 27-10** Atrial flutter in lead II.

**FIGURE 27-11** Atrial fibrillation in lead II.

of short duration are treated the same as stable and unstable atrial flutter. Cardioversion may be indicated for atrial fibrillation that has been present for less than 48 hours, a condition termed acute-onset atrial fibrillation. Cardioversion of atrial fibrillation that has lasted longer than 48 hours should be avoided unless the patient has received anticoagulants, due to the high risk for embolization of atrial thrombi.

For atrial fibrillation of acute onset, the medications quinidine, ibutilide, flecainide, dofetilide, propafenone, procainamide (Pronestyl), disopyramide, or amiodarone (see Table 27-1) may be given to achieve conversion to sinus rhythm (McNamara et al., 2001). Intravenous adenosine (Adenocard, Adenoscan) has also been used for conversion, as well as to assist in the diagnosis. To prevent recurrence and to maintain sinus rhythm, quinidine, disopyramide, flecainide, propafenone, sotalol, or amiodarone may be prescribed. Calcium-channel blockers [diltiazem (Cardizem, Dilacor, Tiazac) and verapamil (Calan, Isoptin, Verelan)] and beta blockers (see Table 27-1) are effective in controlling the ventricular rate in atrial fibrillation, especially during exercise (McNamara, et al., 2001). Use of digoxin is recommended to control the ventricular rate in those patients with poor cardiac function (ejection fraction less than 40%) (Hauptman & Kelly, 1999). In addition, warfarin is indicated if the patient is at higher risk for a stroke (ie, is elderly or has hypertension, heart failure, or a history of stroke). Aspirin may be substituted for warfarin for those with contraindications to warfarin and those who are at lower risk of stroke. The choice of antithrombotic medication can be guided by transesophageal echocardiography. Pacemaker implantation or surgery is sometimes indicated for patients who are unresponsive to medications.

## JUNCTIONAL DYSRHYTHMIAS

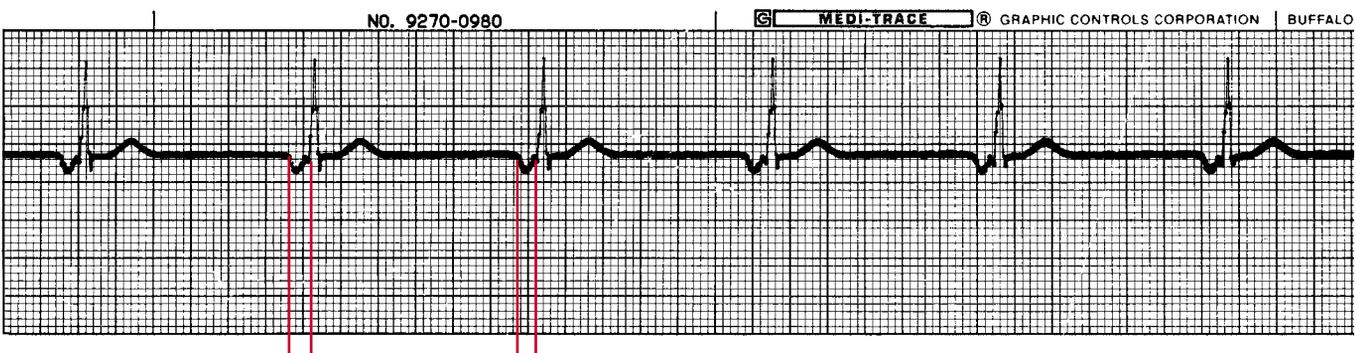

**Premature Junctional Complex.** A premature junctional complex is an impulse that starts in the AV nodal area before the next normal sinus impulse reaches the AV node. Premature junctional complexes are less common than PACs. Causes of premature junctional complex include digitalis toxicity, congestive heart failure, and coronary artery disease. The ECG criteria for premature junctional complex are the same as for PACs, except for the P wave and the PR interval. The P wave may be absent, may follow the QRS, or may occur before the QRS but with a PR interval of less than 0.12 seconds. Premature junctional complexes rarely produce significant symptoms. Treatment for frequent premature junctional complexes is the same as for frequent PACs.

**Junctional Rhythm.** Junctional or idionodal rhythm occurs when the AV node, instead of the sinus node, becomes the pacemaker of the heart. When the sinus node slows (eg, from increased vagal tone) or when the impulse cannot be conducted through the AV node (eg, because of complete heart block), the AV node automatically discharges an impulse. The following are the ECG criteria for junctional rhythm not caused by complete heart block (Fig. 27-12):

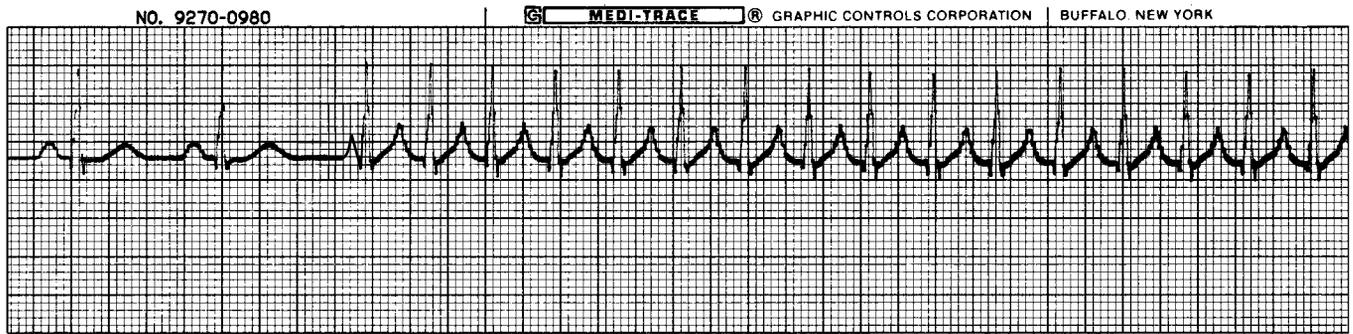

*Ventricular and atrial rate:* Ventricular rate 40 to 60; atrial rate also 40 to 60 if P waves are discernible

*Ventricular and atrial rhythm:* Regular

*QRS shape and duration:* Usually normal, but may be abnormal  
*P wave:* May be absent, after the QRS complex, or before the QRS; may be inverted, especially in lead II

**FIGURE 27-12** Junctional rhythm in lead II; note short PR intervals.

**FIGURE 27-13** AV nodal reentry tachycardia in lead II.

*PR interval:* If P wave is in front of the QRS, PR interval is less than 0.12 second.

*P: QRS ratio:* 1 : 1 or 0 : 1

Junctional rhythm may produce signs and symptoms of reduced cardiac output. If so, the treatment is the same as for sinus bradycardia. Emergency pacing may be needed.

**Atrioventricular Nodal Reentry Tachycardia.** AV nodal reentry tachycardia occurs when an impulse is conducted to an area in the AV node that causes the impulse to be rerouted back into the same area over and over again at a very fast rate. Each time the impulse is conducted through this area, it is also conducted down into the ventricles, causing a fast ventricular rate. AV nodal reentry tachycardia that has an abrupt onset and an abrupt cessation with a QRS of normal duration had been called paroxysmal atrial tachycardia (PAT). Factors associated with the development of AV nodal reentry tachycardia include caffeine, nicotine, hypoxemia, and stress. Underlying pathologies include coronary artery disease and cardiomyopathy. The ECG criteria are as follows (Fig. 27-13):

*Ventricular and atrial rate:* Atrial rate usually ranges between 150 to 250; ventricular rate usually ranges between 75 to 250

*Ventricular and atrial rhythm:* Regular; sudden onset and termination of the tachycardia

*QRS shape and duration:* Usually normal, but may be abnormal

*P wave:* Usually very difficult to discern

*PR interval:* If P wave is in front of the QRS, PR interval is less than 0.12 seconds

*P: QRS ratio:* 1 : 1, 2 : 1

The clinical symptoms vary with the rate and duration of the tachycardia and the patient's underlying condition. The tachycardia usually is of short duration, resulting only in palpitations. A fast rate may also reduce cardiac output, resulting in significant signs and symptoms such as restlessness, chest pain, shortness of breath, pallor, hypotension, and loss of consciousness.

Treatment is aimed at breaking the reentry of the impulse. Vagal maneuvers, such as carotid sinus massage (Fig. 27-14), gag reflex, breath holding, and immersing the face in ice water, increase parasympathetic stimulation, causing slower conduction through the AV node and blocking the reentry of the rerouted impulse. Some patients have learned to use some of these methods to terminate the episode on their own. Because of the risk of a cerebral embolic event, carotid sinus massage is

contraindicated in patients with carotid bruits. If the vagal maneuvers are ineffective, the patient may then receive a bolus of adenosine, verapamil, or diltiazem. Cardioversion is the treatment of choice if the patient is unstable or does not respond to the medications.

If P waves cannot be identified, the rhythm may be called **supraventricular tachycardia (SVT)**, which indicates only that it is not **ventricular tachycardia (VT)**. SVT could be atrial fibrillation, atrial flutter, or AV nodal reentry tachycardia, among others. Vagal maneuvers and adenosine are used to slow conduction in the AV node to allow visualization of the P waves.

## VENTRICULAR DYSRHYTHMIAS

**Premature Ventricular Complex.** Premature ventricular complex (PVC) is an impulse that starts in a ventricle and is conducted through the ventricles before the next normal sinus impulse. PVCs can occur in healthy people, especially with the use of caffeine, nicotine, or alcohol. They are also caused by cardiac ischemia or infarction, increased workload on the heart (eg, exercise, fever, hypervolemia, heart failure, tachycardia), digitalis toxicity, hypoxia, acidosis, or electrolyte imbalances, especially hypokalemia.

In the absence of disease, PVCs are not serious. In the patient with an acute MI, PVCs may indicate the need for more aggressive therapy. PVCs may indicate the possibility of ensuing VT. However, PVCs that are (1) more frequent than 6 per minute,

**FIGURE 27-14** Carotid sinus massage.

(2) multifocal or polymorphic (having different shapes), (3) occur two in a row (pair), and (4) occur on the T wave (the vulnerable period of ventricular depolarization) have not been found to be precursors of VT (Cardiac Arrhythmia Suppression Trial Investigators, 1989). These PVCs are no longer considered as warning or complex PVCs.

In a rhythm called bigeminy, every other complex is a PVC. Trigeminy is a rhythm in which every third complex is a PVC, and quadrigeminy is a rhythm in which every fourth complex is a PVC. PVCs have the following characteristics on the ECG (Fig. 27-15):

*Ventricular and atrial rate:* Depends on the underlying rhythm (eg, sinus rhythm)

*Ventricular and atrial rhythm:* Irregular due to early QRS, creating one RR interval that is shorter than the others. PP interval may be regular, indicating that the PVC did not depolarize the sinus node.

*QRS shape and duration:* Duration is 0.12 seconds or longer; shape is bizarre and abnormal

*P wave:* Visibility of P wave depends on the timing of the PVC; may be absent (hidden in the QRS or T wave) or in front of the QRS. If the P wave follows the QRS, the shape of the P wave may be different.

*PR interval:* If the P wave is in front of the QRS, the PR interval is less than 0.12 seconds.

*P: QRS ratio:* 0:1; 1:1

The patient may feel nothing or may say that the heart “skipped a beat.” The effect of a PVC depends on its timing in the cardiac cycle and how much blood was in the ventricles when they contracted. Initial treatment is aimed at correcting the cause, if possible. Lidocaine (Xylocaine) is the medication most commonly used for immediate, short-term therapy (see Table 27-1). Long-term pharmacotherapy for only PVCs is not indicated.

**Ventricular Tachycardia.** Ventricular tachycardia (VT) is defined as three or more PVCs in a row, occurring at a rate exceeding 100 beats per minute. The causes are similar to those for PVC. VT is usually associated with coronary artery disease and may precede ventricular fibrillation. VT is an emergency because the patient is usually (although not always) unresponsive and pulseless. VT has the following characteristics (Fig. 27-16):

*Ventricular and atrial rate:* Ventricular rate is 100 to 200 beats per minute; atrial rate depends on the underlying rhythm (eg, sinus rhythm)

*Ventricular and atrial rhythm:* Usually regular; atrial rhythm may also be regular.

*QRS shape and duration:* Duration is 0.12 seconds or more; bizarre, abnormal shape

*P wave:* Very difficult to detect, so atrial rate and rhythm may be indeterminable

*PR interval:* Very irregular, if P waves seen.

*P: QRS ratio:* Difficult to determine, but if P waves are apparent, there are usually more QRS complexes than P waves.

The patient’s tolerance or lack of tolerance for this rapid rhythm depends on the ventricular rate and underlying disease. If the patient is stable, continuing the assessment, especially obtaining a 12-lead ECG, may be the only action necessary. Cardioversion may be the treatment of choice, especially if the patient is unstable. Several factors determine the initial medication used for treatment, including the following: identifying the rhythm as monomorphic (having a consistent QRS shape and rate) or polymorphic (having varying QRS shapes and rates); determining the existence of a prolonged QT interval before the initiation of VT; and ascertaining the patient’s heart function (normal or decreased). VT in a patient who is unconscious and without a pulse is treated in the same manner as ventricular fibrillation: immediate **defibrillation** is the action of choice.

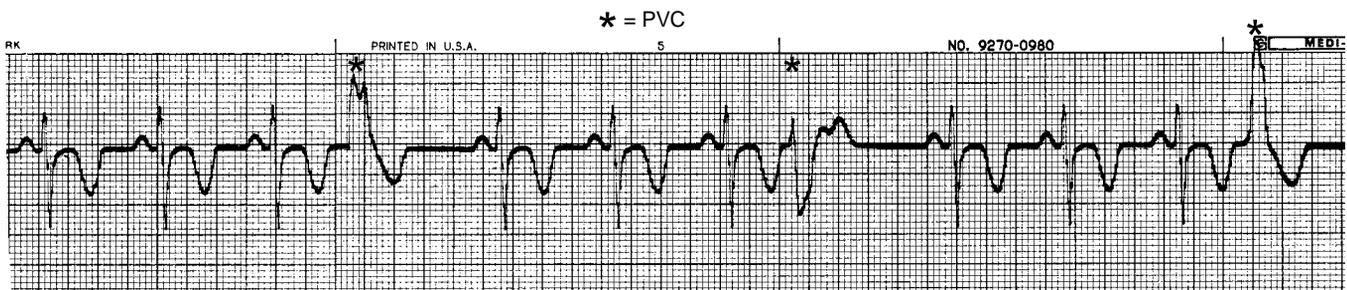

**Ventricular Fibrillation.** Ventricular fibrillation is a rapid but disorganized ventricular rhythm that causes ineffective quivering of the ventricles. There is no atrial activity seen on the ECG. Causes of ventricular fibrillation are the same as for VT; it may also result from untreated or unsuccessfully treated VT. Other causes include electrical shock and Brugada syndrome, in which the patient (frequently of Asian descent) has a structurally normal heart, few or no risk factors for coronary artery disease, and a family history of sudden cardiac death. Ventricular fibrillation has the following characteristics (Fig. 27-17):

*Ventricular rate:* Greater than 300 per minute

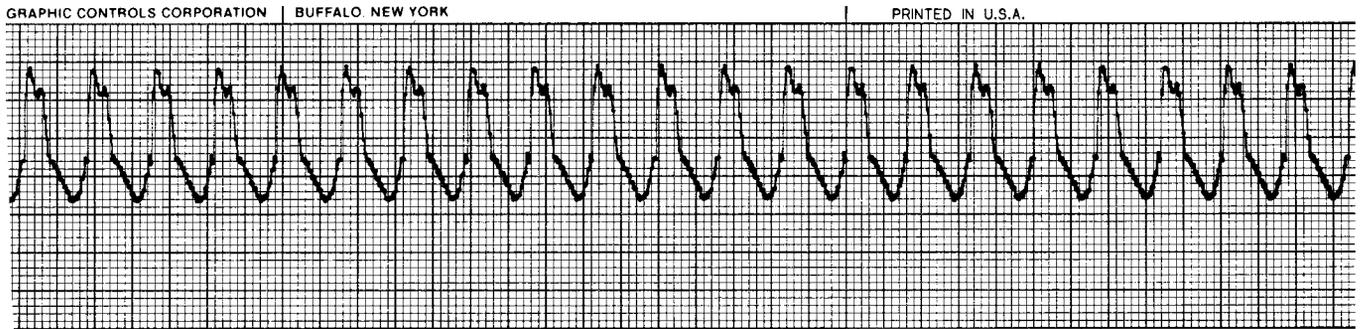

*Ventricular rhythm:* Extremely irregular, without specific pattern

*QRS shape and duration:* Irregular, undulating waves without recognizable QRS complexes

This dysrhythmia is always characterized by the absence of an audible heartbeat, a palpable pulse, and respirations. Because there is no coordinated cardiac activity, cardiac arrest and death are imminent if ventricular fibrillation is not corrected. Treatment of choice is immediate defibrillation and activation of emergency services. The importance of defibrillation is evident in one of the recent changes in basic life support (American Heart Association, 2000): placing a call for emergency assistance and calling for a defibrillator takes precedence over initiating cardiopulmonary resuscitation in the adult victim. Also, application of an automatic external defibrillator (AED) is included in basic life support classes. After defibrillation, eradicating causes and administering vasoactive and **antiarrhythmic** medications alternating with defibril-

**FIGURE 27-15** Multifocal PVCs in quadrigeminy in lead V<sub>1</sub>. Note regular PP interval.

**FIGURE 27-16** Ventricular tachycardia in lead V<sub>1</sub>.

lation are treatments used to try to convert the rhythm to normal sinus rhythm.

**Idioventricular Rhythm.** Idioventricular rhythm, also called ventricular escape rhythm, occurs when the impulse starts in the conduction system below the AV node. When the sinus node fails to create an impulse (eg, from increased vagal tone), or when the impulse is created but cannot be conducted through the AV node (eg, due to complete AV block), the Purkinje fibers automatically discharge an impulse. The following are the ECG criteria when idioventricular rhythm is not caused by AV block (Fig. 27-18):

**Ventricular rate:** Ranges between 20 and 40; if the rate exceeds 40, the rhythm is known as accelerated idioventricular rhythm (AIVR).

**Ventricular rhythm:** Regular

**QRS shape and duration:** Bizarre, abnormal shape; duration is 0.12 seconds or more

Idioventricular rhythm commonly causes the patient to lose consciousness and experience other signs and symptoms of reduced cardiac output. In such cases, the treatment is the same as for pulseless electrical activity if the patient is in cardiac arrest or for bradycardia if the patient is not in cardiac arrest. Interventions may include identifying the underlying cause, administering intravenous atropine and vasopressor medications, and initiating emergency transcutaneous pacing. In some cases, idioventricular rhythm may cause no symptoms of reduced cardiac output. However, bed rest is prescribed so as not to increase the cardiac workload.

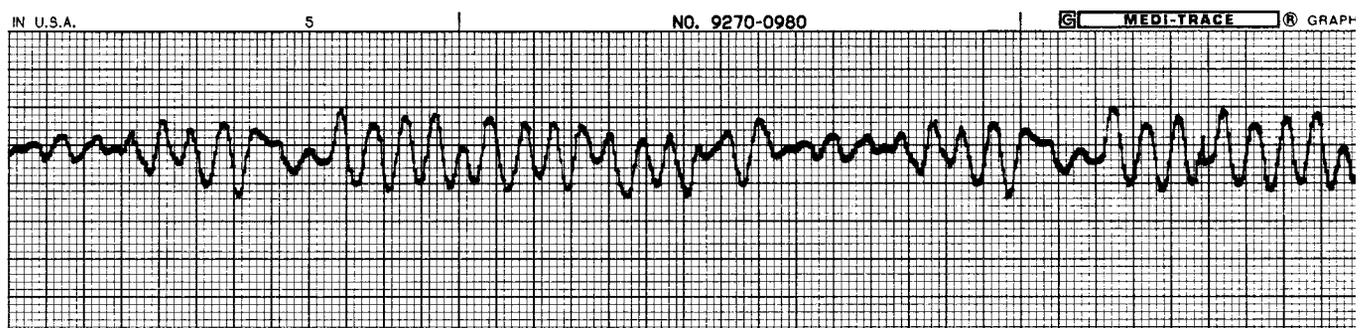

**Ventricular Asystole.** Commonly called flatline, ventricular asystole (Fig. 27-19) is characterized by absent QRS complexes, although P waves may be apparent for a short duration in two

different leads. There is no heartbeat, no palpable pulse, and no respiration. Without immediate treatment, ventricular asystole is fatal. Cardiopulmonary resuscitation and emergency services are necessary to keep the patient alive. The guidelines for advanced cardiac life support (American Heart Association, 2000) state that the key to successful treatment is rapid assessment to identify a possible cause, which may be hypoxia, acidosis, severe electrolyte imbalance, drug overdose, or hypothermia. Intubation and establishment of intravenous access are the first recommended actions. Transcutaneous pacing may be attempted. A bolus of intravenous epinephrine should be administered and repeated at 3- to 5-minute intervals, followed by 1-mg boluses of atropine at 3- to 5-minute intervals. Because of the poor prognosis associated with asystole, if the patient does not respond to these actions and others aimed at correcting underlying causes, resuscitation efforts are usually ended (“the code is called”) unless special circumstances (eg, hypothermia) exist.

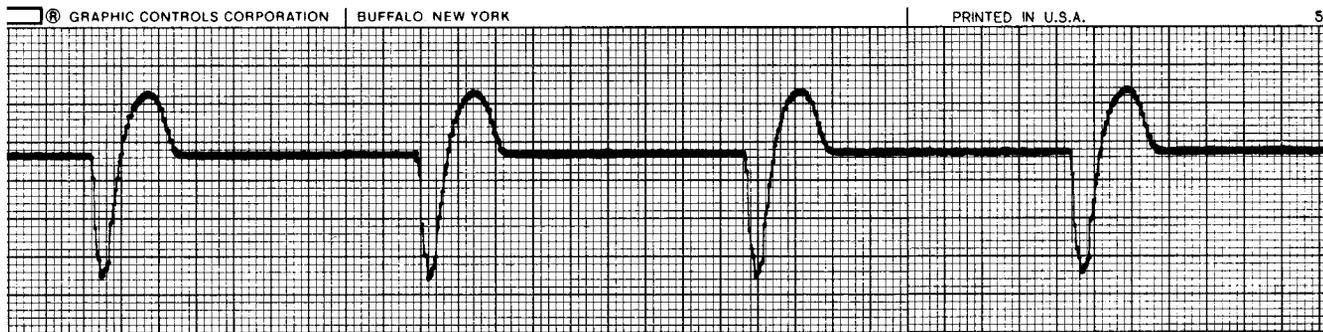

### CONDUCTION ABNORMALITIES

When assessing the rhythm strip, the nurse takes care first to identify the underlying rhythm (eg, sinus rhythm, sinus arrhythmia). Then the PR interval is assessed for the possibility of an AV block. AV blocks occur when the conduction of the impulse through the AV nodal area is decreased or stopped. These blocks can be caused by medications (eg, digitalis, calcium channel blockers, beta-blockers), myocardial ischemia and infarction, valvular disorders, or myocarditis. If the AV block is caused by increased vagal tone (eg, suctioning, pressure above the eyes or on large vessels, anal stimulation), it is commonly accompanied by sinus bradycardia.

The clinical signs and symptoms of a heart block vary with the resulting ventricular rate and the severity of any underlying dis-

**FIGURE 27-17** Ventricular fibrillation in lead II.

**FIGURE 27-18** Idioventricular rhythm in lead  $V_1$ .

ease processes. Whereas first-degree AV block rarely causes any hemodynamic effect, the other blocks may result in decreased heart rate, causing a decrease in perfusion to vital organs, such as the brain, heart, kidneys, lungs, and skin. A patient with third-degree AV block caused by digitalis toxicity may be stable; another patient with the same rhythm caused by acute MI may be unstable. Health care providers must always keep in mind the need to treat the patient, not the rhythm. The treatment is based on the hemodynamic effect of the rhythm.

**First-Degree Atrioventricular Block.** First-degree heart block occurs when all the atrial impulses are conducted through the AV node into the ventricles at a rate slower than normal. This conduction disorder has the following characteristics (Fig. 27-20):

*Ventricular and atrial rate:* Depends on the underlying rhythm

*Ventricular and atrial rhythm:* Depends on the underlying rhythm

*QRS shape and duration:* Usually normal, but may be abnormal

*P wave:* In front of the QRS complex; shows sinus rhythm, regular shape

*PR interval:* Greater than 0.20 seconds; PR interval measurement is constant.

*P: QRS ratio:* 1:1

**Second-Degree Atrioventricular Block, Type I.** Second-degree, type I heart block occurs when all but one of the atrial impulses are conducted through the AV node into the ventricles. Each atrial impulse takes a longer time for conduction than the one before, until one impulse is fully blocked. Because the AV node is

not depolarized by the blocked atrial impulse, the AV node has time to fully repolarize, so that the next atrial impulse can be conducted within the shortest amount of time. Second-degree AV block, type I has the following characteristics (Fig. 27-21):

*Ventricular and atrial rate:* Depends on the underlying rhythm

*Ventricular and atrial rhythm:* The PP interval is regular if the patient has an underlying normal sinus rhythm; the RR interval characteristically reflects a pattern of change. Starting from the RR that is the longest, the RR interval gradually shortens until there is another long RR interval.

*QRS shape and duration:* Usually normal, but may be abnormal

*P wave:* In front of the QRS complex; shape depends on underlying rhythm

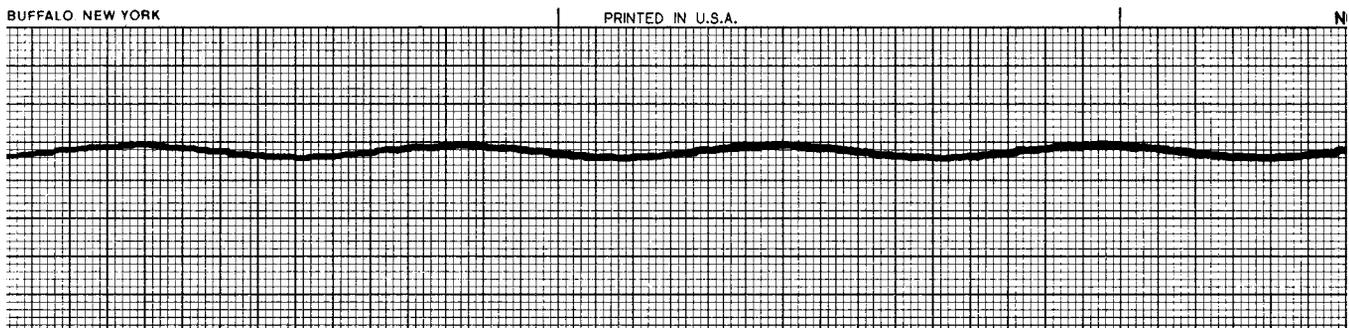

*PR interval:* PR interval becomes longer with each succeeding ECG complex until there is a P wave not followed by a QRS. The changes in the PR interval are repeated between each “dropped” QRS, creating a pattern in the irregular PR interval measurements.

*P: QRS ratio:* 3:2, 4:3, 5:4, and so forth

**Second-Degree Atrioventricular Block, Type II.** Second-degree, type II heart block occurs when only some of the atrial impulses are conducted through the AV node into the ventricles. Second-degree AV block, type II has the following characteristics (Fig. 27-22):

*Ventricular and atrial rate:* Depends on the underlying rhythm

*Ventricular and atrial rhythm:* The PP interval is regular if the patient has an underlying normal sinus rhythm. The RR

**FIGURE 27-19** Asystole. (Always check two different leads to confirm rhythm.)

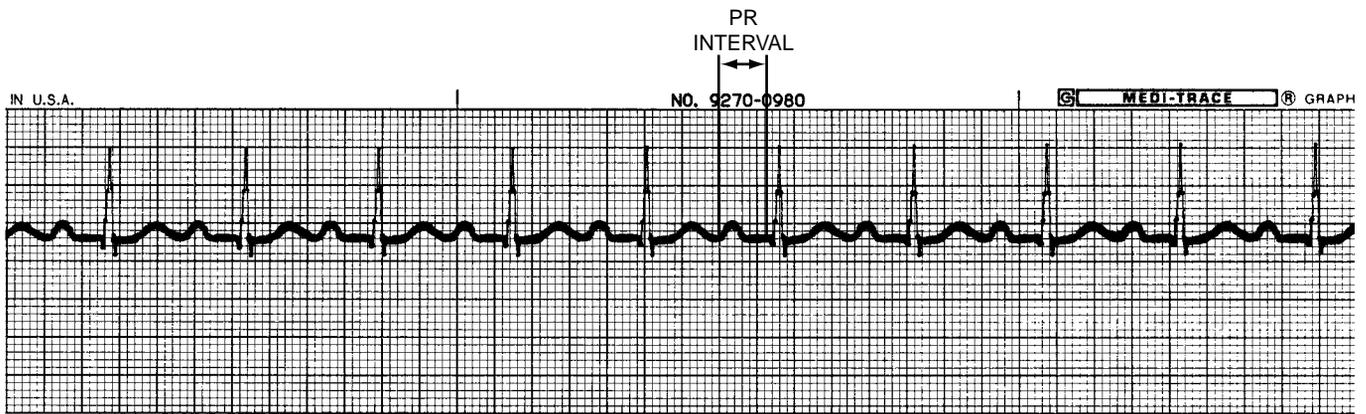

FIGURE 27-20 Sinus rhythm with first-degree AV block in lead II.

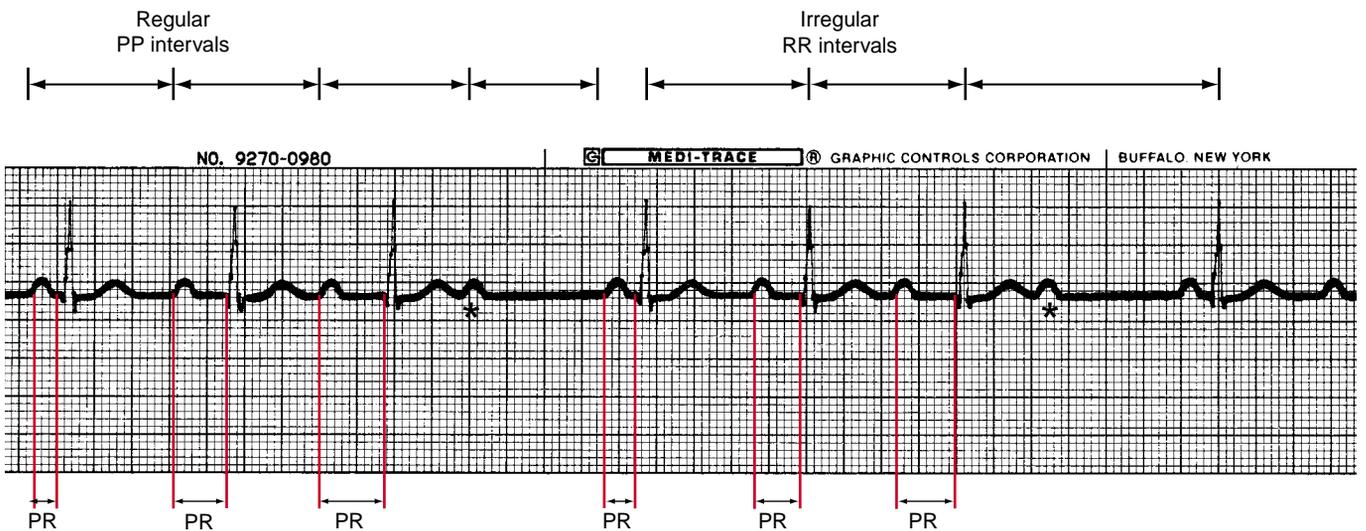

FIGURE 27-21 Sinus rhythm with second-degree AV block, type I in lead II. Note progressively longer PR durations until there is a nonconducted P wave, indicated by the asterisk (\*).

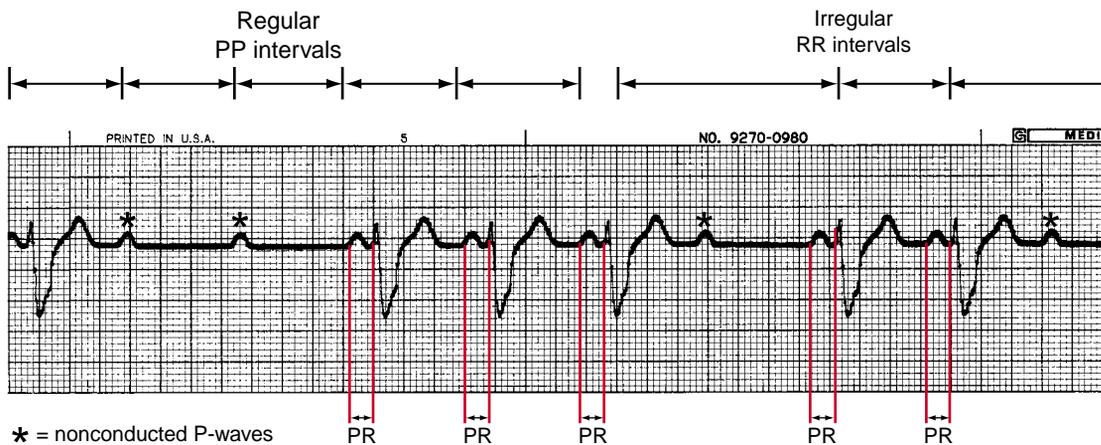

FIGURE 27-22 Sinus rhythm with second-degree AV block, type II in lead  $V_1$ ; note constant PR interval.

interval is usually regular but may be irregular, depending on the P:QRS ratio.

*QRS shape and duration:* Usually abnormal, but may be normal

*P wave:* In front of the QRS complex; shape depends on underlying rhythm.

*PR interval:* PR interval is constant for those P waves just before QRS complexes.

*P: QRS ratio:* 2:1, 3:1, 4:1, 5:1, and so forth

**Third-Degree Atrioventricular Block.** Third-degree heart block occurs when no atrial impulse is conducted through the AV node into the ventricles. In third-degree heart block, two impulses stimulate the heart: one stimulates the ventricles (eg, junctional or ventricular escape rhythm), represented by the QRS complex, and one stimulates the atria (eg, sinus rhythm, atrial fibrillation), represented by the P wave. P waves may be seen, but the atrial electrical activity is not conducted down into the ventricles to cause the QRS complex, the ventricular electrical activity. This is called AV dissociation. Complete block (third-degree AV block) has the following characteristics (Fig. 27-23):

*Ventricular and atrial rate:* Depends on the escape and underlying atrial rhythm

*Ventricular and atrial rhythm:* The PP interval is regular and the RR interval is regular; however, the PP interval is not equal to the RR interval.

*QRS shape and duration:* Depends on the escape rhythm; in junctional escape, QRS shape and duration are usually normal, and in ventricular escape, QRS shape and duration are usually abnormal.

*P wave:* Depends on underlying rhythm

*PR interval:* Very irregular

*P: QRS ratio:* More P waves than QRS complexes

Based on the cause of the AV block and the stability of the patient, treatment is directed toward increasing the heart rate to maintain a normal cardiac output. If the patient is stable and has no symptoms, no treatment is indicated other than decreasing or eradicating the cause (eg, withholding the medication or treatment). If the patient is short of breath, complains of chest pain or lightheadedness, or has low blood pressure, an intravenous bolus of atropine is the initial treatment of choice. If the patient does not respond to atropine or has an acute MI, transcutaneous pacing should be started. A permanent pacemaker may be necessary if the block persists.

## NURSING PROCESS: THE PATIENT WITH A DYSRHYTHMIA

### Assessment

Major areas of assessment include possible causes of the dysrhythmia and the dysrhythmia's effect on the heart's ability to pump an adequate blood volume. When cardiac output is reduced, the amount of oxygen reaching the tissues and vital organs is diminished. This diminished oxygenation produces the signs and symptoms associated with dysrhythmias. If these signs and symptoms are severe or if they occur frequently, the patient may experience significant distress and disruption of daily life.

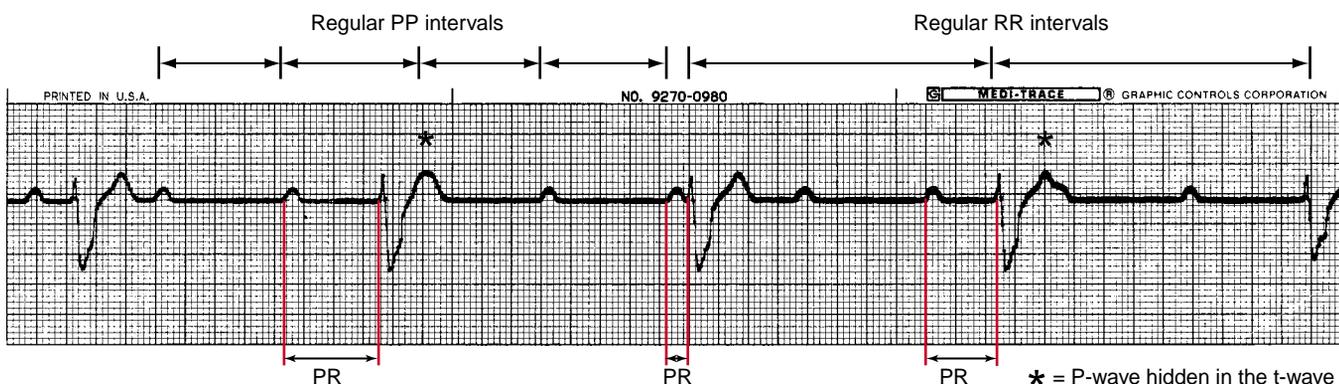

A health history is obtained to identify any previous occurrences of decreased cardiac output, such as syncope (fainting), lightheadedness, dizziness, fatigue, chest discomfort, and palpitations. Coexisting conditions that could be a possible cause of the dysrhythmia (eg, heart disease, chronic obstructive pulmonary disease) may also be identified. All medications, prescribed and over-the-counter (including herbs and nutritional supplements), are reviewed. Some medications (eg, digoxin) can cause dysrhythmias. A thorough psychosocial assessment is performed to identify the possible effects of the dysrhythmia and to determine whether anxiety is a significant contributing factor.

The nurse conducts a physical assessment to confirm the data obtained from the history and to observe for signs of diminished cardiac output during the dysrhythmic event, especially changes in level of consciousness. The nurse directs attention to the skin, which may be pale and cool. Signs of fluid retention, such as neck vein distention and crackles and wheezes auscultated in the lungs, may be detected. The rate and rhythm of apical and peripheral pulses are also assessed, and any pulse deficit is noted. The nurse auscultates for extra heart sounds (especially  $S_3$  and  $S_4$ ) and for heart murmurs, measures blood pressure, and determines pulse pressures. A declining pulse pressure indicates reduced cardiac output. Just one assessment may not disclose significant changes in cardiac output; therefore, the nurse compares multiple assessment findings over time, especially those that occur with and without the dysrhythmia.

### Diagnosis

#### NURSING DIAGNOSES

Based on assessment data, major nursing diagnoses of the patient may include:

**FIGURE 27-23** Sinus rhythm with third-degree AV block and idioventricular rhythm in lead  $V_1$ ; note irregular PR intervals.

- Decreased cardiac output
- Anxiety related to fear of the unknown
- Deficient knowledge about the dysrhythmia and its treatment

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

In addition to cardiac arrest, a potential complication that may develop over time is heart failure. Another potential complication, especially with atrial fibrillation, is a thromboembolic event. If the dysrhythmia necessitates treatment with medication, the beneficial and detrimental effects must be assessed.

### Planning and Goals

The major goals for the patient may include eradicating or decreasing the incidence of the dysrhythmia (by decreasing contributory factors) to maintain cardiac output, minimizing anxiety, and acquiring knowledge about the dysrhythmia and its treatment.

### Nursing Interventions

#### MONITORING AND MANAGING THE DYSRHYTHMIA

The nurse regularly evaluates blood pressure, pulse rate and rhythm, rate and depth of respirations, and breath sounds to determine the dysrhythmia's hemodynamic effect. The nurse also asks patients about episodes of lightheadedness, dizziness, or fainting as part of the ongoing assessment. If a patient with a dysrhythmia is hospitalized, the nurse may obtain a 12-lead ECG, continuously monitor the patient, and analyze rhythm strips to track the dysrhythmia.

Control of the incidence or the effect of the dysrhythmia, or both, is often achieved by the use of antiarrhythmic medications. The nurse assesses and observes for the beneficial and adverse effects of each of the medications. The nurse also manages medication administration carefully so that a constant serum blood level of the medication is maintained at all times.

In addition to medication, the nurse assesses for factors that contribute to the dysrhythmia (eg, caffeine, stress, nonadherence to the medication regimen) and assists the patient in developing a plan to make lifestyle changes that eliminate or reduce these factors.

#### MINIMIZING ANXIETY

When the patient experiences episodes of dysrhythmia, the nurse maintains a calm and reassuring attitude. This demeanor fosters a trusting relationship with the patient and assists in reducing anxiety (reducing the sympathetic response). Successes are emphasized with the patient to promote a sense of confidence in living with a dysrhythmia. For example, if a patient is experiencing episodes of dysrhythmia and a medication is administered that begins to reduce the incidence of the dysrhythmia, the nurse communicates that information to the patient. The nursing goal is to maximize the patient's control and to make the unknown less threatening.

#### PROMOTING HOME AND COMMUNITY-BASED CARE

##### Teaching Patients Self-Care

When teaching patients about dysrhythmias, the nurse presents the information in terms that are understandable and in a manner that is not frightening or threatening. The nurse explains the importance of maintaining therapeutic serum levels of anti-

arrhythmic medications so that the patient understands why medications should be taken regularly each day. In addition, the relationship between a dysrhythmia and cardiac output is explained so that the patient understands the rationale for the medical regimen. If the patient has a potentially lethal dysrhythmia, it is also important to establish with the patient and family a plan of action to take in case of an emergency. This allows the patient and family to feel in control and prepared for possible events.

A referral for home care usually is not necessary for the patient with a dysrhythmia unless the patient is hemodynamically unstable and has significant symptoms of decreased cardiac output. Home care is also warranted if the patient has significant comorbidities, socioeconomic issues, or limited self-management skills that could potentiate the risk for nonadherence to the therapeutic regimen.

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Maintains cardiac output
  - a. Demonstrates heart rate, blood pressure, respiratory rate, and level of consciousness within normal ranges
  - b. Demonstrates no or decreased episodes of dysrhythmia
2. Experiences reduced anxiety
  - a. Expresses a positive attitude about living with the dysrhythmia
  - b. Expresses confidence in ability to take appropriate actions in an emergency
3. Expresses understanding of the dysrhythmia and its treatment
  - a. Explains the dysrhythmia and its effects
  - b. Describes the medication regimen and its rationale
  - c. Explains the need for therapeutic serum level of the medication
  - d. Describes a plan to eradicate or limit factors that contribute to the occurrence of the dysrhythmia
  - e. States actions to take in the event of an emergency

## Adjunctive Modalities and Management

Dysrhythmia treatments depend on whether the disorder is acute or chronic as well as on the cause of the dysrhythmia and its actual or potential hemodynamic effects.

Acute dysrhythmias may be treated with medications or with external electrical therapy. Many antiarrhythmic medications are used to treat atrial and ventricular tachydysrhythmias. These medications are summarized in Table 27-1. The choice of medication depends on the specific dysrhythmia, presence of cardiac failure and other diseases, and the patient's response to previous treatment. The nurse is responsible for monitoring and documenting the patient's responses to the medication and for making sure that the patient has the knowledge and ability to manage the medication regimen.

If medications alone are ineffective in eradicating or decreasing the dysrhythmia, certain adjunctive mechanical therapies are available. The most common are pacemakers for bradycardias and tachycardias, elective cardioversion and defibrillation for acute tachydysrhythmia, and implantable devices for chronic tachydysrhythmia. Surgical treatments, although less common, are also available.

## PACEMAKER THERAPY

A pacemaker is an electronic device that provides electrical stimuli to the heart muscle. Pacemakers are usually used when a patient has a slower-than-normal impulse formation or a conduction disturbance that causes symptoms. They may also be used to control some tachydysrhythmias that do not respond to medication therapy. Biventricular (both ventricles) pacing may be used to treat advanced heart failure that does not respond to medication therapy.

Pacemakers can be permanent or temporary. Permanent pacemakers are used most commonly for irreversible complete heart block. Temporary pacemakers are used (eg, after MI, after open heart surgery) to support patients until they improve or receive a permanent pacemaker.

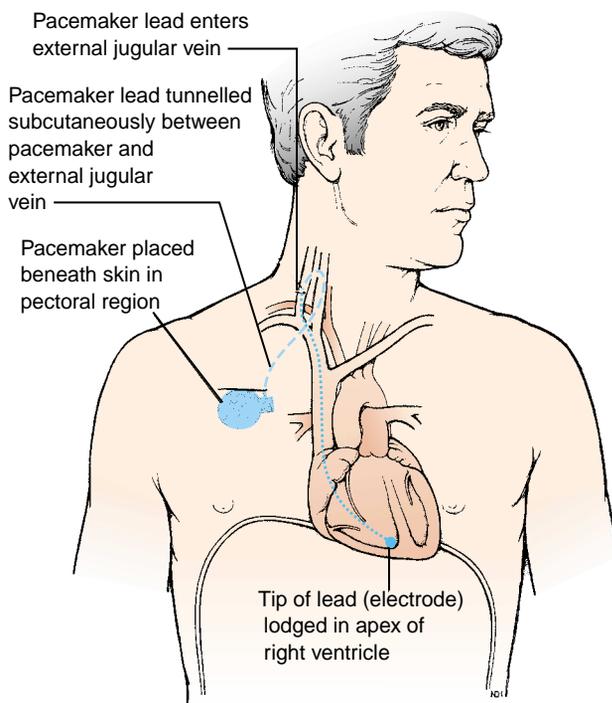

### Pacemaker Design and Types

Pacemakers consist of two components: an electronic pulse generator and pacemaker electrodes, which are located on leads or wires. The generator contains the circuitry and batteries that generate the rate (measured in beats per minute) and the strength (measured in milliamperes [mA]) of the electrical stimulus delivered to the heart. The pacemaker electrodes convey the heart's electrical activity through a lead to the generator; the generator's electrical response to the information received is then transmitted to the heart.

Leads can be threaded through a major vein into the right ventricle (endocardial leads), or they can be lightly sutured onto the outside of the heart and brought through the chest wall during open heart surgery (epicardial wires). The epicardial wires are always temporary and are removed by a gentle tug within a few days after surgery. The endocardial leads may be temporarily placed with catheters through the femoral, antecubital, brachial, or jugular vein (transvenous wires), usually guided by fluoroscopy. The endocardial and epicardial wires are connected to a temporary generator, which is about the size of a small paperback book. The energy source for a temporary generator is a common household battery; monitoring for pacemaker malfunctioning and battery failure is a nursing responsibility. This type of pacemaker therapy necessitates hospitalization of the patient.

The endocardial leads also may be placed permanently, usually through the external jugular vein, and connected to a permanent generator, which is usually implanted underneath the skin in a subcutaneous pocket in the pectoral region or below the clavicle (Fig. 27-24). Sometimes an abdominal site is selected. This procedure is usually performed in a cardiac catheterization laboratory with the patient receiving a local anesthetic. Permanent pacemaker generators are insulated to protect against body moisture and warmth. There are several different energy sources for permanent generators: mercury-zinc batteries (which last 3 to 4 years), lithium cell units (up to 10 years), and nuclear-powered sources such as plutonium 238 (up to 20 years). Some of the batteries are rechargeable. If the battery is not rechargeable and failure is impending, the old generator is removed and the new one is connected to the existing leads and reimplanted in the already existing subcutaneous pocket. This procedure is usually performed with the patient receiving a local anesthetic. Hospitalization of the patient is needed for implantation or battery replacement.

If a patient suddenly develops a bradycardia, emergency pacing may be started with transcutaneous pacing, which most defibrillators are now equipped to perform. AEDs are not able to do transcutaneous pacing (see later discussion). Large pacing ECG electrodes (sometimes the same conductive pads that are used for

**FIGURE 27-24** Implanted transvenous pacing lead (with electrode) and pacemaker generator.

cardioversion and defibrillation) are placed on the patient's chest and back. The electrodes are connected to the defibrillator, which is the temporary pacemaker generator (Fig. 27-25). Because the impulse must travel through the patient's skin and tissue before reaching the heart, transcutaneous pacing can cause significant discomfort and is intended to be used only in emergencies. This type of pacing necessitates hospitalization. If the patient is alert, the use of sedation and analgesia should be discussed with the physician.

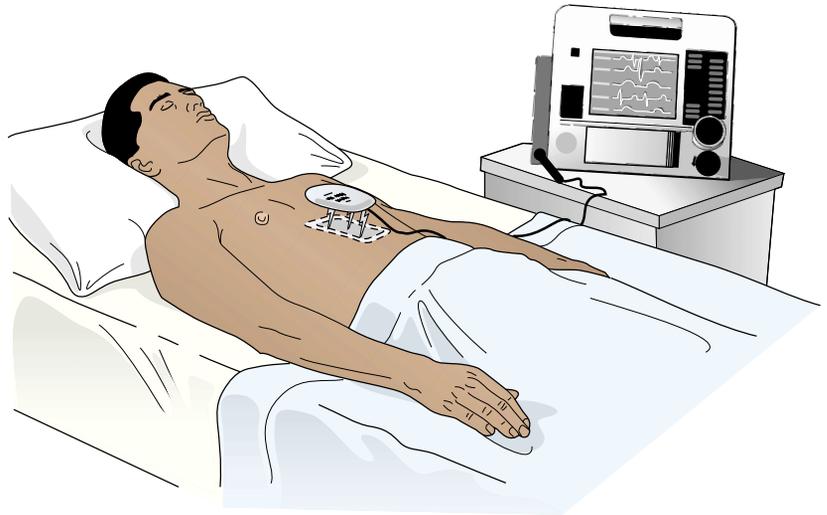

### Pacemaker Generator Functions

Because of the sophistication and wide use of pacemakers, a universal code has been adopted to provide a means of safe communication about their function. The coding is referred to as the NASPE-BPEG code because it is sanctioned by the North American Society of Pacing and Electrophysiology and the British Pacing and Electrophysiology Group. The complete code consists of five letters, but only the first three are commonly used.

The first letter of the code identifies the chamber or chambers being paced—that is, the chamber containing a pacing electrode. The letter characters for this code are A (atrium), V (ventricle), or D (dual, meaning both A and V).

The second letter describes the chamber or chambers being sensed by the pacemaker generator. Information from the electrode within the chamber is sent to the generator for interpretation and action by the generator. The possible letter characters are A (atrium), V (ventricle), D (dual), and O (indicating that the sensing function is turned off).

The third letter of the code describes the type of response by the pacemaker to what is sensed. The possible letter characters used to describe this response are I (**inhibited**), T (**triggered**), D (dual, inhibited and triggered), and O (none). Inhibited response means that the response of the pacemaker is controlled by the activity of the patient's heart; that is, the pacemaker will not func-

**FIGURE 27-25** Transcutaneous pacemaker with electrode pads connected to the anterior and posterior chest walls.

tion when the patient's heart beats but will pace if no beat is sensed. In contrast, triggered response means that the pacemaker will provide a response (pace the heart) when it senses intrinsic heart activity.

The fourth and fifth letters are used only with permanent pacemaker generators. The fourth letter of the code is related to a permanent generator's ability to be programmed or reset. The possible letters are O (none), P (simple programmability), M (multi-programmability; ability to change at least three factors, such as the rate at which pacing is initiated, the rate of pacing, and the amount of energy delivered), C (communicative or telemetry ability; information about the generator may be obtained [read or interrogated] with a hand-held device placed above the chest), and R (rate responsive capabilities; the ability of the pacemaker to change the rate from moment to moment based on parameters such as physical activity, acid-base changes, temperature, rate and depth of respirations, and oxygen saturation). A pacemaker with rate responsive ability will be capable of improving cardiac output during times of increased cardiac demand, such as with exercise.

The fifth letter of the code indicates that the permanent generator has antitachycardia and/or defibrillation capability. The possible letters are P (antitachycardia pacing), S (shock; defibrillation), D (dual—antitachycardia pacing and shock), and O (none). Antitachycardia pacing is used to terminate tachycardias caused by a conduction disturbance called reentry, which is repetitive restimulation of the heart by the same impulse. An impulse or series of impulses is delivered to the heart by the pacemaker at a fast rate to collide with and stop the heart's reentry conduction impulses, and therefore to stop the tachycardia.

An example of a NASPE-BPEG code is DVI:

**D:** Both the atrium and the ventricle have a pacing electrode in place.

**V:** The pacemaker is sensing the activity of the ventricle only.

**I:** The pacemaker's stimulating effect is inhibited by ventricular activity—in other words, it does not create an impulse when the patient's ventricle is active. The pacemaker paces the atrium and then the ventricle when no ventricular activity is sensed for a period of time (the time is individually programmed into the pacemaker for each patient).

The type of generator and its selected settings depend on the patient's dysrhythmia, underlying cardiac function, and age. A straight vertical line usually can be seen on the ECG when pacing is initiated. The line that represents pacing is called a pace-

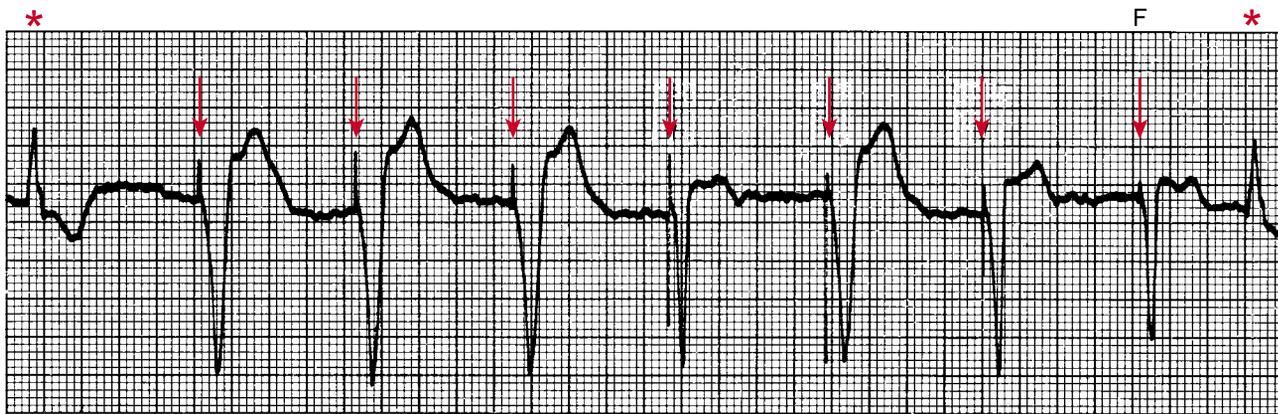

maker spike. The appropriate ECG complex should immediately follow the pacing spike; therefore, a P wave should follow an atrial pacing spike and a QRS complex should follow a ventricular pacing spike. Because the impulse starts in a different place than the patient's normal rhythm, the QRS complex or P wave that responds to pacing looks different from the patient's normal ECG complex. *Capture* is a term used to denote that the appropriate complex followed the pacing spike.

Pacemakers are generally set to sense and respond to intrinsic activity, which is called on-demand pacing (Fig. 27-26). If the pacemaker is set to pace but not to sense, it is called a fixed or asynchronous pacemaker (Fig. 27-27); this is written in code as AOO or VOO. The pacemaker will pace at a constant rate, independent of the patient's intrinsic rhythm. Because AOO pacing stimulates only the atrium, it may be used in a patient who has undergone open heart surgery and develops sinus bradycardia. AOO pacing ensures synchrony between atrial stimulation and ventricular stimulation (and therefore contraction), as long as the patient has no conduction disturbances in the AV node. VOO is rare because of the risk that the pacemaker may deliver an impulse during the vulnerable repolarization phase, leading to VT.

### Complications of Pacemaker Use

Complications associated with pacemakers relate to their presence within the body, and improper functioning. The following complications may arise from a pacemaker:

- Local infection at the entry site of the leads for temporary pacing, or at the subcutaneous site for permanent generator placement
- Bleeding and hematoma at the lead entry sites for temporary pacing, or at the subcutaneous site for permanent generator placement
- Hemothorax from puncture of the subclavian vein or internal mammary artery
- Ventricular ectopy and tachycardia from irritation of the ventricular wall by the endocardial electrode
- Movement or dislocation of the lead placed transvenously (perforation of the myocardium)
- Phrenic nerve, diaphragmatic (hiccupping may be a sign of this), or skeletal muscle stimulation if the lead is dislocated or if the delivered energy (mA) is set high
- Rarely, cardiac tamponade from bleeding resulting from removal of epicardial wires used for temporary pacing

**FIGURE 27-26** Pacing with appropriate sensing (on-demand pacing) in lead  $V_1$ . Arrows denote pacing spike. Asterisk (\*) denotes intrinsic (patient's own) beats, therefore no pacing. F denotes a fusion beat, which is a combination of an intrinsic beat and a paced beat occurring at the same time.

In the initial hours after a temporary or permanent pacemaker is inserted, the most common complication is dislodgment of the pacing electrode. Minimizing patient activity can help to prevent this complication. If a temporary electrode is in place, the extremity through which the catheter has been advanced is immobilized. With a permanent pacemaker, the patient is instructed initially to restrict activity on the side of the implantation.

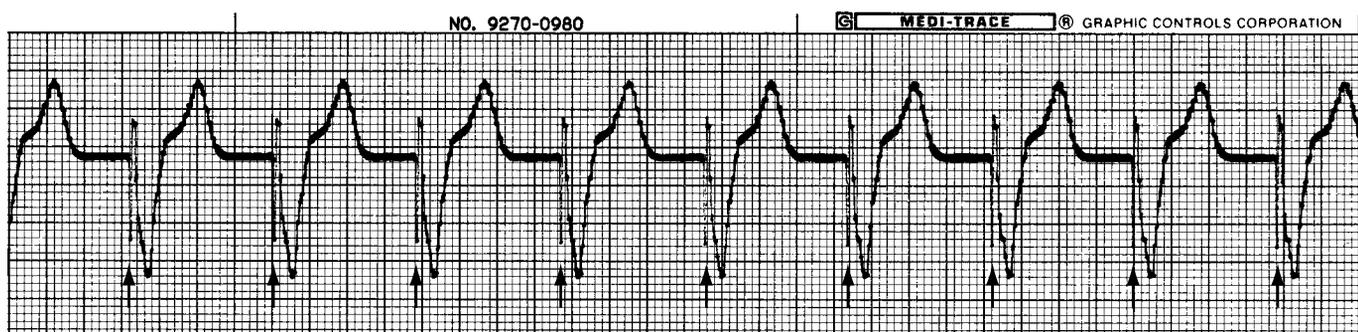

The ECG is monitored very carefully to detect pacemaker malfunction. Improper pacemaker function, which can arise from failure in one or more components of the pacing system, is outlined in Table 27-2. The following data should be noted on the patient's record: model of pacemaker, type of generator, date and time of insertion, location of pulse generator, stimulation threshold, pacer settings (eg, rate, energy output [mA], and duration between atrial and ventricular impulses [AV delay]). This information is important for identifying normal pacemaker function and diagnosing pacemaker malfunction.

A patient experiencing pacemaker malfunction may develop signs and symptoms of decreased cardiac output. The degree to which these symptoms become apparent depends on the severity of the malfunction, the patient's level of dependency on the pacemaker, and the patient's underlying condition. Pacemaker malfunction is diagnosed by analyzing the ECG. Manipulating the electrodes, changing the generator's settings, or replacing the pacemaker generator or leads (or both) may be necessary.

Inhibition of permanent pacemakers can occur with exposure to strong electromagnetic fields (electromagnetic interference). However, recent pacemaker technology allows patients to safely use

most household electronic appliances and devices (eg, microwave ovens, electric tools) as long as they are not held close to the pacemaker generator. Gas-powered engines should be turned off before working on them. Objects that contain magnets (eg, the earpiece of a standard phone; large stereo speakers; magnet therapy products such as mattresses, jewelry, and wraps) should not be near the generator for longer than a few seconds. Patients are advised to use digital cellular phones on the side opposite the pacemaker generator. Large electromagnetic fields, such as those produced by magnetic resonance imaging (MRI), radio and TV transmitter towers and lines, transmission power lines (these are different from the distribution lines that bring electricity into a home), and electrical substations may cause electromagnetic interference. Patients should be cautioned to avoid such situations or to simply move farther away from the area if they experience dizziness or a feeling of rapid or irregular heartbeats (palpitations). Welding and use of a chain saw should be avoided. If such tools are used, precautionary steps such as limiting the welding current to a 60- to 130-ampere range or using electric rather than gasoline-powered chain saws are advised.

The metal of the pacemaker generator may trigger some store and airport security alarms, but these alarm systems will not interfere with the pacemaker function. However, the handheld screening devices used in airports may interfere with the pacemaker. Patients should be advised to request a hand search instead of the handheld screening device. Patients also should be instructed to wear or carry medical identification to alert personnel to the presence of the pacemaker.

**FIGURE 27-27** Fixed pacing or total loss of sensing pacing in lead  $V_1$ ; arrows denote pacing spikes.

Table 27-2 • Assessing Pacemaker Malfunction

PROBLEM	POSSIBLE CAUSE	INTERVENTION
Loss of capture—complex does <i>not</i> follow pacing spike	Inadequate stimulus Catheter malposition Battery depletion Electronic insulation break	Check security of all connections; increase milliamperage. Reposition extremity; turn patient to left side. Change battery. Change generator.
Undersensing—pacing spike occurs at preset interval despite patient's intrinsic rhythm	Sensitivity too high Electrical interference (eg, by a magnet) Faulty generator	Decrease sensitivity. Eliminate interference. Replace generator.
Oversensing—loss of pacing artifact; pacing does <i>not</i> occur at preset interval despite lack of intrinsic rhythm	Sensitivity too low Electrical interference Battery depletion	Increase sensitivity. Eliminate interference. Change battery.
Loss of pacing—Total absence of pacing spikes	Battery depletion Loose or disconnected wires Perforation	Change battery. Check security of all connections. Obtain 12-lead ECG and portable chest x-ray. Assess for murmur. Call physician.
Change in pacing QRS shape	Septal perforation	Obtain 12-lead ECG and portable chest x-ray. Assess for murmur. Call physician.
Rhythmic diaphragmatic or chest wall twitching or hiccuping	Output too high Myocardial wall perforation	Decrease milliamperage. Turn pacer off. Call physician at once. Monitor closely for decreased cardiac output.

## Pacemaker Surveillance

Pacemaker clinics have been established to monitor patients and to test pulse generators for impending pacemaker battery failure. Several other factors, such as lead fracture, muscle inhibition, and insulation disruption, are assessed depending on the type of pacemaker and the equipment available. If indicated, the pacemaker is turned off for a few seconds, using a magnet or a programmer, while the ECG is recorded to assess the patient's underlying cardiac rhythm.

Another follow-up method is transtelephonic transmission of the generator's pulse rate. Special equipment is used to transmit information about the patient's pacemaker over the telephone to a receiving system at a pacemaker clinic. The information is converted into tones, which equipment at the clinic converts to an electronic signal and records on an ECG strip. The pacemaker rate and other data concerning pacemaker function are obtained and evaluated by a cardiologist. This simplifies the diagnosis of a failing generator, reassures the patient, and improves management when the patient is physically remote from pacemaker testing facilities.

## NURSING PROCESS: THE PATIENT WITH A PACEMAKER

### Assessment

After a temporary or a permanent pacemaker is inserted, the patient's heart rate and rhythm are monitored by ECG. The pacemaker's settings are noted and compared with the ECG recordings to assess pacemaker function. Pacemaker malfunction is detected by examining the pacemaker spike and its relationship to the surrounding ECG complexes (Fig. 27-28). In addition, cardiac output and hemodynamic stability are assessed to identify the patient's response to pacing and the adequacy of pacing. The ap-

pearance or increasing frequency of dysrhythmia is observed and reported to the physician.

The incision site where the pulse generator was implanted (or the entry site for the pacing electrode, if the pacemaker is a temporary transvenous pacemaker) is observed for bleeding, hematoma formation, or infection, which may be evidenced by swelling, unusual tenderness, unusual drainage, and increased heat. The patient may complain of continuous throbbing or pain. These symptoms are reported to the physician.

The patient with a temporary pacemaker is also assessed for electrical interference and the development of microshock. The nurse observes for potential sources of electrical hazards. All electrical equipment used in the vicinity of the patient should be grounded. Improperly grounded equipment can generate leakage of current capable of producing ventricular fibrillation. Exposed wires must be carefully covered with nonconductive material to prevent accidental ventricular fibrillation from stray currents. The nurse, working with a biomedical engineer or electrician, should make certain that the patient is in an electrically safe environment.

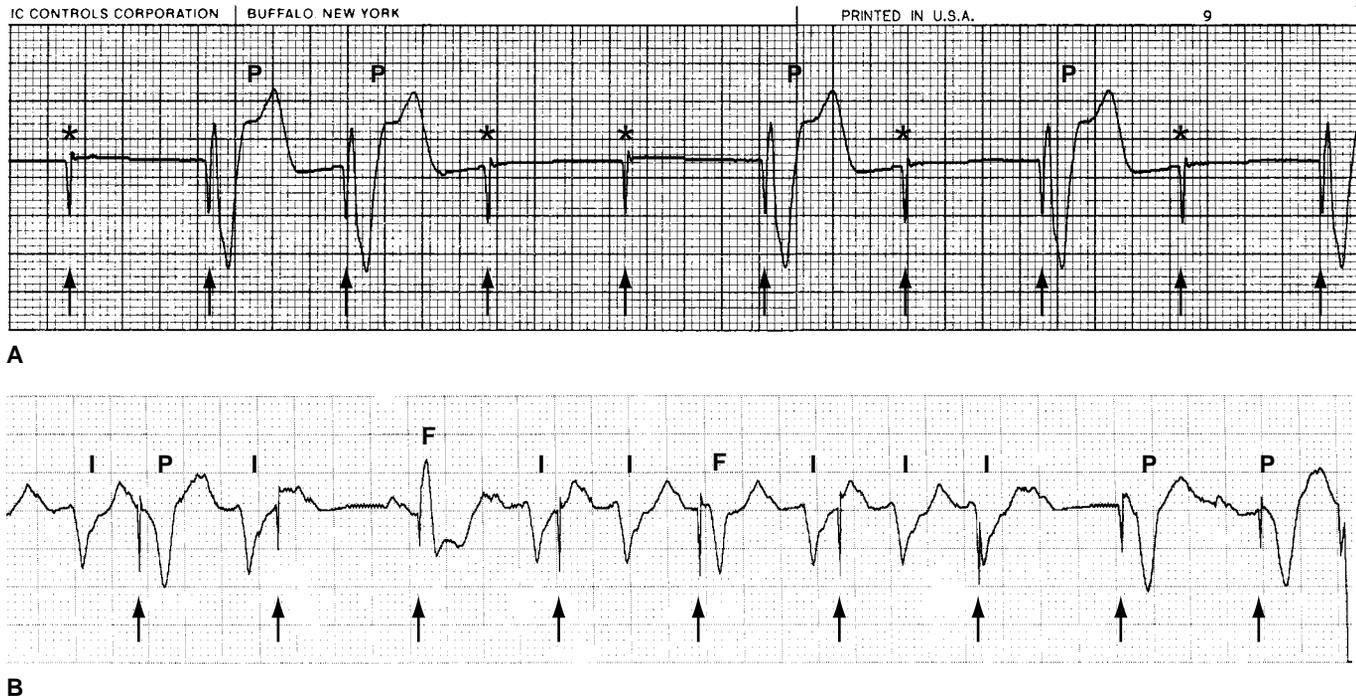

Patients, especially those receiving a permanent pacemaker, should be assessed for anxiety. In addition, for those receiving permanent pacemakers, the level of knowledge and learning needs of the patient and the family and the history of adherence to the therapeutic regimen should be identified.

### Diagnosis

#### NURSING DIAGNOSES

Based on assessment data, major nursing diagnoses of the patient may include the following:

- Risk for infection related to pacemaker lead or generator insertion
- Risk for ineffective coping
- Deficient knowledge regarding self-care program

**FIGURE 27-28** (A) Ventricular pacing with intermittent loss of capture (a pacing spike not followed by a QRS complex). (B) Ventricular pacing with loss of sensing (a pacing spike occurring at an inappropriate time). Key:  $\uparrow$  = pacing spike; \* = loss of capture; P = pacemaker-induced QRS complex; I = patient's intrinsic QRS complex; F = fusion (a QRS complex formed by a merging of the patient's intrinsic QRS complex and the pacemaker-induced QRS complex). Both in lead  $V_1$ .

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment findings, potential complications that may develop include decreased cardiac output related to pacemaker malfunction.

### Planning and Goals

The major goals for the patient may include absence of infection, adherence to a self-care program, effective coping, and maintenance of pacemaker function.

### Nursing Interventions

#### PREVENTING INFECTION

The nurse changes the dressing regularly and inspects the insertion site for redness, swelling, soreness, or any unusual drainage. An increase in temperature should be reported to the physician. Changes in wound appearance are also reported to the physician.

#### PROMOTING EFFECTIVE COPING

The patient treated with a pacemaker experiences not only lifestyle and physical changes but also emotional changes. At different times during the healing process, the patient may feel angry, depressed, fearful, anxious, or a combination of these emotions. Although each patient uses individual coping strategies (eg, humor, prayer, communication with a significant other) to manage emotional distress, some strategies may work better than others. Signs that may indicate ineffective coping include social isolation, increased or prolonged irritability or depression, and difficulty in relationships.

To promote effective coping strategies, the nurse must recognize the patient's emotional state and assist the patient to explore his or her feelings. The nurse may help the patient to identify per-

ceived changes (eg, loss of ability to participate in contact sports), the emotional response to the change (eg, anger), and how the patient responded to that emotion (eg, quickly became angry when talking with spouse). The nurse reassures the patient that the responses are normal, then assists the patient to identify realistic goals (eg, develop interest in another activity) and to develop a plan to attain those goals. The nurse may also teach the patient easy-to-use stress reduction techniques (eg, deep-breathing exercises) to facilitate coping. Education (Chart 27-3) may assist a patient to cope with changes that occur with pacemaker treatment.

### PROMOTING HOME AND COMMUNITY-BASED CARE

#### Teaching Patients Self-Care

After pacemaker insertion, the patient's hospital stay may be less than 1 day, and follow-up in an outpatient clinic or office is common. The patient's anxiety and feelings of vulnerability may interfere with the ability to learn information provided. Nurses often need to include home caregivers in the teaching and provide printed materials for use by the patient and caregiver. Priorities for learning are established with the patient and caregiver. Teaching may include the importance of periodic pacemaker monitoring, promoting safety, avoiding infection, and sources of electromagnetic interference (see Chart 27-3).

### Evaluation

#### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Remains free of infection
  - a. Has normal temperature
  - b. Has white blood cell count within normal range (5,000 to 10,000/mm<sup>3</sup>)

## Chart 27-3

## Home Care Checklist • The Patient With a Pacemaker

At the completion of the home care instruction, the patient or caregiver will be able to:

### Monitor pacemaker function.

- Describe the importance of reporting to physician or pacemaker clinic periodically as prescribed, so that the pacemaker's rate and function can be monitored. This is especially important during the first month after implantation.
- Adhere to monitoring schedule as instructed after implantation.
- Check pulse daily. Report *immediately* any sudden slowing or increasing of the pulse rate. This may indicate pacemaker malfunction.
- Resume more frequent monitoring when battery depletion is anticipated. (The time for reimplantation depends on the type of battery in use.)

### Promote safety and avoid infection.

- Wear loose-fitting clothing around the area of the pacemaker.
- State the reason for the slight bulge over the pacemaker implant.
- Notify physician if the pacemaker area becomes red or painful.
- Avoid trauma to the area of the pacemaker generator.
- Study the manufacturer's instructions and become familiar with the pacemaker.
- Recognize that physical activity does not usually have to be curtailed, with the exception of contact sports.
- Carry medical identification indicating physician's name, type and model number of pacemaker, manufacturer's name, pacemaker rate, and hospital where pacemaker was inserted.

### Electromagnetic interference: Describe the importance of the following:

- Avoid large magnetic fields such as those surrounding magnetic resonance imaging, large motors, arc welding, electrical substations. Magnetic fields can deactivate the pacemaker.
- Some electrical and small motor devices, as well as cellular phones, may interfere with pacemaker function if placed very close to the generator. Avoid leaning directly over devices, or ensure that contact is brief; place cellular phone on opposite side of generator.
- Household items, such as microwave ovens, should not cause any concern.
- When going through security gates (eg, at airports, government buildings) show identification card and request hand search.
- Hospitalization may be necessary periodically to change battery or replace pacemaker unit.

	Patient	Caregiver
Describe the importance of reporting to physician or pacemaker clinic periodically as prescribed, so that the pacemaker's rate and function can be monitored. This is especially important during the first month after implantation.	✓	
Adhere to monitoring schedule as instructed after implantation.	✓	
Check pulse daily. Report immediately any sudden slowing or increasing of the pulse rate. This may indicate pacemaker malfunction.	✓	✓

one paddle may be placed on the front of the chest and the other connected to an adapter with a long handle and placed under the patient's back, which is called an anteroposterior placement (Fig. 27-30).

**NURSING ALERT** When using paddles, apply the appropriate conductant between the paddles and the patient's skin. Do not substitute any other type of conductant, such as ultrasound gel.

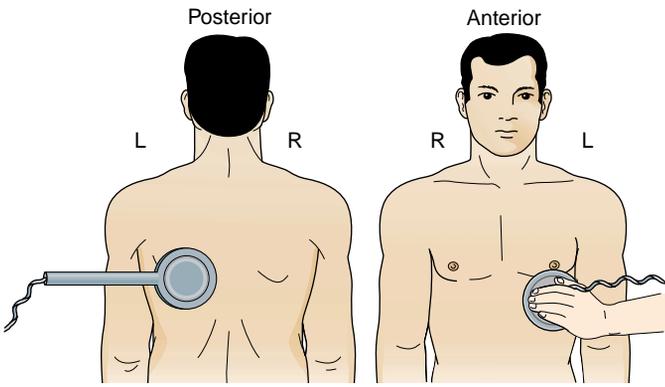

## CARDIOVERSION AND DEFIBRILLATION

Cardioversion and defibrillation are treatments for tachydysrhythmias. They are used to deliver an electrical current to depolarize a critical mass of myocardial cells. When the cells repolarize, the sinus node is usually able to recapture its role as the heart's pacemaker. One major difference between cardioversion and defibrillation has to do with the timing of the delivery of electrical current. Another major difference concerns the circumstance: defibrillation is usually performed as an emergency treatment, whereas cardioversion is usually, but not always, a planned procedure.

Electrical current may be delivered through paddles or conductor pads. Both paddles may be placed on the front of the chest (Fig. 27-29), which is the standard paddle placement, or

**FIGURE 27-29** Standard paddle placement for defibrillation.

**FIGURE 27-30** Anteroposterior paddle placement for defibrillation.

Instead of paddles, defibrillator multifunction conductor pads may be used (Fig. 27-31). The pads, which contain a conductive medium, are placed in the same position as the paddles. They are connected to the defibrillator and allow for hands-off defibrillation. This method reduces the risks of touching the patient during the procedure and increases electrical safety. AEDs use this type of delivery for the electrical current.

Whether using pads or paddles, the nurse must observe two safety measures. First, maintain good contact between the pads or paddles (with a conductive medium) and the patient's skin to prevent electrical current from leaking into the air (arcing) when the defibrillator is discharged. Second, ensure that no one is in contact with the patient or with anything that is touching the patient when the defibrillator is discharged, to minimize the chance that electrical current will be conducted to anyone other than the patient.

When performing defibrillation or cardioversion, the nurse should remember these key points:

- Use multifunction conductor pads or paddles with a conducting agent between the paddles and the skin (the conducting agent is available as a sheet, gel, or paste).
- Place paddles or pads so that they do not touch the patient's clothing or bed linen and are not near medication patches or direct oxygen flow.
- If cardioverting, ensure that the monitor leads are attached to the patient and that the defibrillator is in sync mode. If

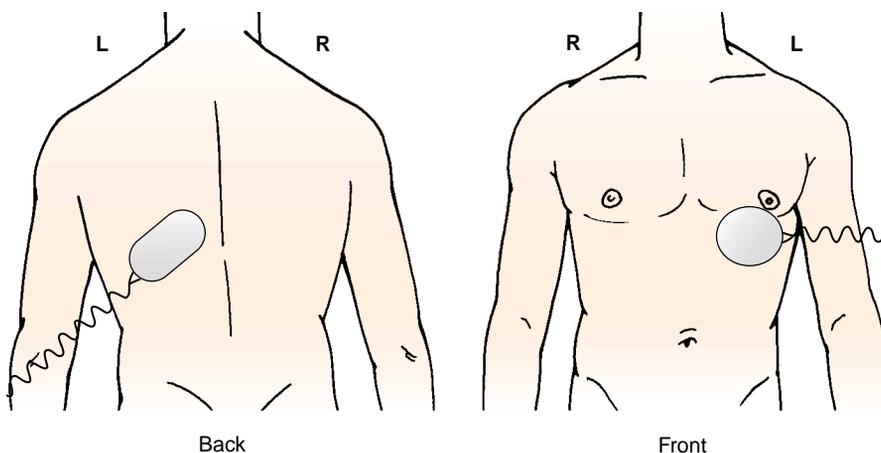

defibrillating, ensure that the defibrillator is not in sync mode (most machines default to the "not-sync" mode).

- Do not charge the device until ready to shock; then keep thumbs and fingers off the discharge buttons until paddles or pads are on the chest and ready to deliver the electrical charge.
- Exert 20 to 25 pounds of pressure on the paddles to ensure good skin contact.
- Before pressing the discharge button, call "Clear!" three times: As "Clear" is called the first time, ensure that you are not touching the patient, bed or equipment; as "Clear" is called the second time, ensure that no one is touching the bed, the patient, or equipment, including the endotracheal tube or adjuncts; and as "Clear" is called the third time, perform a final visual check to ensure you and everyone else are clear of the patient and anything touching the patient.
- Record the delivered energy and the results (cardiac rhythm, pulse).
- After the event is complete, inspect the skin under the pads or paddles for burns; if any are detected, consult with the physician or a wound care nurse about treatment.

## Cardioversion

**Cardioversion** involves the delivery of a "timed" electrical current to terminate a tachydysrhythmia. In cardioversion, the defibrillator is set to synchronize with the ECG on a cardiac monitor so that the electrical impulse discharges during ventricular depolarization (QRS complex). Because there may be a short delay until recognition of the QRS, the discharge buttons must be held down until the shock has been delivered. The synchronization prevents the discharge from occurring during the vulnerable period of repolarization (T wave), which could result in VT or ventricular fibrillation. When the synchronizer is on, no electrical current will be delivered if the defibrillator does not discern a QRS complex. Sometimes the lead and the electrodes must be changed for the monitor to recognize the patient's QRS complex.

If the cardioversion is elective, anticoagulation for a few weeks before cardioversion may be indicated. Digoxin is usually withheld for 48 hours before cardioversion to ensure the resumption of sinus rhythm with normal conduction. The patient is instructed not to eat or drink for at least 8 hours before the procedure. Gel-covered paddles or conductor pads are positioned front and back (anteroposteriorly) for cardioversion. Before cardio-

**FIGURE 27-31** Multifunction pads for defibrillation.

version, the patient receives intravenous sedation as well as an analgesic medication or anesthesia. Respiration is then supported with supplemental oxygen delivered by a bag-mask-valve device with suction equipment readily available. Although patients rarely require intubation, equipment is nearby if it is needed. The amount of voltage used varies from 25 to 360 joules, depending on the defibrillator's technology and the type of dysrhythmia. If ventricular fibrillation occurs after cardioversion, the defibrillator is used to defibrillate the patient (sync mode is *not* used).

Indications of a successful response are conversion to sinus rhythm, adequate peripheral pulses, and adequate blood pressure. Because of the sedation, airway patency must be maintained and the patient's state of consciousness assessed. Vital signs and oxygen saturation are monitored and recorded until the patient is stable and recovered from sedation and the effects of analgesic medications or anesthesia. ECG monitoring is required during and after cardioversion.

## Defibrillation

**Defibrillation** is used in emergency situations as the treatment of choice for ventricular fibrillation and pulseless VT. Defibrillation depolarizes a critical mass of myocardial cells at once; when they repolarize, the sinus node usually recaptures its role as the pacemaker. The electrical voltage required to defibrillate the heart is usually greater than that required for cardioversion. If three defibrillations of increasing voltage have been unsuccessful, cardiopulmonary resuscitation is initiated and advanced life support treatments are begun.

The use of epinephrine or vasopressin may make it easier to convert the dysrhythmia to a normal rhythm with defibrillation. These drugs may also increase cerebral and coronary artery blood flow. After the medication is administered and 1 minute of cardiopulmonary resuscitation is performed, defibrillation is again administered. Antiarrhythmic medications such as amiodarone (Cordarone, Pacerone), lidocaine (Xylocaine), magnesium, or procainamide (Pronestyl) are given if ventricular dysrhythmia persists (see Table 27-1). This treatment continues until a stable rhythm resumes or until it is determined that the patient cannot be revived.

## IMPLANTABLE CARIOVERTER DEFIBRILLATOR

The **implantable cardioverter defibrillator (ICD)** is a device that detects and terminates life-threatening episodes of VT or ventricular fibrillation in high-risk patients. Patients at high risk are those who have survived sudden cardiac death syndrome, usually caused by ventricular fibrillation, or have experienced symptomatic VT (syncope secondary to VT). In addition, an ICD may be indicated for patients who have survived an MI but are at high risk for cardiac arrest.

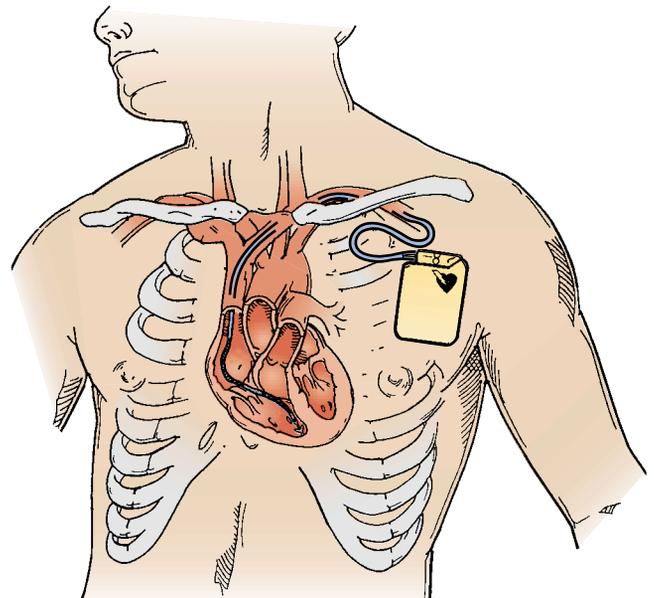

An ICD consists of a generator and at least one lead that can sense intrinsic electrical activity and deliver an electrical impulse. The device is usually implanted much like a pacemaker (Fig. 27-32). ICDs are designed to respond to two criteria: a rate that exceeds a predetermined level, and a change in the isoelectric line segments. When a dysrhythmia occurs, rate sensors take 5 to 10 seconds to sense the dysrhythmia. Then the device takes several seconds to charge and deliver the programmed charge through the lead to the heart. Battery life is about 5 years but varies depending on use of the ICD over time. The battery is checked during follow-up visits.

Antiarrhythmic medication usually is administered with this technology to minimize the occurrence of the tachydysrhythmia and to reduce the frequency of ICD discharge.

The first defibrillator, which was implanted in 1980 at Johns Hopkins University, simply defibrillated the heart. Today, however, several devices are available, and many are programmed for multiple treatments (Atlee & Bernstein, 2001). Each device offers a different delivery sequence, but all are capable of delivering high-energy (high-intensity) defibrillation to treat a tachycardia (atrial or ventricular). The device may deliver up to six shocks if necessary. Some ICDs can respond with antitachycardia pacing, in which the device delivers electrical impulses at a fast rate in an attempt to disrupt the tachycardia, by low-energy (low-intensity) cardioversion, by defibrillation, or all three (Atlee & Bernstein, 2001). Some also have pacemaker capability if the patient develops bradycardia, which sometimes occurs after treatment of the tachycardia. Usually the mode is VVI (V, paces the ventricle; V, senses ventricular activity; I, paces only if the ventricles do not depolarize) (Atlee & Bernstein, 2001). Some ICDs also deliver low-energy cardioversion, and some also treat atrial fibrillation (Bubien & Sanchez, 2001; Daoud et al., 2000). Which device is used and how it is programmed depends on the patient's dysrhythmia.

Complications are similar to those associated with pacemaker insertion. The primary complication associated with the ICD is surgery-related infection. There are a few complications associated with the technical aspects of the equipment, such as premature battery depletion and dislodged or fractured leads. Despite the possible complications, the consensus among clinicians is that the benefits of ICD therapy exceed the risks.

Nursing interventions for the patient with an ICD are provided throughout the preoperative, perioperative, and postoperative phases. In addition to providing the patient and family with explanations regarding implantation of the ICD in the preoperative phase, the nurse may need to manage acute episodes of life-threatening dysrhythmias. In the perioperative and postoperative phases, the nurse carefully observes the patient's responses to the ICD and provides the patient and family with further teaching as needed (White, 2000) (Chart 27-4). The nurse can also assist the patient and family in making lifestyle changes necessitated by the dysrhythmia and resulting ICD implantation (Dougherty, Benoliel, & Bellin, 2000).

**FIGURE 27-32** The implantable cardioverter defibrillator (ICD) consists of a generator and a sensing/pacing/defibrillating electrode.

Chart 27-4

## Home Care Checklist • The Patient With an ICD

At the completion of the home care instruction, the patient or caregiver will be able to:

#### Avoid infection at the ICD insertion site.

- Observe incision site daily for redness, swelling, and heat.
- Take temperature; report any increase.
- Avoid tight restrictive clothing that may cause friction over the insertion site.

#### Adhere to activity restrictions.

- Movement of arm may continue to be restricted until incision heals if the ICD was implanted in pectoral region.
- Avoid heavy lifting.
- Discuss safety of activities (eg, driving) with physician.
- Avoid contact sports.

#### Electromagnetic interference: Understand the importance of the following:

- Avoid large magnetic fields such as those created by magnetic resonance imaging, large motors, arc welding, electrical substations, and so forth. Magnetic fields may deactivate the ICD, negating any effect on a dysrhythmia.
- At security gates at airports, government buildings, or other secured areas, show identification card and request a hand search.
- Some electrical and small motor devices, as well as cellular phones, may interfere with the functioning of the ICD if placed very close to the ICD. Avoid leaning directly over devices, or ensure contact is of brief duration; place cellular phone on opposite side of ICD.
- Household appliances (eg, microwave ovens) should not cause any concern.

#### Promote safety.

- Describe what to do if symptoms occur and notify physician if any discharges seem unusual.
- Maintain a log that records discharges. Record events that precipitate the sensation of shock. This provides important data for the physician to use in readjusting the medical regimen.
- Encourage family members to attend a CPR class.
- Call 911 for emergency assistance if feeling of dizziness occurs.
- Wear medical identification (eg, Medic-Alert) that includes physician information.
- Avoid frightening family or friends with unexpected shocks, which will not harm them. Inform family and friends that in the event they are in contact with the patient when a shock is delivered, they may also feel the shock. It is especially important to warn sexual partners that this may occur.
- Discuss psychological responses to the ICD implantation, such as changes in self-image, depression due to loss of mobility secondary to driving restrictions, fear of shocks, increased anxiety, concerns that sexual activity may trigger the ICD, and changes in partner relationship.

#### Follow-up care

- Adhere to appointments that are scheduled to test electronic performance of ICD. Remember to take log of discharges to review with physician.
- Attend an ICD support group within the area.

## ELECTROPHYSIOLOGIC STUDIES

An electrophysiology (EP) study is used to evaluate and treat various dysrhythmias that have caused cardiac arrest or significant symptoms. It also is indicated for patients with symptoms that suggest a dysrhythmia that has gone undetected and undiagnosed by other methods. An EP study is used to

- Identify the impulse formation and propagation through the cardiac electrical conduction system
- Assess the function or dysfunction of the SA and AV nodal areas
- Identify the location (called mapping) and mechanism dysrhythmogenic foci
- Assess the effectiveness of antiarrhythmic medications and devices for the patient with a dysrhythmia
- Treat certain dysrhythmias through the destruction of the causative cells (**ablation**)

An EP procedure is a type of cardiac catheterization that is performed in a specially equipped cardiac catheterization laboratory. The patient is awake but lightly sedated. Usually a catheter with multiple electrodes is inserted through the femoral vein, threaded through the inferior vena cava, and advanced into the heart. The electrodes are positioned within the heart at specific locations—for instance, in the right atrium near the sinus node, in the coronary sinus, near the tricuspid valve, and at the apex of the right ventricle. The number and placement of electrodes depend on the type of study being conducted. These electrodes allow the electrical signal to be recorded from within the heart (intracardiogram).

The electrodes also allow the clinician to introduce a pacing stimulus to the intracardiac area at a precisely timed interval and rate, thereby stimulating the area (programmed stimulation). An area of the heart may be paced at a rate much faster than the normal rate of **automaticity**, the rate at which impulses are spon-

taneously formed (eg, in the sinus node). This allows the pacemaker to become an artificial focus of automaticity and to assume control (overdrive suppression). Then the pacemaker is stopped suddenly, and the time it takes for the sinus node to resume control is assessed. A prolonged time indicates dysfunction of the sinus node.

One of the main purposes of programmed stimulation is to assess the ability of the area surrounding the electrode to cause a reentry dysrhythmia. One or a series of premature impulses is delivered to an area in an attempt to cause the tachydysrhythmia. Because the precise location of the suspected area and the specific timing of the pacing needed are unknown, the electrophysiologist uses several different techniques to cause the dysrhythmia during the study. If the dysrhythmia can be reproduced by programmed stimulation, it is called inducible. Once a dysrhythmia is induced, a treatment plan is determined and implemented. If, on the follow-up EP study, the tachydysrhythmia cannot be induced, then the treatment is determined to be effective. Different medications may be administered and combined with electrical devices (pacemaker, ICD) to determine the most effective treatment to suppress the dysrhythmia.

Complications of an EP study are the same as those that can occur with cardiac catheterization. Because an artery is not always used, there is a lower incidence of vascular complications than with other catheterization procedures. Cardiac arrest may occur, but the incidence is low (less than 1%).

Patients who are to undergo an EP study may be anxious about the procedure and about its outcome. A detailed discussion involving the patient, the family, and the electrophysiologist usually occurs to ensure that the patient is able to give informed consent and to reduce anxiety about the procedure. Before the procedure, patients should receive instructions about the procedure and its usual duration, the environment where the procedure is performed, and what to expect. Although an EP study is not painful, it does cause discomfort and can be tiring. It may also cause feelings that were experienced when the dysrhythmia occurred in the past. In addition, patients also are taught what will be expected of them (eg, lying very still during the procedure, reporting symptoms or concerns).

Patients need to know that the dysrhythmia may occur during the procedure, but under very controlled circumstances. It often stops on its own; if it does not, treatment is given to restore the patient's normal rhythm. During the procedure, patients benefit from a calm, reassuring approach.

Postprocedural care includes restriction of activity to promote hemostasis at the insertion site. To identify any complications and to ensure healing, the patient's vital signs and the appearance of the insertion site are assessed frequently.

## CARDIAC CONDUCTION SURGERY

Atrial tachycardias and ventricular tachycardias that do not respond to medications and are not suitable for antitachycardia pacing may be treated by methods other than medications and devices. Such methods include endocardial isolation, endocardial resection, and ablation. An ICD may be used with these surgical interventions.

### Endocardial Isolation

Endocardial isolation involves making an incision into the endocardium that separates the area where the dysrhythmia originates from the surrounding endocardium. The edges of the incision are then sutured together. The incision and its resulting scar tissue prevent the dysrhythmia from affecting the whole heart.

### Endocardial Resection

In endocardial resection, the origin of the dysrhythmia is identified, and that area of the endocardium is peeled away. No reconstruction or repair is necessary.

### Catheter Ablation Therapy

Catheter ablation destroys specific cells that are the cause or central conduction method of a tachydysrhythmia. It is performed with or after an EP study. Usual indications for ablation are AV nodal reentry tachycardia, atrial fibrillation, or VT unresponsive to previous therapy (or for which the therapy produced significant side effects).

Ablation is also indicated to eliminate accessory AV pathways or bypass tracts that exist in the hearts of patients with preexcitation syndromes such as Wolff-Parkinson-White (WPW) syndrome. During normal embryonic development, all connections between the atrium and ventricles disappear, except for that between the AV node and the bundle of His. In some people, embryonic connections of normal heart muscle between the atrium and ventricles remain, providing an accessory pathway or a tract through which the electrical impulse can bypass the AV node. These pathways can be located in several different areas. If the patient develops atrial fibrillation, the impulse may be conducted into the ventricle at a rate of 300 times per minute or more, which can lead to ventricular fibrillation and sudden cardiac death. Preexcitation syndromes are identified by specific ECG findings. For example, in WPW syndrome there is a shortened PR interval, slurring (called a delta wave) of the initial QRS deflection, and prolonged QRS duration (Fig. 27-33).

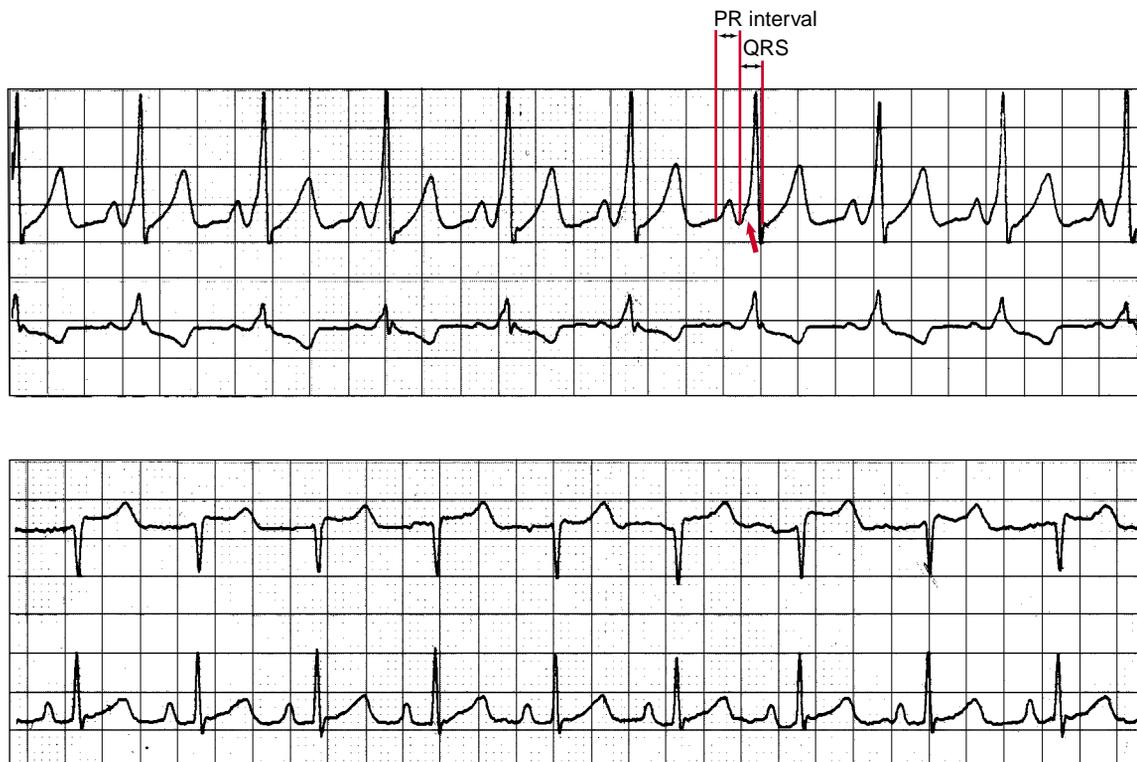

Ablation may be accomplished by three different methods: radiofrequency ablation, cryoablation, or electrical ablation. The most often used method is radiofrequency, which involves placing a special catheter at or near the origin of the dysrhythmia. High-frequency, low-energy sound waves are passed through the catheter, causing thermal injury and cellular changes that result in localized destruction and scarring. The tissue damage is more specific to the dysrhythmic tissue, with less trauma to the surrounding cardiac tissue than occurs with cryoablation or electrical ablation.

Cryoablation involves placing a special probe, cooled to a temperature of  $-60^{\circ}\text{C}$  ( $-76^{\circ}\text{F}$ ), on the endocardium at the site of the dysrhythmia's origin for 2 minutes. The tissue freezes and is later replaced by scar tissue, eliminating the origin of the dysrhythmia.

In electrical ablation, a catheter is placed at or near the origin of the dysrhythmia, and one to four shocks of 100 to 300 joules are administered through the catheter directly to the endocardium and surrounding tissue. The cardiac tissue burns and scars, thus eliminating the source of the dysrhythmia.

During the ablation procedure, defibrillation pads, an automatic blood pressure cuff, and a pulse oximeter are used on the patient, and an indwelling urinary catheter is inserted. The patient is given light sedation. An EP study is performed and attempts to induce the dysrhythmia are made. The ablation catheter is placed at the origin of the dysrhythmia, and the ablation procedure is performed. Multiple ablations may be necessary. Successful ablation is achieved when the dysrhythmia can no longer be induced. The patient is monitored for another 30 to 60 minutes and then retested to ensure that the dysrhythmia will not recur.

Postprocedural care is similar to that for an EP study, except that the patient is monitored more closely, depending on the time needed for recovery from sedation.

### Critical Thinking Exercises

1. You are caring for a 40 year-old male physician who had experienced a cardiac arrest at home, witnessed by his 9-year-old son and 15-year-old daughter. After having an ICD implanted, he appears sullen and withdrawn. On inquiry about how he feels, he replies, "I don't know if this device is a blessing or a punishment!" How would you respond? What other factors are important to assess? Discuss the impact that his children may have on his perception of the device. How would you alter your plan of care to address this patient's psychosocial concerns because he is a physician? How would the plan of care change if, instead of appearing sullen and withdrawn, he appeared irritable and confrontational?

2. Your patient is an active 80-year-old woman who has heart failure and chronic atrial fibrillation. She is taking an angiotensin-converting enzyme inhibitor, a beta-blocker, a diuretic, and digoxin. During your assessment, she tells you that she felt very dizzy this morning. How would you focus your assessment, and why? Identify some of the key assessment factors. What nursing interventions are needed? How would you modify your assessment and interventions if your patient also had chronic obstructive pulmonary disease and renal insufficiency?

# ● Management of Patients With Coronary Vascular Disorders

## **LEARNING OBJECTIVES**

*On completion of this chapter, the learner will be able to:*

1. Describe the pathophysiology, clinical manifestations, and treatment of coronary atherosclerosis.
2. Describe the pathophysiology, clinical manifestations, and treatment of angina pectoris.
3. Use the nursing process as a framework for care of patients with angina pectoris.
4. Describe the pathophysiology, clinical manifestations, and treatment of myocardial infarction.
5. Use the nursing process as a framework for care of patients with myocardial infarction (acute coronary syndrome).
6. Describe the nursing care of a patient who has had an invasive interventional procedure for treatment of coronary artery disease.
7. Describe coronary artery revascularization procedures.
8. Describe the nursing care of the patient treated with cardiac surgery.

In the past, identification and treatment of heart disease focused on white, middle-aged men. However, later studies showed that other segments of the population were also seriously affected by cardiac conditions. Cardiovascular disease is the leading cause of death in the United States for men and women of all racial and ethnic groups, and more women die of cardiovascular disease than all types of cancers combined (American Heart Association, 2001).

## Coronary Artery Disease

Coronary artery disease (CAD) is the most prevalent type of cardiovascular disease. For this reason, it is important for nurses to become familiar with the various types of coronary artery conditions and the methods for assessing, preventing, and treating these disorders medically and surgically.

### CORONARY ATHEROSCLEROSIS

The most common heart disease in the United States is **atherosclerosis**, which is an abnormal accumulation of lipid, or fatty, substances and fibrous tissue in the vessel wall. These substances create blockages or narrow the vessel in a way that reduces blood flow to the myocardium. Studies (Mehta et al., 1998) indicate that atherosclerosis involves a repetitious inflammatory response to artery wall injury and an alteration in the biophysical and biochemical properties of the arterial walls. An association between an infection (eg, gingivitis) and the later development of heart disease is being explored, as is the administration of antibiotics to prevent heart disease. Although authorities disagree about how atherosclerosis begins, they agree that atherosclerosis is a progressive disease that can be curtailed and, in some cases, reversed.

### Pathophysiology

Atherosclerosis begins as fatty streaks, lipids that are deposited in the intima of the arterial wall. Although they are thought to be the precursors of atherosclerosis, fatty streaks are common, even in childhood. Moreover, not all develop into more advanced lesions. The reason why some fatty streaks continue to develop is unknown, although genetic and environmental factors are involved. The continued development of atherosclerosis involves an inflammatory response. T lymphocytes and monocytes (that become macrophages) infiltrate the area to ingest the lipids and then die; this causes smooth muscle cells within the vessel to proliferate and form a fibrous cap over the dead fatty core. These deposits, called **atheromas** or plaques, protrude into the lumen of the vessel, narrowing it and obstructing blood flow (Fig. 28-1). If the fibrous cap of the plaque is thick and the lipid pool remains relatively stable, it can resist the stress from blood flow and vessel movement. If the cap is thin, the lipid core may grow, causing it to rupture and hemorrhage into the plaque, allowing a thrombus to develop. The thrombus may obstruct blood flow, leading to sudden cardiac death or an acute **myocardial infarction (MI)**, which is the death of heart tissue.

The anatomic structure of the coronary arteries makes them particularly susceptible to the mechanisms of atherosclerosis. As Figure 28-2 shows, they twist and turn as they supply blood to the heart, creating sites susceptible to atheroma development. Although heart disease is most often caused by atherosclerosis of the coronary arteries, other phenomena decrease blood flow to the heart. Examples include vasospasm (sudden constriction or narrowing) of a coronary artery, myocardial trauma from internal or external forces, structural disease, congenital anomalies, decreased oxygen supply (eg, from acute blood loss, anemia, or low

## Glossary

**ACE inhibitor (ACE-I):** abbreviation for medications that inhibit the angiotensin-converting enzyme

**acute coronary syndrome (ACS):** signs and symptoms that indicate unstable angina or acute myocardial infarction

**angina pectoris:** chest pain brought about by myocardial ischemia

**atherosclerosis:** abnormal accumulation of lipid deposits and fibrous tissue within arterial walls and lumen

**atheroma:** fibrous cap composed of smooth muscle cells that forms over lipid deposits within arterial vessels and that protrudes into the lumen of the vessel, narrowing the lumen and obstructing blood flow; also called plaque

**collateral circulation:** arteries that supply blood to tissue when the main arterial blood supply is partially or totally obstructed

**contractility:** ability of the cardiac muscle to shorten in response to an electrical impulse

**coronary artery bypass graft (CABG):** a surgical procedure in which a blood vessel from another part of the body is grafted onto the occluded coronary artery below the occlusion in such a way that blood flow bypasses the blockage

**creatinine kinase (CK):** an enzyme found in human tissues; one of the three types of CK is specific to heart muscle and may be used as an indicator of heart muscle injury

**high-density lipoprotein (HDL):** a protein-bound lipid that transports cholesterol to the liver for excretion in the bile; composed of a higher proportion of protein to lipid than low-density lipoprotein; exerts a beneficial effect on the arterial wall

**hormone replacement therapy (HRT):** estrogen, progesterone, or both prescribed for postmenopausal or oophorectomized women

**ischemia:** insufficient tissue oxygenation

**low-density lipoprotein (LDL):** a protein-bound lipid that transports cholesterol to tissues in the body; composed of a lower proportion of protein to lipid than high-density lipoprotein; exerts a harmful effect on the arterial wall

**myocardial infarction (MI):** death of heart tissue caused by lack of oxygenated blood flow; if acute, abbreviated as AMI

**percutaneous coronary intervention (PCI):** an invasive procedure in which a catheter is placed in a coronary artery, and one of

several methods is employed to remove or reduce a blockage within the artery

**percutaneous transluminal coronary angioplasty (PTCA):** a type of percutaneous coronary intervention in which a balloon is inflated within a coronary artery to break an atheroma and open the vessel lumen, improving coronary artery blood flow

**primary prevention:** interventions taken to prevent the development of coronary artery disease

**secondary prevention:** interventions taken to prevent the advancement of existing coronary artery disease

**streptokinase (SK):** a thrombolytic agent

**stent:** a woven mesh that provides structural support to a coronary vessel, preventing its closure

**sudden cardiac death:** immediate cessation of effective heart activity

**thrombolytic:** an agent or process that breaks down blood clots

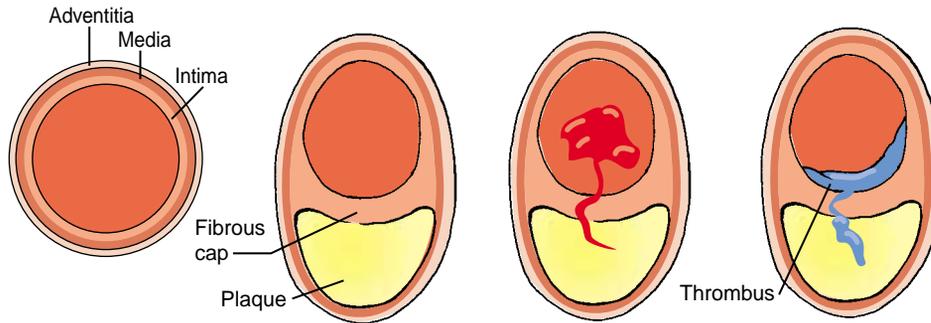

**troponin:** myocardial protein; measurement is used to indicate heart muscle injury

**vasoconstrictor:** an agent (usually a medication) that narrows the blood vessel lumen

**vasodilator:** an agent (usually a medication) that enlarges blood vessel lumen

## Physiology/Pathophysiology

**FIGURE 28-1** Atherosclerosis involves a normally patent artery (A) and an inflammatory response whereby smooth muscle cells proliferate within the blood vessel to form a fibrous cap (B). The proliferation results in deposits, called atheromas or plaques, which protrude into the lumen of the vessel, narrowing it and obstructing blood flow. If the cap ruptures and hemorrhages into the plaque (C), a thrombus (D) may develop and obstruct blood flow further.

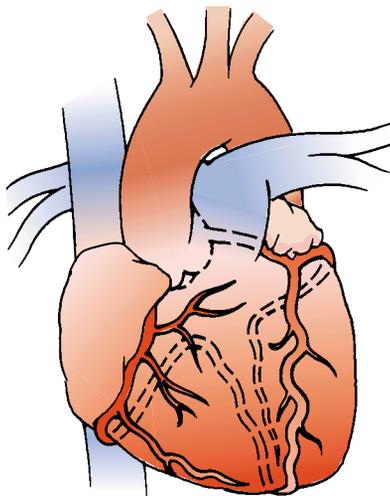

blood pressure), and increased demand for oxygen (eg, from rapid heart rate, thyrotoxicosis, or ingestion of cocaine).

### Clinical Manifestations

Coronary atherosclerosis produces symptoms and complications according to the location and degree of narrowing of the arterial lumen, thrombus formation, and obstruction of blood flow to the myocardium. This impediment to blood flow is usually progressive, causing an inadequate blood supply that deprives the muscle cells of oxygen needed for their survival. The condition is known as **ischemia**. **Angina pectoris** refers to chest pain that is brought about by myocardial ischemia. Angina pectoris usually is caused by significant coronary atherosclerosis. If the decrease in blood supply is great enough, of long enough duration, or both, irreversible damage and death of myocardial cells, or MI, may result. Over time, irreversibly damaged myocardium undergoes degener-

ation and is replaced by scar tissue, causing various degrees of myocardial dysfunction. Significant myocardial damage may cause inadequate cardiac output, and the heart cannot support the body's needs for blood, which is called heart failure (HF). A decrease in blood supply from CAD may even cause the heart to stop abruptly, an event that is called **sudden cardiac death**.

The most common manifestation of myocardial ischemia is acute onset of chest pain. However, an epidemiologic study of the people in Framingham, Massachusetts, showed that nearly 15% of men and women who had MIs were totally asymptomatic (Kannel, 1986). Another study found that 33% of those diagnosed with MI did not present to the emergency room with chest pain (Canto et al., 2000; Ishihara et al., 2000). Those without chest pain tend to be older or women, or to have diabetes or a history of heart failure. Women have been found to have more atypical symptoms of myocardial ischemia (eg, shortness of breath, nausea, unusual fatigue) than men (Meischke et al., 1999). The incidence of prodromal angina (ie, angina a few hours to days before the MI) was found to be significantly lower in patients older than 70 years of age (Ishihara et al., 2000). Other clinical manifestations of CAD may be abnormalities signaled by changes on the electrocardiogram (ECG), high levels of cardiac enzymes, dysrhythmias, and sudden death.

**FIGURE 28-2** Angles of the coronary arteries. The many angles and curves of the coronary arteries contribute to the vessels' susceptibility to atheromatous plaques. Arteries shown as dashed lines supply the posterior wall of the heart.

### Risk Factors

Epidemiologic studies point to several factors that increase the probability that heart disease will develop. Major risk factors include use of tobacco, hypertension, elevated blood lipid levels, family history of premature cardiovascular disease (first-degree relative with cardiovascular disease at age 55 or younger for men and at age 65 or younger for women) and age (>45 years for men; >55 years for women). The Third Report of the Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III [ATP III]; 2001) represents the updated clinical guidelines for cholesterol testing and management. ATP III addresses **primary prevention** (preventing the occurrence of CAD) and **secondary prevention** (preventing the progression of CAD).

ATP III is the standard for cholesterol management. ATP III continues to identify elevated **low-density lipoprotein (LDL)**

cholesterol as the primary target of cholesterol-lowering therapy. Those at highest risk for having a cardiac event within 10 years are those with existing CAD or those with diabetes, peripheral arterial disease, abdominal aortic aneurysm, or carotid artery disease. The latter diseases are called CAD risk equivalents, because patients with these diseases have the same risk for a cardiac event as patients with CAD (Chart 28-1). The possibility of having a cardiac event within 10 years is also determined by points given to several factors, such as age, level of total cholesterol, level of LDL, level of **high-density lipoprotein (HDL)**, systolic blood pressure, and tobacco use. If the total points add up to more than 15 for men or 23 for women, the person has a greater than 20% risk for a cardiac event within 10 years. A composite of lipid and nonlipid risk factors of metabolic origin, called *metabolic syndrome*, is another risk factor for CAD. Metabolic syndrome includes abdominal obesity, an elevated triglyceride level, low HDL level, elevated blood pressure, and impaired function of insulin.

Measurement of other emerging risk factors, such as elevations of Lipoprotein(a) [Lp(a)], remnant lipoproteins, small LDL, fibrinogen, homocysteine, and impaired fasting plasma glucose (110–125 mg/dL), is optional and are not routinely recommended (ATP III, 2001). For example, the Homocysteine Studies Collaboration (2002) found that lower levels of homocysteine, an amino acid, were modestly associated with reduced risk of ischemic heart disease and stroke. The results of these retrospective studies suggest that homocysteine may promote atherosclerosis. A meta-analysis of prospective studies was done that showed a significant association between homocysteine levels and ischemic heart disease as well as between homocysteine and stroke (Wald, Law, & Morris, 2002). The authors recommend a daily intake of approximately 0.8 mg of folic acid to decrease blood homocysteine levels and reduce the risk of ischemic heart disease and CVA (brain attack, stroke). The American Heart Association has stated that until the results of large-scale randomized trials become available, routine testing of homocysteine concentrations cannot be justified (Malinow, Bostom, & Krauss, 1999).

## Prevention

Four modifiable risk factors—cholesterol abnormalities, cigarette smoking (tobacco use), hypertension, and diabetes mellitus—have been cited as major risk factors for CAD and its consequent complications. As a result, they receive much attention in health promotion programs (Chart 28-2).

### Chart 28-1

#### Coronary Artery Disease Risk Equivalents

Individuals at highest risk for a cardiac event within 10 years are those with existing coronary artery disease (CAD) and those with any of the following diseases, which are called CAD risk equivalents:

- Diabetes
- Peripheral arterial disease
- Abdominal aortic aneurysm
- Carotid artery disease

From Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. (2001). Executive summary of the third report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). *Journal of the American Medical Association*, 285(19), 2486–2497.

### Chart 28-2

#### Risk Factors for Coronary Artery Disease

A modifiable risk factor is one over which individuals may exercise control, such as by changing a lifestyle or personal habit or by using medication. A nonmodifiable risk factor is a circumstance over which individuals have no control, such as age or heredity. A risk factor may operate independently or in tandem with other risk factors. The more risk factors individuals have, the greater the likelihood of coronary artery disease. Those at risk are advised to seek regular medical examinations and to engage in “heart-healthy” behavior (a deliberate effort to reduce the number and extent of risks).

#### Nonmodifiable Risk Factors

Family history of coronary heart disease

Increasing age

Gender (heart disease occurs three times more often in men than in premenopausal women)

Race (higher incidence of heart disease in African Americans than in Caucasians)

#### Modifiable Risk Factors

High blood cholesterol level

Cigarette smoking, tobacco use

Hypertension

Diabetes mellitus

Lack of estrogen in women

Physical inactivity

Obesity

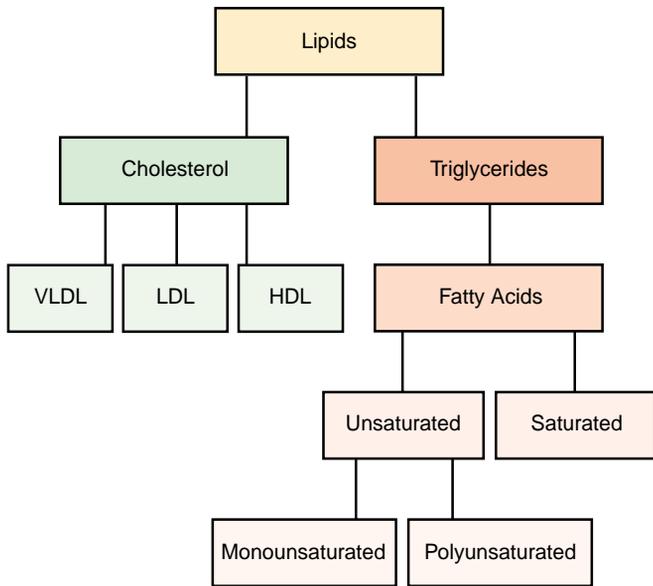

## CONTROLLING CHOLESTEROL ABNORMALITIES

The association of a high blood cholesterol level with heart disease is well established and accepted. The metabolism of fats is important in understanding the development of heart disease.

Fats, which are insoluble in water, are encased in water-soluble lipoproteins to allow them to be transported within a circulatory system that is water-based. Four elements of fat metabolism—total cholesterol, LDL, HDL, and triglycerides—are primary factors affecting the development of heart disease (Fig. 28-3). Cholesterol and the lipoproteins are synthesized by the liver or ingested as part of the diet. All adults 20 years of age or older should have a fasting lipid profile (total cholesterol, LDL, HDL, and triglyceride) performed at least once every 5 years and more often if the profile is abnormal. Patients who have had an acute event (MI), percutaneous coronary intervention (PCI), or **coronary artery bypass graft (CABG)** require assessment of the LDL-cholesterol level within 60 to 365 days after the event (LDL levels may be low immediately after the acute event). Subsequently, lipids should be monitored every 6 weeks until the desired level is achieved and then every 4 to 6 months (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001).

LDL exerts a harmful effect on the arterial wall and accelerates atherosclerosis. In contrast, HDL promotes the use of total cholesterol by transporting LDL to the liver, where it is biodegraded and then excreted. The desired goal is to have low LDL values and high HDL values. The desired level of LDL depends on the patient:

- Less than 160 mg/dL for patients with one or no risk factors
- Less than 130 mg/dL for patients with two or more risk factors
- Less than 100 mg/dL for patients with CAD or a CAD risk equivalent

**FIGURE 28-3** Types of lipids. Elevated levels of cholesterol, VLDL, LDL, and triglycerides, and low levels of HDL are risk factors for the development of atherosclerotic arterial disease, such as coronary artery disease. (VLDL, very low density lipoproteins; LDL, low density lipoproteins; HDL, high density lipoproteins.)

Serum cholesterol and LDL levels can usually be controlled by diet and physical activity. Depending on the patient's LDL level and risk of coronary heart disease, medication therapy may also be prescribed.

The level of HDL should exceed 40 mg/dL and should ideally be more than 60 mg/dL. A high HDL level is a strong negative risk factor (is protective) for heart disease.

Triglyceride is another fatty substance, made up of fatty acids, that is transported through the blood by a lipoprotein. Although an elevated triglyceride level (>200 mg/dL) may be genetic in origin, it also can be caused by obesity, physical inactiv-

ity, excessive alcohol intake, high-carbohydrate diets, diabetes mellitus, kidney disease, and certain medications, such as birth control pills, corticosteroids, and beta-adrenergic blockers when given in higher doses. Management of elevated triglyceride focuses on weight reduction and increased physical activity. Medications such as nicotinic acid and fibric acids (eg, fenofibrate [Tricor], clofibrate [Atromid-S]) may also be prescribed, especially if the triglyceride level is above 500 mg/dL (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001).

Lipoprotein(a), or Lp(a), is a component of LDL and is attached to a special protein called apo(a). The level of Lp(a) is primarily determined by genetics. An elevated level of Lp(a) has been associated with a higher risk of CAD. However, clinical trials have not yet identified methods that lower the level of Lp(a) and have not demonstrated that lower levels of Lp(a) reduce the risk of CAD; therefore Lp(a) is not routinely monitored (Danesh, et al., 2000; Gibbons et al., 1999).

**Dietary Measures.** Table 28-1 provides recommendations of the Therapeutic Lifestyle Changes (TLC) diet (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001). However, these recommendations may need to be adjusted to match the individual patient who has other nutritional needs, such as the requirements for pregnancy or diabetes. To assist in following the appropriate TLC diet, the patient should be referred to a registered dietitian. Other TLC recommendations are weight loss, cessation of tobacco use, and increased physical activity.

Soluble dietary fiber may also help lower cholesterol levels. Soluble fibers, which are found in fresh fruit, cereal grains, vegetables, and legumes, enhance the excretion of metabolized cholesterol. The ability of fiber to reduce serum cholesterol continues to be investigated. Intake of at least 20 to 30 grams of fiber each day is recommended (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001).

Many resources are available to assist people who are attempting to control their cholesterol levels. The National Heart, Lung, and Blood Institute (NHLBI) and its National Cholesterol Education Program (NCEP), the American Heart Association, and the

**Table 28-1 • Nutrient Content of the Therapeutic Lifestyle Changes (TLC) Diet**

NUTRIENT	RECOMMENDED INTAKE
Total calories*	Balance intake and expenditure to maintain desirable weight
Total Fat	25%–35% of total calories
Saturated fat <sup>†</sup>	<7% of total calories
Polyunsaturated Fat	Up to 10% of total calories
Monounsaturated Fat	Up to 20% of total calories
Carbohydrate <sup>‡</sup>	50%–60% of total calories
Fiber	20–30 g/day
Protein	Approximately 15% of total calories
Cholesterol	<200 mg/day

\*Daily energy expenditure should include at least moderate physical activity (contributing approximately 200 k/cal per day).

<sup>†</sup>Trans-fatty acids are formed from the processing (manufacturing, hydrogenation) of vegetable oils into a more solid form. The effects of trans-fatty acids are similar to saturated fats (ie, raising low-density lipoprotein and lowering high-density lipoprotein). Intake of trans-fatty acids should be kept low.

<sup>‡</sup>Carbohydrates should be derived predominately from foods rich in complex carbohydrates, including grains, especially whole grains, fruits, and vegetables.

From Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. (2001). Executive summary of the third report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). *Journal of the American Medical Association*, 285(19), 2486–2497.

American Diabetic Association, as well as CAD support groups and reliable Internet sources, are a few examples of the available resources. Cookbooks and recipes that include the nutritional breakdown of foods can be included as resources for patients. Dietary control has been made easier because food manufacturers are required to provide comprehensive nutritional data on product labels. The label information of interest to a person attempting to eat a heart-healthy diet is as follows:

- Serving size, expressed in household measures
- Amount of total fat per serving
- Amount of saturated fat per serving
- Amount of cholesterol per serving
- Amount of fiber per serving

**Physical Activity.** Regular, moderate physical activity increases HDL levels and reduces triglyceride levels. The goal for the average person is a total of 30 minutes of exercise, three to four times per week. The nurse helps patients set realistic goals for physical activity. For example, the inactive patient should start with activity that lasts 3 minutes, such as parking farther from a building to increase the walking time. For sustained activity, patients should begin with a 5-minute warm-up period to stretch and prepare the body for the exercise. They should end the exercise with a 5-minute cool-down period in which they gradually reduce the intensity of the activity to prevent a sudden decrease in cardiac output. Patients should be instructed to engage in an activity or variety of activities that interest them, to maintain motivation. They should also be taught to exercise to an intensity that does not preclude their ability to talk; if they cannot have a conversation, they should slow down or switch to a less intensive activity. When the weather is hot and humid, the patient should be advised to exercise during the early morning or indoors and wear loose-fitting clothing. When the weather is cold, the patient should be instructed to layer clothing and to wear a hat. The nurse can also advise the patient to avoid adverse weather conditions by participating in local community programs, such as those held at shopping malls. The nurse should inform patients to stop any activity if they develop chest pain, unusual shortness of breath, dizziness, lightheadedness, or nausea.

**Medications.** Medications (Table 28-2) are used in some instances to control cholesterol levels. If diet alone cannot normalize serum cholesterol levels, several medications have a synergistic effect with the prescribed diet. Lipid-lowering medications can reduce CAD mortality in patients with elevated lipid levels and in those with normal lipid levels. The lipid-lowering agents affect the different lipid components and are usually grouped into four types:

- 3-Hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitors or statins (eg, lovastatin [Mevacor], pravastatin [Pravachol], simvastatin [Zocor]; see Table 28-2) block cholesterol synthesis, lower LDL and triglyceride levels, and increase HDL levels. These medications are frequently the initial medication therapy for significantly elevated cholesterol and LDL levels. Because of their effect on the liver, results of hepatic function tests are monitored.
- Nicotinic acids (niacin [Niacor, Niaspan]; see Table 28-2) decrease lipoprotein synthesis, lower LDL and triglyceride levels, and increase HDL levels. The dose of niacin needs to be titrated weekly to achieve therapeutic dosage. Niacin is the medication most often used for minimally elevated cholesterol and LDL levels or as an adjunct to a statin when the lipid goal has not been achieved and the triglycerides are

elevated. Side effects include gastrointestinal upset, gout, and flushing. Because of its effect on the liver, hepatic function is monitored.

- Fibric acid or fibrates (eg, clofibrate [Atromid-S], fenofibrate [Ticor]; see Table 28-2) decrease the synthesis of cholesterol, reduce triglyceride levels, and increase HDL levels. Because they have the potential to increase LDLs, fibrates are the medications of choice for patients with triglyceride levels above 400 mg/dL. Because of the risk of myopathy and acute renal failure, fibrates should be used with caution in patients who are also taking a statin.
- Bile acid sequestrants or resins (eg, cholestyramine [LoCholest, Questran, Prevalite]; see Table 28-2) bind cholesterol in the intestine, increase its breakdown, and lower LDL levels with minimal effect on HDLs and no effect (or minimal increase) on triglyceride levels. These medications are more often used as adjunct therapy when statins alone have not been effective in controlling lipid levels and the triglyceride levels are less than 200 mg/dL. Significant side effects, such as gastric distention and constipation, can occur from using these medications.

Medication therapy is reserved for at-risk patients and is not regarded as a substitute for dietary modification. All of these medications have been shown to reduce major coronary events (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001). Some of these may be used in combination to achieve synergistic effects. For example, LDL cholesterol can be lowered more effectively by adding a low dose of resin to a dose of niacin or statins, or both, than a maximum dose of an individual agent.

Patients with elevated cholesterol levels should be monitored for adherence to the medical plan, the effect of cholesterol-lowering medications, and the development of side effects from cholesterol-lowering medications. Lipid levels are obtained and adjustments made to the diet and medication every 6 weeks until the lipid goal or maximum dose is achieved and then every 6 months thereafter.

### PROMOTING CESSATION OF TOBACCO USE

Cigarette smoking contributes to the development and severity of CAD in three ways. First, the inhalation of smoke increases the blood carbon monoxide level, causing hemoglobin, the oxygen-carrying component of blood, to combine more readily with carbon monoxide than with oxygen. A decreased amount of available oxygen may decrease the heart's ability to pump.

Second, the nicotinic acid in tobacco triggers the release of catecholamines, which raise the heart rate and blood pressure. Nicotinic acid can also cause the coronary arteries to constrict. Smokers have a tenfold increase in risk for sudden cardiac death. The increase in catecholamines may be a factor in the increased incidence of sudden cardiac death.

Third, use of tobacco causes a detrimental vascular response and increases platelet adhesion, leading to a higher probability of thrombus formation. A person with increased risk for heart disease is encouraged to stop tobacco use through any means possible: counseling, consistent motivation and reinforcement messages, support groups, and medications. Some people have found complementary therapies (eg, acupuncture, guided imagery, hypnosis) to be helpful. People who stop smoking reduce their risk of heart disease by 30% to 50% within the first year, and the risk continues to decline as long as they refrain from smoking.

Exposure to other smokers' smoke (passive or second-hand smoke) is believed to cause heart disease in nonsmokers. Oral contraceptive use by women who smoke is inadvisable because

Table 28-2 • Medications Affecting Lipoprotein Metabolism

MEDICATION AND DAILY DOSAGE	LIPID/LIPOPROTEIN EFFECTS	SIDE EFFECTS	CONTRAINDICATIONS
<b>HMG-CoA Reductase Inhibitors (statins)</b>			
Lovastatin (Mevacor) 20–80 mg	LDL ↓ 18–55% HDL ↑ 5–15%	Myopathy, increased liver enzyme levels	Absolute: active or chronic liver disease Relative: concomitant use of certain drugs*
Pravastatin (Pravachol) 20–40 mg	TG ↓ 7–30%		
Simvastatin (Zocor) 20–80 mg			
Fluvastatin (Lescol) 20–80 mg			
Atorvastatin calcium (Lipitor) 10–80 mg			
<b>Nicotinic Acid</b>			
Niacin (Niacor, Niaspan)		Flushing, hyperglycemia, hyperuricemia (or gout), upper gastrointestinal distress, hepatotoxicity	Absolute: chronic liver disease, severe gout Relative: diabetes, hyperuricemia, peptic ulcer disease
Immediate-release nicotinic acid 1.5–3 g	LDL ↓ 5–25% HDL ↑ 15–35%		
Extended-release nicotinic acid 1–2 g	TG ↓ 20–50%		
Sustained-release nicotinic acid 1–2 g			
<b>Fibric Acids</b>			
Fenofibrate (Tricor) 200 mg	LDL ↓ 5–20% (may be increased in patients with high TG)	Dyspepsia, gallstones, myopathy, un- explained non-CHD deaths in World Health Organization study	Absolute: severe renal disease, severe hepatic disease
Clofibrate (Atromid-S) 1000 mg, b.i.d.	HDL ↑ 10–20% TG ↓ 20–50%		
<b>Bile Acid Sequestrants</b>			
Cholestyramine (LoCholest, Questran, Prevalite) 4–16 g	LDL ↓ 15–30% HDL ↑ 3–5%	Gastrointestinal distress, constipation, decreased absorption of other drugs	Absolute: dysbetalipoproteinemia, TG >400 mg/dL Relative: TG >200 mg/dL
Colesvelam (Welchol) 2.6–3.8 g	TG no change or increase		
Colestipol HCl (Colestid) 5–20 g			

HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme A; LDL, low-density lipoprotein; HDL, high-density lipoprotein; TG, triglycerides;

↓ decrease, ↑ increase; CHD, coronary heart disease

\*Cyclosporine (Neoral, Sandimmune, SangCya); macrolide antibiotics (azithromycin [Zithromax], clarithromycin [Biaxin]; dirithromycin [Dynabac]; erythromycin [Aknemycin, E-mycin, Ery-Tab]; various antifungal agents and cytochrome P-450 inhibitors; fibrates; and niacin should be used with appropriate caution).

From Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults. (2001). Executive summary of the third report of the National Cholesterol Education Program (NCEP) Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults (Adult Treatment Panel III). *Journal of the American Medical Association*, 285(19), 2486–2497.

these medications significantly increase the risk of CAD and sudden cardiac death.

Cessation of tobacco use results in a lower rate of cardiac events. Patients should be advised to participate in an educational class, support group, or behavioral program. Use of medications such as the nicotine patch (Nicotrol, Nicoderm CQ, Habitrol) or bupropion (Zyban) may assist with stopping use of tobacco, but do have the same systemic effects: catecholamine release (increasing heart rate and blood pressure) and increased platelet adhesion. These medications should be used for the shortest time and at the lowest effective doses.

### MANAGING HYPERTENSION

Hypertension is defined as blood pressure measurements that repeatedly exceed 140/90 mm Hg. Long-standing elevated blood pressure may result in increased stiffness of the vessel walls, leading to vessel injury and a resulting inflammatory response within

the intima. Hypertension can also increase the work of the left ventricle, which must pump harder to eject blood into the arteries. Over time, the increased workload causes the heart to enlarge and thicken (ie, hypertrophy), a condition that may eventually lead to cardiac failure.

Early detection of high blood pressure and adherence to a therapeutic regimen can prevent the serious consequences associated with untreated elevated blood pressure. Hypertension is discussed in detail in Chapter 32.

### CONTROLLING DIABETES MELLITUS

The relationship between diabetes mellitus and heart disease has been substantiated. For 65% to 75% of patients with diabetes, cardiovascular disease is listed as the cause of death (Braunwald et al., 2001; Grundy et al., 1999). Hyperglycemia fosters dyslipidemia, increased platelet aggregation, and altered red blood cell function, which can lead to thrombus formation. It has been suggested that

these metabolic alterations impair endothelial cell–dependent vasodilation and smooth muscle function; treatment with insulin (eg, Humalog, Humulin, Novolin) and metformin (Glucophage) has demonstrated improvement in endothelial function: improved endothelial-dependent dilation (Gaenger et al., 2002). Diabetes is considered equivalent to existing CAD in its risk of a cardiac event within 10 years (Expert Panel on Detection, Evaluation, and Treatment of High Blood Cholesterol in Adults, 2001). Diabetes is discussed in detail in Chapter 41.

## Gender and Estrogen Level

Because heart disease had been considered to primarily affect white men, the disease was not as readily recognized and treated in women. However, in 1999 in the United States, 512,904 women died because of cardiovascular disease whereas 42,144 women died from breast cancer and 246,006 women died from any form of cancer (American Heart Association, 2002). Women tend to have a higher incidence of complications from CAD (American Heart Association, 2002). African-American women have a mortality rate nearly twice that of Caucasian women (Office for Social Environment and Health Research at West Virginia University, 2001). Women tend not to recognize the symptoms as early as men and to wait longer to report their symptoms and seek medical assistance (Meischke et al., 1999; Penque et al., 1998). In the past, women were less likely than men to be referred for coronary artery diagnostic procedures, to receive medical therapy (eg, **thrombolytic** therapy to break down the blood clots that cause acute MI, or nitroglycerin), and to be treated with invasive interventions, eg, angioplasty (Sheifer et al., 2000). It is anticipated that with better education of the general public and health care professionals, gender and racial differences will have less influence on the diagnosis, treatment, and incidence of complications of heart disease in the future.

In women younger than age 55, the incidence of CAD is significantly lower than in men. However, after age 55, the incidence in women is approximately equal to that in men. The age difference of the incidence of CAD in women may be related to estrogen. Although **hormone replacement therapy (HRT)** for menopausal women had been promoted as prevention for CAD, research studies do not support HRT as an effective means of CAD prevention (Hulley et al., 1998; Mosca, 2000). HRT has decreased postmenopausal symptoms and the risk for osteoporosis-related bone fractures, but HRT also has been associated with an increased risk for CAD, breast cancer, deep vein thrombosis, cerebrovascular accident (CVA, brain attack, stroke), and pulmonary embolism. The Women's Health Initiative (Gebbie, 2002) demonstrated that long-term HRT may have more risks than benefits, and that HRT should not be initiated or continued for primary prevention of CAD.

## Behavior Patterns

Most clinicians believe that stress and certain behaviors contribute to the pathogenesis of CAD and a cardiac event, especially in women. Psychological and epidemiologic studies describe behaviors that characterize people who are prone to heart disease: excessive competitiveness, a sense of time urgency or impatience, aggressiveness, and hostility (Dembroski et al., 1989; Friedman

& Rosenman, 1959; Krantz et al., 2000). A person with these behaviors is classified as type A coronary-prone.

The type A coronary-prone classification may not be as significant as was once thought; evidence of its precise role remains inconclusive (Rozanski et al., 1999). To be on the safer side, however, such a person may be wise to alter behaviors and responses to triggering events and to reduce other risk factors. Nurses can assist these people by teaching them cognitive restructuring and relaxation techniques. Because people who are depressed have worse outcomes, these patients should be assessed for signs and symptoms of depression and, if diagnosed, appropriately treated.

## ANGINA PECTORIS

Angina pectoris is a clinical syndrome usually characterized by episodes or paroxysms of pain or pressure in the anterior chest. The cause is usually insufficient coronary blood flow. The insufficient flow results in a decreased oxygen supply to meet an increased myocardial demand for oxygen in response to physical exertion or emotional stress. In other words, the need for oxygen exceeds the supply. The severity of angina is based on the precipitating activity and its effect on the activities of daily living (Table 28-3).

## Pathophysiology

Angina is usually caused by atherosclerotic disease. Almost invariably, angina is associated with a significant obstruction of a major coronary artery. The characteristics of the various types of angina are listed in Chart 28-3. Identifying angina requires obtaining a thorough history. Effective treatment begins with reducing the demands placed on the heart and teaching the patient about the condition. Several factors are associated with typical anginal pain:

- Physical exertion, which can precipitate an attack by increasing myocardial oxygen demand
- Exposure to cold, which can cause vasoconstriction and an elevated blood pressure, with increased oxygen demand
- Eating a heavy meal, which increases the blood flow to the mesenteric area for digestion, thereby reducing the blood supply available to the heart muscle (In a severely compromised heart, shunting of blood for digestion can be sufficient to induce anginal pain.)
- Stress or any emotion-provoking situation, causing the release of adrenaline and increasing blood pressure, which may accelerate the heart rate and increase the myocardial workload

**Table 28-3 • Canadian Cardiovascular Society Classification of Angina**

CLASS	ACTIVITY EVOKING ANGINA	LIMITS TO ACTIVITY
I	Prolonged exertion	None
II	Walking >2 blocks	Slight
III	Walking <2 blocks	Marked
IV	Minimal or rest	Severe

Adapted from Campeau L. (1976). Grading of angina pectoris. *Circulation* 54, 522–523.

Chart  
28-3

## Types of Angina

- **Stable angina:** predictable and consistent pain that occurs on exertion and is relieved by rest
- **Unstable angina** (also called preinfarction angina or crescendo angina): symptoms occur more frequently and last longer than stable angina. The threshold for pain is lower, and pain may occur at rest.
- **Intractable or refractory angina:** severe incapacitating chest pain
- **Variant angina** (also called Prinzmetal's angina): pain at rest with reversible ST-segment elevation; thought to be caused by coronary artery vasospasm
- **Silent ischemia:** objective evidence of ischemia (such as electrocardiographic changes with a stress test), but patient reports no symptoms

Atypical angina is not associated with the listed factors. It may occur at rest.

## Clinical Manifestations

Ischemia of the heart muscle may produce pain or other symptoms, varying in severity from a feeling of indigestion to a choking or heavy sensation in the upper chest that ranges from discomfort to agonizing pain accompanied by severe apprehension and a feeling of impending death. The pain is often felt deep in the chest behind the upper or middle third of the sternum (retrosternal area). Typically, the pain or discomfort is poorly localized and may radiate to the neck, jaw, shoulders, and inner aspects of the upper arms, usually the left arm. The patient often feels tightness or a heavy, choking, or strangling sensation that has a vise-like, insistent quality. The patient with diabetes mellitus may not have severe pain with angina because the neuropathy that accompanies diabetes can interfere with neuroreceptors, dulling the patient's perception of pain.

A feeling of weakness or numbness in the arms, wrists, and hands may accompany the pain, as may shortness of breath, pallor, diaphoresis, dizziness or lightheadedness, and nausea and vomiting. These symptoms may also appear alone and still represent myocardial ischemia. When these symptoms appear alone, they are called angina-like symptoms. Anxiety may accompany angina. An important characteristic of angina is that it abates or subsides with rest or nitroglycerin.

### Gerontologic Considerations

The elderly person with angina may not exhibit the typical pain profile because of the diminished responses of neurotransmitters that occur in the aging process. Often, the presenting symptom in the elderly is dyspnea. If they do have pain, it is atypical pain that radiates to both arms rather than just the left arm. Sometimes, there are no symptoms ("silent" CAD), making recognition and diagnosis a clinical challenge. Elderly patients should be encouraged to recognize their chest pain–like symptom (eg, weakness) as an indication that they should rest or take prescribed medications. Noninvasive stress testing used to diagnose CAD may not be as useful in elderly patients because of other conditions (eg,

peripheral vascular disease, arthritis, degenerative disk disease, physical disability, foot problems) that limit the patient's ability to exercise.

## Assessment and Diagnostic Findings

The diagnosis of angina is often made by evaluating the clinical manifestations of ischemia and the patient's history. A 12-lead ECG and blood laboratory values help in making the diagnosis. The patient may undergo an exercise or pharmacologic stress test in which the heart is monitored by ECG, echocardiogram, or both. The patient may also be referred for an echocardiogram, nuclear scan, or invasive procedures (cardiac catheterization and coronary artery angiography).

CAD is believed to result from inflammation of the arterial endothelium. C-reactive protein (CRP) is a marker for inflammation of vascular endothelium. High blood levels of CRP have been associated with increased coronary artery calcification and risk of an acute cardiovascular event (eg, MI) in seemingly healthy individuals (Ridker et al., 2002; Wang et al., 2002). There is interest in using CRP blood levels as an additional risk factor for cardiovascular disease in clinical use and research, but the clinical value of CRP levels has not been fully established. The ability of CRP to predict cardiovascular disease when adjusted for other risk factors, how CRP levels can guide patient management, and if patient outcomes improve when using CRP levels must be established before CRP levels are used routinely for patient care (Mosca, 2002).

An elevated blood level of homocysteine, an amino acid, has also been proposed as an independent risk factor for cardiovascular disease. However, studies have not supported the relationship between mild to moderate elevations of homocysteine and atherosclerosis (Homocysteine Studies Collaboration, 2002). No study has yet shown that reducing homocysteine levels reduces the risk of CAD.

## Medical Management

The objectives of the medical management of angina are to decrease the oxygen demand of the myocardium and to increase the oxygen supply. Medically, these objectives are met through pharmacologic therapy and control of risk factors.

Revascularization procedures to restore the blood supply to the myocardium include **percutaneous coronary interventional (PCI)** procedures (eg, **percutaneous transluminal coronary angioplasty [PTCA]**, intracoronary stents, and atherectomy), CABG, and percutaneous transluminal myocardial revascularization (PTMR).

### PHARMACOLOGIC THERAPY

Among medications used to control angina are nitroglycerin, beta-adrenergic blocking agents, calcium channel blockers, and antiplatelet agents.

**Nitroglycerin.** Nitrates remain the mainstay for treatment of angina pectoris. A vasoactive agent, nitroglycerin (Nitrostat, Nitrol, Nitrobid IV) is administered to reduce myocardial oxygen consumption, which decreases ischemia and relieves pain. Nitroglycerin dilates primarily the veins and, in higher doses, also dilates the arteries. It helps to increase coronary blood flow by

preventing vasospasm and increasing perfusion through the collateral vessels.

Dilation of the veins causes venous pooling of blood throughout the body. As a result, less blood returns to the heart, and filling pressure (preload) is reduced. If the patient is hypovolemic (does not have adequate circulating blood volume), the decrease in filling pressure can cause a significant decrease in cardiac output and blood pressure.

Nitrates in higher doses also relax the systemic arteriolar bed and lower blood pressure (decreased afterload). Nitrates may increase blood flow to diseased coronary arteries and through collateral coronary arteries, arteries that have been underused until the body recognizes poorly perfused areas. These effects decrease myocardial oxygen requirements and increase oxygen supply, bringing about a more favorable balance between supply and demand.

Nitroglycerin may be given by several routes: sublingual tablet or spray, topical agent, and intravenous administration. Sublingual nitroglycerin is generally placed under the tongue or in the cheek (buccal pouch) and alleviates the pain of ischemia within 3 minutes. Topical nitroglycerin is also fast acting and is a convenient way to administer the medication. Both routes are suitable for patients who self-administer the medication. Chart 28-4 provides more information.

A continuous or intermittent intravenous infusion of nitroglycerin may be administered to the hospitalized patient with recurring signs and symptoms of ischemia or after a revascularization procedure. The amount of nitroglycerin administered is based on the patient's symptoms while avoiding side effects such as hypotension. It usually is not given if the systolic blood pressure is 90 mm Hg or less. Generally, after the patient is symptom free, the

nitroglycerin may be switched to a topical preparation within 24 hours.

**Beta-Adrenergic Blocking Agents.** Beta-blockers such as propranolol (Inderal), metoprolol (Lopressor, Toprol), and atenolol (Tenormin) appear to reduce myocardial oxygen consumption by blocking the beta-adrenergic sympathetic stimulation to the heart. The result is a reduction in heart rate, slowed conduction of an impulse through the heart, decreased blood pressure, and reduced myocardial **contractility** (force of contraction) that establishes a more favorable balance between myocardial oxygen needs (demands) and the amount of oxygen available (supply). This helps to control chest pain and delays the onset of ischemia during work or exercise. Beta-blockers reduce the incidence of recurrent angina, infarction, and cardiac mortality. The dose can be titrated to achieve a resting heart rate of 50 to 60 beats per minute.

Cardiac side effects and possible contraindications include hypotension, bradycardia, advanced atrioventricular block, and decompensated heart failure. If a beta-blocker is given intravenously for an acute cardiac event, the ECG, blood pressure, and heart rate are monitored closely after the medication has been administered. Because some beta-blockers also affect the beta-adrenergic receptors in the bronchioles, causing bronchoconstriction, they are contraindicated in patients with significant pulmonary constrictive diseases, such as asthma. Other side effects include worsening of hyperlipidemia, depression, fatigue, decreased libido, and masking of symptoms of hypoglycemia. Patients taking beta-blockers are cautioned not to stop taking them abruptly, because angina may worsen and MI may develop. Beta-blocker therapy needs to

#### Chart 28-4 • PHARMACOLOGY Self-Administration of Nitroglycerin

Most patients with angina pectoris must self-administer nitroglycerin on an as-needed basis. A key nursing role in such cases is educating patients about the medication and how to take it. Sublingual nitroglycerin comes in tablet and spray forms.

##### Teaching About Sublingual Nitroglycerin

- Instruct the patient to make sure the mouth is moist, the tongue is still, and saliva is not swallowed until the nitroglycerin tablet dissolves. If the pain is severe, the patient can crush the tablet between the teeth to hasten sublingual absorption.
- Advise the patient to carry the medication at all times as a precaution. However, because nitroglycerin is very unstable, it should be carried securely in its original container (eg, capped dark glass bottle); tablets should never be removed and stored in metal or plastic pillboxes.
- Explain that nitroglycerin is volatile and is inactivated by heat, moisture, air, light, and time. Instruct the patient to renew the nitroglycerin supply every 6 months.
- Inform the patient that the medication should be taken in anticipation of any activity that may produce pain. Because nitroglycerin increases tolerance for exercise and stress when taken prophylactically (ie, before angina-producing activity, such as exercise, stair-climbing, or sexual intercourse), it is best taken before pain develops.
- Recommend that the patient note how long it takes for the nitroglycerin to relieve the discomfort. Advise the patient that if pain persists after taking three sublingual tablets at 5-minute intervals, emergency medical services should be called.

- Discuss possible side effects of nitroglycerin, including flushing, throbbing headache, hypotension, and tachycardia.

##### Teaching About Topical Nitroglycerin

Nitroglycerin is also available in a lanolin-petrolatum base that is applied to the skin as a paste or a patch. Patients who use topical nitroglycerin need additional instruction.

- Advise the patient to read the instructions that accompany the product, because instructions vary according to the preparation. Also remind the patient to rotate the site of application to avoid skin irritation.
- Explain that the area of application needs to be an area that is well perfused for absorption to occur. Therefore, the medication should not be applied to areas with extensive body hair or scar tissue.
- Recommend that the patient protect clothing from the oil base in the paste.
- Explain that a long-term equally spaced dosing schedule of application of topical nitroglycerin is generally avoided to prevent tolerance (when the body does not respond as well to the same amount of medication). Most physicians prescribe application of topical nitroglycerin paste three or four times daily or every 6 hours (excluding the mid-night dose), and application of the nitroglycerin patch every morning and removed at 10 PM. This dosing regimen allows for a 6- to 8-hour nitrate-free period to prevent the body's development of tolerance.

be decreased gradually over several days before discontinuing it. Patients with diabetes who take beta-blockers are instructed to assess their blood glucose levels more often and to observe for signs and symptoms of hypoglycemia.

**Calcium Channel Blocking Agents.** Calcium channel blockers (calcium ion antagonists) have different effects. Some decrease sinoatrial node automaticity and atrioventricular node conduction, resulting in a slower heart rate and a decrease in the strength of the heart muscle contraction (negative inotropic effect). These effects decrease the workload of the heart. Calcium channel blockers also relax the blood vessels, causing a decrease in blood pressure and an increase in coronary artery perfusion. Calcium channel blockers increase myocardial oxygen supply by dilating the smooth muscle wall of the coronary arterioles; they decrease myocardial oxygen demand by reducing systemic arterial pressure and the workload of the left ventricle.

The calcium channel blockers most commonly used are amlodipine (Norvasc), verapamil (Calan, Isoptin, Verelan), and diltiazem (Cardizem, Dilacor, Tiazac). They may be used by patients who cannot take beta-blockers, who develop significant side effects from beta-blockers or nitrates, or who still have pain despite beta-blocker and nitroglycerin therapy. Calcium channel blockers are used to prevent and treat vasospasm, which commonly occurs after an invasive interventional procedure. Use of short-acting nifedipine (Procardia) was found to be poorly tolerated and to increase the risk of MI in patients with hypertension and the risk of death in patients with **acute coronary syndrome** (Braunwald et al., 2000; Furberg et al., 1996; Ryan et al., 1999).

First-generation calcium channel blockers should be avoided or used with great caution in people with heart failure, because they decrease myocardial contractility. Amlodipine (Norvasc) and felodipine (Plendil) are the calcium channel blockers of choice for patients with heart failure. Hypotension may occur after the intravenous administration of any of the calcium channel blockers. Other side effects that may occur include atrioventricular blocks, bradycardia, constipation, and gastric distress.

**Antiplatelet and Anticoagulant Medications.** Antiplatelet medications are administered to prevent platelet aggregation, which impedes blood flow.

**Aspirin.** Aspirin prevents platelet activation and reduces the incidence of MI and death in patients with CAD. A 160- to 325-mg dose of aspirin should be given to the patient with angina as soon as the diagnosis is made (eg, in the emergency room or physician's office) and then continued with 81 to 325 mg daily. Although it may be one of the most important medications in the treatment of CAD, aspirin may be overlooked because of its low cost and common use. Patients should be advised to continue aspirin even if concurrently taking nonsteroidal anti-inflammatory drugs (NSAIDs) or other analgesics. Because aspirin may cause gastrointestinal upset and bleeding, treatment of *Helicobacter pylori* and the use of H<sub>2</sub>-blockers (eg, cimetidine [Tagamet], famotidine [Mylanta AR, Pepcid], ranitidine [Zantac]) or misoprostol (Cytotec) should be considered to allow continued aspirin therapy.

**Clopidogrel and Ticlopidine.** Clopidogrel (Plavix) or ticlopidine (Ticlid) is given to patients who are allergic to aspirin or given in addition to aspirin in patients at high risk for MI. Unlike aspirin, these medications take a few days to achieve their antiplatelet effect. They also cause gastrointestinal upset, including nausea, vomiting, and diarrhea, and they decrease the neutrophil level.

**Heparin.** Unfractionated heparin prevents the formation of new blood clots. Use of heparin alone in treating patients with unstable angina reduces the occurrence of MI. If the patient's signs and symptoms indicate a significant risk for a cardiac event, the patient is hospitalized and may be given an intravenous bolus of heparin and started on a continuous infusion or given an intravenous bolus every 4 to 6 hours. The amount of heparin administered is based on the results of the activated partial thromboplastin time (aPTT). Heparin therapy is usually considered therapeutic when the aPTT is 1.5 to 2 times the normal aPTT value.

A subcutaneous injection of low-molecular-weight heparin (LMWH; enoxaparin [Lovenox] or dalteparin [Fragmin]) may be used instead of intravenous unfractionated heparin to treat patients with unstable angina or non-ST-segment elevation MIs. LMWH provides more effective and stable anticoagulation, potentially reducing the risk of rebound ischemic events, and it eliminates the need to monitor aPTT results (Cohen, 2001). LMWH may be beneficial before and during PCIs and for ST-segment elevation MIs.

Because unfractionated heparin and LMWH increase the risk of bleeding, the patient is monitored for signs and symptoms of external and internal bleeding, such as low blood pressure, an increased heart rate, and a decrease in serum hemoglobin and hematocrit values. The patient receiving heparin is placed on bleeding precautions, which include:

- Applying pressure to the site of any needle puncture for a longer time than usual
- Avoiding intramuscular injections
- Avoiding tissue injury and bruising from trauma or use of constrictive devices (eg, continuous use of an automatic blood pressure cuff)

A decrease in platelet count or skin lesions at heparin injection sites may indicate heparin-induced thrombocytopenia (HIT), an antibody-mediated reaction to heparin that may result in thrombosis (Hirsh et al., 2001). Patients who have received heparin within the past 3 months and those who have been receiving unfractionated heparin for 5 to 15 days are at high risk for HIT.

**GPIIb/IIIa Agents.** Intravenous GPIIb/IIIa agents (abciximab [ReoPro], tirofiban [Aggrastat], eptifibatid [Integrelin]) are indicated for hospitalized patients with unstable angina and as adjunct therapy for PCI. These agents prevent platelet aggregation by blocking the GPIIb/IIIa receptors on the platelet, preventing adhesion of fibrinogen and other factors that crosslink platelets to each other and thereby allow platelets to form a thrombus (clot). As with heparin, bleeding is the major side effect, and bleeding precautions should be initiated.

**Oxygen Administration.** Oxygen therapy is usually initiated at the onset of chest pain in an attempt to increase the amount of oxygen delivered to the myocardium and to decrease pain. Oxygen inhaled directly increases the amount of oxygen in the blood. The therapeutic effectiveness of oxygen is determined by observing the rate and rhythm of respirations. Blood oxygen saturation is monitored by pulse oximetry; the normal oxygen saturation (SpO<sub>2</sub>) level is greater than 93%. Studies are being conducted to assess the use of oxygen in patients without respiratory distress and its effect on outcome.

## ALTERNATIVE THERAPIES

Researchers have reported significant improvement in the exercise endurance of patients with angina who were treated with

acupuncture as well as with an intravenous infusion of a combination of ginseng (*Panax quinquefolium*), astragalus (*Astragalus membranaceus*), and angelica (*Angelica sinensis*) (Ballegaard et al., 1991; Reichter et al., 1991). Coenzyme Q10 was advocated for preventing the occurrence and progression of heart failure (Khatta et al., 2000). However, there have not been large, randomized, placebo-controlled studies that identify the direct beneficial effect from these therapies.

## NURSING PROCESS: THE PATIENT WITH ANGINA PECTORIS

### Assessment

The nurse gathers information about the patient's symptoms and activities, especially those that precede and precipitate attacks of angina pectoris. Appropriate questions are identified in Table 28-4, using a PQRST format. Other helpful questions may be asked. How long does the angina usually last? Does nitroglycerin relieve the angina? If so, how many tablets or sprays are needed to achieve relief? How long does it take for relief to occur?

The answers to these questions form a basis for designing a logical program of treatment and prevention. In addition to assessing angina pectoris or its equivalent, the nurse also assesses the patient's risk factors for CAD, the patient's response to angina, the patient's and family's understanding of the diagnosis, and adherence to the current treatment plan.

### Diagnosis

#### NURSING DIAGNOSES

Based on the assessment data, major nursing diagnoses for the patient may include:

- Ineffective myocardial tissue perfusion secondary to CAD, as evidenced by chest pain or equivalent symptoms
- Anxiety related to fear of death
- Deficient knowledge about the underlying disease and methods for avoiding complications
- Noncompliance, ineffective management of therapeutic regimen related to failure to accept necessary lifestyle changes

### COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Potential complications that may develop include the following, which are discussed in the chapters indicated:

- Acute pulmonary edema (see Chap. 30)
- Congestive heart failure (see Chap. 30)
- Cardiogenic shock (see Chap. 30)
- Dysrhythmias and cardiac arrest (see Chaps. 27 and 30)
- MI (described later in this chapter)
- Myocardial rupture (see Chap. 30)
- Pericardial effusion and cardiac tamponade (see Chap. 30)

### Planning and Goals

The major patient goals include immediate and appropriate treatment when angina occurs, prevention of angina, reduction of anxiety, awareness of the disease process and understanding of the prescribed care, adherence to the self-care program, and absence of complications.

### Nursing Interventions

#### TREATING ANGINA

If the patient reports pain (or the individual's equivalent to pain), the nurse takes immediate action. When a patient experiences angina, the nurse should direct the patient to stop all activities and sit or rest in bed in a semi-Fowler position to reduce the oxygen requirements of the ischemic myocardium. The nurse assesses the patient's angina, asking questions to determine whether the angina is the same as the patient typically experiences. A difference may indicate a worsening of the disease or a different cause. The nurse then continues to assess the patient, measuring vital signs and observing for signs of respiratory distress. If the patient is in the hospital, a 12-lead ECG is usually obtained and scrutinized for ST-segment and T-wave changes. If the patient has been placed on cardiac monitoring with continuous ST-segment monitoring, the ST segment is assessed for changes.

Nitroglycerin is administered sublingually, and the patient's response is assessed (relief of chest pain and effect on blood pressure and heart rate). If the chest pain is unchanged or is lessened but still present, nitroglycerin administration is repeated up to three doses.

Table 28-4 • Assessment of Angina

ACRONYM	FACTORS ABOUT PAIN THAT NEED TO BE ASSESSED	ASSESSMENT QUESTIONS
P	Position/Location Provocation	"Where is the pain? Can you point to it?" "What were you doing when the pain began?"
Q	Quality Quantity	"How would you describe the pain?" "Is it like the pain you had before?" "Has the pain been constant?"
R	Radiation Relief	"Can you feel the pain anywhere else?" "Did anything make the pain better?"
S	Severity	"How would you rate the pain on a 0–10 scale with 0 being no pain and 10 being the most amount of pain?" (or use visual analog scale or adjective rating scale)
T	Symptoms Timing	"Did you notice any other symptoms with the pain?" "How long ago did the pain start?"

From Casey, P. E., Morrissey, A., & Nolan, E. M. (1998). Ischemic heart disease. In M. R. Kinney, B. S. Dunbar, J. A. Brooks-Brunn, et al. (Eds.), *AACN clinical reference for critical care nursing* (4th ed.). St. Louis: Mosby.

Each time, blood pressure, heart rate, and the ST segment (if the patient is on a monitor with ST segment monitoring capability) are assessed. The nurse administers oxygen therapy if the patient's respiratory rate is increased or the oxygen saturation level is decreased. Although there is no documentation of its effect on outcome, oxygen is usually administered at 2 L/min by nasal cannula, even without evidence of respiratory distress. If the pain is significant and continues after these interventions, the patient is usually transferred to a higher-acuity nursing unit.

### REDUCING ANXIETY

Patients with angina often fear loss of their roles within society and the family. They may also be fearful that the pain may lead to an MI or death. Exploring the implications that the diagnosis has for the patient and providing information about the illness, its treatment, and methods of preventing its progression are important nursing interventions. Various stress reduction methods should be explored with the patient. For example, music therapy, in which patients are given the opportunity to listen to selected music through headphones for a predetermined duration, has been shown to reduce anxiety in patients who are in a coronary care unit and may serve as an adjunct to therapeutic communication (Chlan & Tracy, 1999; Evans, 2002). Addressing the spiritual needs of the patient and family may also assist in allaying anxieties and fears.

### PREVENTING PAIN

The nurse reviews the assessment findings, identifies the level of activity that causes the patient's pain, and plans the patient's activities accordingly. If the patient has pain frequently or with minimal activity, the nurse alternates the patient's activities with rest periods. Balance of activity and rest is an important aspect of the educational plan for the patient and family.

### PROMOTING HOME AND COMMUNITY-BASED CARE

**Teaching Patients Self-Care.** Learning about the modifiable risk factors that contribute to the continued development of CAD and resulting angina is essential. Exploring with the patient and

family what they see as their priority in managing the disease and developing a plan based on their priorities can assist with patient adherence to the therapeutic regimen. It is important to explore with the patient methods to avoid, modify, or adapt the triggers for anginal pain. The teaching program for the patient with angina is designed so that the patient and family can explain the illness, identify the symptoms of myocardial ischemia, state the actions to take when symptoms develop, and discuss methods to prevent chest pain and the advancement of CAD. The goals of the educational program are to reduce the frequency and severity of anginal attacks, to delay the progress of the underlying disease, if possible, and to prevent any complications. The factors outlined in the accompanying checklist Chart 28-5 are important in educating the patient with angina pectoris.

The self-care program is prepared in collaboration with the patient and family or friends. Activities should be planned to minimize the occurrence of angina episodes. The patient needs to understand that any pain unrelieved within 15 minutes by the usual methods (see Chart 28-4) should be treated at the closest emergency center; the patient should call 911 for assistance.

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include:

1. Reports that pain is relieved promptly
  - a. Recognizes symptoms
  - b. Takes immediate action
  - c. Seeks medical assistance if pain persists or changes in quality
2. Reports decreased anxiety
  - a. Expresses acceptance of diagnosis
  - b. Expresses control over choices within medical regimen
  - c. Does not exhibit signs and symptoms that indicate a high level of anxiety
3. Understands ways to avoid complications and demonstrates freedom from complications
  - a. Describes the process of angina

Chart 28-5

### Home Care Checklist • Managing Angina Pectoris

At the completion of the home care instruction, the patient or caregiver will be able to:

	Patient	Caregiver

- b. Explains reasons for measures to prevent complications
  - c. Exhibits normal ECG and cardiac enzyme levels
  - d. Experiences no signs and symptoms of acute MI
4. Adheres to self-care program
    - a. Takes medications as prescribed
    - b. Keeps health care appointments
    - c. Implements plan for reducing risk factors

## MYOCARDIAL INFARCTION

### Pathophysiology

MI refers to the process by which areas of myocardial cells in the heart are permanently destroyed. Like unstable angina, MI is usually caused by reduced blood flow in a coronary artery due to atherosclerosis and occlusion of an artery by an embolus or thrombus. Because unstable angina and acute MI are considered to be the same process but different points along a continuum, the term **acute coronary syndrome** (ACS) may be used for these diagnoses. Other causes of an MI include vasospasm (sudden constriction or narrowing) of a coronary artery; decreased oxygen supply (eg, from acute blood loss, anemia, or low blood pressure); and increased demand for oxygen (eg, from a rapid heart rate, thyrotoxicosis, or ingestion of cocaine). In each case, a profound imbalance exists between myocardial oxygen supply and demand.

Coronary occlusion, heart attack, and MI are terms used synonymously, but the preferred term is MI. The area of infarction takes time to develop. As the cells are deprived of oxygen, ischemia develops, cellular injury occurs, and over time, the lack of oxygen results in infarction, or the death of cells. The expression “time is muscle” reflects the urgency of appropriate treatment to improve patient outcomes. Each year in the United States, nearly 1 million people have acute MIs; one fourth of these people die of MI (American Heart Association, 2001; Ryan et al., 1999). One half of those who die never reach a hospital.

Various descriptions are used to further identify an MI: the location of the injury to the left ventricular wall (anterior, inferior, posterior, or lateral wall) or to the right ventricle and the point in time within the process of infarction (acute, evolving, or old).

The ECG usually identifies the location, and the ECG and patient history identify the timing. Regardless of the location of the infarction of cardiac muscle, the goal of medical therapy is to prevent or minimize myocardial tissue death and to prevent complications. The pathophysiology of heart disease and the risk factors involved are discussed earlier in this chapter.

### Clinical Manifestations

Chest pain that occurs suddenly and continues despite rest and medication is the presenting symptom in most patients with an MI (Chart 28-6). One study showed that 2% of patients who eventually were diagnosed with an acute MI were incorrectly discharged and sent home from the emergency department (Pope et al., 2000). Most of these patients presented with atypical symptoms such as shortness of breath; they also tended to be female, younger than 55 years of age, of a minority group, and have normal ECGs. The Framingham Heart Study revealed that 50% of the men and 63% of the women who died suddenly of cardiovascular disease had no previous symptoms (Kannel, 1986). Patients may also be anxious and restless. They may have cool, pale, and moist skin. Their heart rate and respiratory rate may be faster than normal. These signs and symptoms, which are caused by stimulation of the sympathetic nervous system, may be present only for a short time or may not be present, or only some of them

### Chart 28-6 • ASSESSMENT

#### Signs and Symptoms of an Acute Myocardial Infarction (MI) or Acute Coronary Syndrome (ACS)

##### Cardiovascular

Chest pain or discomfort, palpitations. Heart sounds may include  $S_3$ ,  $S_4$ , and new onset of a murmur. Increased jugular venous distention may be seen if the MI has caused heart failure. Blood pressure may be elevated because of sympathetic stimulation or decreased because of decreased contractility, impending cardiogenic shock, or medications. Pulse deficit may indicate atrial fibrillation. In addition to ST-segment and T-wave changes, ECG may show tachycardia, bradycardia, and dysrhythmias.

##### Respiratory

Shortness of breath, dyspnea, tachypnea, and crackles if MI has caused pulmonary congestion. Pulmonary edema may be present.

##### Gastrointestinal

Nausea and vomiting.

##### Genitourinary

Decreased urinary output may indicate cardiogenic shock.

##### Skin

Cool, clammy, diaphoretic, and pale appearance due to sympathetic stimulation from loss of contractility may indicate cardiogenic shock. Dependent edema may also be present due to poor contractility.

##### Neurologic

Anxiety, restlessness, light-headedness may indicate increased sympathetic stimulation or a decrease in contractility and cerebral oxygenation. The same symptoms may also herald cardiogenic shock. Headache, visual disturbances, altered speech, altered motor function, and further changes in level of consciousness may indicate cerebral bleeding if patient is receiving thrombolytics.

##### Psychological

Fear with feeling of impending doom, or patient may deny that anything is wrong.

may occur. In many cases, the signs and symptoms of MI cannot be distinguished from those of unstable angina.

### Assessment and Diagnostic Findings

Diagnosis of MI is generally based on the presenting symptoms, the ECG, and laboratory test results (eg, serial serum enzyme values). The prognosis depends on the severity of coronary artery obstruction and the extent of myocardial damage. Physical examination is always conducted, but the examination alone is insufficient to confirm the diagnosis.

#### PATIENT HISTORY

The patient history has two parts: the description of the presenting symptom (eg, pain) and the history of previous illnesses and family health history, particularly of heart disease. Previous history should also include information about the patient's risk factors for heart disease.

#### ELECTROCARDIOGRAM

The ECG provides information that assists in diagnosing acute MI. It should be obtained within 10 minutes from the time a patient reports pain or arrives in the emergency department. By monitoring the ECG over time, the location, evolution, and resolution of an MI can be identified and monitored.

The ECG changes that occur with an MI are seen in the leads that view the involved surface of the heart. The classic ECG changes are T-wave inversion, ST-segment elevation, and development of an abnormal Q wave (Fig. 28-4). Because infarction evolves over time, the ECG also changes over time. The first ECG signs of an acute MI are from myocardial ischemia and injury. Myocardial injury causes the T wave to become enlarged and symmetric. As the area of injury becomes ischemic, myocardial repolarization is altered and delayed, causing the T wave to invert. The ischemic region may remain depolarized while adjacent areas of the myocardium return to the resting state. Myocardial injury also causes ST-segment changes. The injured myocardial cells depolarize normally but repolarize more rapidly than normal cells, causing the ST segment to rise at least 1 mm above the isoelectric line (area between the T wave and the next P wave is used as the reference for the isoelectric line) when measured 0.08 seconds after the end of the QRS. If the myocardial injury is on the endocardial surface, the ST segment is depressed 1 mm or more for at least 0.08 seconds. The ST-segment depression is usually horizontal or has a downward slope (Wagner, 2001).

MI is classified as a Q-wave or non-Q-wave infarction. With Q-wave infarction, abnormal Q waves develop within 1 to 3 days because there is no depolarization current conducted from necrotic tissue (Wagner, 2001). The lead system then views the flow of current from other parts of the heart. An abnormal Q wave is 0.04 seconds or longer, 25% of the R-wave depth (provided the R wave exceeds a depth of 5 mm), or one that did not exist before the event (Wagner, 2001). An acute MI may cause a significant decrease in the height of the R wave. During an acute MI, injury and ischemic changes are also present. An abnormal Q wave may be present without ST-segment and T-wave changes, which indicates an old, not acute, MI. Patients with non-Q-wave MIs do not develop a Q wave on the ECG after the ST-segment and T-wave changes, but symptoms and cardiac enzyme analysis confirm the diagnosis of an MI.

During recovery from an MI, the ST segment often is the first to return to normal (1 to 6 weeks). The T wave becomes large and

symmetric for 24 hours, and it then inverts within 1 to 3 days for 1 to 2 weeks. Q-wave alterations are usually permanent. An old Q-wave MI is usually indicated by an abnormal Q wave or decreased height of the R wave without ST-segment and T-wave changes.

### ECHOCARDIOGRAM

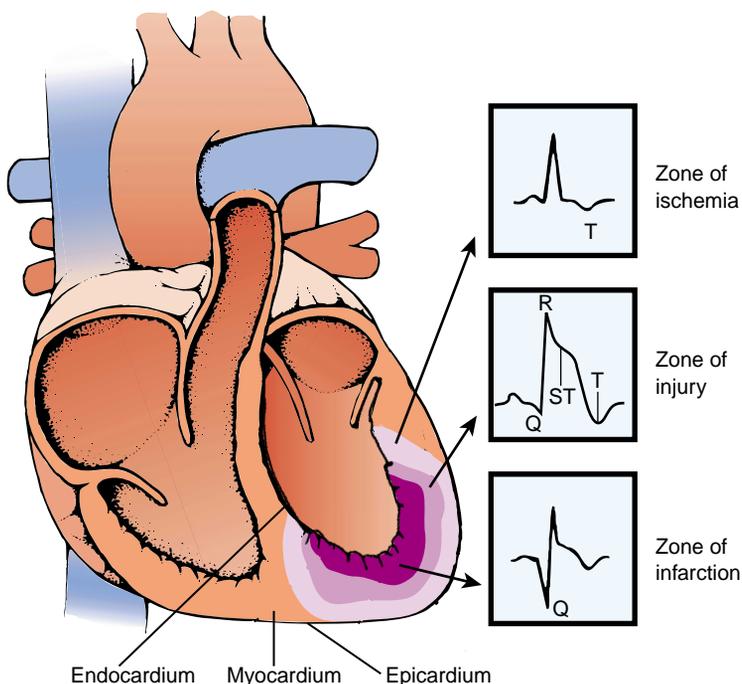

The echocardiogram is used to evaluate ventricular function. It may be used to assist in diagnosing an MI, especially when the ECG is nondiagnostic. The echocardiogram can detect hypokinetic and akinetic wall motion and can determine the ejection fraction (see Chap. 26).

### LABORATORY TESTS

Historically, laboratory tests used to diagnose an MI included **creatin kinase (CK)**, with evaluation of isoenzymes and lactic dehydrogenase (LDH) levels. Newer laboratory tests with faster results, resulting in earlier diagnosis, include myoglobin and troponin analysis. These tests are based on the release of cellular contents into the circulation when myocardial cells die. Table 28-5 shows the time courses of cardiac enzymes. An LDH test is now infrequently ordered because it is not useful in identifying cardiac events (Braunwald et al., 2000).

**Creatine Kinase and Its Isoenzymes.** There are three CK isoenzymes: CK-MM (skeletal muscle), CK-MB (heart muscle), and CK-BB (brain tissue). CK-MB is the cardiac-specific isoenzyme; CK-MB is found mainly in cardiac cells and therefore rises only when there has been damage to these cells. CK-MB assessed by mass assay is the most specific index for the diagnosis of acute MI (Braunwald et al., 2001). The level starts to increase within a few hours and peaks within 24 hours of an MI. If the area is reperfused (eg, due to thrombolytic therapy or PTCA), it peaks earlier.

**Myoglobin.** Myoglobin is a heme protein that helps to transport oxygen. Like CK-MB enzyme, myoglobin is found in cardiac and skeletal muscle. The myoglobin level starts to increase within 1 to 3 hours and peaks within 12 hours after the onset of symptoms.

**FIGURE 28-4** Effects of ischemia, injury, and infarction on ECG recording. Ischemia causes inversion of T wave because of altered repolarization. Cardiac muscle injury causes elevation of the ST segment and tall, symmetrical T waves. With Q-wave infarction, Q or QS waves develop because of the absence of depolarization current from the necrotic tissue and opposing currents from other parts of the heart.

**Table 28-5 • Serum Markers of Acute Myocardial Infarction**

SERUM TEST	EARLIEST INCREASE (HR)	TEST RUNNING TIME (MIN)	PEAK (HR)	RETURN TO NORMAL
Total CK	3–6	30–60	24–36	3 days
CK-MB: isoenzyme	4–8	30–60	12–24	3–4 days
mass assay	2–3	30–60	10–18	3–4 days
Myoglobin	1–3	30–60	4–12	12 hr
Troponin T or I	3–4	30–60	4–24	1–3 wk

Resource assistance by June Price, Laboratory Manager, Kaiser Permanente.

The test takes only a few minutes to run. An increase in myoglobin is not very specific in indicating an acute cardiac event; however, negative results are an excellent parameter for ruling out an acute MI. If the first myoglobin test results are negative, the test may be repeated 3 hours later. Another negative test result confirms that the patient did not have an MI.

**Troponin.** Troponin, a protein found in the myocardium, regulates the myocardial contractile process. There are three isomers of troponin (C, I, and T). Because of the smaller size of this protein and the increased specificity of the troponins I and T for cardiac muscle, these tests are used more frequently to identify myocardial injury (unstable angina or acute MI). The increase in the level of troponin in the serum starts and peaks at approximately the same time as CK-MB. However, it remains elevated for a longer period, often up to 3 weeks, and it therefore cannot be used to identify subsequent extension or expansion of an MI.

## Medical Management

The goal of medical management is to minimize myocardial damage, preserve myocardial function, and prevent complications. These goals are achieved by reperfusing the area with the emergency use of thrombolytic medications or PTCA. Minimizing myocardial damage is also accomplished by reducing myocardial oxygen demand and increasing oxygen supply with medications, oxygen administration, and bed rest. The resolution of pain and ECG changes are the primary clinical indicators that demand and supply are in equilibrium; they may also indicate reperfusion. Visualization of blood flow through an open vessel in the catheterization laboratory is evidence of reperfusion.

## PHARMACOLOGIC THERAPY

The patient with an acute MI receives the same medications as the patient with unstable angina, with the possible additions of thrombolytics, analgesics, and angiotensin-converting enzyme (ACE) inhibitors. Patients should receive a beta-blocker initially, throughout the hospitalization, and a prescription to continue its use after hospital discharge.

**Thrombolytics.** Thrombolytics are medications that are usually administered intravenously, although some may also be given directly into the coronary artery in the cardiac catheterization laboratory (Chart 28-7). The purpose of thrombolytics is to dissolve and lyse the thrombus in a coronary artery (thrombolysis), allowing blood to flow through the coronary artery again (reperfusion), minimizing the size of the infarction, and preserving ventricular function. Even though thrombolytics may dissolve the thrombus, they do not affect the underlying atherosclerotic lesion. The patient may be referred for a cardiac catheterization and other invasive interventions.

Thrombolytics dissolve all clots, not just the one in the coronary artery. They should not be used if the patient has formed a protective clot, such as after major surgery or hemorrhagic stroke. Because thrombolytics reduce the patient's ability to form a stabilizing clot, the patient is at risk for bleeding. Thrombolytics should not be used if the patient is bleeding or has a bleeding disorder. All patients who receive thrombolytic therapy are placed on bleeding precautions to minimize the risk for bleeding. This means minimizing the number of punctures for inserting intravenous lines, avoiding intramuscular injections, preventing tissue trauma, and applying pressure for longer than usual after any puncture.

### Chart 28-7

## Administration of Thrombolytic Therapy

### Indications

- Chest pain for longer than 20 minutes, unrelieved by nitroglycerin
- ST-segment elevation in at least two leads that face the same area of the heart
- Less than 24 hours from onset of pain

### Absolute Contraindications

- Active bleeding
- Known bleeding disorder
- History of hemorrhagic stroke
- History of intracranial vessel malformation
- Recent major surgery or trauma
- Uncontrolled hypertension
- Pregnancy

### Nursing Considerations

- Minimize the number of times the patient's skin is punctured.
- Avoid intramuscular injections.
- Draw blood for laboratory tests when starting the IV line.
- Start IV lines before thrombolytic therapy; designate one line to use for blood draws.
- Avoid continual use of noninvasive blood pressure cuff.
- Monitor for acute dysrhythmias, hypotension, and allergic reaction.
- Monitor for reperfusion: resolution of angina or acute ST-segment changes.
- Check for signs and symptoms of bleeding: decrease in hematocrit and hemoglobin values, decrease in blood pressure, increase in heart rate, oozing or bulging at invasive procedure sites, back pain, muscle weakness, changes in level of consciousness, complaints of headache
- Treat major bleeding by discontinuing thrombolytic therapy and any anticoagulants; apply direct pressure and notify the physician immediately.
- Treat minor bleeding by applying direct pressure if accessible and appropriate; continue to monitor.

To be effective, thrombolytics must be administered as early as possible after the onset of symptoms that indicate an acute MI. They are not given to patients with unstable angina. Hospitals monitor their ability to administer these medications within 30 minutes from the time the patient arrives in the emergency department. This is called *door-to-needle time* (Ryan et al., 1999). The thrombolytic agents used most often are **streptokinase** (Kabikinase, Streptase), alteplase (Activase), and reteplase (r-PA, TNKase). Anistreplase (Eminase) is another thrombolytic agent that may be used.

Streptokinase increases the amount of plasminogen activator, which then increases the amount of circulating and clot-bound plasmin. Because streptokinase is made from a bacterium, its use also entails a risk of an allergic reaction. Vasculitis has occurred up to 9 days after administration. Streptokinase is not used if the patient has been exposed to a recent *Streptococcus* infection or has received streptokinase in the past 6 to 12 months.

Alteplase is a type of tissue plasminogen activator (t-PA). In contrast to streptokinase, alteplase activates the plasminogen on the clot more than the circulating plasminogen. Because it does not decrease the clotting factors as much as streptokinase, unfractionated or low molecular weight heparin is used with t-PA to prevent another clot from forming at the same lesion site. Because t-PA is a naturally occurring enzyme, allergic reactions are minimized, but t-PA costs considerably more than streptokinase.

Reteplase is structurally very similar to alteplase and has similar effects. Anistreplase is similar to streptokinase and has similar effects.

**Analgesics.** The analgesic of choice for acute MI is morphine sulfate (Duramorph, Astramorph) administered in intravenous boluses. Morphine reduces pain and anxiety. It reduces preload, which decreases the workload of the heart. Morphine also relaxes bronchioles to enhance oxygenation. The cardiovascular response to morphine is monitored carefully, particularly the blood pressure, which can be lowered, and the respiratory rate, which can be depressed. Because morphine decreases sensation of pain, ST-segment monitoring may be a better indicator of subsequent ischemia than assessment of pain.

**Angiotensin-Converting Enzyme Inhibitors (ACE-I).** Angiotensin I is formed when the kidneys release renin in response to decreased blood flow. Angiotensin I is converted to angiotensin II by ACE, a substance found in the lumen of all blood vessels, especially the pulmonary vasculature. Angiotensin II causes the blood vessels to constrict and the kidneys to retain sodium and fluid while excreting potassium. These actions increase circulating fluid and raise the pressure against which the heart must pump, resulting in significantly increased cardiac workload. **ACE inhibitors (ACE-I)** prevent the conversion of angiotensin from I to II. In the absence of angiotensin II, the blood pressure decreases and the kidneys excrete sodium and fluid (diuresis), decreasing the oxygen demand of the heart. Use of ACE inhibitors in patients after MI decreases the mortality rate and prevents the onset of heart failure. It is important to ensure that the patient is not hypotensive, hyponatremic, hypovolemic, or hyperkalemic before ACE-I administration. Blood pressure, urine output, and serum sodium, potassium, and creatinine levels need to be monitored closely.

### EMERGENT PERCUTANEOUS CORONARY INTERVENTION (PCI)

The patient in whom an acute MI is suspected may be referred for an immediate PCI. PCI may be used to open the occluded coronary artery in an acute MI and promote reperfusion to the area that has been deprived of oxygen. PCI treats the underlying atherosclerotic lesion. Because the duration of oxygen deprivation is directly related to the number of cells that die, the time from the patient's

arrival in the emergency department to the time PCI is performed should be less than 60 minutes (time is muscle). This is frequently referred to as *door-to-balloon time* (Smith et al., 2001). To perform an emergent PCI within this short time, a cardiac catheterization laboratory and staff must be available.

## Cardiac Rehabilitation

After the MI patient is free of symptoms, an active rehabilitation program is initiated. Cardiac rehabilitation is a program that targets risk reduction by means of education, individual and group support, and physical activity. Most insurance programs, including Medicare, cover the cost of a cardiac rehabilitation program. However, some studies indicate that only 8% to 39% of patients who are candidates for cardiac rehabilitation services typically participate in these programs (Wenger et al., 1995; Williams et al., 2002).

The goals of rehabilitation for the patient with an MI are to extend and improve the quality of life. The immediate objectives are to limit the effects and progression of atherosclerosis, return the patient to work and a pre-illness lifestyle, enhance the psychosocial and vocational status of the patient, and prevent another cardiac event. These objectives are accomplished by encouraging physical activity and physical conditioning, educating patient and family, and providing counseling and behavioral interventions.

Throughout all phases of rehabilitation, the goals of activity and exercise tolerance are achieved through gradual physical conditioning, aimed at improving cardiac efficiency over time. Cardiac efficiency is achieved when work and activities of daily living can be performed at a lower heart rate and lower blood pressure, thereby reducing the heart's oxygen requirements and reducing cardiac workload.

Physical conditioning is achieved gradually over time. It is not unusual for patients to "overdo it" in an attempt to achieve their goals too rapidly. Patients are observed for chest pain, dyspnea, weakness, fatigue, and palpitations and are instructed to stop exercise if any of the symptoms develop. In a monitored program, they are also monitored for an increase in heart rate above the target heart rate, an increase in systolic or diastolic blood pressure more than 20 mm Hg, a decrease in systolic blood pressure, onset or worsening of dysrhythmias, or ST-segment changes on the ECG.

The target heart rate in phase I is an increase of less than 10% from the resting heart rate, or 120 beats per minute. In phase II, the target heart rate is based on the results of the patient's stress test (usually 60% to 85% of the heart rate at which symptoms occurred), medications, and underlying condition. Oxygen saturation may also be assessed to ensure that it remains higher than 93%. If signs or symptoms occur, the patient is instructed to slow down or stop exercising. If the patient is exercising in an unmonitored program, he or she is cautioned to cease activity immediately if signs or symptoms occur and to seek appropriate medical attention. Table 28-6 identifies conditions in which an unmonitored home exercise program is not recommended.

Patients who are able to walk at 3 to 4 miles per hour are usually able to resume sexual activities. The nurse recommends that the patient be well rested and in a familiar setting; wait at least 1 hour after eating or drinking alcohol; and use a comfortable position. The patient is cautioned against anal sex. Sexual dysfunction or cardiac symptoms should be reported to the health care provider.

### PHASES OF CARDIAC REHABILITATION

Cardiac rehabilitation occurs along the continuum of the disease and is typically categorized in three phases. Phase I may begin with the diagnosis of atherosclerosis, which may occur when the

**Table 28-6 • Contraindications to Unsupervised Home Exercise**

High-risk unstable angina (severe CAD)	Symptomatic severe aortic stenosis
Uncontrolled symptomatic dysrhythmia	Active pericarditis, myocarditis
Acute pulmonary embolism or infarction	High degree atrioventricular block
Acute aortic dissection	Resting diastolic BP > 110 mm Hg
Resting systolic BP > 200 mm Hg	Hypertrophic cardiomyopathy
Uncontrolled diabetes (BS > 400 mg/dL)	Active systemic illness or fever
Severe orthopedic problems	Orthostatic decrease in BP by $\geq$ 20 mm Hg with symptoms
Uncompensated symptomatic HF	

CAD, coronary artery disease; BS, blood sugar; BP, blood pressure; HF, heart failure; HR, heart rate.

Adapted from the American College of Cardiology Foundation and the American Heart Association (2002). *ACC/AHA 2002 Guideline Update for Exercise Testing: A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Exercise Testing)*. Available at: <http://www.acc.org/clinical/guidelines/exercise>. Accessed December 3, 2002.

patient is admitted to the hospital for ACS (unstable angina, acute MI). It consists of low-level activities and initial education for the patient and family. Because of the brief hospital stay, mobilization occurs earlier, and patient teaching is prioritized to the essentials of self-care, rather than instituting behavioral changes for risk reduction. Priorities for in-hospital education include the signs and symptoms that indicate the need to call 911 (seek emergency assistance), the medication regimen, rest-activity balance, and follow-up appointments with the physician. The nurse needs to reassure the patient that, although CAD is a lifelong disease and must be treated as such, most patients can resume a normal life after an MI. This positive approach while in the hospital helps to motivate and teach the patient to continue the education and lifestyle changes that are usually needed after discharge. The amount of activity recommended at discharge depends on the age of the patient, his or her condition before the cardiac event, the extent of the disease, the course of the hospital stay, and the development of any complications.

Phase II occurs after the patient has been discharged. It usually lasts for 4 to 6 weeks but may last up to 6 months. This outpatient program consists of supervised, often ECG-monitored, exercise training that is individualized based on the results of an exercise stress test. Support and guidance related to the treatment of the disease and education and counseling related to lifestyle modification for risk factor reduction are a significant part of this phase. Short-term and long-range goals are collaboratively determined based on the patient's needs. At each session, the patient is assessed for the effectiveness of and adherence to the current medical plan. To prevent complications and another hospitalization, the cardiac rehabilitation staff alerts the referring physician to any problems. Outpatient cardiac rehabilitation programs are designed to encourage patients and families to support each other. Many programs offer support sessions for spouses and significant others while the patients exercise. The programs involve group educational sessions for both patients and families that are given by cardiologists, exercise physiologists, dietitians, nurses, and other health care professionals. These sessions may take place outside a traditional classroom setting. For instance, a dietitian may take a group of patients and their families to a grocery store to examine labels and meat selections or to a restaurant to discuss menu offerings for a "heart-healthy" diet.

Phase III focuses on maintaining cardiovascular stability and long-term conditioning. The patient is usually self-directed during this phase and does not require a supervised program, although it may be offered. The goals of each phase build on the accomplishments of the previous phase.

## NURSING PROCESS: THE PATIENT WITH MYOCARDIAL INFARCTION

### Assessment

One of the most important aspects of care of the patient with an MI is the assessment. It establishes the baseline for the patient so that any deviations may be identified, systematically identifies the patient's needs, and helps determine the priority of those needs. Systematic assessment includes a careful history, particularly as it relates to symptoms: chest pain or discomfort, difficulty breathing (dyspnea), palpitations, unusual fatigue, faintness (syncope), or sweating (diaphoresis). Each symptom must be evaluated with regard to time, duration, the factors that precipitate the symptom and relieve it, and comparison with previous symptoms. A precise and complete physical assessment is critical to detect complications and any change in patient status. Chart 28-6 identifies important assessments and possible findings.

Intravenous sites are examined frequently. At least one and possibly two intravenous lines are placed for any patient with ACS to ensure that access is available for administering emergency medications. Medications are administered intravenously to achieve rapid onset and to allow for timely adjustment. Intramuscular medications are avoided because of unpredictable absorption, delayed effect, and the risk of causing elevated serum enzyme levels by injuring muscle cells with an injection. After the patient's condition stabilizes, the intravenous line may be changed into a saline lock to maintain intravenous access.

### Diagnosis

#### NURSING DIAGNOSES

Based on the clinical manifestations, history, and diagnostic assessment data, the patient's major nursing diagnoses may include:

- Ineffective cardiopulmonary tissue perfusion related to reduced coronary blood flow from coronary thrombus and atherosclerotic plaque
- Potential impaired gas exchange related to fluid overload from left ventricular dysfunction
- Potential altered peripheral tissue perfusion related to decreased cardiac output from left ventricular dysfunction
- Anxiety related to fear of death
- Deficient knowledge about post-MI self-care

## COLLABORATIVE PROBLEMS/ POTENTIAL COMPLICATIONS

Based on the assessment data, potential complications that may develop include the following:

- Acute pulmonary edema (see Chap. 30)
- Heart failure (see Chap. 30)
- Cardiogenic shock (see Chap. 30)
- Dysrhythmias and cardiac arrest (see Chaps. 27 and 30)
- Pericardial effusion and cardiac tamponade (see Chap. 30)
- Myocardial rupture (see Chap. 30)

## Planning and Goals

The major goals of the patient include relief of pain or ischemic signs and symptoms (eg, ST-segment changes), prevention of further myocardial damage, absence of respiratory dysfunction, maintenance or attainment of adequate tissue perfusion by decreasing the heart's workload, reduced anxiety, adherence to the self-care program, and absence or early recognition of complications. Care of the patient with an uncomplicated MI is summarized in the Plan of Nursing Care on pages 731–733.

## Nursing Interventions

### RELIEVING PAIN AND OTHER SIGNS AND SYMPTOMS OF ISCHEMIA

Balancing the cardiac oxygen supply with its oxygen demand (eg, as evidenced by the relief of chest pain) is the top priority for the patient with an acute MI. Although medication therapy is required to accomplish this goal, nursing interventions are also important. Collaboration among the patient, nurse, and physician is critical in assessing the patient's response to therapy and in altering the interventions accordingly.

The accepted method for relieving symptoms associated with MI is revascularization with thrombolytic therapy or emergent PCI for patients who present to the health care facility immediately and who have no major contraindications. These therapies are important because, in addition to relieving symptoms, they aid in minimizing or avoiding permanent injury to the myocardium. With or without revascularization, administration of aspirin, intravenous beta-blocker, and nitroglycerin is indicated. Use of a GPIIb/IIIa agent or heparin may also be indicated. The nurse administers morphine for relief of pain and other symptoms, anxiety, and reduction of preload.

Oxygen should be administered along with medication therapy to assist with relief of symptoms. Administration of oxygen even in low doses raises the circulating level of oxygen to reduce pain associated with low levels of myocardial oxygen. The route of administration, usually by nasal cannula, and the oxygen flow rate are documented. A flow rate of 2 to 4 L/min is usually adequate to maintain oxygen saturation levels of 96% to 100% if no other disease is present.

Vital signs are assessed frequently as long as the patient is experiencing pain and other signs or symptoms of acute ischemia. Physical rest in bed with the backrest elevated or in a cardiac chair helps to decrease chest discomfort and dyspnea. Elevation of the head is beneficial for the following reasons:

- Tidal volume improves because of reduced pressure from abdominal contents on the diaphragm and better lung expansion and gas exchange.
- Drainage of the upper lung lobes improves.
- Venous return to the heart (preload) decreases, which reduces the work of the heart.

## IMPROVING RESPIRATORY FUNCTION

Regular and careful assessment of respiratory function can help the nurse detect early signs of pulmonary complications. Scrupulous attention to fluid volume status prevents overloading the heart and lungs. Encouraging the patient to breathe deeply and change position frequently helps keep fluid from pooling in the bases of the lungs.

## PROMOTING ADEQUATE TISSUE PERFUSION

Limiting the patient to bed or chair rest during the initial phase of treatment is particularly helpful in reducing myocardial oxygen consumption ( $m\dot{V}O_2$ ). This limitation should remain until the patient is pain-free and hemodynamically stable. Checking skin temperature and peripheral pulses frequently is important to ensure adequate tissue perfusion. Oxygen may be administered to enrich the supply of circulating oxygen.

## REDUCING ANXIETY

Alleviating anxiety and fears is an important nursing function to reduce the sympathetic stress response. Decreased sympathetic stimulation decreases the workload of the heart, which may relieve pain and other signs and symptoms of ischemia.

Developing a trusting and caring relationship with the patient is critical in reducing anxiety. Providing information to the patient and family in an honest and supportive manner invites the patient to be a partner in care and greatly assists in developing a positive relationship. Ensuring a quiet environment, preventing interruptions that disturb sleep, using a caring and appropriate touch, teaching the patient the relaxation response, using humor and assisting the patient to laugh, and providing the appropriate prayer book and assisting the patient to pray if consistent with the patient's beliefs are other nursing interventions that can be used to reduce anxiety. Frequent opportunities are provided for the patient to privately share concerns and fears. An atmosphere of acceptance helps the patient to know that these concerns and fears are both realistic and normal. Music therapy, in which the patient listens to selected music for a predetermined duration and at a set time, has been found to be an effective method for reducing anxiety and managing stress (Chlan & Tracy, 1999; Evans, 2002). Pet therapy, in which animals are brought to the patient, appears to provide emotional support and reduce anxiety. Administrative and infectious control practitioners are usually involved in developing standards for the animals, animal handlers, and patients who are eligible for pet therapy.

## MONITORING AND MANAGING POTENTIAL COMPLICATIONS

Complications that can occur after acute MI are caused by the damage that occurs to the myocardium and to the conduction system as a result of the reduced coronary blood flow. Because these complications can be lethal, close monitoring for and early identification of the signs and symptoms is critical (see Plan of Nursing Care, pp. 731–733).

The nurse monitors the patient closely for changes in cardiac rate and rhythm, heart sounds, blood pressure, chest pain, respiratory status, urinary output, skin color and temperature, sensorium, ECG changes, and laboratory values. Any changes in the patient's condition are reported promptly to the physician, and emergency measures are instituted when necessary.

## PROMOTING HOME AND COMMUNITY-BASED CARE

### Teaching Patients Self-Care

The most effective way to increase the probability the patient will implement a self-care regimen after discharge is to identify the

## Plan of Nursing Care

### Care of the Patient With an Uncomplicated Myocardial Infarction (Continued)

Nursing Interventions	Rationale	Expected Outcomes
2. Teach patient: <ol style="list-style-type: none"> <li>To adhere to the diet prescribed (for example, explain low-sodium, low-calorie diet)</li> <li>To adhere to activity prescription</li> </ol>	congestion from increased left heart pressures. The association of symptoms and activity can be used as a guide for activity prescription and a basis for patient teaching. <ol style="list-style-type: none"> <li> <ol style="list-style-type: none"> <li>Low-sodium diet may reduce extracellular volume, thus reducing preload and afterload, and thus myocardial oxygen consumption. In the obese patient, weight reduction may decrease cardiac work and improve tidal volume.</li> <li>The activity prescription is determined individually to maintain the heart rate and blood pressure within safe limits.</li> </ol> </li> </ol>	<ul style="list-style-type: none"> <li>Chest x-ray normal</li> <li>Relief of chest discomfort</li> <li>Appears comfortable:               <ul style="list-style-type: none"> <li>Appears rested</li> <li>Respiratory rate, cardiac rate, and blood pressure return to prediscomfort level</li> <li>Skin warm and dry</li> </ul> </li> </ul>

**Nursing Diagnosis:** Potential ineffective peripheral tissue perfusion related to decreased cardiac output

**Goal:** Maintenance/attainment of adequate tissue perfusion

1. Initially, every 4 hours, and with chest discomfort, assess, document, and report to the physician the following: <ol style="list-style-type: none"> <li>Hypotension</li> <li>Tachycardia and other dysrhythmia</li> <li>Activity intolerance</li> <li>Mentation changes (use family input)</li> <li>Reduced urine output (less than 200 mL per 8 hours)</li> <li>Cool, moist, cyanotic extremities</li> </ol>	1. These data are useful in determining a low cardiac output state. An ECG with pain may be useful in the diagnosis of an extension of myocardial ischemia, injury, and infarction, and of variant angina.	<ul style="list-style-type: none"> <li>Blood pressure within the patient's normal range</li> <li>Ideally, normal sinus rhythm without dysrhythmia is maintained, or patient's baseline rhythm is maintained between 60 and 100 beats/min without further dysrhythmia.</li> <li>No complaints of fatigue with prescribed activity</li> <li>Remains fully alert and oriented and without cognitive or behavioral change</li> <li>Appears comfortable               <ul style="list-style-type: none"> <li>Appears rested</li> <li>Respiratory rate, cardiac rate, and blood pressure return to prediscomfort level</li> <li>Skin warm and dry</li> </ul> </li> <li>Urine output greater than 25 mL/hr</li> <li>Extremities warm and dry with normal color</li> </ul>
---	--	--

**Nursing Diagnosis:** Anxiety related to fear of death, change in health status

**Goal:** Reduction of anxiety

1. Assess, document, and report to the physician the patient's and family's level of anxiety and coping mechanisms.	1. These data provide information about the psychological well-being and a baseline so that post-therapy symptoms can be compared. Causes of anxiety are variable and individual, and may include acute illness, hospitalization, pain, disruption of activities of daily living at home and at work, changes in role and self-image due to chronic illness, and lack of financial support. Because anxious family members can transmit anxiety to the patient, the nurse must also identify strategies to reduce the family's fear and anxiety.	<ul style="list-style-type: none"> <li>Reports less anxiety</li> <li>Patient and family discuss their anxieties and fears about death</li> <li>Patient and family appear less anxious</li> <li>Appears restful, respiratory rate less than 16/min, heart rate less than 100/min without ectopic beats, blood pressure within patient's normal limits, skin warm and dry</li> <li>Participates actively in a progressive rehabilitation program</li> <li>Practices stress reduction techniques</li> </ul>
---	--	--

(continued)

## Plan of Nursing Care

### Care of the Patient With an Uncomplicated Myocardial Infarction (Continued)

Nursing Interventions	Rationale	Expected Outcomes
2. Assess the need for spiritual counseling and refer as appropriate.	2. If a patient finds support in a religion, religious counseling may assist in reducing anxiety and fear.	
3. Allow patient (and family) to express anxiety and fear: <ol style="list-style-type: none"> <li>By showing genuine interest and concern</li> <li>By facilitating communication (listening, reflecting, guiding)</li> <li>By answering questions</li> </ol>	3. Unresolved anxiety (the stress response) increases myocardial oxygen consumption.	
4. Use of flexible visiting hours allows the presence of a supportive family to assist in reducing the patient's level of anxiety.	4. The presence of supportive family members may reduce both patient's and family's anxiety.	
5. Encourage active participation in a cardiac rehabilitation program.	5. Prescribed cardiac rehabilitation may help to eliminate fear of death, reduce anxiety, and enhance feelings of well-being.	
6. Teach stress reduction techniques.	6. Stress reduction may help to reduce myocardial oxygen consumption and may enhance feelings of well-being.	

**Nursing Diagnosis:** Deficient knowledge about post-MI self-care

**Goal:** Adheres to the home health care program

Chooses lifestyle consistent with heart-healthy recommendations.

(See Chart 28-8, Promoting Health After MI)

priorities as perceived by the patient, provide adequate education about heart-healthy living, and facilitate the patient's involvement in a cardiac rehabilitation program. Working with patients in developing plans to meet their specific needs further enhances the potential for an effective treatment plan (Chart 28-8).

## Evaluation

### EXPECTED PATIENT OUTCOMES

Expected patient outcomes may include the following:

1. Relief of angina
2. No signs of respiratory difficulties
3. Adequate tissue perfusion
4. Decreased anxiety
5. Adherence to a self-care program
6. Absence of complications

## Invasive Coronary Artery Procedures

### INVASIVE INTERVENTIONAL PROCEDURES

Angina pectoris may persist for many years in a stable form with brief attacks. However, unstable angina is a serious condition that can progress to MI or sudden cardiac death (ACS). Invasive interventional procedures to treat angina and CAD are PTCA, intracoronary stent implantation, atherectomy, brachytherapy, and transmyocardial laser revascularization. All of these procedures are classified as **percutaneous coronary interventions (PCIs)**.

## Percutaneous Transluminal Coronary Angioplasty (PTCA)

PTCA may be used to treat patients who do not experience angina but are at high risk for a cardiac event as identified by non-invasive testing, with recurrent chest pain that is unresponsive to medical therapy, with a significant amount of myocardium at risk but are poor surgical candidates, or with an acute MI (as an alternate to thrombolysis and after thrombolysis) (Smith et al., 2001). The procedure is attempted when the cardiologist believes that PTCA can improve blood flow to the myocardium. PTCA alone is seldom attempted in the patient with occlusions of the left main coronary artery that do not demonstrate **collateral circulation** to the left anterior descending and circumflex arteries. The purpose of PTCA is to improve blood flow within a coronary artery by "cracking" the atheroma.

This invasive interventional procedure is carried out in the cardiac catheterization laboratory. The coronary arteries are examined by angiography, as they are during the diagnostic cardiac catheterization, and the location, extent, and calcification of the atheroma are verified. Hollow catheters, called sheaths, are inserted, usually in the femoral vein or artery (or both), providing a conduit for other catheters. After the presence of atheroma is verified, a balloon-tipped dilation catheter is passed through the sheath along a guide catheter and positioned over the lesion. The physician determines the catheter position by examining markers on the balloon that can be seen with fluoroscopy. When the catheter is properly positioned, the balloon is inflated with a radiopaque contrast agent (commonly called *dye*) to visualize the

## Chart 28-8

## Promoting Health After Myocardial Infarction and Other Acute Coronary Syndromes

To extend and improve the quality of life, a patient who has had an MI must learn to adjust his or her lifestyle to promote heart-healthy living. With this in mind, the nurse and patient develop a program to help the patient achieve desired outcomes.

**Changing Lifestyle During Convalescence and Healing**

Adaptation to a heart attack is an ongoing process and usually requires some modification of lifestyle. Some specific modifications include:

- Avoiding any activity that produces chest pain, extreme dyspnea, or undue fatigue
- Avoiding extremes of heat and cold and walking against the wind
- Losing weight, if indicated
- Stopping smoking and use of tobacco; avoiding second-hand smoke
- Using personal strengths to support lifestyle changes
- Developing heart-healthy eating patterns and avoiding large meals and hurrying while eating
- Modifying meals to align with the Therapeutic Lifestyle Changes (TLC) or the Dietary Approaches to Stopping Hypertension (DASH) diet
- Adhering to medical regimen, especially in taking medications
- Following recommendations that ensure blood pressure and blood glucose are in control
- Pursuing activities that relieve and reduce stress

**Adopting an Activity Program**

Additionally, the patient needs to undertake an *orderly* program of increasing activity and exercise for long-term rehabilitation as follows:

- Engaging in a regimen of physical conditioning with a gradual increase in activity duration and then a gradual increase in activity intensity
- Walking daily, increasing distance and time as prescribed
- Monitoring pulse rate during physical activity until the maximum level of activity is attained
- Avoiding activities that tense the muscles: isometric exercise, weight-lifting, any activity that requires sudden bursts of energy
- Avoiding physical exercise immediately after a meal
- Alternating activity with rest periods (some fatigue is normal and expected during convalescence)
- Participating in a daily program of exercise that develops into a program of regular exercise for a lifetime

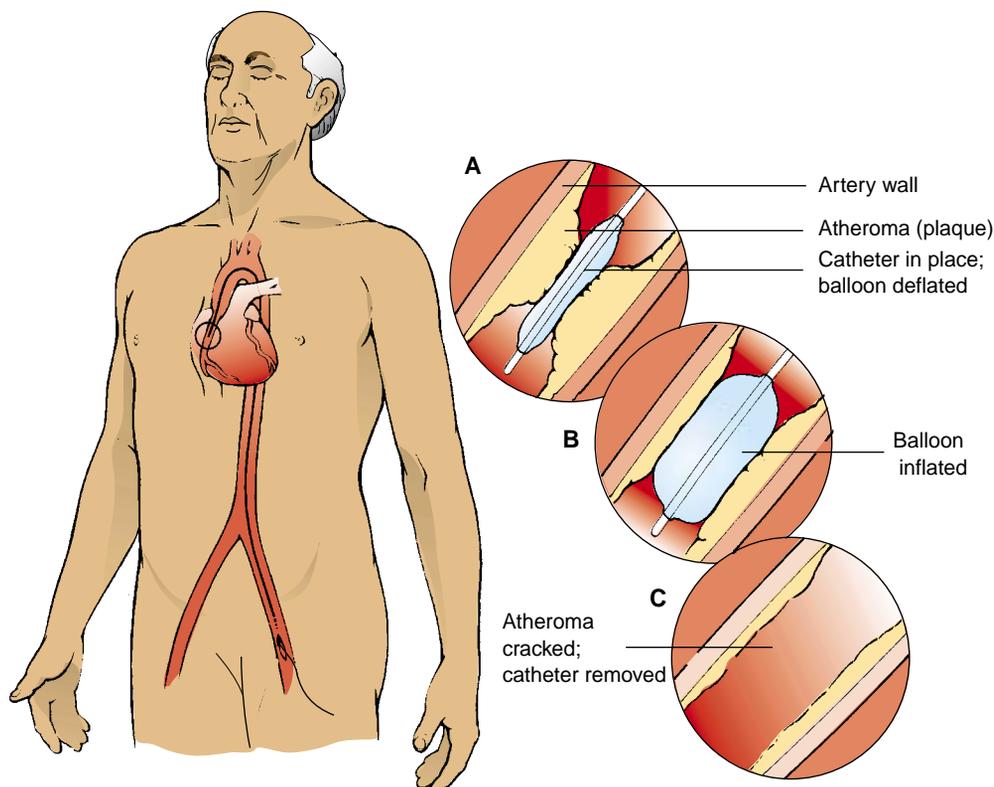

**Managing Symptoms**

The patient must learn to recognize and take appropriate action for possible recurrences of symptoms as follows:

- Call 911 if chest pressure or pain (or anginal equivalent) is not relieved in 15 minutes by nitroglycerin
- Contacting the physician if any of the following occur: shortness of breath, fainting, slow or rapid heartbeat, swelling of feet and ankles

blood vessel and to provide a steady or oscillating pressure within the balloon. The balloon is inflated to a certain pressure for several seconds and then deflated. The pressure “cracks” and possibly compresses the atheroma (Fig. 28-5). The coronary artery’s media and adventitia are also stretched.

Several inflations and several balloon sizes may be required to achieve the desired goal, usually defined as an improvement in blood flow and a residual stenosis of less than 20%. Other gauges of the success of a PTCA are an increase in the artery’s lumen, a difference of less than 20 mm Hg in blood pressure from one side

**FIGURE 28-5** Percutaneous transluminal coronary angioplasty. (A) A balloon-tipped catheter is passed into the affected coronary artery and placed across the area of the atheroma (plaque). (B) The balloon is then rapidly inflated and deflated with controlled pressure. (C) After the atheroma is cracked, the catheter is removed, and blood flow improves.

of the lesion to the other, and no clinically obvious arterial trauma. Because the blood supply to the coronary artery decreases while the balloon is inflated, the patient may complain of chest pain (often called *stretch pain*), and the ECG may display significant ST-segment changes (Jeremias et al., 1998).

### COMPLICATIONS

Possible complications during the PTCA procedure include dissection, perforation, abrupt closure, or vasospasm of the coronary artery, acute MI, acute dysrhythmias (eg, ventricular tachycardia), and cardiac arrest. These may require emergency surgical treatment. Complications after the procedure may include abrupt closure and vascular complications, such as bleeding at the insertion site, retroperitoneal bleeding, hematoma, pseudoaneurysm, arteriovenous fistula, or arterial thrombosis and distal embolization (Table 28-7).

### POSTPROCEDURE CARE

Patient care is similar to that for a cardiac catheterization (see Chapter 26). Many patients are admitted to the hospital the day of the PTCA. Those with no complications go home the next day. During the PTCA, patients receive large amounts of heparin and are monitored closely for signs of bleeding. Most patients also receive intravenous nitroglycerin for a period after the procedure to prevent arterial spasm.

Hemostasis is usually achieved and sheaths are pulled immediately at the end of the procedure by using a vascular closure device (eg, Angio-Seal, VasoSeal, Duett, Syvek patch) or a device that sutures the vessels (Prostar, Perclose). Hemostasis after sheath removal may also be achieved by direct manual pressure, a mechanical compression device (eg, C-shaped clamp), or a pneumatic compression device (eg, FemStop).

The patient may return to the nursing unit with the large peripheral vascular access sheaths in place. The sheaths are removed

after blood studies (eg, activated clotting time) indicate that the clotting time is within an acceptable range. This usually takes a few hours, depending on the amount of heparin given during the procedure. The patient must remain flat in bed and keep the affected leg straight until the sheaths are removed and then for a few hours after to maintain hemostasis. Because the immobility and bed rest usually cause the patient significant discomfort, treatment includes analgesics and sedation.

Several nursing interventions frequently used as part of the standard of care, such as applying a sandbag to the sheath insertion site, have not been shown to be effective in reducing the incidence of bleeding (Christensen et al., 1998; Juran et al., 1999). The method used to achieve hemostasis determines the length of time needed to achieve hemostasis, the duration of bed rest, and the risk of complications (Brachmann et al., 1998; Lehmann et al., 1999; Walker et al., 2001). Sheath removal and the application of pressure on the vessel insertion site may cause the heart rate to slow and the blood pressure to decrease (vasovagal response). An intravenous bolus of atropine is usually used to treat these side effects.

Some patients with unstable lesions and at high risk for abrupt vessel closure are restarted on heparin after sheath removal, or they receive an intravenous infusion of a GPIIb/IIIa inhibitor. These patients are monitored more closely and progressed more slowly.

After hemostasis is achieved, patients usually can be weaned from the intravenous medications, resume self-care, and ambulate unassisted within 1 to 12 hours of the procedure. The duration of immobilization depends on the size of the sheath inserted, the amount of anticoagulant administered, the method of hemostasis, the patient's underlying condition, and the physician's preference. The nurse teaches the patient to monitor the site for bleeding or development of a hard lump that is larger than a walnut. Most patients can return to their usual activities of daily living.

**Table 28-7 • Complications After Percutaneous Transluminal Coronary Angioplasty (PTCA)**

COMPLICATION	SIGNS AND SYMPTOMS	POSSIBLE CAUSES	NURSING ACTIONS
Bleeding or hematoma	Hard lump or bluish tinge at sheath insertion site	Coughing, vomiting, bending leg or hip, obesity, bladder distention, high blood pressure	Keep the head of the bed flat. Insert indwelling urinary catheter if needed. Apply manual pressure at site of sheath insertion. Outline extent of hematoma with a marking pen. If bleeding does not stop, notify physician or nurse practitioner.
Lost or weakened pulse distal to sheath insertion site	Extremity cool, cyanotic, pale, or painful	Arterial thrombus or embolus	Notify physician or nurse practitioner. Anticipate surgery and anticoagulation or thrombolytic therapy.
Pseudoaneurysm and arteriovenous fistula	Pulsatile mass felt or bruit heard near sheath insertion site	Vessel trauma during procedure	Notify physician or nurse practitioner. Anticipate ultrasound-guided compression. Prepare patient for surgery to close fistula.
Retroperitoneal bleeding	Back or flank pain Low blood pressure Tachycardia Restlessness and agitation Decreased hemoglobin Decreased hematocrit	Arterial tear causing bleeding into flank area	Notify physician or nurse practitioner immediately. Stop any anticoagulation medication. Anticipate need for intravenous fluids and/or administration of blood.

## Coronary Artery Stent

After PTCA, a portion of the plaque that was not removed may block the artery. The coronary artery may recoil (constrict) and the tissue remodels, increasing the risk for restenosis (Apple & Lindsay, 2000). A coronary artery stent is placed to overcome these risks. A **stent** is a woven mesh that provides structural support to a vessel at risk of acute closure. The stent is placed over the angioplasty balloon. When the balloon is inflated, the mesh expands and presses against the vessel wall, holding the artery open. The balloon is withdrawn, but the stent is left permanently in place within the artery (Fig. 28-6). Eventually, endothelium covers the stent and it is incorporated into the vessel wall. Because of the risk of thrombus formation in the stent, the patient receives antiplatelet medications (eg, clopidogrel [Plavix] therapy for 2 weeks and lifetime use of aspirin). Some stents have medication which may minimize the formation of thrombi or excessive scar tissue. It is estimated that 50% to 80% of all PCIs involve implanting at least one stent (Braunwald et al., 2001; Smith et al., 2001). Stents may be used in conjunction with PTCA or independently as a PCI. Use of stents without PTCA may decrease procedure time, use of the potentially nephrotoxic contrast agent, radiation exposure, and cost (Apple & Lindsay, 2000). Care of the patient after coronary artery stent placement is the same as for a patient after PTCA.

## Atherectomy

Atherectomy is an invasive interventional procedure that involves the removal of the atheroma, or plaque, from a coronary artery (Smith et al., 2001). Directional (DCA) and transluminal extraction (TEC) coronary atherectomy procedures involve the use of a catheter that removes the lesion and its fragments. Rotational atherectomy uses a catheter with diamond chips impregnated on the tip (called a burr) that rotates like a dentist's drill at 130,000 to 180,000 rpm, pulverizing the lesion (Braunwald et al., 2001). Usually, several passes of these catheters are needed to achieve satisfactory results. Postprocedural patient care is the same as for a patient after PTCA.

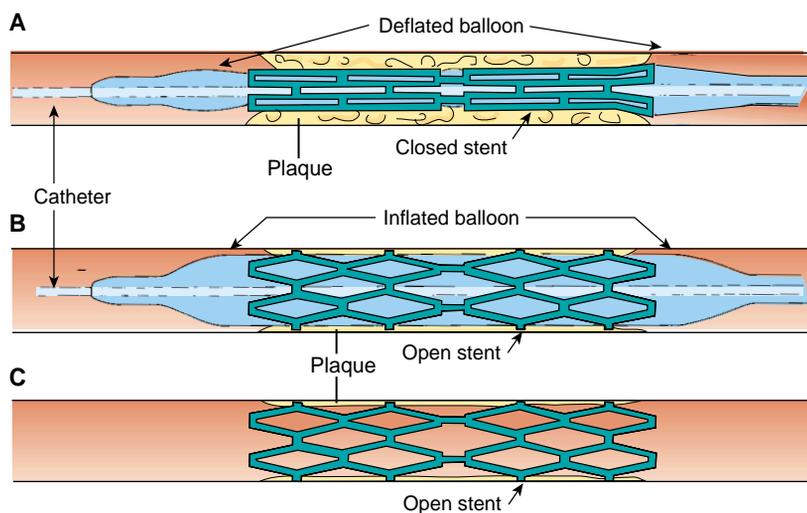

## Brachytherapy

PTCA and stent implantation cause a cellular reaction in the coronary artery that promotes proliferation of the intima of the
